

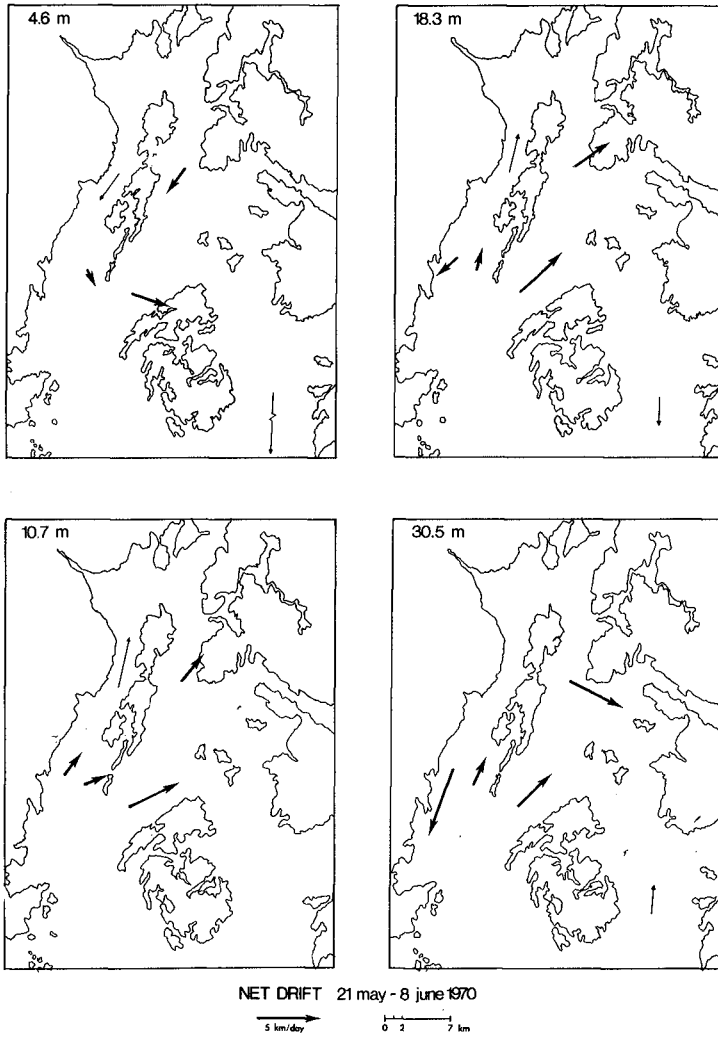

Figure 5

Salinity and temperature data provided some insights into the layered structure of the estuary. Figure 6 shows densities across the bay at several points on both sides of Islesboro Island, confirming earlier work by Haefner (1967) that a deeper fresh water layer lies on the west side of Islesboro. The order of magnitude of the observed data is predicted by application of the Margueles equation (Neumann and Pierson, 1966):

$$\tan \gamma = \frac{-f}{g} \left(\frac{\rho_2 v_2 - \rho_1 v_1}{\rho_2 - \rho_1} \right) \quad (1)$$

where: γ = transverse slope of the density interface
 f = coriolis parameter
 ρ_1, ρ_2 = densities of upper and lower layers
 v_1, v_2 = longitudinal current velocities

Figure 6

Within the range of observed transverse density gradients and with velocities of 5 cm/s upstream and downstream, equation (1) predicts that the pycnocline would be about 0.5 to 1.0 meter deeper on the western shore of the bay than on the eastern shore. Using the longitudinal density slope of the interface (from figure 7), it is possible to estimate the current velocities due to the density gradient alone (no wind) (after Defant, 1961):

$$i_2 = \frac{-2N_z \gamma}{g} \quad (2)$$

$$\gamma = \frac{-i_2 g}{2 N_z} \quad (3)$$

$$u_2 = A(z + h_1)(z + h_2) \quad \text{with } A = -4a\left(\frac{h_2}{h_1} - 1\right)^{-3} \quad (4)$$

$$\gamma = \frac{\rho_1}{\rho_2 - \rho_1} a \left[1 - \frac{\rho_2}{\rho_1} A \right] \quad (5)$$

where: i_2 = slope of the density interface (taken as 3×10^{-4} m/m)
 N_z = vertical eddy viscosity (taken as $0.01 \text{ m}^2/\text{s}$)
 h_2 = depth to bottom (taken as 25m.)
 h_1 = depth of surface layer (taken as 5 m.)
 ρ_1 = density of upper layer (1.025)
 ρ_2 = density of lower layer (1.012)

For small A, iterative solution of equations (2) through (5), suggests that density driven currents on the order of 2 km/day could exist in the Penobscot estuary. Although this is the same order of magnitude as the observed residual currents, this analysis is suggestive only, since the calculated velocity is critically dependent on the observed slope of the density interface. A further test was made of the importance of the density driven flow to the net circulation in the estuary, by applying the numerical model without including the density driven terms. Successful simulation of observed currents would indicate that the density terms could be safely ignored. Failure to achieve reasonable results would require that further modelling efforts be made with the computationally more complex (and expensive) version of the model incorporating the density terms.

Figure 7

The Computer Model

The three-dimensional computer model "GAL" (Galerkin), described in detail in Pearce, et al. (1978), was used in this study to simulate currents in the Penobscot estuary. It uses the following expression of the Navier Stokes equation, neglecting vertical accelerations, density driven currents, and atmospheric pressure gradients:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} = -g \frac{\rho_s}{\rho} \frac{\partial \eta}{\partial x} + fv + \frac{\partial}{\partial x} (N_H \frac{\partial u}{\partial x}) + \frac{\partial}{\partial y} (N_H \frac{\partial u}{\partial y}) + \frac{\partial}{\partial z} (N_V \frac{\partial u}{\partial z}) \tag{6a}$$

in the y direction,

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} = -g \frac{\rho_s}{\rho} \frac{\partial \eta}{\partial x} - fu + \frac{\partial}{\partial x} (N_H \frac{\partial v}{\partial x}) + \frac{\partial}{\partial y} (N_H \frac{\partial v}{\partial y}) + \frac{\partial}{\partial z} (N_V \frac{\partial v}{\partial z}) \tag{6b}$$

The surface boundary condition is specified as a set of horizontal shear stresses:

$$\tau_{sx} = -\rho_s N_V \frac{\partial u}{\partial z} ; \quad \tau_{sy} = -\rho_s N_V \frac{\partial v}{\partial z} \quad (7)$$

A linear slip coefficient defines the bottom boundary:

$$\frac{\partial u}{\partial z} = \frac{-C_b u_b}{N_b} ; \quad \frac{\partial v}{\partial z} = \frac{-C_b v_b}{N_b} \quad (8)$$

where: N_V = vertical component of the eddy viscosity

N_b = value of the vertical eddy viscosity at the bottom boundary

N_H = horizontal component of the eddy viscosity

C_b = bottom slip coefficient

u, v = x and y components of velocity

τ_{sx}, τ_{sy} = x and y components of wind shear stress at surface

u_b, v_b = velocities at the bottom boundary in the x and y directions

η = height of water surface above still water level

ρ_s = water density at surface

ρ = water density at any depth

g = acceleration of gravity

f = coriolis parameter

These equations are solved by assuming a trial solution which specifies the x and y components of velocity as a continuous function of depth, z. The functions used here are:

$$\hat{u} = \frac{\tau_{sx} z^2 (z-H)}{\rho_s H^2 N_b} + \frac{\tau_{sx}}{\rho_s \alpha} \ln \left(\frac{N_b}{N_V} \right) + \sum_{I=1}^{I'} c_I \cos \left(\frac{a_I z}{H} \right) \quad (9a)$$

$$\hat{v} = \frac{\tau_{sy} z^2 (z-H)}{\rho_s H^2 N_b} + \frac{\tau_{sy}}{\rho_s \alpha} \ln \left(\frac{N_b}{N_V} \right) + \sum_{I=1}^{I'} d_I \cos \left(\frac{a_I z}{H} \right) \quad (9b)$$

where the a_I 's are given by the solution to:

$$a_I \tan a_I = \frac{c_b H}{N_b}$$

and where:

$$\alpha = \frac{\partial N_V}{\partial z}$$

c_I, d_I = undetermined parameters whose values represent a solution at location x, y , and time t , and

H = still water depth

Equations (9a) and (9b) are substituted into the Navier-Stokes equation. Since the trial functions are not the exact solutions, there will be an error, or residual, R , associated with this substitution, where:

$$R = \frac{du}{dt} + \frac{\rho_s}{\rho} g \frac{\partial \eta}{\partial x} - \frac{\partial}{\partial x} (N_H \frac{\partial u}{\partial x}) - \frac{\partial}{\partial y} (N_H \frac{\partial u}{\partial y}) - \frac{\partial}{\partial y} (N_V \frac{\partial u}{\partial z}) - fv$$

$$+ \frac{1}{\rho} \frac{\partial P}{\partial x} \neq 0 \quad (10)$$

The Galerkin technique is used to minimize the error by specifying that the sum of the residuals, multiplied by an arbitrary weighting function, over the depth of the water column be zero:

$$\int_{-\eta}^H R \Omega_I dz = 0$$

The weighting function chosen here is:

$$\Omega_I = \cos \left(\frac{a_I z}{H} \right)$$

which takes advantage of the orthogonality of the cosine function to simplify the integrations in the resulting Galerkin statement:

$$\int_0^H R \Omega_I dz = \int_0^H \left\{ \frac{d\hat{u}}{dt} + g\rho_s \frac{\partial \eta}{\partial x} \frac{\Omega_I}{\rho} - \left[\frac{\partial}{\partial x} (N_H \frac{\partial \hat{u}}{\partial x}) + \frac{\partial}{\partial y} (N_H \frac{\partial \hat{u}}{\partial y}) \right] - \left(\frac{\partial N_V}{\partial z} \frac{\partial \hat{u}}{\partial z} \right) - N_V \frac{\partial^2 \hat{u}}{\partial z^2} - f\hat{v} + \frac{1}{\rho} \frac{\partial P_a}{\partial x} \right\} \Omega_I dz = 0 \quad (11)$$

Equations (11) are integrated under the following additional assumptions:

- (a) the convective terms are small and may be neglected
- (b) a linear approximation to the horizontal shear stress terms is appropriate
- (c) η is small with respect to H .

This results in the reduction of the original second order, non-linear momentum equations and the non-homogeneous vertical boundary conditions to a set of $2I'$ linear, first-order partial differential equations in $2I' + 1$ unknown parameters, c_I (x component), d_I (y component), and η . These are coupled to the continuity equation:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = \frac{\partial \eta}{\partial t} \quad (12)$$

and the horizontal boundary conditions. These equations are discretized and solved explicitly for the coefficients by a "split-time" finite difference scheme. The coefficients are substituted into the Galerkin trial solutions (Equations (9)) to yield values for u and v at each grid element.

Model Applications: Inputs

1. Vertical eddy viscosity. GAL should prove useful in modelling stratified flow since the model uses a vertically varying vertical eddy viscosity, N_V . For this application, two different methods of specifying N_V were tried, figure 8. In both cases, the break-point in the piece-wise linear form occurred at the assumed density interface, 5 meters below the surface.
2. Wind. A southwest wind at 5 m/s was applied to the modelled estuary, ramped up from zero to maximum velocity in one tidal cycle. The appropriateness of this input was confirmed with lighthouse keepers' observations of wind at Matinicus Rock (26 kms. south of the study area's southern boundary). They had been taken at approximately 3 hour intervals and showed that southerly winds prevailed during the study period.

3. Other input parameters. River discharge was taken as $1300 \text{ m}^3/\text{s}$. This is near the maximum discharge for the Penobscot and is a representative flow for the study period.

The bottom slip coefficient was used as a tuning parameter and varied in magnitude from 0.01 to 0.001 m/s.

A rectangular grid spacing of 1016 meters was chosen as the maximum that could place at least three grid elements across the narrowest section of the bay. With less than three elements in the transverse direction, the no-flow horizontal boundary condition leads to spurious results at those points. The Courant condition, equation (13), governed model stability with the result that for the maximum depths of 130 meters encountered, a maximum time step of 20 seconds was used in the model runs.

$$\Delta t \leq (2gh_{\max})^{-1/2} \Delta L \quad (13)$$

Figure 8

Model Application: Results

The model provides a reasonable representation of the instantaneous currents as shown by a typical velocity profile, Figure 9 (Figure 9 shows the modelled currents at maximum flood and five profiles of the measured data taken about the time of maximum flood). Residual currents were not well represented. Figure 10 shows a plot of the residual currents from one of the most encouraging runs to date. While the magnitudes compare favorably to data, directions are merely suggestive of those found in the data.

We conclude, based on these comparisons and on the evidence cited earlier, that during the time of spring runoff, the density driven residual currents are of the same order of magnitude as the residual currents from other causes. In order to properly consider density driven currents, the model GAL is now being appropriately modified.

The Use of Array Processors for Numerical Modelling
of Tidal Estuary Dynamics

by D. Prandle*, E.R. Funke**,
N.L. Crookshank*** and R. Renner****

1.0 INTRODUCTION

The use of array processors for the numerical modelling of estuarine systems is discussed here in the context of "hybrid modelling", however, it is shown that array processors may be used to advantage in independent numerical simulations. Hybrid modelling of tidal estuaries was first introduced by Holz (1977) and later by Funke and Crookshank (1978). In a hybrid model, tidal propagation in an estuary is simulated by dynamically linking an hydraulic (or physical) scale model of part of the estuary to a numerical model of the remaining part in a manner such that a free interchange of flow occurs at the interface(s). Typically, the elevation of the water surface at the boundary of the scale model is measured and transmitted to the numerical model. In return, the flow computed at the boundary of the numerical model is fed directly into the scale model.

This approach enables the extent of the scale model to be limited to the area of immediate interest (or to that area where flow conditions are such that they can be most accurately simulated by a scale model). In addition, since the region simulated by the numerical model can be extended almost indefinitely, the problems of spurious reflections from downstream boundaries can be eliminated.

In normal use, numerical models are evaluated on the basis of computing requirements, cost and accuracy. The computer time required to simulate one tide cycle is, in itself, seldom of interest except in so far as it affects the above criteria. However in hybrid modelling this parameter is often paramount since concurrent operation of the numerical and scale models requires that the former must keep pace with the latter.

The earlier hybrid model of the St. Lawrence (Funke and Crookshank, 1978) involved a one-dimensional numerical model of the upstream regions of the river. However, future applications are likely to involve extensive two-dimensional numerical simulation. Consequently the

* Visiting Scientist, **Senior Research Officer, ***Systems Manager, Hydraulics Laboratory, National Research Council of Canada, Ottawa, Canada.
**** Chief Scientist, Canadian Astronautics Ltd., Ottawa, Canada.

computational power required will be considerable and almost certainly in excess of the power of present-day mini-computers. The use of a substantial main frame machine is complicated by both the cost and the requirement for a high priority real time service. Thus the use of an array processor/mini-computer combination was examined to bridge this gap in computational power.

Section 2 describes a hybrid model of the Bay of Fundy with the details of the numerical scheme given in section 3. Sections 4, 5 and 6 describe, in some detail, various aspects relating to the usage of the array processor. Finally section 7 provides a comparison of the performance of the array processor against that of both a mini-computer and two main frame machines.

2.0 THE BAY OF FUNDY HYBRID MODEL

In order to subject the development project to the rigors of a practical application, a suitable estuary was selected. The Bay of Fundy offered several advantages. For one, there exists a proven explicit model (Greenberg, 1976) which covers both the Bay of Fundy and the Gulf of Maine, down to the Continental Shelf. Secondly, there is a considerable interest in the electric power potential of the Fundy tide and it was felt that the experience gained from the pilot model study may benefit future investigations whenever the Bay of Fundy tidal power development progresses to the engineering design stage. With these considerations in mind, the construction of a pilot hybrid model was initiated with Cumberland Basin and Shepody Bay forming the physical model and the remainder of the estuary down to the Continental Shelf forming the numerical model. Fig. 1 illustrates the general outline of this estuary, and includes the schematization employed for the finite difference scheme. The small "boxed-in" area in the upper right hand corner of the diagram is simulated by a physical model. Fig. 2 illustrates the outline of this scaled model and its relationship to the numerical model. The computer in this hybrid model serves the dual functions of being both host to the array processor and at the same time, being the data acquisition system and feedback controller for the discharge control pump (Funke, Crookshank and Wingham, 1980).

Fig. 3 gives the timing diagram of a typical hybrid model. It should be noted that the "hatched" pulses represent the regular clock pulses which, for the Bay of Fundy model, occur every 0.3 seconds. Shortly after each pulse, a data transfer takes place which transmits the last calculated discharge value Q_I from the array processor to the control computer. The data acquisition phase follows immediately, monitoring among other variables, the water elevation H_I which is then transmitted back to the array

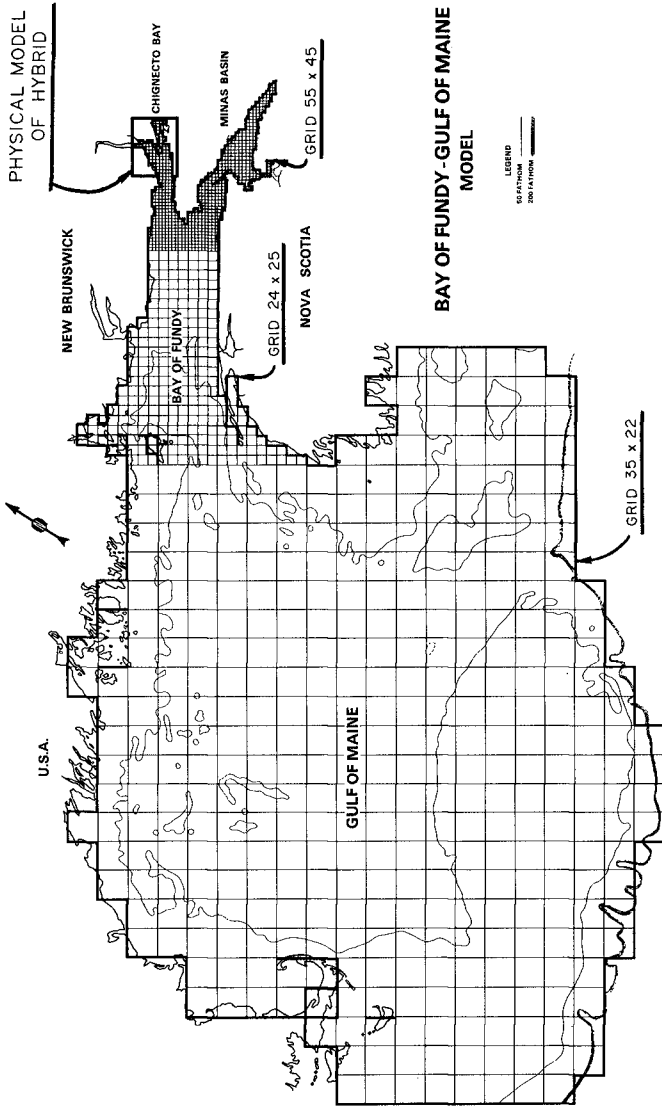

FIG. 1
SCHEMATIC REPRESENTATION OF BAY OF FUNDY

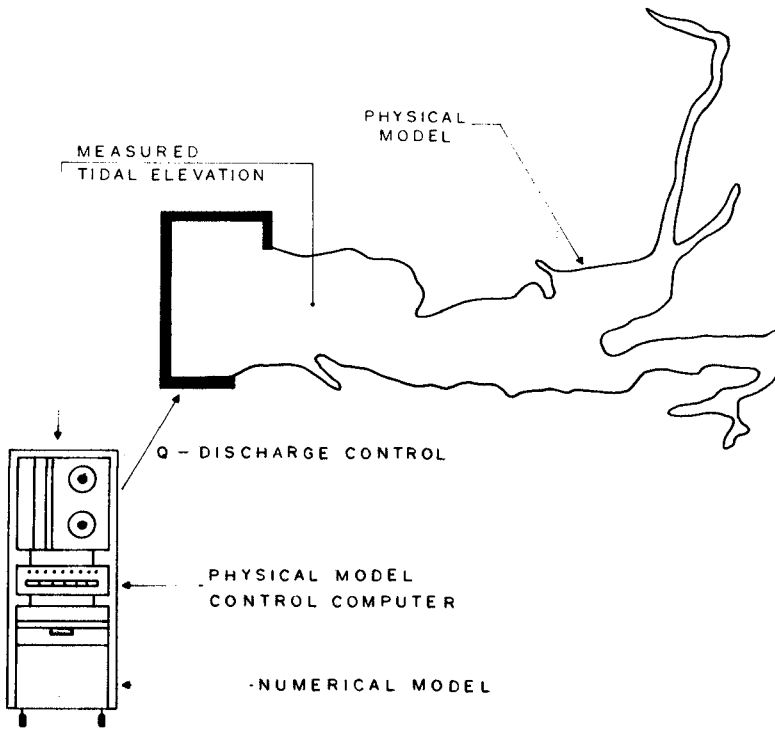

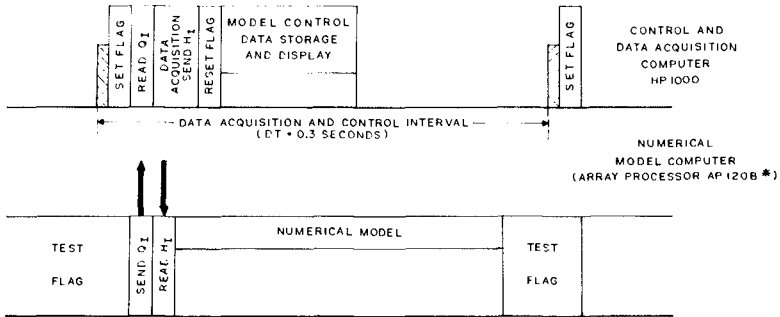

FIG. 2 HYBRID MODEL OF CUMBERLAND BASIN AND SHEPODY BAY

processor. Next comes the model control phase and while the control computer is engaged in achieving the required discharge, the array processor must solve one time step of the numerical model. Since clock pulses for the Bay of Fundy hybrid model occur every 300 milliseconds, the computational time available for one time step of the numerical model must be somewhat smaller. In fact, sufficient time must remain to complete all the data acquisition and the data transfer between the host computer and the array processor. In addition one wants to have some margin of safety so that the "ping-pong" interchange between the two machines can never get out of synchronism.

FIG. 3 TIMING DIAGRAM FOR HYBRID MODEL

3.0 THE EXTENT OF THE MATHEMATICAL MODEL

The estuary dynamics of the mathematical model for the present Bay of Fundy is based on the following equations:

$$\text{x-motion: } \frac{\partial U}{\partial t} + g \frac{\partial Z}{\partial x} + f \frac{U \cdot (U^2 + V^2)^{1/2}}{(D + Z)} - \Omega \cdot V = 0$$

$$\text{y-motion: } \frac{\partial V}{\partial t} + g \frac{\partial Z}{\partial y} + f \frac{V \cdot (U^2 + V^2)^{1/2}}{(D + Z)} + \Omega \cdot U = 0$$

$$\text{continuity: } \frac{\partial Z}{\partial t} + \frac{\partial}{\partial x} [U \cdot (D + Z)] + \frac{\partial}{\partial y} [V \cdot (D + Z)] = 0$$

where U and V are the velocities in the x and y direction,
 D is the depth below mean water,
 Z is the tidal elevation about the mean,
 f is the friction term, and
 Ω is the Coriolis parameter.

Fig. 4 shows the schematization using a finite difference, explicit method with a staggered mesh and forward difference

FIG. 4 DEFINITION OF FINITE GRID ELEMENT

in time. The differential equations are thus approximated by the following.

$$U'_{x,y} = (U_{x,y}/\Delta t + g(Z_{x,y} - Z_{x-1,y})/\Delta x - \Omega \cdot \bar{V}) / (1/\Delta t + F_x)$$

where:

$$\bar{V} = (V_{x,y} + V_{x-1,y} + V_{x,y+1} + V_{x-1,y+1})/4$$

and

$$F_x = f \cdot (U_{x,y}^2 + \bar{V}^2)^{1/2} / ((D_{x,y} + D_{x-1,y} + Z_{x-1,y})/2)$$

$$V'_{x,y} = (V_{x,y}/\Delta t + g(Z_{x,y} - Z_{x,y-1})/\Delta y + \Omega \cdot \bar{U}) / (1/\Delta t + F_y)$$

where:

$$\bar{U} = (U_{x,y} + U_{x+1,y} + U_{x,y-1} + U_{x+1,y-1})/4$$

and

$$F_y = f \cdot (\bar{U}^2 + V_{x,y}^2)^{1/2} / ((D_{x,y} + D_{x,y-1} + Z_{x,y} + Z_{x,y-1})/2)$$

and

$$Z'_{x,y} = \left(Z_{x,y}/\Delta t + [U_{x+1,y} \cdot (D_{x+1,y} + D_{x,y} + Z_{x,y} + Z_{x+1,y}) - U_{x,y} \cdot (D_{x,y} + D_{x-1,y} + Z_{x,y} + Z_{x-1,y})] / (2 \cdot \Delta x) + [V_{x,y+1} \cdot (D_{x,y+1} + D_{x,y} + Z_{x,y+1} + Z_{x,y}) - V_{x,y} \cdot (D_{x,y} + D_{x,y-1} + Z_{x,y})] / (2 \cdot \Delta y) \right)$$

Fig. 1 shows that the area to be modelled is subdivided into three zones. The Gulf of Maine is represented by a 35 x 22 grid. The Bay of Fundy area has three times the resolution with a 24 x 25 grid. Finally the upper reaches of the Bay have again three times the resolution with a 55 x 45 grid.

Fig. 5 shows that five finite grid elements form the boundary with the scaled model. It is anticipated that each of these five elements could control an appropriate interface pump. However, for the pilot model now under construction, only one elevation, Z_I , is measured and the numerical model supplies the average discharge through the boundary by means of the averaging formula given in Fig. 5.

4.0 A BRIEF DESCRIPTION OF ARRAY PROCESSOR HARDWARE

An array processor (AP) is a digital data processor which is specifically and optimally designed to process long data vectors. Typically, one can say that the longer the data vector or vectors, the more advantageous is the array processor as a "number cruncher".

Array processors are peripheral to so-called host computers. Their advantage must, of course, be measured relative to their host computer. For this reason, it is quite common now to find array processors interfaced to mini-computers rather than to larger main frame machines. The list of references suggests some papers which offer more technical information on various array processors.

Fig. 6 shows the major components of a typical array processor "Floating Point Systems Inc. AP120B", i.e. the machine used for this particular study. From this diagram several pertinent features can be recognized:

ASSUME: $Z_{X_0, Y_0} = Z_{X_0, Y_1} = Z_{X_0, Y_2} = Z_{X_0, Y_3} = Z_{X_0, Y_4} = Z_I$

$$Q_I = \sum_{i=Y_0}^{Y_4} \Delta y \cdot U_{x_0, i} \cdot (D_{x_0, i} + D_{x-1, i} + Z_{x_0, i} + Z_{x-1, i}) / 2$$

FIG. 5 INTERFACE DETAILS BETWEEN NUMERICAL AND SCALED MODEL

- (a) The AP has separate and independent memory components for data, program store and table constants. This permits not only some parallel processing but also an optimum choice of word length for instructions and data respectively. For example, the AP120B has a 64 bit instruction word which may control up to ten different operations more or less at the same time. On the other hand, the data word is 38 bits long with 28 bits used as mantissa and 10 bits as exponent. This is a worthwhile improvement over the usual 32 bit data formats especially for the type of problem described by this paper.
- (b) The AP has parallel arithmetic processors which may operate on data concurrently.
- (c) Data processing may take place in a "pipeline" fashion so that data words move progressively through successive stages. Each stage may require in the order of

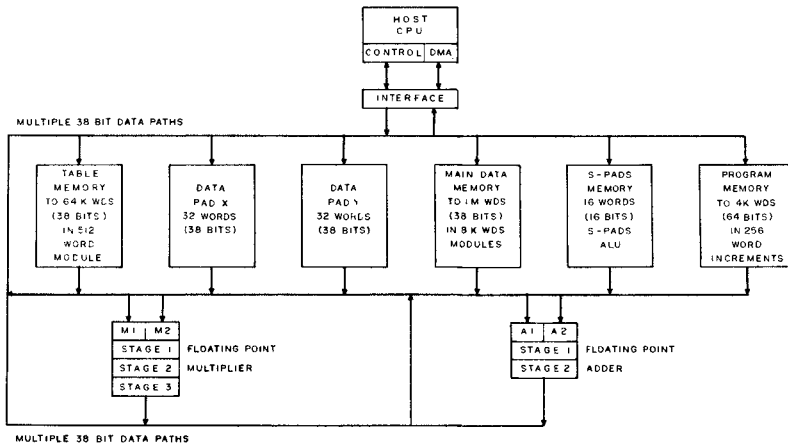

FIG. 6 GENERAL SYSTEM DIAGRAM FOR AP122B ARRAY PROCESSOR

167 nanoseconds. Once the "pipeline" is filled, solutions are returned back to the data memory at the same 167 nanosecond rate. It is both the parallel processing and the "pipelining" which gives these processors their phenomenal speed.

- (d) The interface between the host computer and the AP is of particular importance in appreciating the operation of the machine in relation to its host. In the usual configuration depicted by Fig. 6, all AP-programs and data come from the host and results are returned to the host. An executive program in the host keeps track of the programs which are required in the AP program store and if a particular program which is being called is not, at that time, resident in the AP, it must be transferred there into whatever free area is available. If the program store is filled to capacity, then the last program in will be the first program to be overlaid, and hence destroyed.

Data transfer to and from the AP is usually costly in time. Consequently an awareness of these operational and hardware features can affect the manner in which an AP program is written for best performance.

5.0 ARRAY PROCESSOR APPLICATION TO BAY OF FUNDY MODEL

Fig. 7 illustrates the particular computer and

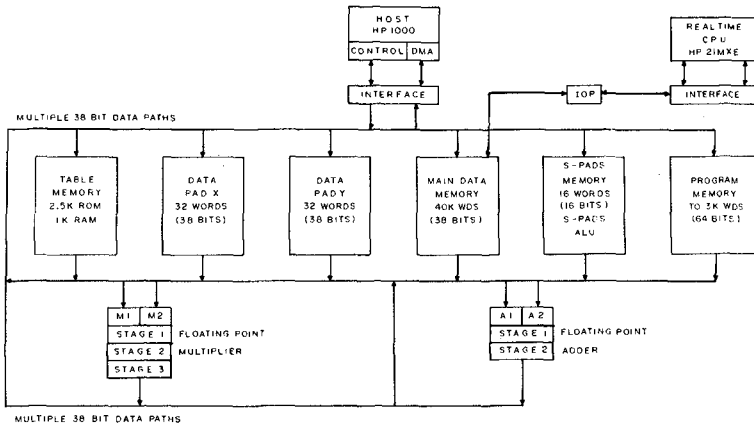

FIG. 7 THE ARRAY PROCESSOR CONFIGURATION AS FOR B OF F MODEL

array processor configuration which is being used for the Bay of Fundy pilot hybrid model. It may be noted that the host computer is a Hewlett-Packard HP-1000 model 45, while the data acquisition and on-line, digital control computer is the HP-21MXE computer. Although the configuration of Fig. 6 could have served the requirements of the hybrid model, the configuration of Fig. 7 was selected in order to get a better overall system utilization. This is of particular importance since the hybrid model is not the only real time activity which is being supported concurrently by this H.P. computer system (Funke, Crookshank and Wingham, 1980).

The DMA interface to the host computer in Fig. 7 is the usual channel for transmission of AP-programs and for initial model constants. The entire Bay of Fundy numerical model, as described in section 3.0, is down-loaded in this way prior to commencement of actual model operation. Once in operation, data related to the tidal elevation is transmitted from the data acquisition computer to the AP via the input/output processor box (IOP) and the resultant discharge data travels on the same channel in the opposite direction. In this manner, the array processor is an autonomous, dedicated numerical model, completely freeing the host computer for other activity.

A suitable "logical" switch was provided to run the numerical model of the Bay of Fundy either as a hybrid model or as a completely independent numerical model. In the former case a boundary exists at the entrance to the Cumberland and Shepody Basins and boundary information is transmitted via the IOP. In the latter case, this boundary does not exist as the two basins are included in the numerical model.

In order to monitor the progress of tidal propagation through the numerical model, the solutions for tidal elevation at each grid point are also transmitted to the data acquisition and control computer at each control step. In this manner one may treat the data in a similar fashion to other data which were acquired through instrumentation on the physical model.

6.0 PROGRAMMING ARRAY PROCESSORS

Whereas the array processors offer substantial improvements in processing speed, the effort required to exploit their power may still be substantial. For this reason it is a definite advantage to have the help of an expert consultant who can quickly solve the usual "teething" problems and who can pilot the project around the various pitfalls.* However, there is a significant and promising development in progress which may overcome many obstacles.

There are four different ways by which the Floating Point Systems Inc. AP120B may be programmed. Each of these offers certain advantages or disadvantages which must be traded off.

6.1 FORTRAN Calls to Existing Library Subprograms

Fig. 8 gives a typical example of a program task which requires various vector and matrix operations. The first portion in Fig. 8 describes this task as a conventional FORTRAN code. Following this, one may recognize calls to various subroutines which serve

- (a) to initialize the AP,
- (b) to transfer data from the host to the AP, and
- (c) to cause a wait until the transfer of data is complete.

It is worth noting that the data memory in the AP is addressed here in terms of absolute addresses and these must be generated before the data transfer calls can

be made. Other arguments specify typically how many elements are to be transferred and what format conversion is to take place.

The subsequent calls deal with the actual solution of the problem. One may recognize vector multiply and vector addition operation which make reference to the various arrays in terms of their addresses in AP memory. In order to make these routines as general as possible, they have been designed to permit operation either on consecutive elements (i.e. arguments No. 2, No. 4 and No. 6 are set to 1) or on alternate or arbitrarily spaced arguments. It is typical for the list of arguments to be organized as "SOURCE1", "SOURCE2" and "DESTINATION". For each of these the order is always "WHERE", "HOW MANY" and "NUMBER OF SKIPS - 1". Prior to the data transfer from AP to host a "WAIT FOR AP READY" must also be invoked.

It should be noted that the DO-loop and the calculation of the "JHB" parameter are executed in the host computer and for each pass through the DO-loop a transfer of subroutine arguments to the AP will be implemented. This is not the fastest way of running the solution but it does offer a relative simplicity in implementation.

The disadvantages of this approach are:

- (a) Programming is limited to existing algorithms in the various libraries supplied by the manufacturer,
- (b) Special requirements, such as conditional branches, require FORTRAN coding in the host computer with the consequent loss of speed due to repeated interchange of information between the host and the AP,
- (c) Addressing of variables and arrays in the AP must be implemented in terms of absolute addresses with a subsequent loss of the convenience and power of a mnemonic address structure which is inherent to FORTRAN and
- (d) Although each AP subprogram has been coded in an optimum fashion, any special requirements, which could benefit from some of the various hardware features of the AP, cannot be accommodated.

6.2 Programming with the Vector Function Chainer Language

The Vector Function Chainer is an AP programming language of a somewhat higher power than the simple calling of precoded library subprograms. This language allows not only the creation of new AP library subprograms, but it also permits some simple, FORTRAN-like statements for execution in the array processor rather than the host computer.

Fig. 9 gives an example of a subprogram for a

FIG. 9 EXAMPLE AP PROGRAM USING VECTOR FUNCTION CHAINER

matrix/vector addition which was created using the vector function chainer. This example illustrates some of the features of this language such as the calling of other existing subprograms, the creation of absolute addresses by arithmetic statements and the use of the logical IF-statement.

Fig. 10 shows the procedure by which a vector function chainer program is implemented. The source code of the program is first processed by the vector function chainer and the resultant output is a "second stage" source code in the AP assembler language. This assembler must also process the code which is then fed through the AP linking loader which serves to satisfy calls to the AP-library. The result of these operations leads to a third-stage source code which is in the host FORTRAN language. However, this code is quite unreadable as it consists of no more than a subroutine definition and termination statements and a long list of DATA statements with integer values. Each integer word is a quarter of a 64 bit instruction word which forms part of the desired AP program.

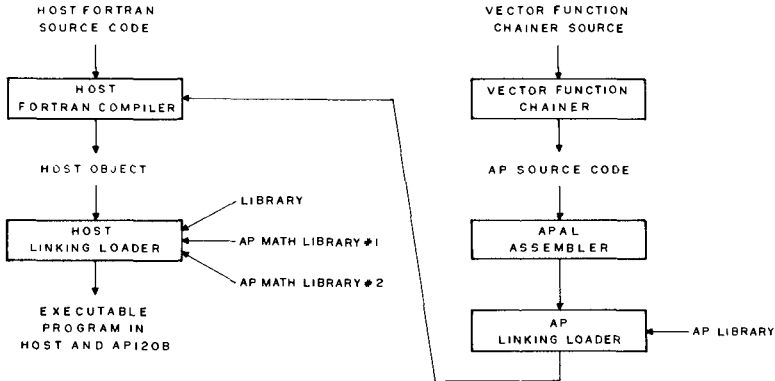

FIG. 10 USE OF VECTOR FUNCTION CHAINER

This third stage source program now represents the newly created member of an AP subprogram library. Before execution it must be compiled together with its calling FORTRAN program by the host FORTRAN compiler and then loaded in the usual fashion.

The vector function chainer offers greater programming power than the approach described under section 3.1. It is equally cumbersome in the management of absolute addresses but since addresses and additional branches defined by the vector function chainer language are computed within the AP, the repeated information transfer between the host computer and the AP is eliminated and a considerable speed-up of the solution times is achievable. The explicit model of the Bay of Fundy was coded in this manner.

6.3 Programming by Using the AP-FORTRAN Compiler

A more recent addition to the bag of tricks for programming is a FORTRAN compiler for the array processor. It offers potentially many significant advantages over any other approach and promises to make the array processor a truly general purpose computer which can bring low cost, high speed computation into the reach of anyone who has a need for it.

In order to code a task in AP FORTRAN, it is necessary to define that portion of a program which is to run on the array processor as distinct from the host computer. This portion must be coded as a standard FORTRAN subprogram. If all of the task is to run on the AP, it is still necessary to have a host program that simply states:

```

READ ARG1,ARG2
CALL NAME(ARG1,ARG2, ... ARGN)
WRITE ARGN
END

```

The subroutine NAME must be processed by the AP FORTRAN compiler which will take care of all data transfers to and from the AP and the associated wait-calls. It can handle any type of linear or non-linear functional relationships and any multi-dimensional array configuration. However, the usual data input/output function via the host computer's peripherals must be looked after by the host computer.

Fig. 11 shows the procedure for implementing an AP pro-

FIG. 11 USE OF AP FORTRAN COMPILER

gram by the AP FORTRAN compiler. The source code of the subroutine 'NAME' is first processed by the AP FORTRAN compiler. This must be done on a larger 32 bit computer as the compiler is not, at present, operational on 16 bit computers. However, its output may be run on 16 bit host computers which provide, after linking-loading, a secondary source code in host FORTRAN. As before, this source code consists substantially of DATA statements only and looks quite similar to the third stage source code produced by the vector function chainer described in section 6.3.

At this time, the community of users of an AP-FORTRAN compiler is still relatively small and general experience in its use must yet be established. However, for the purpose of the Bay of Fundy hybrid model study, an investigation was carried out for the purpose of:

- (a) establishing the suitability of either the explicit or the implicit method for numerical models with regard to array processor operations, and
- (b) establishing the effectiveness of the AP-FORTRAN compiler vis à vis the Vector Function Chainer as a means for implementing the implicit model on the AP.

Table 1
COMPARISON OF AP-FORTRAN WITH VECTOR FUNCTION CHAINER

	AP PROGRAM STORE WORD	PROCESSING SPEED PER TIME STEP**	NO. OF DAYS WORD TO IMPLEMENT PROGRAM*
VECTOR FUNCTION CHAINER	2700	1.5 s	7 days
AP-FORTRAN COMPILER	2200	1.5 s	1 day

* From an original statement of the model in terms of a correctly working program in host computer FORTRAN.

** 48 steps per tidal cycle

The comparison of Table 1 favours the AP-FORTRAN compiler. This came as a surprise because other users had indicated that both the required program store and the solution time would increase as a consequence of using the AP-FORTRAN compiler.* It may be possible that the nature of the particular program or the manner in which the program was coded using the vector function chainer could both affect the results. Nevertheless the authors' experience has been most encouraging even though there still are some minor errors in the AP-FORTRAN compiler.

6.4 Programming by Using the AP Assembler Language

In order to get the greatest processing speed with the least amount of required program store, it is necessary to use assembly language. This option was considered as a last resort for the Bay of Fundy hybrid model if other programming methods had not brought the solution speed within the real time constraints imposed by the physical model.

* Verbal communications

The assembly language permits direct control over all registers, data buses and arithmetic units. The price for this additional flexibility and power is the greater language complexity. As a result it is difficult and costly to learn the language and very time consuming to create an error-free program. Coding by the AP assembly language is considered practical only for those situations where the additional speed justifies the additional cost in program development effort.

7.0 COMPARISON OF AP PERFORMANCE TO OTHER COMPUTERS

Comparisons between computers are meaningful only in terms of specific benchmark programs which contain a specific mix of computational operations. For this reason it is necessary to point out that this comparison applies strictly to the solution of a system of finite difference equations describing estuary dynamics.

The original numerical model of the Bay of Fundy (Greenberg, 1976) uses an explicit method, a schematization similar to Fig. 1 and a time step of 30 seconds in prototype time. Because of the particular interests in the Minas Basin, that area was originally schematized with a finer grid than the one shown in Fig. 1. However, the hybrid model of the Cumberland and Shepody Basins does not require this detailed representation of the Minas Basin and therefore the schematization of Fig. 1 could be adopted. As a consequence, the time step could also be increased to 1 minute in prototype time. The execution times which are listed in Table 2 apply to one semi-diurnal cycle of a tide and, the execution times for the explicit model are based on a time step of 1 minute.

Since the original Greenberg model was not run under exactly these conditions, the time for the CDC CYBER 74 (equivalent to a CDC 6600) can only be estimated.

A finite difference implicit model of the Bay of Fundy was tested with 15 minute time step in prototype time. For the particular requirements of the hybrid model, this implicit method is not considered economically justified. At \$1.00 per word for AP data storage, this model is substantially more expensive to implement.

In assessing the results shown in Table 2, one additional factor is the usefulness of an in-house machine for other applications. In buying time on a main-frame machine, the cost involved includes a significant proportion relating to peripheral equipment which may not be required for present purposes. Thus while it is difficult to obtain accurate costs for main frame time, Table 3 shows that the complete array processor/mini-computer package costs less

than \$150 000 - a figure considerably less than the annual expenditure involved with many large model studies.

Table 2
Comparison of Execution Times for Fundy Models

	EXPLICIT MODEL 1 MINUTE TIME STEP 750 STEPS/CYCLE		IMPLICIT MODEL 15 MINUTE TIME STEP 48 STEPS/CYCLE	
	MINUTES	MEMORY	MINUTES	MEMORY

PARAMETER IDENTIFICATION IN ESTUARINE MODELING

Wen-Sen Chu¹ and William W-G. Yeh²

INTRODUCTION

Parameter Identification (PI) algorithm is an optimization procedure that systematically searches the parameters embedded in a mathematical model. These parameters are not measurable from a physical point of view. The optimization is based on the minimization of a selected norm of the differences between the solution of the mathematical model and scattered observations collected from the system.

Parameter identification (or inverse problem) has been studied in groundwater systems extensively for the past decade (15), and it has also drawn many researchers in the fields of open-channel flow and estuarine modeling since 1972 (1,2,9,17). All the past estuarine PI works in the literature are confined to the one-dimensional case, and hydrodynamics and transport equations are treated separately.

This study deals with PI in a two-dimensional vertically-averaged estuarine salinity model. The salinity transport equation is coupled with the hydrodynamics equations. The coupled relationship introduces extra density terms in the hydrodynamics equations, which must be solved simultaneously with the transport equation.

One of the most difficult problems in PI is the collection of needed observations from the system which is being modeled. With limited exception, the currently available data from the prototype estuaries are not adequate for the purposes of developing a PI algorithm. This is usually critical in quantity (the number of stations and/or the period of time) and in quality (noise of data). However, if an operational hydraulic model is available, the data could then be obtained economically and accurately under an ideally controlled environment. The large amount of data that can be collected from a hydraulic model of an estuary will provide a sufficient number of observations and the required initial and boundary conditions for the development of a PI algorithm. The use of the estuary hydraulic model could provide a better source of prototype data than would be available from the real estuary. It will be much easier to distinguish between the inadequacy of the mathematics and the inadequacy of our understanding of the prototype. Thus, it will give us an idea of how well we could expect to mathematically model the real estuary if we had an unlimited amount of prototype data. Additionally, when these types of data are used in PI, parameters can be optimally identified and the mathematical model can then be used conjunctively with the hydraulic model for prototype applications, provided that the mathematical model is consistently formulated. How well a hydraulic model simulates the prototype estuary is not considered in this study.

²Professor, School of Engineering and Applied Science, University of California, Los Angeles, California 90024.

A tidally averaged approach is adopted to furnish the mathematical model solutions for the purpose of PI. This particular approach solves the dynamic steady-state conditions of the variables as represented by their time-averaged values. The mathematical model of this type is a boundary-value problem, and it is solved by an implicit-explicit iterative scheme (3,4). The rationale of using a tidally averaged model in PI is based upon the assumption that the parameters to be identified are time-invariant, i.e., the parameters have the same values in the transient and dynamic steady-state conditions.

The Error Function Method (1,4) is used with minimax criterion in the optimization. Error function is linearized so that when it is used with the minimax criterion, the optimization problem can be transformed into a Linear Programming (LP) problem.

TIDALLY AVERAGED APPROACH

In order to formulate the two-dimensional vertically averaged mathematical model (See Figure 1) that approximates the prototype conditions as represented by the fixed-bed hydraulic model, the following transient equations are used (11,12):

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + g \frac{\partial \xi}{\partial x} + g \langle i \rangle_x + g \frac{u(u^2 + v^2)^{1/2}}{C^2 H} = 0 \quad (1)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + g \frac{\partial \xi}{\partial y} + g \langle i \rangle_y + g \frac{v(u^2 + v^2)^{1/2}}{C^2 H} = 0 \quad (2)$$

$$\frac{\partial \xi}{\partial t} + \frac{\partial (Hu)}{\partial x} + \frac{\partial (Hv)}{\partial y} = 0 \quad (3)$$

$$\frac{\partial (Hs)}{\partial t} + \frac{\partial (Hus)}{\partial x} + \frac{\partial (Hvs)}{\partial y} - \frac{\partial}{\partial x} \left(HD_x \frac{\partial s}{\partial x} \right) - \frac{\partial}{\partial y} \left(HD_y \frac{\partial s}{\partial y} \right) = 0, \quad (4)$$

in which u , v are the velocities in x , y directions; ξ is a tidal elevation with respect to mean sea level h ; $H = \xi + h$; s is salinity; C is the Chezy's coefficient; D_x and D_y are the dispersion coefficients; g is gravitational acceleration; and $\langle i \rangle_x$ and $\langle i \rangle_y$ are the density slope terms induced by salinity. The density terms can be represented in English unit system by (12, 14):

$$\langle i \rangle_x = \frac{1.94 \times 10^{-3}}{1.94 + 1.94 \times 10^{-3} \sigma_t} \frac{\partial \sigma_t}{\partial x} \cdot \frac{H}{2} \quad (5)$$

$$\langle i \rangle_y = \frac{1.94 \times 10^{-3}}{1.94 + 1.94 \times 10^{-3} \sigma_t} \frac{\partial \sigma_t}{\partial y} \cdot \frac{H}{2} \quad (6)$$

Fig. 1.- Two-Dimensional Estuarine Coordinate System

in which σ_t is the oceanographical sigma-tee function whose values depend upon salinity and temperature.

Coriolis force and wind stress are not included in Eqs. (1) and (2) to conform with the hydraulic model conditions.

For the purpose of this study, the following equation is used for Chezy's C:

$$C = \sqrt{2g/f} \quad , \quad (7)$$

in which f is the Darcy's roughness coefficient, which can be assumed to be time-invariant (5).

Using previous findings (8,10,11), the dispersion coefficients can be written as:

$$D_x = DCX \cdot H \cdot |u| \cdot g^{1/2} \cdot C^{-1} \quad (8)$$

$$D_y = DCY \cdot H \cdot |v| \cdot g^{1/2} \cdot C^{-1} \quad , \quad (9)$$

in which DCX and DCY are assumed to be constants representing the characteristics of the particular estuary; and $|u|$, $|v|$ are the velocities in x and y directions.

When the boundary conditions of the transient model can be assumed to be periodic, all transient variables will reach a dynamic steady-state after a long period of time. These dynamic steady-state variables are constant over time when they are averaged over the period. They are defined as tidally averaged variables when the period used is a tidal cycle.

When Eqs. (1) to (9) are tidally averaged, they can be written as (3,4):

$$U \frac{\partial U}{\partial x} + v \frac{\partial U}{\partial y} + g \frac{\partial \hat{\xi}}{\partial x} + g \langle \bar{i} \rangle_x + g \frac{U(U^2+V^2)^{1/2}}{C^2 H} = 0 \quad (10)$$

$$U \frac{\partial V}{\partial x} + v \frac{\partial V}{\partial y} + g \frac{\partial \hat{\xi}}{\partial y} + g \langle \bar{i} \rangle_y + g \frac{V(U^2+V^2)^{1/2}}{C^2 H} = 0 \quad (11)$$

$$\frac{\partial (\bar{H}U)}{\partial x} + \frac{\partial (\bar{H}V)}{\partial y} = 0 \quad (12)$$

$$\frac{\partial}{\partial x} (\bar{H}US) + \frac{\partial}{\partial y} (\bar{H}VS) - \frac{\partial}{\partial x} \left(\bar{H}D_x \frac{\partial S}{\partial x} \right) - \frac{\partial}{\partial y} \left(\bar{H}D_y \frac{\partial S}{\partial y} \right) = 0, \quad (13)$$

and,

$$\langle \bar{i} \rangle_x = \frac{1.94 \times 10^{-3}}{1.94 + 1.94 \times 10^{-3} \sigma_t} \frac{\partial}{\partial x} \sigma_t \cdot \bar{H} \quad (14)$$

$$\langle i \rangle_y = \frac{1.94 \times 10^{-3}}{1.94 + 1.94 \times 10^{-3} \bar{\sigma}_t} \frac{\partial \bar{\sigma}_t}{\partial y} \cdot \frac{\bar{H}}{2} \quad (15)$$

$$C = \sqrt{2g/f} \quad (16)$$

$$\bar{D}_x = DCX \cdot \bar{H} \cdot |U| \cdot g^{1/2} \cdot C^{-1} \quad (17)$$

$$\bar{D}_y = DCY \cdot \bar{H} \cdot |V| \cdot g^{1/2} \cdot C^{-1}, \quad (18)$$

in which U , V , $\hat{\xi}$, S , $\langle i \rangle$ are the tidally averaged values of u , v , ξ , s , $\langle i \rangle$; and \bar{H} is equal to $h + \hat{\xi}$. The detailed mathematics of this approach are given by Chu and Yeh (3) and Chu (4) which will not be included here. The key assumption for the averaging process is that all the transient variables have small amplitudes in time. The concept of the averaging process is similar to the one that was used in vertical averaging by Leendertse (11).

The parameters to be identified in the above tidally averaged model are the Darcy's roughness coefficient f , and the two dispersion constants DCX and DCY . The parameters, by the previous assumptions, will have the same values in both the transient and the tidally averaged models.

The distinct advantage of using the tidally averaged approach, despite the above-mentioned assumptions, is the saving of computing cost. If a transient model is used for PI, long term integration is likely to be required to generate solutions that are commensurate with observations. Since most of the identification schemes require an iterative search process, such long term integration can easily discourage the modelers' desire for PI, let alone their concerns over the accumulated errors generated by such extended runs.

Equations (10) through (18) are solved by an implicit-explicit, alternating direction, iterative finite difference scheme developed by Chu and Yeh (3). The method is conceptually similar to the multi-operational, implicit-explicit scheme by Leendertse for the transient problem (11). Instead of integrating in time, an acceleration parameter is used for each iteration. The convergence of the proposed scheme is fairly rapid for hydrodynamics and slow for salinity transport. Since its development, the algorithm has been numerically verified through a series of test problems (3,4). These test problems include various initial and boundary conditions. The results showed that the numerical model is applicable to any two-dimensional estuarine problem. Detailed computational aspects of the scheme are given in Chu and Yeh (3) and Chu (4) and they will not be covered here.

PARAMETER IDENTIFICATION ALGORITHM

The selected norm for this study is the minimax criterion, which minimizes the absolute value of the maximum error among all observation stations in the domain. Mathematically, it is to

$$\min_{\vec{D}} \max_{1 \leq i \leq M} \sum_{k=1}^L |w_{ik} \epsilon_{ik}|, \quad (19)$$

in which \vec{D} represents the parameter vector in the model; and ϵ_{ik} is the error at station i of the k th variable which is collected as observation. Equation (19) implies that all k variables are observed at the same stations, $i = 1, \dots, M$. w_{ik} in Equation (19) is a weighting factor. These weighting factors are necessary to reflect widely differing numerical values and units.

If tidal elevations and salinities are available at stations $i = 1, \dots, M$, we can rewrite Equation (19) as:

$$\min_{\vec{D}} \max_{1 \leq i \leq M} \left\{ |w_{i1} \epsilon_i| + |w_{i2} \eta_i| \right\} \quad (20)$$

$$\epsilon_i = \hat{\xi}_i - \xi_i^* \quad (21)$$

$$\eta_i = S_i - S_i^* \quad (22)$$

in which $\hat{\xi}^*$ and S^* are the observations.

In this study, ϵ_i and η_i are assumed to be functions of the parameters only; i.e., it is assumed that the differences between the model solutions and the observations are due to incorrect quantification of the model parameters. Given this assumption, error function can be written in vector notation as:

$$\vec{\epsilon}(\vec{D}) = (\epsilon_1(\vec{D}), \dots, \epsilon_M(\vec{D})). \quad (23)$$

$$\vec{\eta}(\vec{D}) = (\eta_1(\vec{D}), \dots, \eta_M(\vec{D})). \quad (24)$$

The parameter vector \vec{D} can be written as $\vec{D} = (\vec{F}, DCX, DCY)$, in which DCX and DCY are assumed to be pure constants.

By Taylor's theorem, Equations (23) and (24) can be expanded at some initially estimated parameters \vec{D}^0 as

$$\vec{\epsilon}^1(\vec{D}^1) = \vec{\epsilon}^0(\vec{D}^0) + J(\vec{\epsilon}^0, \vec{D}^0)(\vec{D}^1 - \vec{D}^0) + \text{H.O.T.}, \quad (25)$$

$$\vec{\eta}^1(\vec{D}^1) = \vec{\eta}^0(\vec{D}^0) + J(\vec{\eta}^0, \vec{D}^0)(\vec{D}^1 - \vec{D}^0) + \text{H.O.T.}, \quad (26)$$

in which the superscript 1 represents the new estimates; H.O.T. are the higher order terms; and $J(,)$ is the Jacobian matrix.

When H.O.T. are dropped, Equations (25) and (26) become linear with the Jacobian being approximated by finite difference. The finite difference version of the Jacobian is referred to by Becker and Yeh (1) as the Influence Coefficient Matrix.

After transforming Equation (20) to a linear objective function, the optimization problem becomes a linear programming problem. Physical constraints representing parameter lower and upper bounds can be imposed for optimization to ensure realistic solutions.

The solutions of the LP will provide the minimized error and a set of new parameters \hat{D}^1 . These new parameters then become the initial estimates for the next iteration. The algorithm continues until the convergence criteria are satisfied. Two types of convergence criteria are proposed in this method; they are 1) stop when $|J^K| < \delta_1$, and 2) stop when $|J^{K+1} - J^K| < \delta_2$, in which J^K is the objective value of the LP solution at the Kth iteration, and δ_1 and δ_2 are two arbitrarily selected small constants.

The most important merit of the proposed method is that it is independent of the mathematical model, and it can be implemented and solved efficiently in any modern computer facility where packaged routines are available for linear programming problems.

NUMERICAL EXAMPLE

Suisun Bay in California was selected for this study (see Figure 2). Tidal elevations and salinities were obtained in the Suisun Bay portion of the San Francisco Bay - Delta Hydraulic Model in Sausalito, California (13). The finite difference schematization of Suisun Bay is shown along with the installed observation stations in Figure 3. Bathymetric schematization was obtained according to the actual blueprints for the construction of the model (13).

The first PI attempt assumes that all the unknown parameters are constant valued in the domain. The physical bounds set for the parameters are: 1) $0.01 < f < 0.1$ (which corresponds to the Chezy's C values between 25 ft $^{1/2}$ /sec and 80 ft $^{1/2}$ /sec), 2) $1000 < DCX < 7000$, and 3) $1000 < DCY < 5000$. These physical bounds are determined not only by the physical laws but also by computational experience through sensitivity analyses of the parameter values. For example, through various test runs, it was determined that the dispersion constants DCX and DCY would have to be enlarged in order to "reflect" the boundary salinities toward the interior of the domain.

The PI algorithm started with a set of initial estimates of: 1) $f^0 = 0.05$, 2) $DCX^0 = 3500$, and 3) $DCY^0 = 3000$. The computed solutions using the estimated parameters are compared with the observations in Table 1. The convergence property of this run is shown in Table 2.

The second attempt of the PI is much more refined. The roughness coefficient is assumed to be spatially distributed in Suisun Bay. The dispersion constants remain constant valued because of their insensitivity in the model simulations.

Given the above proposed distributed parameter assumption, the PI algorithm would have to identify roughness coefficient at all nodal points. This is such a large task that it is almost impossible to accomplish with the fastest computer available. Furthermore, parameter values between the nodes show discontinuities which do not have any physical meaning. This difficulty has been resolved with the help of the finite element concept by Yeh and Yoon (16) and Yoon and Yeh (18) in PI problems of groundwater flow.

It appears that roughness parameter space in Suisun Bay can be adequately represented by the four corner nodes with bilinear basis functions (4,16). Mathematically, it is

$$f(x,y) = \sum_{i=1}^4 f_i \phi_i(x,y), \quad (27)$$

in which f_i 's are the corner nodal values; and ϕ_i 's are the bilinear basis functions. With Equation (27), the parameter values in any grid point of Suisun Bay could be calculated given nodal values of f_i 's. The algorithm is then to identify the four nodal values (f_i 's) instead of searching through all the grid points.

The physical bounds and the initial estimates for the parameters remained the same in this run. The algorithm converged in eight iterations. The optimally estimated roughness parameters vary from 0.07 to 0.1, which correspond to the Chezy's values of 25 ft ^{1/2}/sec to 30 ft ^{1/2}/sec. The distributed values as estimated by the PI algorithm are shown in Figure 4. The optimal dispersion constants converged to be at 7000 and 1000. The computed solutions using the optimal parameters are compared with the observations in Table 3. The convergence property of this run is shown in Table 4.

To validate the results of calibration, the optimized parameters were used as input data along with a different set of boundary conditions, which were consistent with the experimental set up, in the tidally averaged numerical model to produce solutions. These solutions were compared with the experimental data taken from the San Francisco Bay-Delta Hydraulic Model. The boundary conditions (fresh water inflow and tide) used in the verification and the corresponding experiment were different from the boundary conditions used in the calibration.

Since there is no significant difference in results between the lumped parameter and distributed parameter approach (see Tables 1 and 3), the lumped parameters were used for verification. The verification run started with a set of initial conditions (identical to the ones used in calibration), boundary conditions, and the optimized parameters which are: 1) $f = 0.06$, 2) $DCX = 7000$, and 3) $DCY = 5000$ (see Table 1). The verification results and the boundary conditions used are presented in Table 5.

DISCUSSION AND CONCLUSION

cant amount of computing time in PI, the convergence of the solution scheme is still slow; especially when the transport equation is coupled with the hydrodynamics. The solutions of hydrodynamics alone will usually converge within 200 iterations with variable acceleration parameters (3,4). Nevertheless, when salinity transport equation is calculated with hydrodynamics, the algorithm will typically require 400 iterations to converge. The convergence of salinity values depends on the corresponding hydrodynamics. When the magnitudes of hydrodynamics (velocities and tides) are small, the convergence property of salinities is also influenced by the initial conditions of salinity (3,4). This particular computational problem is solved by a series of semi-heuristic rules that are determined from the computational experience (4).

When the transient numerical model is simulated, the outputs of the model are generally insensitive to different values of dispersion constants (DCX, DCY). In one particular simulation for example, two sets of dispersion constants which differed in value as great as 100 times produced only 1 to 5% changes in salinities in ten tidal cycles. Nevertheless, when tidally averaged numerical model is simulated with the true boundary values collected from the hydraulic model, it was found that the dispersion constants would have to be enlarged in order to "reflect" the ocean boundary salinities toward the interior of the domain. One of the conceivable reasons for this phenomenon is the strong net outflow from the delta to the ocean. This limited increase of the internal salinity values in the domain in tidally averaged numerical model is due to the inherent nature of the boundary value problems (Eqs. 10 to 14). Other factors that may cause the inflation of the dispersion constants include: the finite difference schematization, the vertical averaging, the tidal averaging, and the various model approximations.

The proposed PI algorithm is independent of the numerical model by virtue of the error function approach. By the definition of error function and the problem formulations, the identification algorithm can be programmed separately from the numerical model. In other words, the method can be easily implemented with any numerical model for PI purposes, provided that enough data are available.

The calibration and verification of the tidally averaged numerical model have been successfully performed. In both attempts, the maximum deviations between the model results and field observations came from the particular station in Grizzly Bay. In the schematization of the entire study area, the inflow from Suisun Slough which is next to Montezuma Slough was ignored. The performance of the mathematical model depends not only on its parameter values, but also on the schematizations. Other important factors that could contribute the discrepancies include noises in observations and errors in data processing of boundary conditions and observations (4).

In each iteration of PI, the numerical model has to be solved once for each parameter in order to generate the influence coefficient matrix. In the lumped parameter approach, (three constant parameters for the entire domain), it took three iterations for the PI scheme to converge. (The numerical models had been solved by $3 \times 3 + 3 = 12$ times.) This lumped parameter PI case used 20 minutes of IBM 360/91 computing time at a cost of \$150 dollars.

1. Introduction

Numerical models for the simulation of tidal waves in estuaries have become a standard tool of coastal engineers. Before they can be applied to practical problems, they have to be calibrated against nature. The basis for calibration is normally a representative set of tidal curves (natural field data), which has to be reproduced by the numerical model. Generally, the calibration is performed by empirically tuning certain parameters, until a fairly good agreement between measured and calculated quantities is obtained. In most cases, this is a "trial-and-error" process which may become very time-consuming, and which strongly depends on the intuition and experience of the user.

In order to make the process of calibration more effective, and to ensure that the best possible agreement between nature and numerical model is achieved, a calibration method has been developed to determine the parameters of the numerical model automatically by means of a mathematical method of optimization. The method is applied to a one-dimensional numerical model of the Elbe River.

2. Numerical Model

For the numerical river model, the common assumptions of vertically and horizontally averaged velocities, and of hydrostatic pressure distribution are made. The basic equations are derived from the conservative principles for momentum

$$\int \left(\frac{1}{gA} \frac{\partial Q}{\partial t} + \frac{1}{g} \frac{Q}{A^2} \left(\alpha + \frac{b_s}{b} \right) + \left(1 - \frac{\alpha}{g} \frac{Q^2}{A^3} b_s \right) \frac{\partial h}{\partial s} - I_s + I_v \right) ds = 0 \quad (1)$$

and for mass

$$\int \left(b \frac{\partial h}{\partial t} + \frac{\partial Q}{\partial s} \right) ds = 0 \quad (2)$$

where A stands for the stream area, b_s for the stream width, and b for the top width. s is the space coordinate along the river axis, Q the flux in this direction, and h gives the variation of the free surface.

The quantity I_s stands for the bottom slope, I_v for the friction losses, and α is a velocity coefficient.

These integral formulations are integrated directly. Adopting a finite element concept, and using linear trial functions in space and time for the description of the water level h and the flux Q , an implicit formulation of second order accuracy is obtained. The scheme is identical with that proposed by Preissmann (1960), and can alternatively be derived from a finite difference formulation for a finite control scheme. An analysis of the numerical properties of this scheme was presented by Evans (1977).

The numerical model was applied to the Elbe river, covering its tide-influenced length of 139.1 km from the North Sea (Cuxhaven) to Hamburg (St. Pauli) and further upstream to Geesthacht (Fig. 1). The model had to take into account islands and banks. For the discretization an average element length of about 1 km was chosen. A rather high resolution of the topography was thus obtained.

Fig. 1: One-dimensional Elbe model

For the description of bottom friction, the Taylor formulation

$$I_v = \frac{r|v|v}{g h} \quad (3)$$

was used, r is the friction parameter.

3. "Trial-and-Error" Calibration

The numerical model calculates the time-dependent variation of the free surface, and the water flux along the river. The calculated values depend

on a chosen set of friction parameters. They have to be determined from a calibration of the model, which aims at hindcasting some typical measured states in nature. Normally the calibration is performed with respect to a set of tidal curves only, since data on velocities are more difficult to get. During the process of calibration, the friction parameters are varied empirically until a fairly good agreement between calculated and measured data is obtained. So the calibration is actually performed in a "trial-and-error" manner. In each iterative step, the "degree of agreement" between computed and measured data should be determined according to some analytic criteria. This can be done efficiently on the computer only, unless the criteria for the calibration are strongly simplified.

The really crucial point of any "trial-and-error" calibration, however, is the estimate of a new parameter set for the next iteration step. It is difficult to make a good guess, due to the non-linearity of the numerical model. The model user needs a good deal of experience and intuition. In order to overcome this drawback, an automatic calibration method (Januszewski, 1980) was developed, based on the theory of mathematical optimization. This method is independent of any user's "feeling" and determines an optimal parameter set in accordance with any user-defined criteria and error bounds.

4. Optimized Calibration

The strategy for an automatic and optimal determination of friction parameters leads to a closed optimization system which is shown in Fig. 2. The numerical model is the basic element of this system. In the later application on the Elbe river, a numerical model will be used, for which the initial and boundary conditions z_o and z_R must be prescribed.

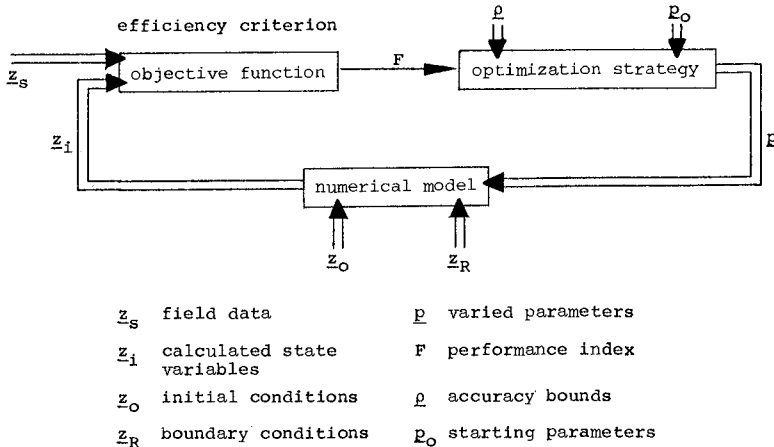

Fig. 2: Strategy for Optimized Calibration

\underline{z} is the vector of state variables which are the free surface and the fluxes or velocities at any cross-section. These quantities are either computed by the numerical model, giving the vector \underline{z}_1 , or measured in the field, and then giving the vector \underline{z}_2 . The computed vector \underline{z}_1 depends on the parameter vector \underline{p} which contains the friction parameters.

In the closed calibration loop an initial parameter set \underline{p}_0 has to be chosen as input for the numerical model, which calculates the vector \underline{z}_1 . This vector has to be compared with the corresponding field data set in \underline{z}_2 . For the Elbe model, this comparison was made for the water levels, as they were the only available field data. The analytic criterion, in accordance to which the comparison is being made, and the definition of which is open to the model user, is called the objective function. The comparison between calculated and measured state variables results in a scalar quantity, the performance index F . This is a measure for the agreement achieved between measured and calculated values.

The performance index is now the input for the optimization strategy, which generates a new set of parameters. This new parameter vector \underline{p} is the output of the optimization strategy and in turn the input for a second cycle of the closed optimization system.

The iteration stops following a convergence test which is made during each cycle just before a new parameter set is calculated. For this test, the model user has to define the wanted accuracy bound ρ , according to which three tests are made:

a comparison of the actual values and those of the preceding iteration step, for all elements of the parameter vector \underline{p}

$$p_v - p_{v-1} \leq \epsilon \quad (4)$$

a test on the achieved improvement of the performance index F

$$|F_v - F_{v-1}| \leq \eta_1 \quad (5)$$

and a test on the performance index itself

$$F \leq \eta_2 \quad (6)$$

Calibration is completely automatized in the outlined closed loop. The model user influences the calibration run only by specifying the error bounds, and by defining the objective function. So he is still controlling the physics of the calibration, but has got rid of a lot of manual work.

4.1 Objective Function

The objective function describes the error between calculated and measured data. It should define a scalar non-negative quantity, the performance index F , which depends on the parameter set \underline{p} . The optimal parameter set \underline{p} is obtained when the error between computed and measured data is minimized. The obtained minimum should be a global one.

For the application to the Elbe model, the objective function was defined as the sum of the squares of the differences between measured and calculated state values taken at all time steps for the tidal period and at

all locations for which field data were given.

$$F(\underline{p}) = \int_{t_0}^{t_1} (\underline{z}_s(t) - \underline{z}_i(t, \underline{p}))^T (\underline{z}_s(t) - \underline{z}_i(t, \underline{p})) dt \quad (7)$$

The advantage of this formulation lies in the fact that the differences over the total time of the tidal period are equally weighted, i.e. the differences are minimized with respect to phase and amplitude.

In order to find the optimal parameter vector \underline{p} , the objective function has to be differentiated with respect to all components of the vector \underline{p} .

$$\left. \frac{\partial F(\underline{p})}{\partial p_j} \right|_{\underline{p}=\underline{p}^*} = 2 \int_{t_0}^{t_1} (\underline{z}_s - \underline{z}_i)^T \left. \frac{\partial \underline{z}_i}{\partial p_j} \right|_{\underline{p}=\underline{p}^*} dt = 0, \quad 1 \leq j \leq n \quad (8)$$

A minimum for $F(\underline{p})$, at least in a local sense is obtained, when the derivative is equal to zero. The parameter vector \underline{p}^* corresponds to $\min F(\underline{p})$. This condition is fulfilled in three cases.

- 1) The derivative of computed state values

$$\frac{\partial \underline{z}_i}{\partial p_j}$$

is independent of the friction parameters, which means that the problem is not correctly posed.

- 2) The product

$$(\underline{z}_s - \underline{z}_i)^T \frac{\partial \underline{z}_i}{\partial p_j}$$

is equal to zero, which means that both functions $(\underline{z}_s - \underline{z}_i)$ and $\frac{\partial \underline{z}_i}{\partial p_j}$ are orthogonal, and thus independent of each other.

This result is meaningless.

- 3) The deviation $(\underline{z}_s - \underline{z}_i)$ is equal to zero. This is exactly the desired result for a perfect calibration.

The first derivative, however, does only give a necessary condition for a local minimum. A global minimum is obtained, if the second derivative is positive - semi-definite. This can be shown for each iteration step, as long as the objective function is based on an error-squared formulation.

The numerical model is integrated for discrete steps in the time domain, and thus the objective function too has to be formulated in a discrete manner.

$$F(\underline{p}) = \sum_{k=1}^{T_{\max}} (\underline{z}_s - \underline{z}_{i,k}(\underline{p}))^T \underline{A} (\underline{z}_s - \underline{z}_{i,k}(\underline{p})) \quad (9)$$

To this formulation, a symmetric matrix \underline{A} is added, which allows for an arbitrary weighting of different elements of the error vector $(\underline{z}_s - \underline{z}_i)$.

Depending on the model user's experience and on the application he has in mind, it is also possible to use other objective functions. For the Elbe model

computations, the correlation coefficient $r_{j,si}$ was alternatively introduced:

$$F(\underline{p}) = \sum_{j=1}^N (1 - r_{j,si}) \quad (10)$$

which is based on an error-squared formulation, too. Other statistical measures can also be used.

The error computation must refer to all the tidal curves, as in the case of the Elbe model. It can be extended to include the velocities, too, or it can be restricted to tidal high and low water alone. The choice of the objective function is open to the user, and this means that automatic calibration does not become a black-box system.

4.2 Optimization Strategy

Optimization strategy is a mathematical procedure for finding the minimum value of the performance index. Due to the non-linearity of the St. Venant equations (1,2), it is impossible to find the minimum \underline{p}^* of the objective function, i.e. $\underline{p}^* = \min F(\underline{p})$, in an explicit way. So the second method of Powell (1964), which is a method taken from the scope of non-linear programming, is applied for finding the minimum by a sequential search strategy. It is based on a direct searching technique which avoids the computation of derivatives for the objective function $F(\underline{p})$, which in turn depends on the non-linear St. Venant equations, and is rather complicated.

The principle of the searching strategy is explained by figure 3.

Fig. 3: Second Method of Powell

It is assumed that the objective function $F(\underline{p})$ is a convex function. In a three-dimensional representation which is chosen for reasons of simplicity of the graphical sketch, the objective function $F(\underline{p}) = \text{const.}$ defines isolines in the $p_1 - p_2$ domain. Starting from an initial estimate \underline{p}_0 , two linear independent searching directions are defined. The minimum of $F(\underline{p})$ is determined subsequently and independently in each direction. This leads to a new parameter vector \underline{p}_1 . This procedure is repeated iteratively. To make the searching process efficient, a test is performed after each iteration step to find out whether the search directions should be the same for the next step, or whether they should be varied. A criterion on this is given by the determinant of the search directions. It will attain its maximum for orthogonal, and thus linear independent searching directions. So for each iteration step a new direction, which is defined from the starting value $F(\underline{p})$ to the computed value $F(\underline{p})$ at the end of the step, is introduced and tested. If the direction determinant, computed by omitting the first search direction and including the new one, is bigger than it was in the step before, the new direction is accepted. The search for the minimum for $F(\underline{p})$ in each independent direction is effected by means of the method of quadratic interpolation, which avoids the computation of derivatives. An example for this strategy is given by figure 4.

Fig. 4: Quadratic Interpolation

Starting with a value $F(\underline{p})$, neighbouring values

$$F(\underline{p} + \Delta \underline{p}), F(\underline{p} + 3\Delta \underline{p}), F(\underline{p} + 7\Delta \underline{p}), F(\underline{p} + \dots)$$

are computed, until the last value is bigger than the preceding one. An

additional value is computed in the center of the last interval, and then the minimum is determined by quadratic interpolation. This procedure is rather efficient, as it basically corresponds to a binary searching strategy.

5. Results

The suggested method for optimized automatic calibration was applied to the section from Grauerort Geesthacht of the described Elbe river model (Fig. 1). This section, which is also given in figure 6, has a length of 74.6 km. The one-dimensional model for this part of the river was divided into 17 branches to include the islands and the highly branched Hamburg harbour (St. Pauli). Measured data were available at 5 locations along the river, which are marked by dots in figures 1 and 6. The model was run with constant inflow prescribed at Geesthacht, and a tidal curve given at Grauerort.

It was assumed that for this river section the friction parameters may be independently varied within 4 areas as shown in figure 6. At least one measured data set has to be available within each area, as otherwise no performance index can be determined for this area, and consequently the problem would not have a unique solution.

Figure 5 shows a comparison between "trial-and-error", or manual, and the optimized automatic calibration for the location Seemannshöft.

The calibration was performed for the first 12.5 hours of the tidal curves shown in figure 5, which correspond to the first tide on August 22, 1975.

The objective function for the manual calibration was the difference between measured and calculated values at tidal high and low water only. In the manually-performed calibration, friction parameters which depend on the flow direction were used. The obtained calibration is nearly perfect at high and low water, but not so good for the gradient at falling water.

For the automatic calibration, the friction parameters were assumed to be constant over the tidal period. Moreover, as a time-step of 10 minutes was used in the numerical model, the error was also minimized at about 75 points per tidal period, and per location, for which measured data were given. So amplitude and phase error equally weighted and in more detail were taken into account by this strategy. The phase error reduction leads to a much better agreement of the tidal curves. This will probably result in a much better representation of the velocities, the wave height, however, is too small.

The automatic calibration was performed to an accuracy of less than 0.005 m per location and time-step. The obtained friction parameters are given in the table of figure 6.

The variation of the parameters is explained from the typical cross section shapes of the river, which are approximately trapezoidal in area I, and much more complicated in areas III and IV. Moreover, the system is highly branched in the areas II to IV, and especially in the harbour area II simplifications with respect to the discretization have been made.

The given results were obtained by using the sum of the squares of the differences between measured and computed values as objective function.

Fig. 5: Comparison Manual to Automatic Calibration

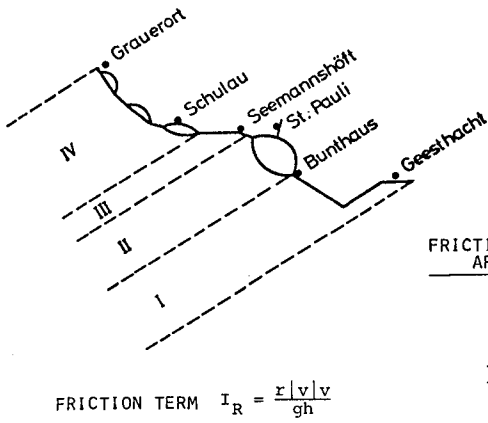

Fig. 6: Friction Parameters after Calibration

Alternatively, a calibration was performed, using the correlation coefficient (ρ) as objective function. For the same error bounds, a correlation coefficient of 0.99965 was obtained. The correlation as well as the relation of computed versus measured data is given in figure 7. The computation time for the calibration was reduced by about 20 % in comparison with the error-squared function.

Fig. 7: Calibration using Correlation Coefficient

During calibration it was found that the numerical model was very sensitive to all parameter changes. Small increments on the optimal parameter set increased the value of the objective function considerably. This might easily lead to many poor estimates on new parameter sets in the "trial-and-error" calibration. It is confirmed by a comparison of the internal statistics, which was made over the number of computer runs for manual and automatic calibration. The optimization strategy required 33 runs for the given bounds, whereas about 60 variations of the parameter were necessary for the manual calibration. The manual calibration demanded for a careful and time-consuming data analysis, and repeated plotting. A trained engineer was kept busy by this job for weeks. The automatic calibration was performed within one computer run in one night. The obtained results cannot be improved, unless the error bounds are reduced. Moreover, the actual bound up to which the calibration was performed, is a useful information for the model user 's prognostic applications of the model.

6. Conclusion

A method from the field of mathematical optimization was applied for the calibration of a one-dimensional river model. The model starts from the St. Venant equations which are solved numerically. The optimization leads to a closed system, so that the calibration can be performed automatically within one computer run. This leads to considerable savings in manpower and computer time. The physical transparency for the hydraulic engineer is maintained. The engineer still defines the criteria according to which the calibration is performed. The parameter set finally obtained is the best and only combination of parameters which is obtainable within a given error bound.

ABSTRACT

For many years stability theories have been used both to design inlets and to appraise the performance of them. There are a variety of approaches to the formulation of stability criteria ranging from the purely empirical (Stevenson, 1884 - cited by Bruun & Gerritsen, 1958; O'Brien, 1931; Bruun, 1977) to the generalised analytical (Escoffier, 1940; Bruun & Gerritsen, 1958; Keulegan, 1967; O'Brien and Dean, 1972).

In 1966 a seemingly small perturbation made to the inlet of Wallis Lake resulted in significant changes to the estuary. The direct application of existing stability theories was of marginal value in explaining these changes and predicting the stable regime that the estuary may ultimately reach. This paper highlights some of the limitations of existing stability theories, presents a new method of

Plate 1 Wallis Lake inlet in 1952 and 1974
(northern breakwater constructed in 1966).

dynamic behavioural analysis, outlines the case study of an estuary to which existing stability theories could not be effectively applied but to which the behavioural analysis produced interesting results, and recommends the direction in which further research could yield beneficial results.

1. INTRODUCTION

The twin towns of Forster and Tuncurry are sited on the banks of the entrance channel to Wallis Lake (Figure 1); an estuary located 220 km north of Sydney on the New South Wales coastline. The economic viability of the towns is based on the fishing, oyster and tourist

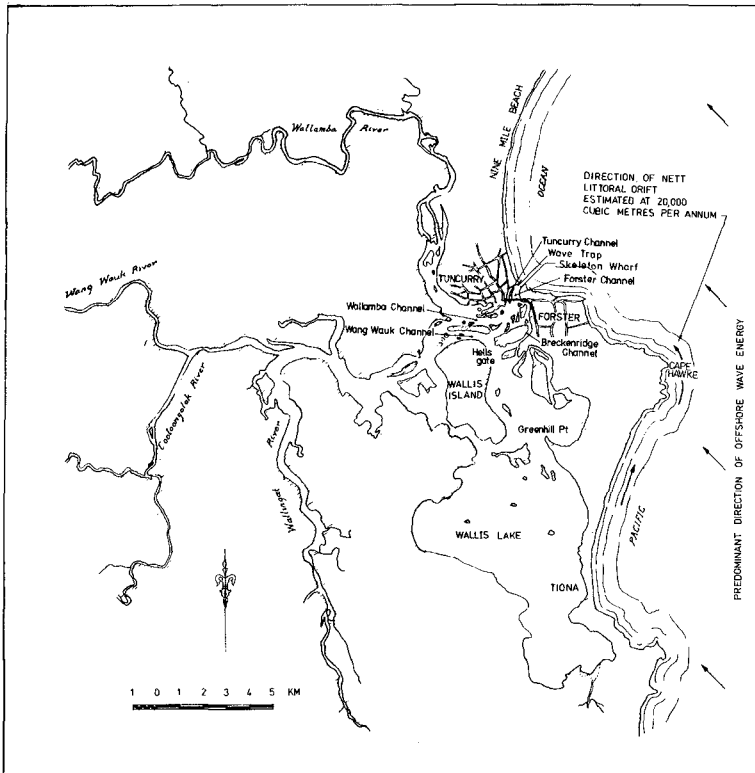

Figure 1 Locality Sketch

industries which focus on the amenity of the estuary and nearby coastal waters. Hence, the entrance conditions and hydraulic characteristics of the estuary are vital factors regarding the existence and development of the region.

Wallis Lake has a plan area of 100 square kilometres and an average depth of 3 m. Three rivers - the Coolongolok, the Wang Wauk and the Wallingat - enter the north-western sector of the estuary. The Wallamba River enters the northern part of the estuary amongst a confusion of small islands and channels. Whilst the four rivers and the lake all share the same ocean entrance, three major and several minor channels connect the river/lake system to the coast. In the vicinity of the ocean inlet the channel system simplifies to the Tuncurry (northern) and Forster (southern) channels.

The average daily fresh water flow in these rivers is small compared with the tidal flows and only extreme flood events have any influence on the estuarine channels. The tidal prism at the higher spring tides is some 18×10^6 cubic metres (ocean tidal range 1.93 m). The average annual flood has a total discharge of about 30×10^6 cubic metres, but the stilling basin effect of the lake greatly damps the potential of floods to scour the entrance channels. This century there has only been one very large flood through the system. This flood occurred in 1929 and had an estimated total discharge of 250×10^6 cubic metres. It caused considerable scouring of the entrance channels.

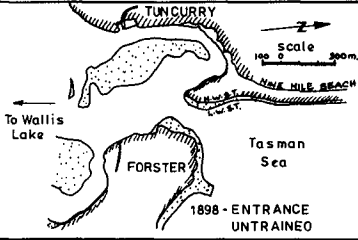

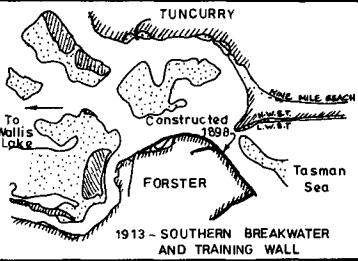

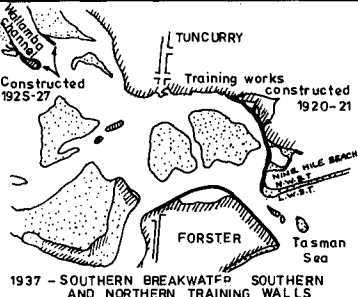

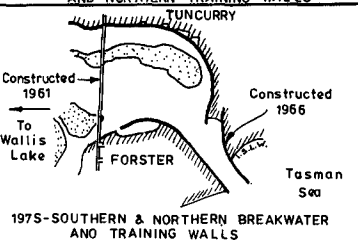

The inlet is located on a moderate to high energy coastline. However, the entrance is somewhat protected from the predominant southeasterly swells by Cape Hawke (Figure 1). The nett littoral drift is northerly and is estimated to be in the order of 20,000 cubic metres per annum. Studies are presently underway to further assess this littoral drift estimate and to develop a more detailed description of the coastal processes in this region.

2. HISTORICAL DEVELOPMENT AND EFFECTS OF ENTRANCE WORKS

In its natural state prior to the construction of any training works the inlet comprised a series of sandy, shoal filled channels that meandered across a wide, beach ridge plain. Both the location and cross-section of the ocean entrance varied with time. Over the past 82 years various entrance training works have been constructed to improve the navigability of both the entrance and estuarine channels and to cater for the historical trend towards larger ocean going trawlers. These works are summarised in Table 1.

It was not possible to fully assess the impact of works carried out before 1966 on the estuary/inlet system due to the paucity of data. However, indications are that from 1898 to 1966 the estuary mouth exhibited many of the typical features of single breakwater inlets. These features include an asymmetrical entrance bar with a channel that meandered across it, large shifting swash shoals, a marginal flood tide channel on the unprotected (northern) side and shifting shoals in the lower entrance channel region. Immediately inside the inlet a twin flood/ebb channel system had developed.

Table 1 History of Entrance Works taken from Hydrographic Plans

YEAR OF SURVEY	DESCRIPTION	
1898	Untrained entrance	
1913	<p>Southern breakwater and training wall</p> <p>In 1898 a contract was let for the construction of a breakwater (500m) and training wall (560m) along the southern (Forster) embankment</p>	
1937	<p>Northern training works and bay shoal stabilisation attempt.</p> <p>In 1919 further works at the entrance were carried out by constructing a 380m long training wall on the northern (Tuncurry) side of the inlet.</p> <p>The work was completed in 1922 and was followed in 1925 and 1928 by the construction of training walls within the estuary in an attempt to stabilise the internal sand bars.</p>	
1975	<p>Northern breakwater and extension of southern breakwater.</p> <p>By 1966 a 460m long breakwater had been constructed on the Tuncurry side of the inlet and the Forster breakwater had been extended by 90m.</p> <p>The width between the breakwaters is 120m.</p>	

Figure 2 History of Estuary Tidal Ranges

The Forster (southern) channel predominantly conveyed the flood tide whereas the Tuncurry (northern) channel predominantly conveyed the ebb. Tidal gradients presented on hydrographic charts indicate that prior to 1966, entrance works had no significant impact on tidal ranges or phasings throughout the estuary.

Following the construction of the northern breakwater in 1966 there was a dramatic increase in tidal ranges throughout the estuary (Figure 2). Associated with this change was an accentuation of the distortion between flood and ebb tidal hydrographs, a marked change in the predominance of tidal channels and the scouring of the entire 3 km estuary channel system; a scouring mode which is showing no sign of reversal to the present day.

3. STABILITY THEORIES

Approaches to the formulation of the most commonly used stability criteria fall into two basic categories:

- (i) The empirical approach - the identification of parameters relating cause and effect followed by the development of simple relationships between these parameters using coefficients which have been derived from many field observations.
- (ii) The generalised analytical approach - the development of generalised formulae from mechanism understanding and description.

3.1 Empirical Approach

Bruun and Gerritsen (1958) outlined the history of stability theories from Stevenson (1884) through the work of O'Brien (1931) up to that proposed by Bruun and Gerritsen in their 1958 paper.

One of the most popular empirical approaches is based on the work of O'Brien (1931). O'Brien proposed that the stable inlet cross-sectional area could be determined from the tidal prism using the relationship:

$$A = 1000 \left(\frac{\Omega}{640} \right)^{0.85} \quad (1)$$

where

A = inlet cross-sectional area
 Ω = tidal prism

Considerable embellishment of this model has been carried out by O'Brien (1969) and others, the most notable being Jarret (1976) who has presented prism/area relationships for estuaries with various inlet configurations and tidal conditions.

These predictive prism/area relationships are of marginal value to analytical work. The reasons for this are that firstly, the scatter of field data points around the predictive curve implies that the relationship is at best approximate and secondly, for estuaries with long and complex entrance channels connecting the water body to the ocean it is virtually impossible to relate an equivalent theoretically determined stable channel cross-sectional area to channels in the field.

Bruun (1977, 1978) has advanced the empirical approach by proposing a method which considers the relationship between littoral drift and the tidal prism of the estuary. This approach represents a shift in emphasis of pertinent parameters from the morphological (cross-sectional area) to those describing forces (sediment transport). In essence, this approach is concerned with entrance bar conditions. Bruun contends that the stability of an inlet must be analysed in terms of the ability of the tidal flow to flush out the sediments that are carried by wave and current action to the inlet gorge. On this basis he proposes that inlets be classified in terms of Ω/M ratios, where

Ω = tidal prism
M = sediment feed to the gorge

Low ratios (less than 50) are indicative of poor entrance conditions whereas high ratios (greater than 150) are indicative of good entrance conditions. This approach is simply one of classification by parameter ratios and has severe limitations if it is to be used as a predictive tool.

However, it is important to be aware of the development, limitations and strengths of the empirical approaches as they represent significant steps down the path of understanding inlet dynamics.

3.2 Analytical Approach

Of the generalised analytical approaches, that presented by O'Brien and Dean (1972) is a significant contribution to inlet mechanism understanding. It is based on the earlier well documented work of Escoffier (1940) and Keulegan (1967). This method relates the bay tide phasing and amplitude to that of the ocean tide through the hydraulic characteristics of the entrance channel. The approach is applicable to small inlets and large tidal estuaries on shorelines where littoral drift is small. It favours estuaries with relatively short and regular entrance channels connecting the water body to the ocean. With this method of analysis, through the construction of an Escoffier diagram,

the status of an inlet at any point in time can be examined and the ultimate stable cross-sectional area of the entrance channel can be predicted. The O'Brien and Dean method is outlined below as it forms a basis from which the analytical approach adopted for the Forster/Tuncurry study was developed.

Keulegan developed the relationships between the repletion coefficient K and the tidal phase lag, and the ratio of the bay-to-ocean tidal amplitudes, a_b/a_o . These relationships are shown in Figure 3. The repletion coefficient may also be expressed as a function of the hydraulic and geometric properties of the estuary in the following way:

$$K = \frac{T}{2\pi a_o} \cdot \frac{Ac}{Ab} \cdot \sqrt{\frac{2gR}{Ken + Kex + \frac{fl}{4R}}} \quad (2)$$

where

- T = tidal period
- a_o = amplitude of the ocean tide
- Ac = inlet cross-sectional flow area
- Ab = surface area of the basin
- g = gravitational constant
- Ken, Kex = entrance and exit head losses of the entrance channel
- f = friction factor
- l = friction length
- R = hydraulic radius of entrance channel

Keulegan also presented the relationship between the repletion coefficient and the dimensionless maximum velocity in the inlet $V'max$, as shown in Figure 4. The maximum velocity through a specific inlet is given by equation (3):

$$Vmax = V'max \cdot \frac{2\pi}{T} \cdot a_o \cdot \frac{Ab}{Ac} \quad (3)$$

Figure 3

Figure 4

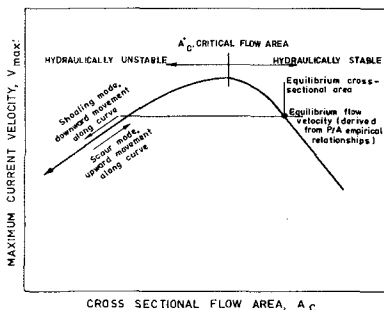

Figure 5 Generalised inlet hydraulic stability curve, or "Escoffier Diagram".

Where equations (2) and (3) and Figure 4 are used together a range of inlet hydraulic conditions can be calculated in terms of the maximum velocity versus cross-sectional flow area. The inlet mechanics are portrayed by the inlet stability curve (Escoffier diagram - Figure 5).

It can be seen from this diagram that an induced change in the cross-sectional flow area of an hitherto hydraulically stable inlet will result in either a change in inlet current velocity which will work to return the inlet towards its equilibrium size by appropriate deposition or scour, or, if the induced area change is so large as to reduce the cross-sectional area below the critical flow area, making the inlet

hydraulically unstable. An hydraulically unstable inlet is characterised by increasing friction with decreasing cross-sectional area. The result is that if any natural or man-induced change in flow area occurs this is accompanied by a change in the flow velocity which will, by inducing scour or deposition, perpetuate the induced area change. Since area changes are perpetuated, an hydraulically unstable inlet will either continuously scour until a stable flow area is achieved (unstable scour mode) or its will continuously shoal until inlet closure (unstable shoaling mode).

Many limitations of this model have been documented by Bruun (1977, 1978). In particular, major difficulties are encountered in determining the equivalent length and cross-sectional area of a long and complex entrance channel system. However, the major failing of the model is that it can not be used as a predictive tool in situations where significant perturbations such as those associated with the construction of breakwaters are or will be made to the entrance bar of the inlet. Moreover, if it is desired to predict the effect of such perturbations the O'Brien and Dean model cannot be used for the reason that an Escoffier diagram representing the range of future likely hydraulic characteristics cannot be constructed if more than one parameter (A_c and consequently R) is varied.

Following on from the O'Brien and Dean approach, Bruun (1978) shifted the emphasis to sediment transport considerations on the basis that stability must reflect the ability of sediment to move through the inlet in such a way that nett deposition does not occur. Bruun suggests that inlet analysis be undertaken by calculating sediment transport:

- (i) in the gorge (entrance channel),

- (ii) in the region between the inlet and the ocean bar,
- (iii) in the ocean channel including its passage over the bar, and
- (iv) in the bay channels.

It is then possible to construct a quantitative sediment budget from which erosion and depositional areas may be identified, hence a model of estuary/inlet behaviour can be constructed.

The limitations of the Bruun approach are less obvious than those of O'Brien and Dean. There are difficulties in accurately carrying out many of the required calculations. The sediment budget determination may in many cases be very sensitive to these inaccuracies. Further, there is no well documented method to determine sediment transport in the region of the ocean bars for differing inlet configurations. Finally the method is not readily adapted to situations where relatively long channels connect the bay to the ocean.

4. INLET BEHAVIOURAL APPROACH

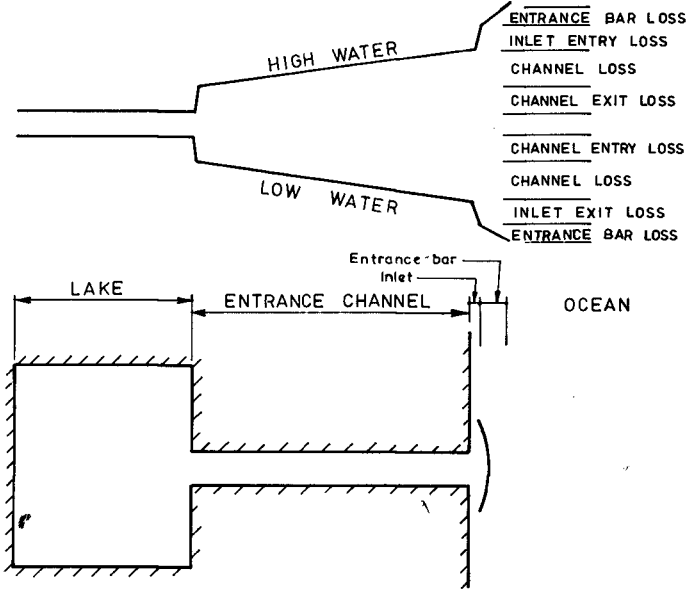

The concepts of O'Brien and Dean and Bruun may be modified and used in a complimentary manner when studying the changes induced by major inlet forcing works such as breakwater construction. Extension of these approaches has led to the development of an inlet behavioural approach which allowed studies to be undertaken on typical New South Wales inlets. This behavioural approach included the recognition and inclusion of the following:

There are two major sources of head loss between the forcing function (ocean tide) and the bay response. These are the head loss over the entrance bar and the losses associated with the hydraulic characteristics of the inlet and entrance channel (Figure 6). When constructing the Escoffier diagram for a particular estuary the following approach is used (Czerniak, 1977 - see Section 3.2):

- (i) A_b/a_o is calculated from existing data and K is determined from Figure 3.
- (ii) Equation (2) is solved for l using K and known values of R, Ac, T, a_o , Ab, f, Ken and Kex. The latter six parameters are assumed not to vary.
- (iii) The hydraulic stability curve is computed using equations (2) and (3) and Figure 4 with only Ac (and consequently R) varying over the entire range.

In equation (2), four head loss parameters (Ken, Kex, f, l) are used to describe the total impedance of the tidal inlet and entrance channels to the flow. This implies that the forcing function a_o (the amplitude of the ocean tide) is applied immediately outside the inlet. Hence, a_o is not a true ocean tidal amplitude unless entrance bar losses are negligible.

SCHEMATISED ESTUARINE HYDRAULIC LOSSES

SCHEMATISED PLAN OF ESTUARY

Figure 6 Generalised head loss diagram for inlet/estuary system

Accordingly, a_0 should be defined as the amplitude of the tide immediately outside the inlet. This is not in accord with Bruun's recommendation that a_0 be determined from outer coast ranges.

Sediment budgeting as proposed by Bruun can be modified by the application of regime theory to the inlet hydraulics both

before and after the perturbation to provide a predictive numerical-descriptive model.

5. APPLICATION OF BEHAVIOURAL ANALYSIS

It has been identified that changes to head loss over the ocean bar are important when considering the impact of inlet modification on estuary behaviour because such modifications can significantly affect the forcing function of the system. Moreover, changes to tractive stresses and the regions over which they act can be expected to radically alter sediment transport paths and the quantities of sediment involved in the budget.

An essential part of inlet behavioural analysis includes an examination of changes to the hydraulic and sediment transporting characteristics of the ocean bar following inlet modification works. The changes to the hydraulic characteristics can be analysed in terms of alterations to the head loss over the bar and in the inlet due to modifications to the inlet cross-sectional shape, velocities and frictional properties. The modification of sediment supply to the inlet gorge must include examination of:

- (i) Changes to tractive stress patterns resulting from modifications to tidal flow patterns across the bar.
- (ii) Changes to velocity profiles resulting from increased/decreased inlet efficiency.
- (iii) Changes to the sediment entrainment and depositional rates resulting from morphological modifications to the ocean bar and hence areas over which increased bed shear due to wave effects occur.
- (iv) Changes to wave setup effects, hence their relationship to flood/ebb hydraulic gradients.

Having determined the changes in head loss characteristics, the regime equations of Engelund and Hansen (1967 - cited by Bruun, 1978) can be considered with the Manning formula to predict changes to the friction slope in the estuary channels. The Engelund-Hansen equations can be expressed in the following way:

$$B \propto Q^{0.525} \quad (4)$$

$$D \propto Q^{0.317} \quad (5)$$

$$A \propto Q^{0.842} \quad (6)$$

$$V \propto Q^{0.158} \quad (7)$$

Using equations (5) and (7) with Manning's formula in the form:

$$S = \left(\frac{v_m n}{R^{2/3}} \right)^2 \quad (8)$$

and with D approximating R for wide shallow channels, the behavioural change slope ratio is:

$$\frac{S_{ultimate}}{S_{prior}} = \left(\frac{Q_{ultimate}}{Q_{prior}} \right)^{-0.107} \quad (9)$$

Finally, with the above information and certain assumptions the response rate of the estuary from the pre-perturbated condition to the "ultimate" condition can be mapped. From this history, using an appropriate sediment transport formula, it is possible to predict sediment movements and future scour/depositional patterns.

The analysis of the Wallis Lake estuary will be used to illustrate the method.

6. APPLICATION OF INLET BEHAVIOURAL ANALYSIS TO WALLIS LAKE ESTUARY

The construction of the northern breakwater at Forster/Tuncurry in 1966 resulted in profound changes to the Wallis Lake estuary. The inlet behavioural analysis was used to predict the ultimate configuration and size of the inlet channels, to predict the response time of the estuary to the perturbation and to assess the impact of proposed further perturbations in the lower estuary regions.

6.1 Ocean Bar/Inlet Morphology and Flow Patterns (also see Druery and Nielsen, 1980)

Figure 7 shows typical current flow paths, velocity distributions and sediment transport paths pertaining to the inlet before the northern breakwater was constructed. During ebb flow sediments were entrained on the channel shoals and carried to sea through the inlet. As the ebb jet expanded the flow velocity reduced. The asymmetrical nature of the jet expansion resulted in a skewed velocity distribution and sediments were deposited in the low energy region along the edge of the swash shoals. A large separation eddy developed on the northern side of the jet resulting in an inlet directed current through the northern marginal flood tide channel (see Figure 7). This feature resulted in the formation of an opposing current on the northern side of the entrance and produced a head loss to the ebb tide flow. Wave action from the predominant southeasterly swells carried sediment northward along the swash bars. During flood tide sediments were entrained on the swash bars and carried into the inlet.

The construction of the northern breakwater in 1966 resulted in significant alterations to the bar morphology, tidal flow paths and sediment movement patterns (Figure 8). On ebb tide the jet expansion became more symmetrical. The interception of the marginal flood tide channel and large swash shoals by the breakwater resulted in the elimination of the large flow separation eddy and the inlet directed

current during ebb flow. The breakwater has also caused a redirection of the flood tide flow which became orientated along the centreline of the breakwaters. Figure 9 summarises the pertinent changes caused by the northern breakwater construction, the salient points being the reduction to the sediment entrainment area of tidal currents over the entrance bar during flood tide, the reduction in area on the bar affected by increased bed shear due to wave effects and the increase in ruling depths on the bar.

6.2 Head Loss at the Entrance

A significant reduction in the total head loss over the entrance bar has occurred. An estimate of this reduction was obtained by comparing the tidal envelopes measured before (1961) and after (1978) the breakwater construction (Figure 10). On the assumption that the tidal envelope in the region of the bar approximates the peak instantaneous head loss over the bar, the head losses for the higher spring tide ranges have been reduced from 0.19 m to 0.11 m (0.08 m reduction) for high waters and from 0.24 m to 0.18 m (0.06 m reduction) for low waters.

It is estimated that the inlet losses have reduced from about 0.1 m to about 0.05 m which is a measure of the increased hydraulic

Figure 7 Littoral processes at a single breakwater entrance

Figure 8 Littoral processes at a double breakwater entrance

Figure 9 Differences between single and double breakwater entrances

efficiency of the new trapezoidal section between the breakwaters, as outlined by Bruun (1978).

In the O'Brien and Dean approach the inlet entry losses are accounted for by Ken, the entry head loss coefficient. The entry head loss is:

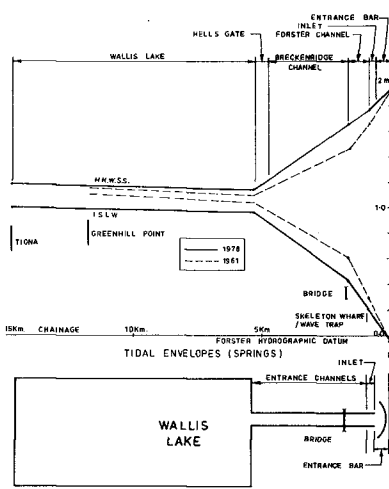

$$\text{Ken} \cdot \frac{u^2}{2g}$$

Dean (1971, cited by Bruun, 1978) recommends a value of Ken = 0.25 for inlets with exposed breakwaters. O'Brien and Dean (1972) recommend a value of Ken + Kex = 1.3. As a value of Kex = 1 is usually adopted (Bruun, 1978) then this sets Ken = 0.3. These values were also adopted by Czerniak (1977).

In this application, given peak velocities of about 2 m/s during the highest spring tides and for a measured inlet head loss of about 0.05m, a value of Ken = 0.25 was calculated. This value is in accordance with the recommended values cited above. It is clear that the generalised analytical model of O'Brien and Dean does not take into account head losses that occur over the ocean bar.

6.3 Regime/Gradient Analysis

An estimate of the ultimate stable channel regime and the total response time of the estuary was made by a generalised analytical appraisal of the channel hydraulics. The assumptions made include:

SCHEMATISED PLAN OF ESTUARY

Figure 10 1961 and 1978 tidal envelopes for Wallis Lake inlet/estuary system

- (i) The ultimate head loss values between the traffic bridge and the ocean were reached within a short period of time after the northern breakwater was constructed.
- (ii) The channels are erodable between the traffic bridge and the lake, hence regime equation apply.
- (iii) The hydraulic gradients at peak flows are proportional to the gradients of the tidal envelope at spring tides.
- (iv) The tidal range in the lake is proportional to the tidal prism and discharge.
- (v) Manning's "n" in the various channels remains constant throughout the response period, that is, there will be no significant change in the composition of the sediments or in bed forms in the channels.
- (vi) The tidal prism in 1966 is equal to the tidal prism in 1961 - necessary because of lack of data.

Based on assumptions (i), (iv) and (v) a relationship between discharges and hydraulic gradients was developed:

$$\frac{Q_{1966}}{Q_{1966}} = \frac{(1.65 - 0.37 \frac{S_{ult}}{S_{1966}})_{HHWSS} - (0.43 + 0.43 \frac{S_{ult}}{S_{1966}})_{ISLW}}{0.06 \text{ (lake tidal range, 1966)}} \quad (10)$$

Equations (9) - Section 5 - and (10) were solved graphically (Figure 11) resulting in the following regime parameters:

- (i) Tidal prism (HHWSS) = 67,000 cubic metres, a tenfold increase.
- (ii) Lake range = 0.60 m (increase from 0.06 m).
- (iii) Channel velocities increase by 44%.
- (iv) Channel depths double.
- (v) Channel widths treble.

Figure 11 Solution of regime/gradient equations

Given that there was a threefold increase in tidal prism between 1967 and 1978 (see Figure 10), and assuming that the rate of increase was and will remain constant, it will take 50 years from 1967 for the estuary to fully respond to the northern breakwater construction.

The assumptions and the basis for these predictions are at this point of time felt to be suboptimal. However, the methodology employed is considered to be reasonable. In the case of Forster/Tuncurry a number of factors will further influence the ultimate result:

- The presence of indurated sands at some locations in the estuary will act to control and modify channel erosion patterns, hence the predicted tidal range in the lake may never be realised.
- The extent of the oyster leases throughout the estuary will have an effect on erosion patterns and may invalidate the Mannings "n" assumption.

6.4 Sediment Budget Analysis

The increase in the efficiency of the inlet has resulted in an increase in bar depths with a resulting reduction in wave setup effects. There has also been a reduction to the area on the entrance bar over which threshold shear stresses are exceeded during flood tide. The nett result of these effects has been to enhance the ebb tide sand transporting capabilities and to reduce the sediment feed to the inlet during flood tides.

Sediment transport rates under tidal current action were calculated at various locations in the lower entrance region using the Ackers and White (1973) approach. This approach was used for reasons of convenience as the computational steps have been automated on our office computers. The results at each gauging station were plotted in terms of transport rate vs velocity and a curve in the form:

$$Q = kv^n \quad (11)$$

where

- Q = sediment transport rate
- k = constant
- v = average channel velocity

was fitted to each set of results. It was found that n varied from about 4 to about 6 over the monitoring stations. The mean grain size of the sand is about 0.3 mm and depths of flow were in the order of a few metres. This result is therefore in close agreement with the A.S.C.E. recommendation which sets $n = 5$, and it is also in accord with the analysis carried out by Costa and Isaacs (1977).

For each tidal gauging sediment transport rates were calculated at hourly and, in some instances, half hourly intervals. The transport rate/time curve was integrated to give the sediment load for the tidal gauging. Annual sediment transport rates were calculated based on statistics of annual tidal ranges and derived relationships between tidal ranges and tidal discharges.

To check the validity of this approach it was assumed that the sediment transport rates remained constant over the period since the northern breakwater was constructed and the sediment budget was calculated (Figure 12) and compared with that obtained from the analysis of hydrographic surveys. The analysis was carried out for two sections of the estuary (see Figure 12). Limitation to the extent of the hydrographic surveys dictated that different time periods for the two sections were analysed. However, it was felt that this in itself provided further proof of consistency of the results.

The values are given in Table 2 from which it can be seen that a remarkably good agreement was obtained.

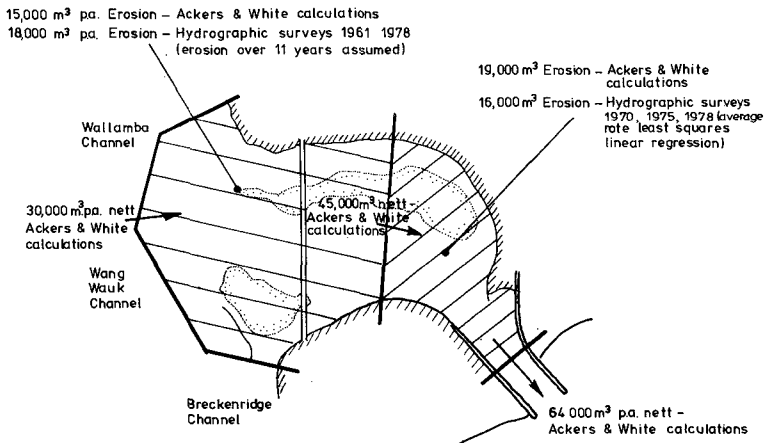

Figure 12 Sediment budget for lower entrance channel region at Forster/Tuncurry

TABLE 2

Comparison of Theoretically Determined and Measured Erosion Rates

Section (See Figure 12)	Period of Analysis	Erosion of entrance shoals (cubic metres per annum)	
		As predicted by Transport Calcs.	As given by Hydro-survey
From breakwater to section D/S of bridge	1970 - 1978	19,000	16,000
From section D/S of bridge to section U/S of bridge	1967 - 1978	15,000	18,000

The calculated sediment budget for the estuary was therefore adopted. From this it can be seen that the nett sediment movement has been directed out of the estuary, considerable scour has occurred in the lower entrance channel region and, as sediments are not carried into the entrance channels from the lake during ebb tide, the upper region of the entrance channel system is scouring. These effects have been dramatically borne out in the field where scouring has resulted in severe subsidence of the traffic bridge with piers settling 400 mm, erosion of the untrained channel banks throughout the estuary with some channels doubling in waterway cross-sectional area, increased upstream penetration of marine sand flood tide deltas. Further; a significant accretion on nine mile beach has occurred since 1966 as a result of the sediment being supplied to the coastal littoral system from the "point source" generated within the estuary by the breakwater construction.

7. CONCLUSIONS

The construction of a northern breakwater at Forster/Tuncurry converted the previous single breakwater entrance into a double breakwater entrance. This perturbation, unlike the previous one occasioned by the construction of the first breakwater, caused significant changes to the tidal prism, the inlet entry and exit head loss characteristics and the entrance bar morphology. Existing stability theories were unable to describe the changes or predict the future consequences of the perturbation. The long and complex estuary channel system connecting the ocean inlet to the "bay" region, Wallis Lake, provided additional complications.

It was necessary to adopt a new approach of "Inlet Behavioural Analysis" which was based on a combination and extension of past methods.

The major features of this approach included:

Examination and description of changes to ocean bar morphology, current patterns and entrainment condition in order to identify

the relevant parameters and their importance with respect to the changes.

- . Determination of the impact of the perturbation on ocean bar/inlet efficiency. That is, determination of head loss variation caused by changes to bar morphology, flood/ebb current patterns and cross-sectional optimality at the entrance - particularly between the breakwaters.
- . Use of a regime type approach to predict the propagation and distribution of the changed hydraulic conditions at the entrance throughout the inlet-estuary system.
- . The development of a predictive sediment budget model based on sediment transport formula and the calculated hydraulic conditions from the regime analysis.
- . The use of this sediment budget model and conceptual hydraulic model to chart the future of the estuary and determine the time span over which impacts from the perturbation will occur.

Application of this approach to Forster/Tuncurry produced interesting results which at this point of time - 14 years after the perturbation - are in good agreement with field observations.

The magnitude of the "ultimate" changes, that is, a tenfold increase in tidal prism (a threefold change has already occurred), a doubling of channel depths, a trebling of channel widths and a 50 year adjustment period is difficult to contemplate. This end result may however never be realised due to the simplistic assumptions which were made in the analysis and the development of controls such as the exposure of indurated sand rock bars, which were not considered in the study.

The increasing need to be able to adequately predict long term impacts of entrance training works has shifted the emphasis away from the static "stability analysis" approach towards the more dynamic one of "behavioural analysis". The methodology outlined in this paper is seen as an attempt by the authors to respond to this need.

The authors keenly look forward to discussion and guidance on this matter. An exciting field of future research must be undertaken to overcome many of the crude assumptions and simplifications which have been made to date.

1. INTRODUCTION

Tidal basins and tidal rivers especially in areas of agricultural and industrial interest are more and more regulated and improved for different reasons such as draining, disposal of waste water, shipping and storm flood protection. This is - up to now - mainly done by dams, dikes, training walls, channel dredging, storm surge control barriers, etc..

In general, the tidal motion (tidal range and tidal velocities) in the whole system is affected by these man-made changes in the cross-sectional area of the tidal river. The hydrographical effects caused by such artificial constructions in tidal rivers have been outlined in the papers of H.G. WITTMER and al.(12). However, the morphological consequences of such measures are largely unknown.

The analysis of a real system, such as the EIDER-Estuary at the German Bay, which was affected by both a reduction in its tidal prism by the construction of a tidal dam in 1936, and by a reduction of its cross-sectional area by a storm surge control barrier in 1972, must therefore be highly appreciated.

In general, the most important changes of a tidal regime are caused by two different types of artificial influences:

- horizontal reductions of the tidal volume (for instance by damming-off a tidal river)
- vertical reductions of the cross-section(s) at any particular part of the tidal regime (for instance by storm surge control barriers or training walls)

In both cases the existing equilibrium conditions are disturbed and the relationships between the horizontal and vertical components of the tidal motion are distorted more or less according to the distance from the structure. As a con-

sequence, the resulting pattern of flow and sediment transport is changed into a net flood-oriented flow. This leads to a very heavy siltation in the tidal system and consequently to a shrinking of the cross-sections.

An exact prediction of the sedimentation rates to be expected in tidal basins as a consequence of artificial constructions is not possible so far. However, the application of some simple equilibrium conditions, as have been used for the hindcasting of the sedimentation rates in the Eider-Estuary, seems to prove that an approximate evaluation of the morphological changes in a tidal system is nevertheless possible.

2. EQUILIBRIUM CRITERIA

Stability investigations of tidal basin inlets show the most important relationship between the cross-sectional area (F) and the associated mean tidal prism (V). Estuaries and tidal rivers follow - within certain boundary conditions - nearly the same relationship.

All the existing equilibrium criteria are based on the fundamental concept of correlating characteristical horizontal and vertical parameters of the system. In the following, two discharge oriented approaches shall be discussed in this paper.

W. HENSEN (2) defined a stability parameter (c_f) as an average flood current velocity under natural flow conditions as follows:

$$c_f = \frac{V}{D_f \cdot F_{fm}} \quad (1)$$

with: V = mean tidal prism
 D_f = duration of flood
 F_{fm} = mean cross-sectional area (about half-tide)
 c_f = average flood current velocity

Due to HENSEN, the equilibrium condition of a tidal system is given if the calculated c_f -value remains a constant, i.e.

$$c_f = c_{eq} = \text{const.} \quad (2)$$

Although no fundamental research about this regime constant has been carried out, the average flood and ebb current velocities in tidal basins and tidal rivers with fine sand and silt seem to be of the order of $c_f \sim 0,67 \text{ m/s}$ (2).

A more detailed and especially vertically differentiated relationship was elaborated by E. RENGGER (10).

When the continuity equation for non-steady flow is applied

to any cross-section (s_i, z_i) of a tidal basin within the mean tidal range (ζ) the mean current velocity (\bar{u}) can be derived with a good accuracy as follows:

$$\bar{u} = \frac{A}{F} \cdot \bar{v} \quad \text{or} \quad \frac{u}{v} = \frac{A}{F} = \varphi(\zeta) \quad (3)$$

with: A = horizontal cross-section within the
 F = vertical cross-section mean tidal
 \bar{v} = mean velocity of tidal range $\zeta = z'/H$
 rise and fall

The equilibrium conditions of a tidal system were found to depend on a certain general vertical distribution $\varphi^m(\zeta)$ and on a reference value $\varphi_R(H)$.

The morphological characteristic $\varphi^m(\zeta^m)$ is significant for the type of the tidal regime, whereas the reference value ($\varphi_R(H)$) obviously seems to depend on the mean tidal range (H).

3. GENERAL REMARKS ON THE REGIME CHANGING CONCEPT

As has been pointed out before, the two most important effects on a tidal regime are changes in the horizontal and vertical cross-sections. In both cases the existing hydrodynamical equilibrium is disturbed by the artificial constructions. The morphological reactions of the system (in most cases heavy sedimentation) show at first an increasing tendency but tend to reach a new state of equilibrium with time.

The mean flow characteristics of the system $u(z')$ and c_f are directly related to the morphological changes of the tidal basin. This can be shown by the two formulas mentioned before:

$$\text{from (1)} \quad c_f \sim \left[\frac{V}{F_{fm}} \right] = \left[\frac{\int_0^H A dz'}{F_{fm}} \right] \quad (4)$$

$$\text{from (2)} \quad u(z') \sim \left[\frac{A(z')}{F(z')} \right] \quad (5)$$

where F_{fm} and $F(z')$ are the terms in which morphological changes are represented.

As a first step and for a rather good estimate of the expected changing of the regime, only the morphological terms of both formulas need to be analyzed. The most important assumption for this analysis is, however, that the equilibrium criterias mentioned before can be applied furthermore to the remaining tidal influenced part of the system. In other words, the hydrodynamical components of the equilibrium approaches ($c_f = c_{eq}$, D_f , $u(z')$ and $v(z')$) are of an universal importance and remain of the same numerical order as given in the former state.

4. STAGES OF MORPHOLOGICAL REACTIONS

With respect to the general remarks on the regime changing concept of tidal basins due to artificial constructions four typical stages of morphological reactions can be distinguished (Table 1):

Stage of time	Criteria		Stability
I. $t_1 = t_{eq}$ (exist) existing condition	$C_{f1}/C_{eq} \approx 1$	$u_1/u_{eq} \approx 1$	stable (assumed)
II. t_2 , just influenced by artificial construction	$C_{f2}/C_{eq} \gtrless 1$	$u_2/u_{eq} \lesseqgtr 1$	non stable
III. t_3 period of change	$C_f(t)/C_{eq} \rightarrow 1$	$u(t)/u_{eq} \rightarrow 1$	different degrees of instability towards stability
IV. $t_3 = t_{eq}$ (exp.) expected new equilibrium	$C_f/C_{eq} = 1$	$u/u_{eq} = 1$	stability

TABLE 1: Stages of morphological reactions

In stage II the two alternative signs indicate either reduction (symbol <) or enlargement (symbol >) of the tidal system.

The different morphological time stages for a schematic reduction of a tidal basin - for instance by the construction of a tidal dam - are shown for the two equilibrium approaches of HENSEN and RENGGER (in figure 1 and 2, respectively). The figures show a schematical tidal basin and the parameters of state used in the approaches. The morphological changes to be expected are indicated for the different stages. The equations for the calculation of the corresponding cross-sections F are listed in Table 2 for the two different approaches.

Stage I: Existing condition

The existing condition is assumed to be in a dynamical equilibrium, i.e. no net sediment transport between ebb and flood current exists. The equilibrium state is represented by the c_f - and u - values, which vary within the mean tidal range ($0 \leq z' \leq H$). The equilibrium condition is shown

$$u \cong v \cdot \left[\frac{A_T - (A_R + A_S)}{(F - F_S)} \right]$$

Figure 2

in figure 1 and 2 for the two approaches.

Stage II: Directly after reduction of the tidal volume

The initial change of the significant parameter is caused by the man-made construction (tidal dam, see figure 1). Due to the location of the dam and the corresponding reduction of the tidal volume (V_R and $A_R(z')$, fig. 1 and 2), the velocity-pattern within the remaining part of the tidal basin will also change ($c_f - c_R$, $u - u_R$) as a natural hydrodynamical reaction.

Stage III: Period of time dependent morphological changes

As a consequence of the reduction in tidal volume, the existing sediment transport is changed into a resulting flood-oriented sediment transport. The latter will cause a continuous reduction in the cross-sections (F) of the remaining part of the tidal basin. The shrinking of the tidal basin will in turn affect the tidal motion in it (see fig. 1 and 2 - stage III). This process of morphological and hydrological changes will continue until a new state of equilibrium is reached.

Stage IV: Expected new equilibrium

The expected new state of equilibrium at the end of the time dependent morphological and hydrological changes in the tidal basin can only be predicted by means of a rough approximation. This is due to the fact that in both methods only the vertical and horizontal morphological parameters are considered to be variable, whereas all other variables are kept constant. The calculated cross-sections (F_{calc}) must therefore be considered as an upper limit of the expected ones, i.e. (see figure 1, stage IV and table 2):

$$F_{exp} < F_{calc} = F_{fm} - F_S \quad (6)$$

In the following, the approximated forecasting equations are applied to the case of the Eider-River at the German Bight where a considerable part of the tidal volume was dammed-off by the construction of a tidal dam in 1936 and a storm-surge barrier was built at its ocean entrance in 1972.

5. APPLICATION OF THE FORECASTING METHODS TO THE EIDER RIVER

General remarks: The tidal river of the Eider which flows into the inner German Bay had been dammed-off by a tidal dam at Nordfeld in 1936 (see figure 3).

Due to the construction of the dam, the initial tidal volume of the estuary was reduced by approximately 12 Mio m^3 . As a result of this reduction in tidal volume, a heavy accumulation of silt and sediment was observed downstream of the tidal dam in the following 30 years. By means of

Stage of Reactions	Approaches for the calculation of the cross-sections (F)	Method of E. RENGER (1978)
I. Existing equilibrium condition	Method of W. HENSEN (1937) $F_{f_m} \sim \frac{V_T}{C_f}$	Method of E. RENGER (1978) $F \sim \frac{A_T}{u}$ (all variables vary with (z') within the mean tidal range)
II. Stage directly after the reduction of the tidal volume	$F_{f_m} \sim \frac{ V_T - V_R }{ C_f - C_R } = \frac{\text{calc. } V}{(C_f - C_R)}$	$F \sim \frac{ A_T - A_R }{ u - u_R } = \frac{\text{calc. } A}{(u - u_R)}$
III. Period of time dependent morphological changes	$F_{f_m}(t) = F_{f_m}(I) - F_S(t)$ $F_{f_m}(t) \sim \frac{ V_T - V_R - V_S}{(C_f - C_R)} = \frac{\text{calc. } V - V_S}{(C_f - C_R)}$ with: $Df(t) \approx \text{const.}$ $C_R \rightarrow 0$ $V_S \sim \text{increasing from zero}$ $F_S \sim \text{increasing from zero}$	$F(t) = F(I) - F_S(t)$ $F(t) \sim \frac{(A_T - A_R) - A_S}{(u - u_R)} = \frac{\text{calc. } A - A_S}{(u - u_R)}$ with: $v(t) \approx \text{const.}$ $u_R \sim 0$ $A_S \sim \text{increasing from zero}$ $F_S \sim \text{increasing from zero}$
IV. Expected new equilibrium	$\exp F_{f_m} < \text{calc. } F_{f_m} \sim \frac{\text{calc. } V - V_S}{C_f(\text{eq})} < \frac{\text{calc. } V}{C_f(\text{eq})}$	$\exp F \cdot F < \text{calc. } F \sim \frac{\text{calc. } A - A_S}{u(\text{eq})} < \frac{\text{calc. } A}{u(\text{eq})}$

Figure 3

soundings carried out at certain intervals, a total sedimentation of about 50 Mio m³ has been determined downstream of the dam covering an area of about 25 km² over a length of 30 km. A detailed description of the time-dependent morphological changes in the Eider basin can be found in reference (4) .

In the following, an attempt is made to hindcast the observed morphological changes in the Eider river by means of the two methods discussed before. In particular, the shrinking of the tidal volume below MHW and MLW is investigated and compared with the prototype measurements (7,8,9).

Hindcasting of the cross-sections: As has been outlined before, the new cross-sections to be expected after the construction of the tidal dam and the restoration of a new morpho-dynamical equilibrium (see figure 1, stage IV) can be determined by means of the following equation:

$$\text{calc } F_{fm} = \frac{\text{calc. } V}{D_f \cdot c_f(\text{eq})} = \frac{V_t - V_R}{D_f \cdot c_f(\text{eq})} \quad (7)$$

For reasons already discussed before, the calculated F_{fm} -values according to equation (7) are somewhat higher than the actual values (exp F_{fm}) to be expected for each cross-

section, i.e. calc. $F_{fm} > exp.F_{fm}$. The former can therefore be considered as an upper limit of the expected new cross-sections.

In Table 3, the results of the calculations for two different cross-sections of the Eider-River (profiles 78 and 115, see figure 3) are presented for four different years. The first calculation was carried out for year 1935, when the tidal dam was not yet built (Figure 1, stage I). The second calculation (1936) corresponds to stage II (fig.1), i.e. summarises the situation after the construction of the dam, whereas the calculations for the years 1967 and 1976 show the situation in the Eider river during the morphological changes (stage III and IV, respectively).

All parameters used for calculating the new cross-sections F_{fm} had to be taken from the tidal system at stages I (existing condition) and II (situation directly after the completion of the tidal dam). These values are printed in bold in Table 3.

CALCULATION OF THE EXPECTED CROSS - SECTIONS
OF THE EIDER

year	Vol (10 ⁶ m ³)		D _l (min)		F _{fm} (m ²)		c _t (m/s)		
	PROFILE 78	115	78	115	78	115	78	115	
1935	17.9	26.2	352	362	1600	1790	0.52	0.67	
1936	5.9	14.2	310	320	1600	1790	0.20	0.41	
1967	5.3	12.8	315	320	500	820	0.53	0.81	
1976	5.1	12.3	320	322	324	640	0.82	0.98	
CALCULATED:					530	970	m ²		

Table 3

As can be seen from the figures in Table 3, there is a reduction of 12 Mio m³ in tidal volume due to the construction of the tidal dam. The remaining tidal volumes of 14,2 Mio m³ (profile 115) and 5,9 Mio m³ (profile 78) decrease, however, with time due to the heavy accumulation of silt and sand in the upper part of the estuary.

An even more pronounced effect could be observed for both profiles in the decrease in cross-sectional area (Table 3). The measurements obtained for 1976 might already be slightly affected by the influence of the new tidal control barrier which was built in 1972 at the ocean entrance of the Eider river. The values obtained for 1967 show, however, a fairly good agreement with the calculated F_{fm} -values according to equation (7).

Hindcasting of tidal volumes: During the last 6 years, systematic evaluations of about 25 existing tidal basins of the inner German Bay, were carried out by the Franzius-Institute, University of Hannover/Germany, which led to some general stability criteria for these tidal basins with a mean tidal range of about 3,0 m. It could be shown that the tidal volume V of a basin depends clearly on its drainage area E . The empirically determined relationship for the volumetric capacity of the tidal basin at MLW as well as for the mean tidal volume V_{Tm} are as follows (8,10):

$$\text{Mean tidal volume: } V_{Tm} = 1,65 \cdot E^{1,036} \quad (8)$$

$$\text{Capacity at MLW : } V_{MLW} = 4,39 \cdot E^{1,643} \quad (9)$$

where volumes V are in $(10^6 \cdot m^3)$ and drainage areas E in (km^2) .

The two equations were applied to the Eider basin between the dam at Nordfeld (built in 1936) and the storm surge barrier (built in 1972) at its ocean entrance (see figure 3).

Because of the complex form of the Eider basin, two different approaches were used in the attempt to hindcast the observed sedimentation rates. For this, the Eider basin was subdivided into a basin (B) and a channel part (C), as shown in figure 3.

In the first approach, the sum of the areas B and C was used as significant drainage area, i.e. $E = B + C$, whereas in the second approach only the drainage area of the basin part (B) was used as variable and the remaining volume of the channel part (C) of about 12 Mio m^3 was added to the tidal volumes calculated by means of equations (8) and (9).

The results are shown in the table of figure 3. The calculations were carried out for 2 different tidal levels (MHW and MLW) and for the mean tidal range (MTR). As can be seen from the results, the hindcasted volumes (in Mio m^3) are in a rather good agreement with the values obtained by systematic soundings in 1967 (see table in figure 3).

6. FORECASTING OF THE INFLUENCE OF THE STORM SURGE CONTROL BARRIER, BUILT IN 1972

As has been pointed out in the introductory remarks, a change in the morphology of a tidal basin can also be caused by a local narrowing down of the existing cross-section of the basin, as for example by a storm surge control barrier. An artificial construction of this kind acts like a singular discontinuity within the horizontal distribution of the cross-sections along the river axis.

The effect of such discontinuities on the morphological reaction of a tidal system has been recently investigated by

several authors (6,8,11). In general, an abrupt narrowing down of an existing cross-section of a tidal basin by means of an artificial construction leads to a distortion of the tidal wave with a partial reflection of the latter. The horizontal and vertical velocity components $u(t)$ and $v(t)$ of the tidal motion are changed which results in a distorted flow pattern on both sides of the construction. As a result, the transport capacity of the tidal flow is changed with a higher concentration of silt and sediment in the upper layers. This leads to an increase in the transport range of the sediments, especially under flood conditions.

The net effect of the narrowing down of the cross-section will be an accumulation of sediment and silt on both sides of the construction, the amount of which depending upon the degree of contraction.

At the new storm surge control barrier at the mouth of the Eider river (figure 3), heavy sedimentation was observed upstream and seaward of the construction since its completion in 1972.

By applying the tidal basin concept to the Eider basin restricted by the control barrier, an attempt can be made to forecast the sedimentation rates to be expected within the remaining basin. Using the two different approaches as mentioned before, an upper and lower limit for the reduced tidal volume to be expected could be determined. The results are shown in the table of figure 3. As can be seen from the calculated values, some additional 22 to 25 Mio m^3 of silt and sedimentation must be expected under MHW within the Eider basin (compared with 1967) until a new state of morphological equilibrium is reached (7). The evaluated soundings along the Eider river since 1972 seem to support this prediction (see figure 4).

7. CONCLUSIONS

The knowledge of morphological changes to be expected in tidal rivers and basins as a result of man-made constructions such as dykes, dams and tidal control barriers is of high interest for future decisions in tidal regions of agricultural and economical value. It was the aim of this paper to present two empirical approaches by means of which a prediction of the morphological reaction of a tidal system and an estimate of expected sedimentation rates is possible.

By using prototype measurements from the Eider River, it could be shown that the observed sedimentation rates were in fairly good agreement with obtained theoretical values from the two empirical approaches. Although further systematic research is needed in this respect, it seems that the two methods discussed in this paper promise to be a

FIGURE 4

good tool in the prediction of sedimentation rates to be expected in tidal basins and tidal rivers due to artificial constructions in the tidal regime.

1. INTRODUCTION

One of the characteristics of the North Sea between the British Isles, the Netherlands, Germany and Denmark is the occurrence of heavy storm surges especially in autumn and winter with heights of about 4 m above spring highwater. Coastal areas and especially the estuaries of the tidal rivers are hit by these storm surge events. The mean tidal range at the German coast comes to about 3 m with relatively low daily and semimonthly inequalities of less than 0.5m.

Within the framework of long-term developments of the navigation channels of the estuaries as well as of the storm surge protection works, physical model tests had to be carried out in order to predict the influences of such measures on the storm surge heights to be expected.

2. GENERAL REMARKS ON THE SIMULATION OF TIDES IN PHYSICAL MODELS

In connection with these model tests the question as to the artificial roughness pattern in distorted tide models necessary for simulating different types of storm surges had to be investigated. The simulation of unsteady alternating currents and water level elevations of a mean tide in a physical model of an estuary can be attained by a roughness pattern of artificial elements fixed over the total tidal cycle. For mean tides, determined as the mean of a long-term sequence of tides in an estuary which is morphologically in a state of equilibrium (morphology of the model), a roughness pattern denoted as "similar to prototype" can be defined. In principle, a roughness pattern different from the "similar to prototype" roughness should be neces-

sary for the simulation of other tides in this particular morphological state of the model.

It must certainly be taken into account that the "similar to prototype" roughness will be more and more restricted to the calibration tide and to the corresponding morphological situation with increasing distortion of the model.

Storm tides can only be reproduced incompletely in long models of estuaries when conventional methods are used, i.e. appropriate tide generation without reproducing wind effects and fixing the roughness pattern in the model. Specific current distributions basically different from current distributions of mean tides must be considered.

3. INVESTIGATIONS ON THE INFLUENCE OF TIDAL FLAT ROUGHNESS

The results of several tests within the framework of basic investigations at the University of Hannover as well as in the Laboratories of the Federal Government in Hamburg will show the influence of the roughness pattern in a model and especially its importance on the success of each investigation.

The subject of the investigations were storm surges in the Elbe Estuary in Germany. The Outer Elbe is characterised by wide tidal flats on both sides of the navigation channel. Upstream of the real coastline the dominant portion of the cross section of the Elbe River is the navigation channel accompanied by more or less wide smaller flats partly higher than mean highwater. For this case a physical tidal model with a distortion of 5, that means 1:500 for the lengths and 1:100 for the depths, of the Elbe Estuary was constructed (Fig. 1). The overall length of the part of the Elbe reproduced in the model is about 170 km from the seaward boundary up to the tidal boundary fixed by a weir.

Figure 2 shows schematically a longitudinal section of high-water elevations of a special type of storm surge in the Elbe Estuary.

The black line shows the storm surge highwaters actually measured along the estuary.

The dashed line represents the highwaters found in the model which had been equipped with conventional roughness elements such as barbed wire or small concrete blocks. In this model it was not possible to achieve a course of storm surges really similar to prototype. In the downstream area of the estuary with wide tidal flats the water level elevations do not follow the real highwater line well-known from the event in the nature. Only in that region where the cross sections of the estuary are reduced, are the model line and the nature line at least parallel to each other.

In order to raise the model highwaters up to the natural highwaters the storm surge curve of the control station was

Fig. 1

General map of the Elbe Estuary and model boundaries

raised to a certain height above the real height. The result is demonstrated with the dotted line. It is obvious that the highwater line in the model was only raised nearly parallel to the dashed highwater line. So this measure was not successful in obtaining a highwater line similar to prototype.

On the other hand, similar problems did not arise in reproducing storm surges in another physical tide model of the Elbe Estuary with the same scales but with a seaward boundary upstream of the flat areas.

4. IMPORTANCE OF REAL SIMULATION OF TIDAL FLAT ROUGHNESS

The outstanding result of the tests described above was the realization of the importance of the flat areas in the downstream areas of the model. The flat areas, even in a model with a distortion of 5, seem to be hydraulically too rough, and this is caused by the shallow water depths and a model bottom surface with a relative roughness which is too great. The influence of roughness in the flat areas must not be neglected. It is a serious mistake to accept a storm tide in a model under the assumption that the model tide which occurs accidentally is only one of a great number of different possible storm surge tides. In order to show the

Fig. 2
Storm surge highwaters in the prototype and in the model
(schematically)

importance of the demand for the real simulation of the roughness pattern on the flats, that means a smoothing of the relative roughness, some tasks of storm surge investigations are to be briefly mentioned.

Model investigations of storm surges in general refer to the prediction of storm surge heights to be expected after more or less serious artificial changes of the morphological situation of an estuary (Fig. 3). Basically two types of changes can be imagined.

Fig. 3

Storm surge protection works in the Elbe Estuary

1. Because of the development of a harbour in the upper region of an estuary, such as Hamburg on the Elbe River about 100 km upstream of the point where the Elbe flows into the North Sea, deepenings of about 4 m as well as enlargements of the width of the navigation channel in several steps over a couple of decades became necessary.

In this case the deepening will result in an increase of the amplitude of a storm surge wave, which results in higher highwaters.

In addition, basic considerations confirmed by SIEFERT (1) led to the conclusion that with the increasing depths of the navigation channel the efficiency of the discharge in the deepened portion of the estuary increases. From

the MANNING-STRICKLER formula it can be derived that, assuming certain simplifications, the efficiency is increased by nearly the square of the additional water depth. When the main channel of the estuary is deepened the remaining efficiency of the flat areas becomes less and less important for the course of the storm surge.

2. In order to minimize the risk of flooding in lower regions on both sides of the estuary, existing storm surge protection facilities have to be reinforced or new structures such as dikes in front of newly reclaimed areas for human and industrial settlements have to be planned. This means that certain portions of the cross sections, in general with low efficiency of the discharge, will not yet be available for the filling and emptying of the upper estuary. The effect on the storm surge heights is dependent on the importance of these portions of the cross sections for the discharge. The resulting effect on the storm surge in an estuary caused by reducing the cross section by means of dikes is, in any case, an increase of roughness, which leads to higher partial reflections of the tidal wave downstream of the construction measure and to corresponding reductions of the amplitude of the tidal wave upstream.

5. DEVELOPMENT OF EFFECTIVE ROUGHNESS ELEMENTS

5.1 GENERAL REMARKS

A method therefore had to be found for overcoming the roughness effect of the tidal flat areas including the effect of winds blowing in the direction of the floodstream which cannot be reproduced directly in a physical model. The rise of storm surges had to be accelerated in order to obtain higher peak water elevations in the lower region of the estuary. On the other hand, the fall of the storm surges in the lower regions had to be decelerated in order to postpone the turn of the flood currents in the upper region of the estuary.

5.2 MOMENTUM JETS

On the basis of an idea being developed in the Hydraulics Laboratories of the Federal Government in Hamburg, momentum jets were used to achieve the required effect.

This new method was proved in pretests in a plume with a width of 1 m. 8 jets of about 4 up to 8 cm³/s each were pressed out of nozzles with diameters of 3 mm, located in horizontal tubes arranged at a distance of about 2 m across the plume (Fig. 4). Jets were injected in the direction of the plume flow as well as against the plume flow. The discharge of the plume came to about 16 l/s with a water depth of about 20 cm.

Fig. 4
Test facilities for momentum jets

The results of the pretests showed a remarkable decrease of the longitudinal gradient of water level elevations, which means an increase of the roughness coefficient of MANNING-STRICKLER. In this case increasing the roughness coefficient means increasing smoothness.

The momentum jets were found to be even still more effective when directed against the flow. It was possible to achieve remarkable roughness effect which led to an increase of the gradient, for instance, from 1 ‰ to 6 ‰ .

Dependent on the distribution of momentum jets in the model as well as on the control of the jet intensity, the desired gradients of the flow can be achieved in a limited range.

The use of the jets in the flat areas of the downstream region of the estuary (Fig. 5) was as successful as expected.

Fig. 5
Location of momentum jets in the model

The course of the storm surge over the whole estuary was in almost good agreement with the natural course.

5.3 PENDULUM STRIPS

However, the fall of the storm tide after highest highwater had to be corrected by additional roughness elements effective only in the ebbstream phase. Fixed roughness elements for the simulation of mean tides are thus modified by flexible roughness elements in the form of pendulum strips (Fig. 6). These strips are raised by flood currents and placed in a vertical position by ebb currents, which causes increased friction in the flow direction, while the flood currents are not influenced by this kind of roughness element. The use of flexible roughness elements yielded a still better agreement between model and prototype storm surges.

Fig. 6
Pendulum strips

6. CONCLUSION

It was possible to find out the reason for the difficulties in reproducing storm surge events in physical models of estuaries with wide flat areas. The importance of the necessity of not underestimating the influence of flat areas on the simulation of storm tides was pointed out.

On this basis a new method for such investigations including the consideration of the influence of local winds was developed and successfully applied. By means of momentum jets and pendulum strips it was possible to achieve a good agreement with natural courses of storm surges.

Finally it should be pointed out that up to now the idea for this new method and its application exists for one physical tide model after some basic tests in a plume. However, further research is needed, in particular to modify the facilities of this new development.

CHAPTER 150

COMMENTS ON TIDAL ENTRANCES ON SANDY COASTS

by

Morrrough P. O'Brien, * Hon.M. ASCE

FLOW AREA-TIDAL PRISM

The information necessary for computation of the tidal prism is available in charts and tide tables for many inlet-bay systems. Empirical correlations have been developed by Le Conte in 1905, O'Brien in 1931 and 1969, and others, which showed the flow area to be a unique function of the tidal prism for the sets of data studied. However, the data underlying these correlations were derived from inlets with semi-diurnal tides, typical of the Atlantic and Pacific Coasts of the United States. Jarrett in 1976 showed that such correlations are not valid for diurnal and mixed tides, such as occur along the Gulf Coast.

Stevenson in 1874 pointed out that the scouring capacity of the tide must include the number of tidal cycles per year. Since the number of tidal cycles in any period of time is inversely proportional to their duration, the integrated scouring capacity of the tidal flow through an inlet channel should be independent of the duration of the tidal cycle and should depend primarily on the tidal discharge. If the maximum rate of tidal discharge (Q_{\max}) and the variation of discharge throughout the tidal cycle are identical for two inlets subjected to tidal cycles of different duration, the scouring capacity of the two inlets would be the same over equal periods of time. The conclusion is that Q_{\max} should provide a more generally valid basis for correlation with the flow area than does the tidal prism alone and one which may be valid at hydraulic model scale and for inlets maintained by the seiching of nontidal lakes, as at Duluth. Bruum (1978) used the correlation of the flow area with Q_{\max} in his studies.

Keulegan's (1951) analysis of inlet flow yielded the relationship

$$Q_{\max} = \pi CP/T \quad (1)$$

Here, C is a coefficient which ranges from 0.81 to 1.0, with 0.86 as a generally applicable value. The minimum flow area A_C should be correlated with either Q_{\max} or (P/T) to be applicable to diurnal, semi-diurnal, and mixed tides and to periodic flows in general.

If the maximum rate of discharge to be correlated with the flow area has been measured directly, rather than derived from the tidal prism through Eq. 1, this value must be corrected to that which would occur on a standard range of tide. This correction will require, in

* Dean Emeritus and Professor Emeritus, College of Engineering, University of California, Berkeley.

effect, the establishment of a rating curve, or discharge coefficient for the inlet. Furthermore, the corrected maximum rates of discharge on flood and ebb are seldom equal and a choice must be made as to which phase is generally more effective in maintaining the flow area. The first correlations were based on Pacific Coast data where the tide shows a diurnal inequality, with the "long-runout" following higher high water and the diurnal range, and the related strong ebb current was selected for the correlation. This characteristic is not found in Atlantic and Gulf coast tides and, for these inlets, the spring range has usually replaced the diurnal range. Although the ratio of the spring range to the mean range is numerically about equal to that of the diurnal range, the hydraulic effects may be very different, since ebb may not be dominant over flood at the time of the spring range. In future studies of the correlation between tidal discharge and flow area, use of the mean tidal range would probably be more significant. The generalized correlation between tidal flow and flow area might be

$$A_c = f(Q_{\max}) \text{ or } f\left(\frac{\pi CP}{T}\right) \quad (2)$$

depending upon whether the measured flow or the or the tidal prism, from charts and tide gages, is the source of data.

HYDRAULIC CHARACTERISTICS

Brown-Keulegan Analysis - Brown (1928) analyzed the flow through a tidal inlet on the basis of the following simplifying assumptions:

- The tidal variations in both ocean and bay are sinusoidal.
- The flow area of the inlet channel (below MSL) is constant (prismatic) from ocean to bay.
- The surface area of the bay does not vary with the tide stage in the bay.
- The surface of the bay remains horizontal throughout the tidal cycle.
- The depth of the inlet channel is large as compared with the range of tide.
- The difference in head necessary to accelerate the mass of water in the inlet channel is neglected.
- There is no surface runoff into the bay.

These assumptions are repeated here to emphasize the degree to which Brown's inlet-bay system was idealized; the configurations of almost all real inlets differ markedly from these assumptions.

Keulegan (1951) recognized that a sinusoidal tide in the ocean would not produce a sinusoidal tide in the bay because the flow through the inlet channel is proportional to the square root of the difference in head; otherwise, he made the same assumptions as Brown. He found

that the ratio of the tide in the bay to that in the ocean, the lag of slack water in the inlet channel after HW or LW in the ocean, and the maximum velocity in the inlet channel could be represented as functions of a dimensionless quantity which he designated as the repletion coefficient,

$$K = \frac{T}{2\pi a_0} \frac{A_C}{A_B} \sqrt{\frac{2ga_0}{F}} \quad (3)$$

The quantities in Eq. 3 are the major variables affecting inlet flow. This coefficient provides a useful means of ordering and analyzing inlet flow data, even though it is based on highly idealized assumptions. Keulegan compared his results with those of Brown in the high range of K-values, where the difference should be greatest, and found that Brown's method yielded values of maximum velocity between 10 and 15 percent greater than did his method. Probable errors in the data usually available are of the same magnitude as the difference between the relationships developed by Brown and Keulegan and Brown's method is much simpler in application. Following Brown, assume that the tidal fluctuations in the bay are sinusoidal. High water in the bay occurs at slack water in the inlet channel; the amplitude of the bay oscillation (a_b) is related to the ocean amplitude (a_0) and the lag of slack water after HW or LW in the ocean (ϵ , deg) as

$$a_b = a_0 \cos \epsilon \quad (4)$$

If the flow conditions in the inlet are as assumed, the difference, Δ , defined as

$$\Delta = \frac{a_b}{a_0} - \cos \epsilon \quad (5)$$

should be zero. When Δ is plotted as a function of inlet size, small inlets show a random scatter about the zero line but, with increasing size of inlet, the values of Δ become increasingly positive. Refinement of the value of Δ by using the more precise method of Keulegan plus corrections for the effects of variations in the flow area and the bay area with tide stand and of the inertia of the mass of water in the inlet channel would probably reduce the scatter of points somewhat but would not explain the systematic increase of Δ for large entrances. The entrances included in this study show fairly good agreement with the flow area-tidal prism correlation.

The explanation of the increasing value of Δ with size of inlet is believed to be that the flow through the inlet channel is not wholly of the "hydraulic" type assumed but is, in some degree, that of a long wave. A good illustration of this difference is the flow at the mouth of the St. Johns River (Florida) where the value of Δ is approximately 0.95; the strength of flood very nearly coincides with HW and the strength of ebb with LW; the lag of slack water is 92° and the ratio of the ranges, a_b/a_0 is 0.90. This entrance leads into a river channel leaving substantially constant average depth and width; the characteristics of the flow are those of a long wave in shallow water.

Considering tidal entrances of increasing width, the depth does, in general, not increase in proportion to the width, and it seems reasonable that the tide should enter large entrances primarily as a wave. If this is the case, the average velocity in the channel should follow approximately the equation

$$u = a_0 \left(\frac{g}{h} \right)^{1/2} \quad (6)$$

Comparing Eq. 6 with the average of flood and ebb currents reported in the Current Tables for a few representative entrances:

	Mean Ocean Range (ft)	Mean Inlet Range (ft)	Lag Slack Water (deg)	Average Depth (ft)	u_w (ft/sec)	From Tables
Narrows	4.5	4.5	64	61	3.3	3.1
Delaware	4.4	4.1	44	38	2.0	3.1
Chesapeake	3.5	2.9	116	25	2.0	2.1
Port Royal	6.4	6.4	51	40	2.9	3.0
St. Johns R.	5.4	4.9	92	31	2.7	3.5
San Francisco	4.2	4.0	56	176	0.9	5.3

The ocean range shown in this table is the range on the outer coast remote from the entrance; the range at "inlet" is that at the station at or inside the throat. At San Francisco, the throat section (Golden Gate) is bounded by rock and the width there is small in proportion to the depth.

If the calculation of the lag angle and of the ratio of ranges is refined by considering the effects of inertia, flow area, bay surface area and surface runoff, the positive value of Δ may be an indicator of the extent to which the flow through the inlet channel is "hydraulic," as assumed by Brown and Keulegan, or "long wave."

Corrections for the effects of deviations from the simplifying assumptions of Brown and Keulegan have been studied by Oliveira (1970), King and Shemdin (1974), Seelig and Sorensen (1978), Mehta and Ozsoy (1978), Escoffier and Walton (1979), and others.

Other useful approximate relationships, derived on the assumption that the tide in the bay is sinusoidal, are that the maximum head difference between ocean and bay and the maximum channel velocity

$$h_{\max} = 2a_0 \sin \epsilon \quad (7)$$

$$V_{\max} = \left(\frac{2ga_0 \sin \epsilon}{F} \right)^{1/2} \quad (8)$$

Equation 8 is a convenient means of determining the impedance of an entrance because a_0 , ϵ , and V_{\max} can be obtained for many entrances

from the tide and current tables. If ϵ and V_{\max} are not available, they may be measured at the throat section with little difficulty.

O'Brien and Clark (1973) used Eq. 8 to compute the value of the impedance (F) for a number of inlet channels having simple geometry and to determine the value of the friction coefficient (f) and the Manning roughness coefficient (n) from

$$F = 1 + \frac{fLc}{4Rc} \quad (9)$$

$$n = 1.48 Rc^{1/6} \left(\frac{f}{8g} \right)^{1/2} \quad (10)$$

Entrances	Lc(H)	Rc(H)	F	f	n
Fire Island	33,100	13.8	16	0.025	0.022
E. Rockaway	11,100	13.7	10.5	0.047	0.022
Indian River	4,200	10.6	15.3	0.143	0.051
St. Marys	15,200	32.8	7.6	0.057	0.039
Lake Worth	1,900	20.9	5.9	0.220	0.071
Humboldt B.	2,690	17.9	5.1	0.110	0.049
San Diego	18,860	40.9	6.7	0.049	0.038

Keulegan measured the friction loss in the relatively uniform inlet channel at Indian River between the ocean and the seaward side of the bridge; his value of n was 0.046. The value in the table included the head loss through the bridge piers. No direct measurements were available for comparison with the other figures in the table, but the close agreement for Indian River lends credence to the other values.

STABILITY OF INLETS

Escoffier (1940) treated the stability of an inlet from the purely hydraulic standpoint by assuming progressive changes in the flow area and hydraulic radius and computing the corresponding maximum tidal velocity during a tidal cycle. He showed that there is a critical flow area at which the maximum tidal velocity is greatest and concluded that, at larger areas, the inlet will be stable because a decrease in area will cause increases in the maximum velocity and in the scouring capacity. Conversely, at areas less than the critical area, an inlet will be unstable because a decrease in area will cause a decrease in velocity. O'Brien and Dean (1972) modified this approach by making assumptions regarding the manner in which sediment encroachment would change the effective length as well as the flow area and hydraulic radius. Their results also showed a critical flow area and maximum tidal velocity with implications regarding stability similar to those of Escoffier.

Bruun (1978) treats inlet stability in terms of the balance between the scouring capacity of the tidal flow, represented by

Q_{\max} , and the magnitude of the littoral transport. This approach, which is believed to be basically sound, considers the two major factors affecting inlet stability, but its quantitative application is limited by the uncertainty over the magnitude of the littoral transport at many inlets, especially regarding the local sand movement under storm wave intensity. Oliveira (1970) broadened the Brown-Keulegan analysis of inlet flow by including the effects of varying both flow area and lagoon surface area during the tidal cycle and computed the scouring capacity of the tidal currents; he showed that the bed load capacity reached a maximum value when the Keulegan coefficient of repletion was within the range $0.6 < K < 0.8$. His other results of significance were that the duration of the ebb phase exceed the flood and that the mean level in the bay was above that in the ocean.

Consider first an inlet-bay system which fulfills the Brown-Keulegan assumptions. The maximum hydraulic power available for scouring the channel occurs when the head and the related rate of discharge are at their maximum values; the maximum head available is a function of the phase difference between the ocean and bay tides.

$$\begin{aligned}
 P_{\max} &= w Q_{\max} h_{\max} \text{ (Max. Power)} \\
 Q_{\max} &= \frac{\pi C P}{T}; \quad P = 2 a_b A_B \\
 a_b &= a_o \sin \epsilon; \quad h_{\max} = 2 a_o \cos \epsilon \\
 P_{\max} &= \frac{4w\pi C}{T} A_B a_o^2 \sin \epsilon \cos \epsilon \quad (11)
 \end{aligned}$$

Consequently, the maximum hydraulic power would be available in the inlet channel under the idealized conditions assumed if the lag angle ϵ is 45° , corresponding to $K \cong 0.63$. The total energy available on either the flood or ebb phases would be

$$E = \frac{8}{\pi} \cdot A_B a_o^2 \cos \epsilon \sin \epsilon \quad (12)$$

Again, the maximum value corresponds to $\epsilon = 45^\circ$ and $K \cong 0.63$.

These relationships are pertinent to the analysis of the stability of an inlet because the energy available will increase or decrease as changes in the geometry or the hydraulic characteristics change the value of K . If $K > 0.64$, a decrease in K would cause an increase in the energy available for scouring the channel; such a decrease might be caused by a choking down of A_b , or an increase in F , or both. Conversely, if $K < 0.64$, a decrease in K will bring a decrease in the energy available, which may then lead to a further decrease in the value of K .

The obvious disparity between the simplifying assumptions made by Brown and Keulegan and the configuration of real inlet-bay systems and between their theoretical results and field measurements has led to studies of the effects of deviations from the assumed conditions, as

mentioned earlier, and it is now possible to correct, at least approximately, for such effects as are caused by variations in the surface area of the bay, the inertia of the mass of water in the inlet channel and so forth. The coefficient of repletion

$$K = \frac{T}{2\pi a_0} \frac{A_C}{A_B} \sqrt{\frac{2ga_0}{F}} \quad (13)$$

includes the major variables affecting the hydraulics of an inlet-bay system, and it appears to be the most illuminating single descriptor of such systems. Of the variables entering K , the impedance, F , is usually that one most in question; its value may be determined, at least approximately, by methods described earlier.

The coefficient of repletion should be regarded as one of a number of dimensionless parameters which may be used to describe quantitatively real inlet-bay systems. Used in this sense, the quantitative relationships between K and the magnitude and occurrence of maximum energy and other variables will probably be altered to some degree by the interaction with the other parameters. As mentioned earlier, Oliveira (1970) employed a numerical model to determine the effect of systematic variations of the flow area and the surface area on the scouring capacity at the throat and found that this capacity had a maximum value in the range $0.6 < K < 0.8$ for the conditions he considered, indicating that the maximum for real inlets may not lie far from that of the idealized models of Brown and Kuelegan.

It should be emphasized that this discussion has dealt only with the energy available for maintaining an inlet channel. The effectiveness of this energy in doing so will depend upon the initial configuration and hydraulic conditions and on the character of the changes which occur subsequently. A large value of the coefficient of repletion should signify a strong capability for maintaining a stable channel and a low value, the reverse; corrections for the effect of variations in flow area, inertia and other effects will improve the accuracy in predicting the actual value of K at which the energy would be a maximum. Such calculations require, however, assumptions regarding changes in the configuration or the hydraulic conditions which would induce a change in K ; the uncertainty here is of the same nature as that involved in the other approaches to stability, previously discussed.

The energy considerations discussed here may shed some light on the method of formation of barrier islands and inlets. If an embayment is gradually enclosed by the growth of a sand spit, the value of the repletion coefficient would be very large initially but would decrease as the spit continued to grow and to reduce the flow area; this process would increase the energy available for scouring the opening and presumably this process would continue until the tidal discharge becomes capable of sweeping away the littoral transport and establishing an equilibrium condition. However, the maximum energy potentially available for maintaining an inlet might not be sufficient to balance the littoral transport, in which case the spit would continue to grow and gradually close

the opening, passing through a condition of marked instability before closure. On the other hand, if the barrier has been developed as a continuous ridge, such inlets as are formed in it might have any initial coefficients of repletion.

INLET CLOSURE

The final closure of natural inlets occurs primarily under storm conditions. It is also true that waves and surge from extreme storm conditions occasionally enlarge or open inlets. These notes deal with the closure of inlets by wave conditions which are abnormal relative to the local wave climate but which are not so extreme as to overwash or break through the adjacent sand spits. There are examples of inlets which have been closed under non-storm conditions by a persistent or excessive littoral transport, but these inlets were, for the most part, small artificial cuts; under such conditions of excessive transport, natural inlets are usually found to be long-since closed, leaving a fresh-water lagoon as the evidence that an inlet once existed.

An important factor in the conditions which determine whether or not an inlet will be closed is the configuration of the shore and bottom seaward of the throat; the volume of sand in offshore shoals, jetties, overlapping or offset spits, rocky headlands and other natural or artificial features in the vicinity of the channel may affect both the volume of sand movement required for closure and the rate of deposition. The variety of such conditions is almost unlimited; data on the conditions which have caused closure should be categorized under inlet configurations. These notes consider a simple inlet channel without jetties through a straight, sandy shoreline with ebb-tide outer bar and zero offset. On a segment of coast exposed to essentially the same wave climate under normal weather conditions, storms may produce substantial differences in winds, wave characteristics and surge within relatively short distances and over short time intervals. Observations on the conditions which actually caused closure are subject to considerable uncertainty and much scatter of the data is to be expected. The duration of storms is at most a few days and is the same for small and large inlets on the same segment of coast. Closure of an inlet requires time for the movement of material and the closure of a large inlet should require either a longer duration or a greater intensity of wave-induced sand movement than for the closure of a small one.

There have been a number of studies of the conditions under which inlets close. Johnson (1974), Sedwick (1975) and Mehta and Hou (1974) have proposed criteria which differ in detail but which, in essence, compare the sand-transporting capacity of the wave climate with the potential scouring capacity of the tide and have located a boundary zone between closed and open inlets by examples from the Pacific Coast, Florida and Long Island. Data on this phenomenon are not plentiful and almost none pertain to the actual conditions at the time of closure. If an inlet has been closed for some time, the data regarding tidal prism and scouring capacity consist of the surface area of the lagoon and the tide range and duration in the ocean; hydraulic analysis of the flow

conditions would be questionable, and the potential tidal prism has been used. On the other side of this boundary are the small inlets which are still open; the specific wave intensities to which they have been subjected is usually uncertain, and a representative figure has been derived from the wave climate. Apparently, there is only one example of the measurement of waves and tides during closure of a natural inlet, and that a very small one (Mehta and Hou, 1974); there is one set of laboratory tests on closure (Saville and Simmons, 1957). However, despite these limitations these studies have served to define approximately criteria which separate closed and open inlets and which clearly show an upward trend in the required wave intensity with increasing tidal prism.

The studies of closure just mentioned yielded criteria which were based upon average or representative conditions, such as the tidal prism on a mean range of tide or the annual or seasonal average wave intensity; they are not representative of the actual conditions existing at the time of closure and, consequently, they should be regarded as an indication of the vulnerability of an inlet to closure; over an extended period of time, an inlet with a value of the criterion in the "closed" region will probably close sometime, but it may not do so. The equilibrium condition of an inlet is really the statistical average of conditions which change somewhat with every change in incident waves and tide range; perhaps what is visualized as the equilibrium conditions is the bathymetry "frozen" in a survey. If the concept of equilibrium as the balance between wave-induced sand movement and tidal scour is correct, even the most stable inlets must experience continuous changes under the influence of the sequence of tidal ranges and the variations in normal wave conditions. Littoral transport along the adjacent shore moves sand toward or away from the vicinity of the inlet; waves plus flood and ebb currents bypass sand across the inlet, store it in ebb or flood shoals, or carry it to deep water. What is the nature of the changes in this regimen caused by an abrupt transition to storm conditions? The littoral transport is a function of the alongshore component of wave power per unit length of shore. The tidal currents may be altered slightly by the storm surge and consequent super elevation of the bay. The volume of sand movement onshore or offshore from the ebb shoal and bottom is probably some function of the tidal currents plus the component of wave power perpendicular to the shore, multiplied by the width of the inlet opening. Under the normal range of wave and tide conditions, sand movements balance and change is minimal but a drastic increase in wave power probably results in a strong shoreward sand movement, which is large as compared with the concurrent littoral drift. Considering the conditions existing at the time of closure, a criterion suggested is

$$M = \frac{W \cdot I_p \cdot T_F}{P_E a_b} \quad (14)$$

where:

- W = width of throat
- I_p = component of wave power perpendicular to shore per unit length
- T_F = duration of flood

a_b = range of tide in bay
 P_E = volume of the ebb tide.

This criterion is the ratio of the energy delivered by wave action during the flood phase of the tidal cycle studied to the energy available in the ebb flow of the same tidal cycle. Since the tide range and the wave intensity will vary during a storm, this criterion should be computed, if possible, for each cycle during a storm. Other quantities might be substituted, if more convenient. The concept represented is that the wave energy delivered over the width of an inlet will dominate the sand movement during a storm and will be the principal agent of closure.

Data necessary for developing a quantitative criterion of closure will be extremely difficult to obtain in nature. Hydraulic models may offer a means of establishing, at least qualitatively, the relative importance of the variables, such as the onshore component of wave power. Although surface wave models may not be distorted and this requirement leads to large models, a compensating factor is that the turbulence of breaking waves seems to permit smaller models for similarity. The experiments of Mayor-Mora (1973) and the CERC-WES program (Saville and Simmons, 1957) seems to show that movable-bed wave models of reasonable size responded to waves and currents in a manner similar, in flow characteristics, to the behavior of natural inlets.

SYMBOLS

a_b	range of tide in bay
a_o	amplitude of the ocean tide (range = $2a_o$)
a_B	amplitude of tide in the bay
A_B	surface area of the bay
A_C	flow area at the throat below MSL
b	surface width of inlet throat at MSL
c	Keulegan coefficient to correct the tidal prism for nonsinusoidal tide in bay
E	potential tidal energy available for scouring the channel on either phase of the tide
F	impedance of the inlet channel ($= \Sigma k + f L_c / 4 R_c$)
f	friction coefficient
g	gravitational force per unit mass
h	difference between surface elevations of ocean and bay
I_p	component of wave power shore normal per unit length of shore
k	coefficient of velocity head loss
K	coefficient of repletion
L_c	length of hypothetical channel of area A_C having same friction loss as real channel
M	criterion of closure
n	roughness coefficient in Manning's equation
P_{max}	maximum tidal power
P	volume of the tidal prism
P_E	volume of a particular ebb tide

Q_{\max}	the maximum rate of discharge during either phase of the tidal cycle
R_c	hydraulic radius of A_c
T	duration of the tidal cycle
T_F	duration of flood
W	width of throat
ϵ	lag of slack water after HW or LW

CHAPTER 151

TIDAL PRISM-INLET AREA RELATIONS FOR SMALL TIDAL INLETS

R.J. BYRNE, R.A. GAMMISCH and G.R. THOMAS

Virginia Institute of Marine Science
College of William and Mary
Gloucester Point, Virginia, 23062, U.S.A.

ABSTRACT

Fourteen tidal inlets within the lower Chesapeake Bay were studied to examine whether significant differences existed in their hydraulic behavior relative to the larger oceanic inlets hitherto studied. Measurements included simultaneous external and internal tides, gaging of discharge through a tidal cycle, measurements of inlet geometry, and basin area. The results indicate that: a.) smaller inlets ($A_c < 100 \text{ m}^2$) depart from the relationship between inlet throat area and tidal prism developed for oceanic inlets; b.) examination of inlet width versus depth indicates the departure from ocean inlet geometry occurs at A_c values between 100 and 500 m^2 ; c.) the maximum velocity in smaller inlets is significantly less than oceanic inlets (~ 0.35 vs 1.0 m/s); d.) tidal phase lags and tidal range ratio were generally equal. However, for conditions of significant tide range reduction, the low water phase lags more closely approximated the tide range ratio.

INTRODUCTION

It is generally recognized that inlets possessing a stable entrance cross-section reflect a dynamic balance between wave driven sand transport processes tending to close the entrance and the tidal flows tending to maintain the channel. A relationship between the tidal prism and the inlet throat cross-sectional area was presented by O'Brien (1969, and earlier); for inlets without jetties

$$A_c = 2.0 \times 10^{-5} \Omega, \text{ (FT)} \quad (1)$$

Jarrett (1976), analyzing a larger data set of inlets on the U.S. coasts, found differences between the Atlantic, Pacific and Gulf Coasts which he attributed to wave climate and tidal characteristics.

Rather than base the correlation upon the integral of the discharge, Bruun (1978, and earlier work) has related the throat area with maximum discharge as it, or the maximum velocity, more clearly designates the relevant bottom shear stress. For inlets of large depth relative to the tide range, Keulegan's analysis (1967) indicates the maximum discharge is proportional to the discharge. Thus, under simplified conditions, the two approaches are closely related. In both cases, the correlation between minimum flow area and the hydraulic parameter are taken to represent the condition of sedimentary equilibrium.

Departures from "equilibrium" conditions have also been considered by Escoffier (1940, 1977) and O'Brien and Dean (1972), who utilized the

analysis of Keulegan (1967). Basically, the approach gives an estimation of the resulting maximum velocity due to a change in the inlet area which is then compared with the velocity associated with the corresponding "equilibrium" area as derived, under simplifying assumptions, from Equation 1 or similar plots. The procedure provides a basis for prediction as to whether the inlet area will tend to return to "equilibrium" or toward closure. It is important to note that the method depends upon the empirically derived relationship between flow area and hydraulic parameters.

PURPOSE OF THE STUDY

Most previous studies have focused on oceanic inlets with relatively large entrances (throat areas $> 10^2 \text{m}^2$) or in small models (throat areas $< 10^{-1} \text{m}^2$). This study focuses on natural tidal inlets, the dimensions of which fall between oceanic inlets and the model scale. Interest in this mid-range exists because of increasing demand to improve navigability into such inlet-basin systems fringing the Chesapeake Bay. Moreover, the model results of Mayor-Mora (1977) suggested that very small systems may depart from the relationships developed for oceanic inlets. Those results showed that for a given tidal prism, the inlet area was an order of magnitude higher than that predicted by extrapolation of the oceanic inlet data.

Fourteen tidal inlets without jetties, Figure 1, in the lower Chesapeake Bay were studied in 1978 and 1979. The cross-sectional area of the channel throats varied between 25m^2 and 0.5m^2 so the data set extends the observed range of natural inlets by two orders of magnitude. The data set for each inlet includes basin and "ocean" tides, discharge gaged through a full tide cycle, the geometrical characteristics of the inlet channel, and the planform characteristics of the basin. The exposure to wave action varied widely with the fetch ranging between fractions of a kilometer to tens of kilometers. To insure that true inlet systems were considered, only those entrances connecting to basins with a tide range reduction or inlets whose histories otherwise demonstrated a dynamic balance between littoral drift and tidal scour were selected. A complete description of the inlet-basin systems, including available aerial photography, is given in Byrne, *et al.* (1980).

This paper reports on: a.) the observed inlet area-tidal prism relationship; b.) the geometry of the inlet throat; c.) the observed maximum channel velocity; d.) the observed phase lags between ocean and basin tides.

METHODS

Tides. The external and basin tidal fluctuations were measured either with Fisher-Porter recording gages, recording bubbler gages, or graduated plastic tubes with a small orifice to filter out wind wave action. In most cases, the external and internal tide measuring devices were leveled to a common datum.

Discharge. Instantaneous tidal discharge was obtained as the sum of area weighted velocity readings from an array of current meter across the channel. The vertical position of the small ducted impellor meters (Byrne and Boon, 1973) was maintained at 0.6 the water depth and values determined were accepted as local vertically averaged mean velocity.

Throat geometry. Channel cross-section profiles were obtained with level and rod reference to the tide recorders.

Basin area. Basin area was determined from aerial photography or plane table mapping with separate consideration given to total basin area and the fraction filled by marsh. The area-height relationship of the basins is currently under study (see also Boon and Byrne, 1981).

DISCUSSION OF RESULTS

Tidal prism-inlet area relationship

The relationship between tidal prism and inlet area, for semi-diurnal tidal conditions, is shown in Figure 2 for 15 Chesapeake Bay inlets, the model results of Mayor-Mora (1977) with tide and waves, and 34 Atlantic coast inlets (without jetties) presented by Jarrett (1976). The least square fit for these data sets are, in metric units:

$$\begin{array}{l} \text{Jarrett data:} \\ m = 34 \end{array} \quad \begin{array}{l} A_C = 6.954 \times 10^{-6} \Omega^{1.14} \\ \text{corr. coeff. } (r) = 0.97 \end{array} \quad (2)$$

$$\begin{array}{l} \text{Chesapeake Bay:} \\ m = 15 \end{array} \quad \begin{array}{l} A_C = 9.902 \times 10^{-3} \Omega^{0.61} \\ r = 0.87 \end{array} \quad (3)$$

$$\begin{array}{l} \text{Mayor-Mora:} \\ m = 17 \end{array} \quad \begin{array}{l} A_C = 7.61 \times 10^{-3} \Omega^{0.68} \\ r = 0.95 \end{array} \quad (4)$$

$$\begin{array}{l} \text{Chesapeake Bay plus Mayor-Mora:} \\ m = 32 \end{array} \quad \begin{array}{l} A_C = 8.079 \times 10^{-3} \Omega^{0.64} \\ r = 0.98 \end{array} \quad (5)$$

For the Chesapeake Bay data set (Tables 1 and 2), the tidal prism could be calculated either from the product of the open basin area and the spring tide range or from the integrated discharge curves which were then linearly scaled to spring tide range.

The ratio of the two prism values was found to vary directly with the open water fraction of the total basin area. This result may be expected since the calculation of prism as the product of tide range and open water basin area neglects the actual basin area-height conditions of the system. The values plotted in Figure 2 are the tidal prisms calculated from the discharge.

Mayor-Mora's experiments were conducted with combined scaled tidal action and waves. Tidal prism was calculated as the product of basin area and tide range. Since a natural quartz sand distribution $d_{50} = 0.34$ mm) was used, scale effects may be important.

Review of extant aerial photography indicates that the Chesapeake Bay inlets included in this study have existed for at least a decade which suggests they are not ephemeral. When only a single survey is performed on an inlet, the observed correspondence between inlet channel area and hydraulic parameters (prism, discharge, etc.) is assumed to approximate the condition of sedimentary equilibrium. Modulations around an average equilibrium flow area occur with changes in wave conditions and tidal height variations but recovery from extreme events may take only days (Byrne, et al., 1974). The inlet sites herein presented are exposed to relatively weak littoral drift so disturbances from "equilibrium" may require longer recovery times. Moreover, those systems with relatively large upland drainage basins (i.e. No. 1, Cubitt Creek) may have periodically large freshwater outflow which temporarily enlarge the channel throat area.

Given the assumption that the inlets studied do approximate conditions of sedimentary equilibrium, the results displayed in Figure 2 indicate the inlet area-tidal prism relationship deduced for oceanic inlets does not apply to smaller natural inlets. Inspection of the plotted points and the least squares analyses suggests that the transition zone between the oceanic and smaller inlets occurs near $A_c \approx 100 \text{ m}^2$ to 500 m^2 .

Geometry of the inlet throat

Oceanic inlets are generally considered to be hydraulically wide (hydraulic radius \approx mean depth). However, for smaller channels to remain stable, the cross-section must become more efficient. For example, for the oceanic inlets plotted in Figure 2 (Jarrett, 1976), the average value of $W/R \approx 337$ whereas the average value of $W/D = 23$ for the smaller Chesapeake Bay inlets herein reported. A dimensionless downstream view of channel geometry, scaled to a reference semi-circular cross-section, is shown in Figure 3. For comparison, a channel cross-section from Mayor-Mora's model results are included.

The departure of the width-depth characteristics of mid-range and model inlets from the ocean inlets is shown in Figure 4 (Mehta, 1976; Winton, 1979). While there is appreciable scatter in the data, the departure zone between the trend of the larger oceanic inlets alone and that of a smooth curve through all of the data appears to lie at an inlet area of about 100 to 500 m^2 , the same zone observed in the inlet area-tidal prism plot (Fig. 2).

Figure 3. Dimensionless inlet throat geometry.

Figure 4. Width-depth relationship for inlets without jetties. After Winton, 1979.

Maximum velocity versus inlet area

As previously mentioned, the scouring capacity of the tidal current to maintain the inlet entrance may be represented by the maximum discharge ($Q_{\max} = A_c V_{\max}$). If the constraints leading to a sinusoidal time variation in discharge are accepted, the "equilibrium" relationship between channel area and tidal prism may be used to calculate the corresponding Q_{\max} or V_{\max} (Keulegan and Hall, 1950; O'Brien, 1969; Bruun, 1974). Following O'Brien:

$$\Omega = \int_0^{T/2} a v dt ,$$

and if $v = V_{\max} \sin \frac{2\pi t}{T} ,$

then $\Omega = \frac{A_c V_{\max} T}{\pi}$ or $Q_{\max} = \frac{\pi \Omega}{T} .$ (6)

Equation 6 may be expected to hold when $A_c \approx$ constant, and by definition, the duration of the ebb and flood currents are equal.

Combining Equations 1 and 6 and with $T = 12.4$ hours, O'Brien found $V_{\max} = 1.06$ m/s (3.5 fps). This value corresponds rather closely with values of $V_{\max} = 1.0 \pm 15\%$ m/sec reported by Bruun (1967) and Jarrett (1976) for a number of oceanic inlets.

Keulegan and Hall (1950) tested Equation 6 against gaged discharge at four oceanic inlets and concluded that a coefficient was required to account for deviations from a sinusoidal discharge ($Q_{\max} = C(\pi\Omega/T)$, $C = 0.86$). In his later theoretical development of inlet hydraulics for conditions of constant basin and channel areas, Keulegan (1967) found that the coefficient, C , may vary between 0.8 and 1.0.

The purpose of this section is to examine the relationship between V_{\max} and A_c for the smaller tidal inlets studied. As shown in Table 1, the channel cross-sectional area changes appreciably during the tidal cycles giving rise to distortions in the velocity time history. For comparative purposes, Figure 5 presents the measured values of V_{\max} with those calculated from Equation 6 for a smooth curve drawn through the combined data in Figure 1. That segment of the V_{\max} versus A_c curve derived from the Jarrett (1976) data ($A_c > 10^2$ m) indicate a decrease in V_{\max} as A_c increases. This result would arise as well from the application of Equation 6 to Equation 2 since the exponent in Equation 2 is greater than 1. This is likely to be an anomaly arising from a limited data set.

Three data sets are presented in Figure 5. Data associated with channel areas less than 10^{-1} m² are V_{\max} values averaged for flood and ebb from the model results from Mayor-Mora. The mid-range inlets of

Figure 5. Observed maximum velocity versus throat cross-sectional area, A_c . Solid line is derived from smooth curve through points in Figure 2 and application of Equation 6. Data points for $A_c > 10^2 \text{m}^2$ from Jarrett (1976), points for $A_c < 10^2 \text{m}^2$ from Mayor-Mora (1977).

Chesapeake Bay ($10^{-1}\text{m}^2 < A_c < 10^2\text{m}^2$) represent the ebb and flood averaged values of V_{\max} after adjusting to spring tide conditions with $V_{\max}/\sqrt{ga_0}$ as the scaling parameter (Table 2). The unadjusted V_{\max} values were taken from curves of $\bar{v}(t) = q(t)/a_c(t)$ for each inlet. The data for $A_c > 10^3\text{m}^2$ are taken from Jarrett (1976) for inlets on the Atlantic U.S. Coast.

Inspection of Figure 5 indicates that V_{\max} for the model and mid-range (Chesapeake Bay) inlets cluster around the value of $V_{\max} \approx 0.35$ m/s. This may represent a limiting condition for the active transport of medium to fine sand sized sediments in the entrances and thus act as the limiting V_{\max} for stable inlets.

Phase lags and durations of flow

The analysis of Keulegan (1967) indicates that for a sinusoidal "ocean" tide and a horizontal water surface response in the basin (basin small relative to tide wave length), the tide range ratio (R_o/R_b) should equal the cosine of the phase lag between the times of high (low) water in the "ocean" and those of the lagoon. Keulegan's analysis was based, as well, on the assumption that the inlet depth was large relative to the tide, and that the inlet hydraulics were controlled by local head differences rather than a progressive wave through the entrance. O'Brien and Clark (1973) attempted to test the theoretical expectation for U.S. inlets using available current and tide data. Recognizing the appreciable scatter in the data, they concluded that for smaller entrances ($A_c/(\frac{1}{3}R_o)^2 < 10^4$) the theoretical expectation was reasonably approximated.

For small tidal inlets, the channel cross-sectional area may vary significantly during the tidal excursion which results in a distortion of the velocity time history such that a longer ebb flow duration over a reduced flow area is required to balance an equivalent tidal prism. Such were the conditions considered by Mayor-Mora in model experiments. He found the ebb flow durations to be greater than the flood durations and, correspondingly, that the phase lags between high waters were shorter than predicted in the Keulegan analysis while the low water lags were longer.

The mid-range inlets herein reported have significant variation in entrance channel area during the tidal excursion (high water area to low water area ranging between 1.6 to 9.5, Table 1). Accordingly, the observed distortions in the ebb and flood flow durations may be expected (Table 2). However, variations in the basin area with tidal stage induce an opposing effect leading to longer flood durations (Mota-Oliveira, 1970; Boon and Byrne, 1981).

Given the distorted durations of flow, Seabergh (1979) indicates that the phase lags may be weighted by the duration of ebb and flood flow:

$$\epsilon = \frac{\Delta t \text{ between basin and ocean high (low) tide}}{\text{duration of flood (ebb) flow}} \times 180^\circ$$

Inspection of Table 2 indicates there is generally good agreement between the tide range ratio, R_b/R_o , and $\cos \epsilon$. In those cases where there is substantial reduction of the basin tide range (inlets 2, 3, 5, 6, 9, 11), the ebb phase lag more closely corresponds to the resultant tide range ratio. Inlet 13 is an anomalous case arising from the fact that this entrance, crossing the foreshore of a beach, becomes perched at low tide which controls the basin tide range.

CONCLUSIONS

- 1.) The data on smaller tidal inlets indicate significant departures from the oceanic inlets in the relationship between throat cross-sectional area and tidal prism. For the cases studied, namely inlets on the Atlantic United States coast subject to semi-diurnal tides, the departures appear to exist for inlet areas less than 500 m^2 .
- 2.) Examination of the relationship between inlet width and depth also suggests a departure between the oceanic inlets and the smaller natural and model inlets at throat area values between $100\text{-}500 \text{ m}^2$.
- 3.) Within smaller tidal inlets characterized by large flow area variations with tidal stage, the maximum velocity is significantly lower than that observed in the larger inlets (0.35 m/s vs 1 m/s). It is suggested that these low maximum velocities may represent the limiting condition of inlet stability.
- 4.) The idealized relationship (Keulegan, 1967) between the tide range ratio and tidal phase lag,

$$R_b/R_o = \cos \epsilon$$

was found generally to hold when the time lag between "ocean" and basin tides were scaled by the duration of ebb or flood flow. When there was substantial reduction in the basin tides, the low tide phase lags more correctly predict the tide range ratio. This is probably due to the higher inlet impedance at low tide.

A COASTAL INLET WITH FIXED BED
AND MOBILE SIDES

R.C. Nelson

Senior Lecturer, Civil Engineering Division,
Deakin University, Australia.

and

A.J. Keats

Engineer, Geelong Waterworks
and Sewerage Trust, Australia.

1. INTROOUCTION:

The coastal inlet dealt with in this paper has a fixed bed of exposed rock and mobile side boundaries of sand that overlies the bed rock platform.

The work was undertaken to investigate the response of the throat section to natural hydraulic and meteorological events and to observe the nature and rate of recovery of the inlet after the more extreme events. These events included sea and swell states, wind, freshwater flood flows and short term changes in mean sea level (storm surges or meteorological tides). The three year study involved the inlet at the mouth of the Barwon River, Victoria, Australia (see Figure 1). The work forms part of a continuing study to assess the impact of engineering works on the stability of the estuary and inlet, and was required to assist in delineating the natural inlet variability from that due to engineering works. The study described here looked specifically at the inlet throat section which refers to the short narrow waterway connecting the estuary with the sea. The inlet throat section at Barwon Heads is well defined and is shown in Figure 1.

The inlet itself is free of training walls and is normally flanked by sandy beaches. However, the depth of the inlet is limited by a bed of rock (see Figure 2), there being, in effect, unlimited mobility on a side boundary only. The study therefore included

FIGURE 1: LOCALITY SKETCH

an investigation to see if such an inlet conformed to equilibrium criteria developed from inlets with unrestricted bed mobility.

Some results of previous investigations on the estuary and inlet were reported by Nelson (1977).

2. DESCRIPTION OF INLET:

The Barwon Heads inlet is located west of Port Phillip Heads and is backed by an estuary 9 km long, joining Lake Connearre with the sea. The lake is 9 km² in area. The tidal limit lies on the river 1.5 km upstream of the lake. The tide at the inlet is semidiurnal with significant diurnal inequality. The mean spring tide range at the inlet (astronomical tide) is 1.56 m and in the lake is 0.15 m. Superimposed on this astronomical tide is a significant meteorological tide range observed to be at least 0.8 m. An investigation of the meteorological tide has been reported elsewhere (Keats, 1979). During the three year study the maximum and minimum still water levels observed on the gauge at the inlet were 2.48 m and 0.02 m respectively. The mean sea level for the three year period of study was 1.03 m on the gauge.

The total catchment area above the inlet is 4400 square kilometres with an average annual catchment rainfall of about 660 mm, of which only 80 mm per year, on average, passes the catchment outlet as runoff. Higher runoff proportions occur during heavy storm or prolonged wet periods. Most flood flows occur as a result of heavy winter and early spring rainfalls.

For at least 80 per cent of the time the inlet experiences insignificant freshwater inflows. The peak tidal discharges at the inlet during these dry periods range from 230 m³/s (measured) on a mean spring tide range to 80 m³/s (measured) on a neap tide.

The tidal prism of the inlet, as determined by continuous monitoring of discharge over a tide cycle, is 2.3 million cubic metres for a mean spring tide range.

Winds in Bass Strait have a predominant westerly component and therefore, sea states from the south west predominate in the region of Barwon Heads. Swell from the south west is also dominant and originates in the Southern Ocean. The result is a net littoral transport along the coast from west to east in the region of Barwon Heads.

Sand samples taken from the inlet from time to time indicate a median diameter of 0.20 mm to 0.25 mm.

3. DATA COLLECTION:

3.1 Tidal Discharges and Tidal Prism:

The tidal prism of the inlet was obtained by tidal gauging where continuous observation of velocities was made during a tide cycle at a cross section several hundred metres upstream of the throat section. Area velocity methods were used to convert this data to a relationship of discharge versus time, from which the tidal prism was readily obtainable. The measurements were made from a boat using a fan type current meter. Velocity measurement traverses were made over both width and depth and the process continually repeated. The exercise was done for several different tide ranges ensuring the availability of reliable data on tidal discharges and prism.

3.2 Inlet Throat Survey Data:

The variation with time of the area below mean sea level (Figure 4) was generated from regular surveys of the inlet throat section, supplemented by visual assessments made during intermediate inspections. The latter were generally made following extreme events or during weekly maintenance visits to the tide recorder located at the cross section. All surveys were made at the same cross section located as shown in figure 1. The cross section was retrievable from fixed markers and was always at the point of minimum width no matter what the overall geo-

metric characteristics of the inlet were at any point in time. The survey of other cross sections from time to time confirmed that this point of narrowest width was in fact the point of minimum cross section area. An echo sounder was used to obtain bed levels in submerged regions and normal level survey methods used for above water regions. Surveys were undertaken, where possible, at or near low tide when sea and swell penetration were minimum. The mean sea level used was the average for the 3 years of the study, namely 1.03 metres on the Barwon Heads tide gauge.

3.3 Bed Rock Levels:

Bed rock levels are shown in figure 2. Where natural surface was above low tide level, rock levels were obtained using a mobile drilling rig. Rock levels in the channel were obtained using steel rod probing techniques immediately after floods when most of the underwater rock was cleared of sand and exposed by the flood.

3.4 Barwon River Freshwater Flows:

River flow (figure 4) was monitored using a rated river flow station at Geelong. River levels were obtained using a staff gauge, read at least once daily, and more frequently, as required during floods. River levels were converted to river discharges using a rating curve generated from a total of 40 river discharge gaugings, covering the whole range from near zero flow up to a maximum measured discharge of 735 cubic metres per second. The highest estimated discharge at Geelong during the three year investigation was 580 cubic metres per second (figure 4) and therefore no extrapolation of the rating curve was required.

3.5 Surface Winds and Sea State:

Regional surface wind velocities and direction (figure 4) were estimated indirectly from isobaric pressure gradients. The data was extracted from Australian Region, Sea Level Synoptic Charts at six hourly intervals for the duration of the study. The charts used were those corresponding to 0000, 0600, 1200 and 1800 hours G.M.T. Average offshore regional winds were thought to have more meaning in this study as sea state activity can be inferred from it. No recorded offshore wave data was available and since wave action and associated littoral drift has an important influence on inlet geometry, it was necessary to identify severe sea state occurrences and its general direction. These can be identified from the graph showing average daily wind vectors. Prevailing sea state conditions and direction over longer periods can be inferred from the graph showing average monthly wind vectors.

20	19.10.77	192	88	2.1	41
21	6.12.77	202	114	1.7	66

Two wind recording stations do exist within a 16 km radius of Barwon Heads, one on the coast and one inland, but these are influenced by diurnal and topographic effects and would not be indicative of the offshore regional influences responsible for sea state conditions.

The data in figure 4 demonstrates the predominance of westerly winds. The only months during the study where an easterly component predominated over a westerly component were February and March.

3.6 Swell State:

The data in figure 4 were obtained from visual estimates made by the lighthouse keeper at Point Lonsdale, 10 km to the east of Barwon Heads. The estimates were for swell conditions and not sea conditions, a distinction which was made by the observer. The reliability of the data was dependent on the experience of the observer.

3.7 Sea Levels:

These were obtained from a tide recorder located at the throat inlet section for the duration of the three year study. The data was recorded in analogue chart form and digitised manually at one hourly intervals for computer analysis. The daily mean sea levels (meteorological tide) shown in figure 4 demonstrate that high levels (storm surges) were associated with strong and sustained westerly winds and unusually low levels were associated with easterly gales. A study of weather and associated sea levels at Barwon Heads has been reported elsewhere (Keats, 1979). Generally speaking the average monthly mean sea levels were lowest in February.

4. INLET BEHAVIOUR:

4.1 General Variability:

The cross section area below mean sea level varied from a minimum of 149 m^2 to a maximum of 276 m^2 . The envelope of sand surface elevation over the study period (figure 2) represents the prism of sand worked over during that period. The prism of sand below mean sea level was 171 m^3 per metre length of inlet and 331 m^3 per metre length of inlet for the whole cross section. The gross volume changes (absolute sum of the changes between each survey) were 501 m^3 per metre length of inlet below mean sea level and 912 m^3 per metre length of inlet for the whole cross section. Nevertheless, net changes within the cross section between the first and last survey were only small being $+7 \text{ m}^3$ per metre length of inlet below mean sea level and $+30 \text{ m}^3$ per metre length of inlet for the whole cross section.

The maximum depth of sand movement within the total cross section was 2.9 m. Bed rock was always exposed in the bottom of the

inlet restricting the water depth that could be attained (figure 3). The maximum depth of the inlet, therefore, varied little. Major adjustments in cross section area were achieved by movement of the inlet's eastern boundary as the sand spit extremity forming that boundary, retreated or advanced over the bed rock.

The inlet itself remained fixed in general location, this being attributable in no small way to the influence of Point Flinders.

4.2 Inlet Area Enlargement:

Flood flows, even if relatively small, had a significant influence on the area below mean sea level. The two flood flows of 1976, which occurred within a four week period, increased the cross section considerably, mainly by removing sand from above the base rock on the east side of the inlet. At Geelong, the larger of these two floods had a return period of ten years and the smaller a return period of three. Enlargement was again detected during the two floods of 1977 which also occurred within a four week period. The enlargement was again effected by the removal of sand from above the base rock on the east side of the section. The larger of these two floods had a return period at Geelong of five years and the smaller flood a return period of four years. The results are not inconsistent with a relationship where the inlet throat area after a flood is highly dependent on the magnitude of the flood peak such that the larger the flood peak the larger the resulting cross section area.

It should be understood that the peak flood discharge through the inlet occurs four to five days after the storm which produced it. Therefore it need not be coincident with extremes of other parameters such as gale force winds, high seas and high daily mean sea levels, which may have accompanied the storm responsible for the flood flows. The flood peaks shown for Geelong in figure 4 would have occurred two to three days after heavy rainfall on the upper catchment. The peak flows through the inlet at Barwon Heads would have occurred about 36 hours later again and would have been attenuated considerably below the peak at Geelong. Investigations undertaken so far, indicate that major flood peaks at Barwon Heads are at least 20 to 30 percent less than those observed at Geelong.

Other inlet enlargements did occur during periods well isolated from flood events, when river flows approached cease to flow conditions. Typically, these were periods which experienced -

- a. High daily mean sea level events (storm surges).
- b. Prolonged west to south west wind events where the average daily surface wind speed in Bass Strait exceeded 40 km per hour for 5 or more consecutive days. This also implies prolonged periods of high sea state from the south west.
- c. Exceptionally heavy swell events from the south fo west quarter.

Those periods immediately preceding cross sections 6, 8 and 16 fall into this category.

Enlargement during severe storm periods is contrary to expected behaviour. Most investigators report inlet channel reduction during such periods because of increased littoral drift rates. One possible explanation is that during exceptionally high tides, significant amounts of sea and swell do penetrate to the throat region and impinge on the sea wall on the Barwon Heads side of the inlet. This is particularly so during south westerly gales when high tide still water levels of 2.4 m are not uncommon and this is often sufficient to submerge the base of the sea wall on the west side of the inlet. The waves are reflected from the wall obliquely across the inlet, interacting with the incident waves, creating severe turbulence in the shallower edge regions on both sides of the estuary. The turbulence would tend to keep sand in suspension, it then being moved out of the region by prevailing tidal currents.

One enlargement that does not fit the patterns previously described is that resulting in cross section 3. The river was near cease to flow condition and strong winds from the south west exceeded average daily values of 40 km/hr in only one storm that lasted for only two consecutive days. There was, however, an earlier easterly gale when average daily surface winds exceeded 40 km/hr for two consecutive days. Despite the fact that this was only a two day event, and that daily mean sea levels were unusually low, the inlet's greater exposure to the easterly direction, combined with the later south westerly storm, must have enabled enough wave energy to reach the inlet to create sufficient turbulence to remove sand from the region.

4.3 Inlet Area Reduction:

The data record shows that periods of reducing cross section area are typically those which -

- a. Follow the winter and spring flood periods.
- b. Have falling or more moderate monthly mean sea levels.
- c. Are free of prolonged, extreme wind events when the daily average surface wind speed in Bass Strait exceeds 40 km/hr for three or more consecutive days. That is when more moderate sea states prevailed.
- d. Are generally free of exceptionally heavy swell events.

These characteristics are evidenced in all three years of the data record following winter and spring floods. The fact that these four characteristics are linked together is not surprising because they are not mutually independent. Low river flows, less extreme mean sea levels and less severe sea and swell states are associated with more moderate wind and weather conditions (Nelson and Keats 1978).

The rate of area reduction can be both rapid and sustained following a flood period. After the floods of September and October 1976, the cross section reduced at a peak rate of 30 square metres per month for a 28 day period immediately following the flood and sustained an average reduction rate of 16 square metres per month for a 131 day period, to produce a total reduction of 76 square metres. Following the floods of July and August 1977 the cross section reduced at a peak rate of 28 square metres per month over a 47 day period immediately following the flood and sustained an average reduction rate of 26 square metres per month over a 74 day period to produce a total reduction of 68 square metres.

The bulk of the material responsible for the area reduction was, in both instances, deposited on top of the base rock on the east side of the cross section so that the east side boundary gradually encroached toward the centre of the section. This is contrary to the general west to east movement of littoral drift prevailing along the coast. Sand tracer experiments have not been made to determine the precise cause of this local behaviour but wave pattern observations suggest the following explanation. The predominant south westerly waves refract and diffract around Point Flinders resulting in a wave direction near the end of the sand spit favourable to the movement of material back into the inlet from the east side. This material would be that washed out by flood flows together with some which appears to be deposited on a shallow bank on the east side of the inlet after bypassing the inlet from west to east.

The inflow of material from the east side and its deposition in the throat section only occurs during milder wave conditions. Severe and prolonged south west gales and their associated abnormally high sea levels cause the opposite effect as described in section 4.2.

4.4 Overall Influence of Floods:

Figure 5 is a plot of inlet throat area below mean sea level against peak river discharge at Geelong immediately preceding the inlet survey. Included is one survey taken after the flood of November 1978 which was the largest flood since 1952. While this is well isolated from the continuity of the main study period it is very valuable in assessing the inlet's response to flood flows. The area range shown on the zero discharge line, represents inlet surveys well isolated from flood events. It indicates the range of cross section area that can occur under the influence of varying wind, wave and meteorological tide conditions. Those points shown coupled with significant river discharges, demonstrate that the range of cross section area possible during flood flows is reduced, being minimised when the peak flood flows at Geelong are about 250 m³/s to 300 m³/s. For higher flows at Geelong the cross section area at the inlet is a function of the freshwater discharge only and independent of prevailing wind, wave and sea level conditions.

FIGURE 5: FLOOD FLOW INFLUENCE

5. EQUILIBRIUM CRITERIA CONSIDERATIONS:

Table 1 and figures 2, 3 and 4 demonstrate the geometric variability of the Barwon Heads inlet over the period of investigation. Of particular interest was the variability of the cross section area below mean sea level (1.03 m).

The mean area was 218 square metres with a standard deviation of 28 square metres representing 13 percent of the mean. The minimum observed area was 149 square metres and the maximum 276 square metres representing a range of from minus 32 percent to plus 27 percent of the mean. For comparative purposes discussed below, the standard deviation in log A was required and was determined to be 0.058. Investigators have found that the area below mean sea level depends primarily on the tidal prism of the upstream water body. Linear regression analysis on the logarithms of these two parameters yield equations of the form

$$A = bP^c$$

where A is the cross section area below mean sea level, P is the tidal prism and 'b' and 'c' are constants. Figure 6 shows a plot of data for eight North American inlets without training walls, published by O'Brien (1969). The cross section area at each inlet was generally estimated from one set of survey data. Data for the Barwon Heads inlet is also shown, based on the mean of twenty-one surveys. Linear regression analysis on the nine points yields equation (1).

$$A = 1.08 \times 10^{-4} p^{0.97} \quad (1)$$

where A is in square metres and P is in cubic metres. A measure of the data scatter and the degree of uncertainty involved in using this equation is given by the standard error in log A which was 0.066. The standard error in log A must be used since the linear regression analysis was done on the logarithms of A and P. However, an indication of the physical significance is obtained by realising that a standard error of 0.066 in log A represents a range of from minus 14 percent to plus 16 percent about the most likely value of A.

The standard error associated with log A in equation (1) approximates the standard deviation associated with the 21 observed values of log A at Barwon Heads. It seems the entire uncertainty associated with equation (1) could be explained by the natural variability associated with each inlet. Therefore, attempts to reduce the uncertainty associated with equation (1) by investigating the influence of other parameters, such as grain size or by improving the accuracy, resolution and compatibility of the various data used to estimate areas and prisms at each inlet will, on their own, produce minimal rewards. They must be coupled with observations of the variability induced at individual inlets by varying hydraulic and meteorological conditions.

FIGURE 6: INLET AREA VERSUS TIDAL PRISM

The Barwon Heads data demonstrates that inlet area based on one survey (or even two or three surveys) can give quite misleading information as to the prevailing or average geometric characteristics. When a group of such data is assembled from different inlets (eg. O'Brien's data of figure 6), the degree by which the observed area varies from the mean will differ from inlet to inlet depending on the antecedent conditions experienced at each inlet prior to it being surveyed.

Of further interest in this study was whether an inlet like Barwon Heads conformed to equilibrium criteria developed from inlets with unrestricted bed mobility. Two empirical criteria are considered here. The first concerns the relationship between an inlet's cross section area and its tidal prism. The data plot of figure 6, together with the regression analysis indicate that the Barwon Heads data fall well within the expected range as determined from inlets with unlimited bed mobility. The second criterion refers to the inlet's mean maximum tidal velocity for a mean spring tide. Bruun and Gerritsen (1960) demonstrated that

$$Q_{\max} \dot{=} A \quad (2)$$

This implies that the maximum tidal velocity for a stable inlet is approximately 1.0 m/s. At Barwon Heads the ratio of the maximum

discharge (mean spring tide) to the mean cross section area below mean sea level is 1.06 m/s. However, if the phasing between the discharge and water level variations with time are taken into account the actual maximum velocity is nearer 0.9 m/s. The data again agree closely with those determined from inlets with unlimited bed mobility.

6. SUMMARY AND CONCLUSIONS:

- a. While the depth of the inlet remained fixed by the bed rock, the variation in cross section area and width were such that their maximum observed values were approximately double their minimum values. Major adjustments in cross section area were achieved by the retreat or advance of the inlet's sandy eastern boundary across the underlying rock platform.
- b. Freshwater flood flows had by far the most significant influence on inlet area change (enlargement) but recovery was both rapid and sustained. High meteorological tides combined with severe and prolonged south westerly sea and swell states also created area enlargements, contrary to expected behaviour. Area reduction always occurred following floods and during periods when more moderate seas and swell prevailed together with more moderate mean sea levels.
- c. Bed rock was always exposed in the bottom of the inlet restricting the depth that could be attained. Despite this, the inlet's tidal prism and average cross section area below mean sea level, conformed closely to equilibrium criteria developed from inlets with unlimited bed mobility. The same finding applied to the inlet's mean maximum tidal velocity.
- d. The statistical uncertainties associated with predicting an inlet's equilibrium cross section area from existing equilibrium equations, are approximately the same as those associated with the natural variability of any one inlet, if the Barwon Heads observations are typical. Therefore, attempts to refine equilibrium equations will not be profitable unless coupled with studies, over a period of time, of the response of individual inlets to varying hydraulic and meteorological conditions.

INLETS/ESTUARIES DISCHARGING INTO SHELTERED WATERS

H.P. Riedel¹M.R. Gourlay²SUMMARY

Tidal prism - cross sectional area relationships and tidal velocities have been measured for inlet entrances and along the length of the estuary for four creeks entering the sheltered waters on the South East Queensland coast, Australia. It has been found that the inlet entrance tidal prism - cross-sectional area relationship is controlled by the magnitude of littoral drift. The tidal prism - cross-sectional area relationship along the estuary is believed to be common to all tidal estuaries landward of the region where littoral drift has an influence.

For tidal inlets on sheltered coasts with tidal prisms of the order of 10^6 m^3 , the mean maximum velocity during spring tides at the inlet entrance is about 0.3 to 0.4 m/s.

1. INTRODUCTION

For the design of a new international airport at Brisbane, it was necessary to reclaim an existing stable creek and to divert floodwaters to an artificial inlet. In order to design an artificial inlet which would be stable, or at least have predictable characteristics, a study was undertaken by and for the design authority, the Australian Government Department of Housing and Construction, to investigate the characteristics of inlets and estuaries discharging into sheltered waters.

The site for the airport is shown in Figure 1 where Serpentine Creek will be reclaimed and an artificial inlet excavated about two kilometres to the north. Both Serpentine Creek and the artificial inlet discharge into Moreton Bay which is approximately 30 km wide by 50 km long. It follows that the wave climate at the inlet entrance will be mild with wave periods and heights rarely exceeding 5 seconds and 1.5 metres respectively. Littoral drift rates are consequently low, probably less than $10,000 \text{ m}^3$ per annum. With these considerations, it was thought that the economic design of an artificial inlet should not be based on relationships derived for tidal inlets on open coasts; e.g. O'Brien (1969), Bruun (1978), Jarrett (1976).

In order to obtain relationships upon which the design of a predictable inlet and estuary may be based, field studies were undertaken to measure the characteristics of inlets in protected waters.

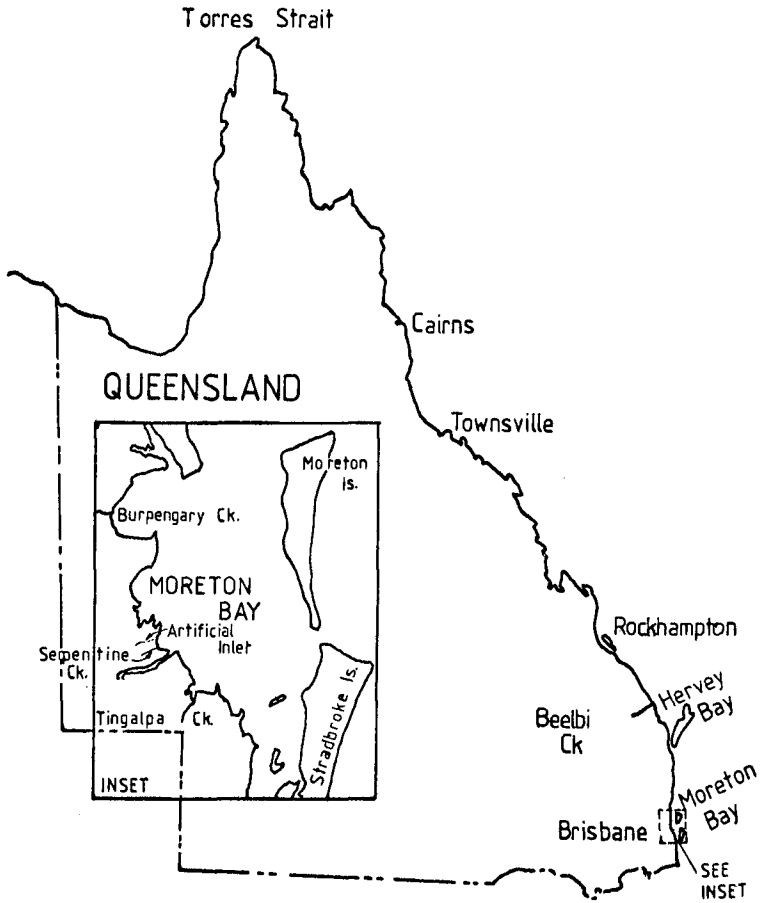

FIGURE 1 Locality Plan

Comparisons were also made with data obtained by others. Geomorphological and sedimentological studies of Serpentine Creek and adjoining areas were also undertaken to obtain an understanding of the recent (Holocene) geological history and sedimentation processes; Gourlay (1979).

2. PREVIOUS STUDIES

An understanding of the stability of inlets/estuaries must be based on a sound understanding of the tidal hydraulics, flood flows, wave mechanisms and sedimentary aspects. However, the degree of importance of each of these influences depends to some extent on the exposure of the inlet to the open ocean.

There have been numerous studies of tidal inlets on exposed coasts. Summaries of these studies and the factors controlling these inlets have had wide publication, in particular those of O'Brien (1969) and Bruum (1978). These studies relate mainly to inlets between the ocean and bays, rather than inlets and an associated tidal estuary. Information on tidal inlets and estuaries discharging into bays or a sheltered section of the ocean is fairly scarce, and there is little published data. Very recently, Byrne et al (1980) have obtained a comprehensive set of data for inlets in Chesapeake Bay. Also, because of the variability possible in bay shape and bathymetry, the generalisations possible for the open coast may not be possible for sheltered inlets.

For Australian inlets/estuaries discharging into relatively sheltered waters very few publications have been found which are quite relevant to this study. Many of these publications are internal to their relevant organisations, which indicates that there may be other data obtained by others which has not been reported in an accessible form. It is possible that a similar situation exists in other countries where, because the studies for small inlets tend to be small scale, the results are not readily accessible. Consequently, a literature search of data obtained outside Australia has not been attempted for sheltered inlets.

Perhaps the most relevant study to this investigation is that published by Apelt (1977) which investigates the existing Serpentine Creek. Figure 2 shows a plot of tidal prism vs cross-sectional area along the Serpentine estuary. It also includes the data from other relatively sheltered estuaries for which information was available, namely Georges River, N.S.W. (Munro et al 1967), Mooloolah River, Qld. (Nittim 1974) and Pine River, Qld. (Cameron McNamara 1978). The Mooloolah River in South East Queensland discharges into the ocean at a rather sheltered location on an exposed coastline about 150 km north of Brisbane where the littoral drift is relatively small. The Georges River, N.S.W., discharges into Botany Bay south of Sydney. The Pine River discharges into Moreton Bay, but is a much larger estuary than the other estuaries in Moreton Bay considered in this paper.

FIGURE 2 AUSTRALIAN INLET-ESTUARY DATA
SHELTERED LOCATIONS

For reference, O'Brien's line for exposed inlet entrances has been included. Figure 2 shows that for each of these Australian inlets the tidal prism characteristics at the entrance and along the estuary fall well below the open coast inlet line.

Figure 2 also shows tidal prisms for the entrance to Burpengary Creek and the Caboolture River in Moreton Bay which also fall well below the open coast line. These sets of data do show quite a wide scatter and were considered inadequate for the purposes of designing an artificial inlet and estuary. Much of the scatter may be attributed to a large variation in scale of the estuaries, and to river flows that may dominate tidal flows. For the system under study, it was expected that tidal characteristics would control the long term shape of the inlet and estuary.

3. FIELD MEASUREMENTS

Tide, current and limited hydrographic data were obtained for four inlets and associated estuaries in South East Queensland. Chosen were:

Beelbi Creek in Hervey Bay, and
Tingalpa, Serpentine and Burpengary Creeks in Moreton Bay.

Each inlet was selected because its scale, tidal range and exposure were similar to that of the proposed artificial inlet. For each creek the spring tidal range is about 2 metres outside the entrance, and the tidal prisms ranged from $0.8 \times 10^6 \text{ m}^3$ for Burpengary Creek to $1.4 \times 10^6 \text{ m}^3$ for Beelbi Creek.

The prevailing wind system for this section of coast is south easterly, as typified by the wind rose for Cape Moreton in Figure 3. The wind rose for Cape Moreton may give an exaggerated impression of the dominance of the south east wind, because the recording station has direct exposure to this wind direction. Winds within Moreton Bay and Hervey Bay would be slightly modified by the adjacent land masses.

From Figures 1 and 3 it is apparent that each of these creek entrances is well protected from swell waves, as well as receiving a large degree of protection from short period waves generated from the dominant south east wind direction.

Perhaps the most variable factor between the selected creeks was the nature of the sediments. All the creeks entering Moreton Bay have similar sediments, with silts and clays on the banks and fine sand on the creek bed. In the downstream areas the depth of these fine materials is generally in excess of 1.5m. The upstream reaches show more variability, with Tingalpa Creek crossing several rock bars within the region of tidal influence.

FIGURE 3 WIND ROSE

Beelbi Creek has much coarser sediments throughout its length. Areas showing fine sand or silt on the bed are only superficial deposits and much of the creek bed is underlain with gravel. Silt or fine sand thickness rarely exceeds 0.5m within the creek bed. There are quite coarse sediments at the downstream end of Beelbi Creek, particularly in the flood channel. A detailed sedimentological study of these creeks was beyond the scope of this paper, although this type of study has been completed for the Serpentine Creek (Gourlay 1979).

4. DATA

The data obtained consisted of:

- (a) Tide records at three or four stations along each creek during at least one spring tide.
- (b) Tidal velocities at up to four sections along each creek during the period for which tidal records were made.
- (c) Hydrographic survey of each creek sufficient to define cross-sectional areas and tidal prisms along the length of the estuary.

The data was reduced to give mean maximum velocity across each section monitored over a mean spring tidal range (V mean max.), and the cross-sectional area (A) and tidal prism (P) at sections every 0.5 to 1 kilometre along the estuary. Figure 4 shows the V mean max. for both flood (F) and ebb (E) tides for each creek as a function of distance upstream from the creek mouth. With the exception of the flood data point at the 5 km mark of Beelbi Creek, the data points show a consistent picture, with velocities at the creek entrance of about 0.3 to 0.4 m/s dropping to 0.2 to 0.3 m/s at the upstream limit of tidal influence. There was negligible rainfall (river flow) before or during all the measurement periods.

Figure 5 shows the data for tidal prism vs cross-sectional area for the length of the estuaries to the limit of the tidal influence. The data for Serpentine Creek has been modified from that shown in Figure 2. A correction has been made by deducting the tidal prism of Schultz canal - an excavated channel at the upstream end of Serpentine Creek. This correction has been justified on the basis that the lower reaches of the Serpentine have not had time to readjust to the extra tidal prism introduced by the Schultz channel. This correction results in a better agreement between the four sets of data.

5. DISCUSSION

It is quite clear from the data presented that the stability characteristics of small inlets discharging into sheltered waters are quite different from those for large systems connected through an exposed shoreline.

FIGURE 4 INLET/ESTUARY TIDAL VELOCITIES

FIGURE 5 S.E. QUEENSLAND INLET/ESTUARY DATA
SHELTERED LOCATIONS

However, it is suggested that the difference is purely in terms of scale. The mechanisms are the same in both instances.

5.1 Inlet Only

Table 1 summarises the velocity at the inlet entrance for each of the four creeks considered.

TABLE 1

V mean max. : FOR CREEKS ENTERING SHELTERED WATERS ON THE SOUTH EAST QUEENSLAND COAST

Creek	V mean max. (m/s)	
	Flood Tide	Ebb Tide
Serpentine	0.30	0.31
Tingalpa	0.31	0.32
Burpengary	0.37	0.29
Beelbi	0.35	0.42

By comparison, for about 50 inlets on exposed coasts on the U.S.A. and in Europe, Bruun (1978) reports that in almost all cases $0.8 < V \text{ mean max.} < 1.2 \text{ m/s}$. In a similar manner, Figure 5 shows that for a given cross-sectional area of the inlet entrance, the tidal prism for exposed coast inlets is roughly 2 to 3 times those of the sheltered inlets reported herein.

An explanation for the marked difference between the four creeks and those reported for open coasts is that the littoral drift is on order of magnitude lower for the shorelines across which the South East Queensland creeks discharge.

The effect of the littoral drift is to try to infill the entrance of the inlet, whereas the tidal flow through the inlet entrance combats this by moving at a velocity fast enough to scour any material deposited in the entrance. If the tidal velocity is not large enough, the entrance will reduce in size until either the velocity increases to a sufficiently high scouring velocity, or the entrance is closed. With the large littoral drift on exposed shorelines, it follows that a large quantity of sediment must be moved by tidal velocities each tidal cycle, and this velocity for a stable inlet is of order of 1 m/s.

In contrast, for sheltered inlets the littoral drift rate is small and, consequently, a much smaller volume of material needs to be moved out of the entrance each tidal cycle. Figure 5 shows that the tidal cross-sectional area of the entrance to sheltered tidal inlets is much larger than for exposed inlets for a given tidal prism, and, it follows that velocities will be much lower. The measured velocities of 0.3 to 0.4 m/s are sufficient to initiate sediment motion for the sediments encountered, and, although

the velocities are low, they are sufficient to counteract the low littoral drift rates.

Confirmation of the consistency of the P - A relationships of the inlets reported here, and those of others, is strengthened by the results reported by Byrne et al (1980). Figure 6 shows the inlet P - A relationships for exposed coasts, sheltered coasts, very small natural inlets and model scale inlets.

5.2 Estuary

Confirmation of the influence of littoral drift upon inlet tidal prism - cross-sectional area relationships is found when the relationship between P and A along the estuaries is considered. Figure 7 combines data from Figures 2 and 5 and includes the Yaquina River in Oregon, U.S.A., which discharges into the ocean on an exposed coast. Goodwin et al (1970).

For all these estuaries the P - A relationship is approximately the same as the P - A relationship for the entrances of the four small estuaries studied here, and this relationship is very different from that for inlet channels on exposed coastlines. The entrance channel data of Byrne et al (1980) for inlet entrances are an order of magnitude smaller than these South East Queensland entrances, and are consistent, as can be seen on Figure 6. All the estuaries have entrance cross-sections with greater areas than indicated by the open coast line, except the Yaquina River whose cross-section falls on the O'Brien line. This is consistent with its exposed location. The inference is that for estuaries where tidal flow, rather than flood discharge, determine the form, a stable P - A relationship may be predicted, provided the littoral drift rate is known. The littoral drift rate effectively controls the entrance cross-sectional characteristics, but upstream from the limit of influence of littoral drift all the estuaries investigated have a similar P - A relationship.

As previously proposed by Nelson (1977) this inference can be taken one step further by postulating on Figure 6 a generalised estuary (tidal) P - A line for the estuary outside the region of littoral drift influence. See Figure 8. The underlying assumption, which is validated by the data examined for inlet estuary systems, is that any littoral drift tends to choke the entrance area. Field data for a range of tidal estuaries would be required to completely test this hypothesis.

6. CONCLUSIONS

- (A) Tidal prism - cross-sectional area (P - A) relationships may be used for describing tidal inlets, provided a distinction is drawn between the entrance and locations along the length of the estuary.

FIGURE 6 INLET ENTRANCES
ALL SCALES

FIGURE 7 INLET - ESTUARY COMPARISON

FIGURE 8 PROPOSED TIDAL ESTUARY LINE

- (B) The O'Brien P - A representation holds for exposed coasts where there is a large littoral drift. At the other end of the scale are inlets with small littoral drift which fall on a P - A line well below the exposed coast line.
- (C) The P - A line for inlet entrances lies above the P - A line for the length of the estuary. As littoral drift reduces for smaller inlets which are permanently open, the estuary line approaches the inlet more closely.

7. ACKNOWLEDGEMENTS

The authors wish to thank the Secretary of the Department of Housing and Construction for permission to publish this paper, and gratefully acknowledge discussions with colleagues in the Maritime Works Branch. The work was undertaken while Dr. Riedel was employed by this Department. Nevertheless, the opinions expressed herein are those of the authors.

CHAPTER 154

THE CORPS OF ENGINEER'S GENERAL INVESTIGATION OF TIDAL INLETS

Robert M. Sorensen*

Introduction

During the past decade the U.S. Army Corps of Engineers has been conducting a General Investigation of Tidal Inlets (GITI). The GITI was an applied research program through which a wide range of inlet phenomena relating to Corps responsibilities for coastal navigation and recreation, prevention of beach erosion, and control of coastal flooding were investigated. The program was managed by the U.S. Army Coastal Engineering Research Center (CERC); specific research projects were conducted by CERC, the U.S. Army Waterways Experiment Station (WES), private consultants, and universities.

The various GITI research efforts can be divided into five categories: 1) field studies of the hydraulics and sedimentary dynamics of selected inlets, 2) analysis of historic field data, 3) numerical models of inlet hydraulics, 4) movable and fixed-bed physical inlet models, and 5) other miscellaneous inlet studies. Research results are being published in a special report series. The number, title, author and date of each report are listed in the Appendix - GITI Reports.

The intent of this paper is to summarize GITI research efforts and, based on key results of this research as well as recent Corps field experience, to recommend new areas for research.

Field Studies of Tidal Inlets

Corpus Christi Water Exchange Pass in Texas is a two mile long prismatic channel (8 ft by 120 ft) with short entrance jetties that was dredged across the barrier island to connect Corpus Christi Bay and the Gulf of Mexico. Field studies of the pass and adjacent beaches were conducted from the time of channel construction in 1972 to 1975 (GITI 8, 9).

Water levels were continuously measured at each end of the channel and twenty tidal-cycle discharge surveys were conducted over the three-year study period to document tidal cycle, lunar, seasonal and longterm changes in channel hydraulics. During the first year of pass operation, average channel frictional resistance increased by approximately 50 percent and even greater resistance variability was observed during individual tidal cycles. This is demonstrated by typical plots of Manning's n and water level differential versus time (Figure 1). At times there was a strong progressive increase in resistance as flood or ebb flow

* Chief, Coastal Processes and Structures Branch, U. S. Army Coastal Engineering Research Center, Ft. Belvoir, Virginia 22060

Figure 1 Temporal variation of Manning's n and tidal differential, CCWEP, Texas (GITI 10)

developed followed by a rapid drop as flow reversed; at other times no trend in channel resistance was observed.

Temporal flow resistance variations of the magnitude demonstrated in Figure 1 will have a significant impact on inlet flow regimes as well as on our ability to accurately predict inlet hydraulic response by applying physical and numerical models. There is a strong need for additional field and possibly laboratory investigations to define the causes for this resistance variation and the field conditions under which it can occur.

Periodic bathymetric surveys of the bay and gulf entrances, the pass, and adjacent beaches were also made and results related to wave climate (visual observations), gulf tide levels, local winds, channel discharge, and estimated longshore transport rates. Inlet stability analyses proposed by O'Brien (1931, 1969), Escoffier (1940), and Bruun and Gerritsen (1960) concur with the continuing channel shoaling observed during the field study period.

The other GITI field study involved a two-year program of data collection at North Inlet, a natural tidal inlet in South Carolina (GITI 10, 16). Water level differentials and inlet discharge were measured, visual wave observations were made to determine longshore energy flux and sediment transport, beach profiles and inlet hydrography were periodically measured and compared to historic hydrographic charts, and sediment samples were collected and analyzed.

Calculated values of Manning's n show a similar range of values as those found at the Corpus Christi Water Exchange Pass. Also, occasional less well defined progressive increases in Manning's n were observed during the flood and ebb phases of the tidal cycle. The average peak ebb/flood velocity ratio in the inlet gorge was 1.22, the ebb dominance being attributed to the greater efficiency of water exchange at high tide because of a significantly larger bay surface area.

This and other field studies of tidal inlets have investigated sediment transport modes and patterns, and resulting erosion and deposition environments in the inlet and vicinity. Additional field work is needed to thoroughly define natural inlet sediment bypassing mechanisms as a function of inlet geometry, tidal range, and incident wave climate. The results must then be used to develop artificial inlet bypassing schemes that will maintain a navigable channel with a minimum of dredging and construction of permanent structures. Most typical bypassing schemes consist of fixed structures that establish a sediment trap and control the navigation channels. Such schemes are too costly to construct at many inlets. The ideal bypassing system would employ a dredging program that is flexible and reacts to the natural channel and sediment bypassing conditions.

Inlet channels stabilized by jetties may maintain an adequate

channel between the jetties but it is usually necessary to conduct maintenance dredging across the outer bar (seaward of the jetties). Additional field and possibly laboratory and analytical studies are needed to define the rates and patterns of shoaling to be expected in this portion of the channel. Better understanding of the shoaling patterns will allow a more effective program of overdredging in anticipation of the subsequent shoaling that will occur.

Analysis of Historic Field Data

Using data primarily for the Pacific coast inlets, O'Brien (1931, 1969) established a power function relationship between the mean cross-section area of the inlet throat and the diurnal or spring range tidal prism. Combining O'Brien's data, data from a few other sources (92 data points total) and an analysis of additional Atlantic and Gulf coast inlets (70 data points), Jarrett (GITI 3) developed tidal prism-inlet area relationships for a total of 108 inlets (162 data points). His tidal prism data development used both the "cubature method" which employs measured tide ranges throughout the bay at the instant when slack water occurs at the inlet, and the "NOS current data method" based on current measurements at the inlet throat.

The prism-area data were presented for combinations of three physical categories (all inlets, unjettied and single jetty inlets, and dual jetty inlets) and four geographical categories (inlets on all coasts, Atlantic inlets, Pacific inlets, Gulf inlets). Power function regression curves were fit and 95% confidence limits were established. Figure 2 is a typical result. The prism-area relationships for unjettied and single jetty inlets did vary somewhat for the three coasts, probably because of the differences in tidal and wave characteristics. In no cases was there significant variation from the original O'Brien relationship.

It is reasonable to expect that other relationships besides that relating tidal prism and inlet throat area could be formed between pairs of inlet geometric parameters. An investigation of hydrographic charts and air photographs for 67 natural inlets in the U.S. was conducted: "to isolate a set of parameters than can be used to quantify inlet geometry, to analyze relationships between the basic parameters selected, and to analyze the relationships between inlets based upon the parameters selected" (GITI 20). Over 50 parameters were evaluated and 13 were selected for detailed investigation. They are the inlet channel length and minimum width; the average and maximum depth of the inlet channel at the minimum width; the depth at the crest of the outer bar; the area of the ebb tidal delta; and eigenvectors of the minimum width channel cross section (three), the channel thalweg profile (two), and the ebb tidal delta shape (two).

Linear regression and R^2 analyses of all combinations of pairs of the 13 parameters were performed. Several strong relationships were found. For example $AED = 3.92 \times 10^{-7} L^{1.71}$ ($R^2 = 83.4$ percent) where AED is the area of the ebb tidal delta (square miles) and L is length of the channel from the point of minimum channel width to the

Figure 2 Prism vs area for Atlantic coast inlets with one or no jetties. (GITI 3)

crest of the outer bar (feet).

The parameters defining the gross scale dimensions and shape of the ebb tidal delta and the channel showed a strong relationship to the minimum width channel cross-sectional area (represented by the product of the average depth and width). However, there was no strong correlation with either the channel width or average depth separately. Apparently, the channel width and depth at the minimum width are free to adjust to the wave climate while the cross sectional area is controlled by the tide (tidal prism).

The multivariate statistical method of cluster analysis was used to evaluate tendencies for the various geometric parameters to define groups or clusters of inlets. Then, discriminant analysis was used to

test the strength of these clusters

The 67 inlets can be grouped into six well defined clusters plus five inlets that do not form a cluster or fit into any of the basic six clusters. The various clusters do exhibit some stratification based on size and some based on geographic location but these factors are not strong enough to solely explain the resultant clustering. As an example, Figure 3, shows the channel width and length groupings for the six clusters.

Figure 3 Channel width-length relationships for six inlet clusters. (GITI 20)

An analysis of the dynamic nature of inlet geometry was conducted by determining the temporal variation of selected inlet geometric parameters (GITI 21). This effort employed from four to twenty-one air photographs at each of 51 inlets. Geometric parameters used included the minimum entrance width, the channel length, and the thalweg position and orientation. These parameters were quantified from the air photographs and non-dimensionalized to remove size effects; then the temporal rates of change of the dimensional and non-dimensional parameters were evaluated. Somewhat arbitrary limits were set on each parameter to delineate stable and unstable inlets and to allow grouping or classification based on this delineation.

Both the geometric pattern and stability analyses provide much insight into the geometric characteristics of natural inlets but the information has not been related to causative factors e.g. wave climate, tide characteristics, net and gross longshore sediment transport. The important next step will be to conduct these analyses. Another, potentially fruitful area of research will be to evaluate the specific changes in the various geometric parameters as inlet structures are constructed (realizing that some of the parameters would be strongly controlled by structures such as dual jetties).

In 1957 an eight-mile channel was dredged across Padre Island and Laguna Madre to the Intracoastal Waterway at Port Mansfield, Texas. Gulf and laguna tide elevations, channel current velocities, and channel hydrographic data were collected periodically from 1957 to 1975. Longshore transport rates were estimated from wave hindcast data for the Gulf.

These data were analyzed to evaluate the channel's hydraulic response, shoaling patterns, and resulting stability (GITI 12). Strong channel instability, indicated by channel shoaling patterns and a required dredging rate of 350,000 cubic yards/year is in agreement with the stability criteria proposed by O'Brien (1931), Escoffier (1940), and Bruun and Gerritsen (1960). The length of the channel across the barrier island (3 miles) and the small Gulf tidal range are such that no channel crosssectional area would develop sufficient scouring velocities to eliminate the need for maintenance dredging.

Another effort was a study of thirteen tidal inlets each having a single updrift or downdrift jetty in order to evaluate the response of the entrance channel to jetty construction (GITI 19). This effort used information from periodic hydrographic charts, some of which date back to the 1890's.

In all cases, the channel thalweg was driven toward the jetty by wave action and the resulting longshore sediment transport, regardless of the inlet-bay orientation and resulting tidal flow patterns, the direction of net longshore sediment transport, or the orientation of the jetty. Channel cross section areas decreased up to 40 percent with the construction of a single jetty. In some cases the tendency of a channel

to migrate toward a jetty was so strong that undermining of the jetty occurred. In cases where two jetties were eventually constructed and one had deteriorated so sand could move over or through the jetty, channel movement toward the underiorated jetty was observed.

Numerical Models of Inlet Hydraulics

Available mathematical models for inlet hydraulic calculations vary greatly in complexity and commensurate cost (time, money, expertise) of application. They range from the simple one-dimensional model (e.g. Keulegan, 1967; King, 1974) which makes very restrictive assumptions about channel and bay geometry, sea water level time-histories, bay surface level variations, etc. to the complex two-dimensional finite difference numerical models that compare with physical hydraulic models in capability. The former are useful for simple quick preliminary calculations while the latter, operated by specialists, will provide the detailed flow pattern and water level information necessary for final design of major inlet developements. There was a need for an intermediate level model that would yield information on the velocity pattern at an inlet for relatively complex inlet-bay hydrography and nonsinusoidal sea water levels but that could be operated by Corps field offices without the need for special expertise and substantial investment of time and money. To satisfy this need a spatially integrated quasi two-dimensional numerical model was developed (GITI 14).

To apply the model, a somewhat subjective net of subchannels and cross sections is drawn at the inlet (see Figure 4). GITI 14 provides guidance for drawing the net. The one-dimensional equation of motion, with the friction term at each time step being evaluated by spatially integrating over the net, is solved simultaneously with the continuity equation for the inlet-bay in a time-marching fashion. This yields the inlet discharge and bay water level at each time step. Given the instantaneous inlet discharge, the velocity at each grid section can be calculated. Important capabilities of the model include: any sea level variation as a function of time (tsunami, storm surge, complex tide) may be specified; more than one inlet can connect the sea and bay; river inflow and surface runoff can be considered; and the bay surface area can vary with the surface elevation. Limitations include: wind stress and Coriolis effects are neglected, and the bay water surface is assumed to remain horizontal.

As part of an effort to evaluate the effectiveness of mathematical and physial models of tidal inlet hydraulics, an RFP was issued and studies were funded to calibrate and apply three mathematical models for predicting water-surface time histories and current velocities at Masonboro Inlet, N.C. (GITI 6, Appendices 2, 3 and 4).

One was a simple lumped parameter model that extended the method developed by Keulegan (1967) by allowing for variable bay surface area, a nonprismatic inlet channel, a nonsinusoidal ocean tide, inclusion of inertial effects, and surface inflow to the bay. The other two were two-dimensional (vertically integrated) finite difference model using explicit solution schemes and having their genesis in the hurricane

Figure 4 - Net and flood flow velocity distribution, Masonboro Inlet, N.C. (GITI 14)

surge model of Reid and Bodine (1968). GITI 6 is a summary discussion of inlet hydraulic models and a comparison of the effectiveness of the three mathematical models applied to Masonboro Inlet. Figure 5 shows a typical calculated flood flow pattern at the entrance to Masonboro Inlet using one of the two-dimensional models.

Implicit and explicit finite difference models of inlet hydraulics have been steadily improved since the applications discussed above were completed in the early 1970's. They now provide an extremely effective tool for detailed inlet investigations. The next development should be to include sediment transport in inlet numerical models. Perhaps this should be done in two steps. The first step would be to develop a model in which regions of erosion and deposition are determined without quantifying transport rates and the resulting changes in hydrography. The second step would be to develop a complete interactive hydraulic/sediment transport model that quantifies sediment transport rates, resulting bed elevation changes, and resulting tidal flow modifications.

Figure 5 - Flood flow pattern at Masonboro Inlet entrance calculated using two-dimensional finite difference model (GITI 6 App. 2).

Movable and Fixed Bed Physical Models

A concrete distorted scale hydraulic model of Masonboro Inlet was included in the evaluation of the effectiveness of mathematical and physical tidal inlet hydraulic models (GITI 6, Appendix 1; GITI 15). The model, constructed (at WES) to a 1:60 vertical scale and 1:300 horizontal scale, was run with and without waves to evaluate the effect of waves on tidal flow patterns. The general result of the comparison (GITI 6) is that the physical model and the two-dimensional finite difference numerical models are about equally effective in predicting resulting flow velocities and water level time-histories in the inlet and bay. The physical model can include the effects of waves which can improve simulation of flow patterns on the ocean bar and inlet throat as well as resulting bay water levels. It also simulates finer scale turbulence. Numerical models, which are less expensive to operate and easier to store for future use, can simulate wind stress, Coriolis acceleration, and atmospheric pressure gradients.

To further evaluate numerical and physical inlet hydraulic models, additional tide, current, wave and hydrographic data were collected at Masonboro Inlet at a later date (July 1974). The models were operated for the new ocean tide and inlet channel hydrographic conditions to predict channel velocities and bay levels for comparison with measured data. For details of the comparison see GITI 22. Generally, the conclusions of GITI 6 were confirmed.

Before the Masonboro Inlet physical model was destroyed a variety of supplementary tests was conducted (GITI 18). These included an evaluation of: 1) the effects of various level weirs in a proposed south jetty as well as in the existing north jetty (see Figure 4), 2) the effects on inlet flow patterns of closure of any of the three interior channels (see Figure 4), and 3) the efficacy of various sediment tracer materials (sand, expanded shale, ground pumice and plastic) in qualitatively predicting observed shoal and scour trends.

A movable bed (0.34 mm sand) model investigation of basic tidal inlet behavior was conducted at the University of California Hydraulic Engineering Laboratory (GITI 11). Jettied and unjettied prismatic channels of various cross sectional areas were cut across a barrier island to connect an ocean and bay. Experiments were run with a sinusoidal ocean tide and, in some runs, ocean waves or steady bay inflow. Data collection included bay and ocean tide levels, wave characteristics, channel velocities, channel cross sections and centerline profiles, and overhead photographs to define bed forms.

Calculations using simple mathematical models (Keulegan 1967; GITI 6, Appendix 4) satisfactorily predicted the maximum channel velocity and the bay tide range, high and low water time lag, and superelevation.

Comparison with tidal prism versus channel area relationships for prototype inlets (GITI 3) showed that for a given tidal prism the area was an order of magnitude larger than the area predicted by an extrapolation of the prototype curve. Wave action reduced these areas up to 40 percent.

One tool for evaluating the effects of proposed structures and other modifications on tidal inlets is the movable bed hydraulic model. They are the most difficult of all movable bed models because the entrance to a tidal inlet is a region of strong current and wave effects combined. The only known U.S. movable bed tidal inlet models were the seven conducted by WES from 1939 to 1969. GITI 17 presents an evaluation of the effectiveness of six of these models as well as a review of the state-of-the-art of movable bed model similitude requirements and suggested similitude conditions that should be observed in future movable bed inlet model studies.

Movable bed model calibration is achieved by operating the model to produce changes observed in the field between successive hydrographic surveys. If additional field surveys are available the model is operated to verify that it predicts these changes. Five of the WES models were evaluated by quantitatively investigating the accuracy of calibration as no field data were available for subsequent model verification. A sixth model (Galveston Harbor Entrance) had post channel modification data available for evaluation of model verification.

In general, the report concludes that calibration of the five models was unsatisfactory in terms of their reproduction of prototype hydrographic changes between field surveys. Entrance channel shoaling rates and patterns predicted by the Galveston model were not in agreement with subsequent prototype observations.

Deficiencies observed are believed to be caused by: scale and lab effects caused by nonsimilarity between model and prototype processes and conditions; insufficient historical and contemporary data to allow adequate model calibration and operation; and oversimplification of prototype conditions in the model.

In an appendix to the report WES provides background information on the purposes for conducting the model studies, practical limitations encountered, and results of positive practical value achieved by the model studies.

Miscellaneous

Information compiled on over 6000 inlet photographs during the search for imagery for the inlet geometry and stability classification studies is listed in GITI 2. Included are: inlet name and geographic coordinates, photograph date and scale, georef grid square, agency holding photograph, and NOS chart covering the inlet.

An indepth annotated bibliography of over 1000 books, journal

papers, and published and unpublished reports on the geologic, hydraulic and engineering aspects of tidal inlets has been compiled in GITI 4. It covers material dated up to 1973.

GITI 5 is a collection of memoranda by M.P. O'Brien giving miscellaneous thoughts on the hydraulic behavior and stability of tidal inlets. It also recommends a series of field and laboratory studies.

In GITI 13 Escoffier reviews most of the important basic developments concerning analysis of the hydraulics and stability of tidal inlets. He also summarizes functional design requirements for the development of inlets and briefly presents four case studies. The most valuable contribution of this report is the extension of his original inlet stability concept (Escoffier 1940).

In 1940 Escoffier presented a diagram in which the mean channel velocity (ordinate) was plotted against the channel cross-sectional area (abscissa) for a range of areas starting from zero. He assumed that a constant channel velocity (horizontal line) defines equilibrium conditions for the inlet, and its intersection point with the first curve defines the stable inlet area. In GITI 13 Escoffier uses O'Brien's prism-area relationship to show that the equilibrium velocity is not constant but increases with channel area. He presents the new version of his diagram (Figure 6) as a plot of dimensionless mean velocity, v , versus Keulegan's repletion coefficient, K to yield the inlet stability point B.

Figure 6 - Escoffier inlet stability diagram (GITI 13).

He further reasons that an indication of the stability of an inlet is given by $\lambda = \frac{v_{max}}{vE}$. When $\lambda < 1$ no channel area could be stable for the given channel length, bay area and ocean tide. When $\lambda > 1$ a stable channel is possible, the degree of stability being indicated by the magnitude of λ . An evaluation of this concept using data for a series of inlets of known historic stability is needed.

Summary

The General Investigation of Tidal Inlets was a varied and effective program of inlet studies that has made significant contributions to supporting the Corps' Civil Works effort. However, continued inlet research is needed and should receive high priority as part of the Corps' coastal engineering research program.

SATELLITE APPLICATIONS ON A
COASTAL INLET STABILITY STUDY

Yu-Hwa Wang
Maritime Systems Engineering Department
Texas A&M University at Galveston

INTRODUCTION

It is known that longshore drift of alluvial material occurs along sandy barrier islands. Inlets between these barrier islands intercept the normal littoral drift, resulting in a net loss of sand from the beaches. During a flood tide, sand is brought into the inlet and part of it is retained to form the inner bar; during ebb cycle, part of the sand is jettied out into the ocean to form an outer bar. The reversing flows of flood and ebb cycles may also cause deposition or scouring on the bottom of inlet channels.

There are two sets of parameters pertinent to the behavior of inlets. The first set deals with the changes in the dynamic bottom configuration (i.e. the movement of inner and outer bars, the choking or scouring of the inlet channel). The second set of parameters regards the driving forces of the coastal system (i.e. wave climate, tide, wind and currents). Understanding the interrelationship of these two sets of parameters lead to the solution of stabilizing the inlet. The time sequential dynamic interrelationships and natural tendencies of inlets are well-portrayed on available Landsat imageries.

The techniques of mapping the sand bars and their movements are traditionally done by a sounding boat and survey team. The derived point and line information are then used to produce the contour map of the bottom. Extensive interpolations are needed because many details between the points and lines are missing. The operation is expensive and the procedures are time consuming. Techniques using remote sensing can be used to monitor the changes that take place, reducing costs and increasing efficiency.

Eventhough standard procedures have not yet been established, the satellite sensing of bottom features has progressed considerably in recent years. Sherman (1975), Middleton and Barber (1976), Hubbard (1977), and Lyzenga and Thomson (1978) all demonstrated that it is possible to correlate the radiance values of multi-spectral images, such as Landsat imagery, with the depth related information in shallow water. The present study is one more example of such an effort.

IMAGE ANALYSIS AND INTERPRETATION

Two Landsat magnetic tapes (1974 and 1976) covering Pinellas County shoreline was obtained and displayed on the screen of an IMAGE 100 computer. Spectral radiance values were derived from the magnetic tape for various key locations in the Clearwater Beach area as it is shown by the dark squares in Figure 1. These radiance values were later used to compare with ground truth observation and measurement. Typical scene of the image manipulations are given in Figures 2 through 7. Figure 2 shows a cluster rendition of the study area in general. The land water boundary is nicely shown in Figure 7. These two figures are used as reference figures for the comparison with the specific signatures, their extent and location in Figures 3, 4, 5 and 6. In Figure 3, the large shaded dark area in the left one third (approximately) of the picture represented the area of water depth greater than 10 feet. The dark shaded area in Figure 4 was identified as the grass bed. Figure 5 showing the intermediate water depth region of 4 to 10 feet was found to surround the barrier island chain. The extremely shallow water areas were found in Figure 6.

The natural navigation channel at Clearwater Pass can be clearly observed in the enlargement picture on the north-east corner of Figures 8 and 9. Figure 9 is a binary computer printout showing the results of Golay Cluster techniques. The enlargement picture in Figure 10 (also a binary printout) gave the location of shoals.

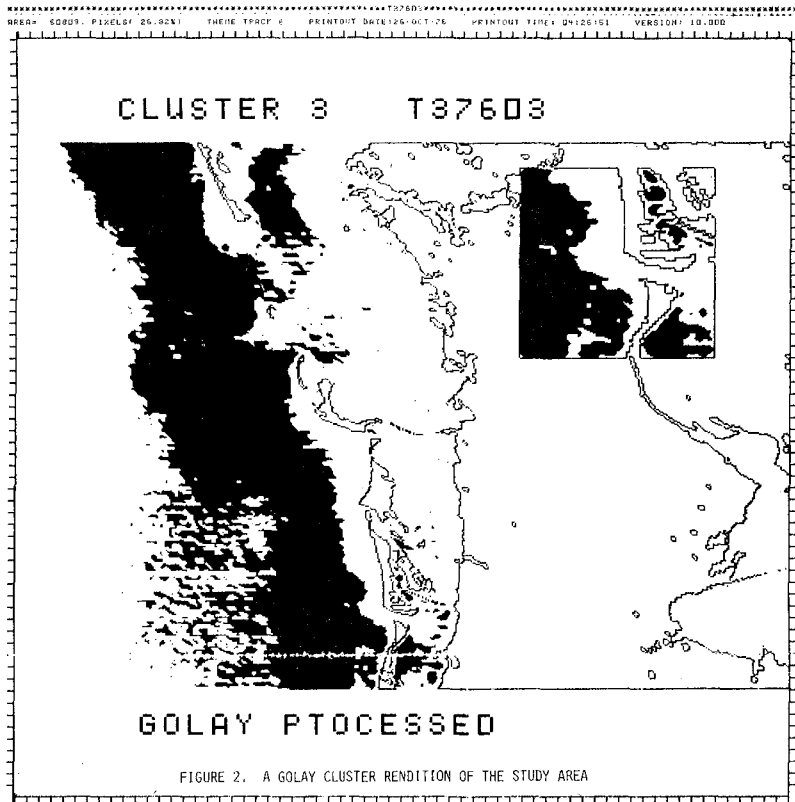

GROUND TRUTH

A team equipped with survey instruments and sounding gear were sent to determine shallow water bottom conditions. The inlets cross sectional area and the shoaling region were measured by sounding and survey. These ground truth observations were used for the comparison with radiance values of the Landsat imagery.

The difficulty encountered during ground truth operations was the identification of the bottom condition by boat. An analogy to this would be best described by an old saying: "When you are in the forest, you don't see the trees." To improve the situation, two flights were flown to collect low altitude photographs. The first set of photos covered a shoreline of approximately ten miles in length, and the flight line was along the beach. The second flight emphasized on the Clearwater Pass and on the bay area.

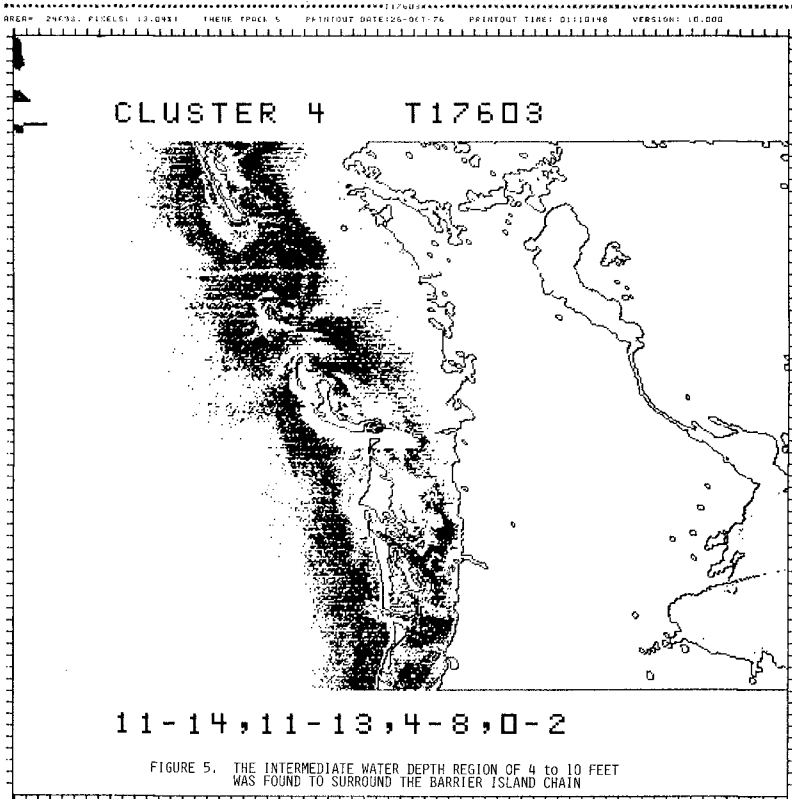

The hydrographic measurements together with the aerial photos constitute the basis of ground truth for interpretation and calibration of the Landsat imageries. The reader is directed to the two reports by Wang, et al (1977) for ground truth details.

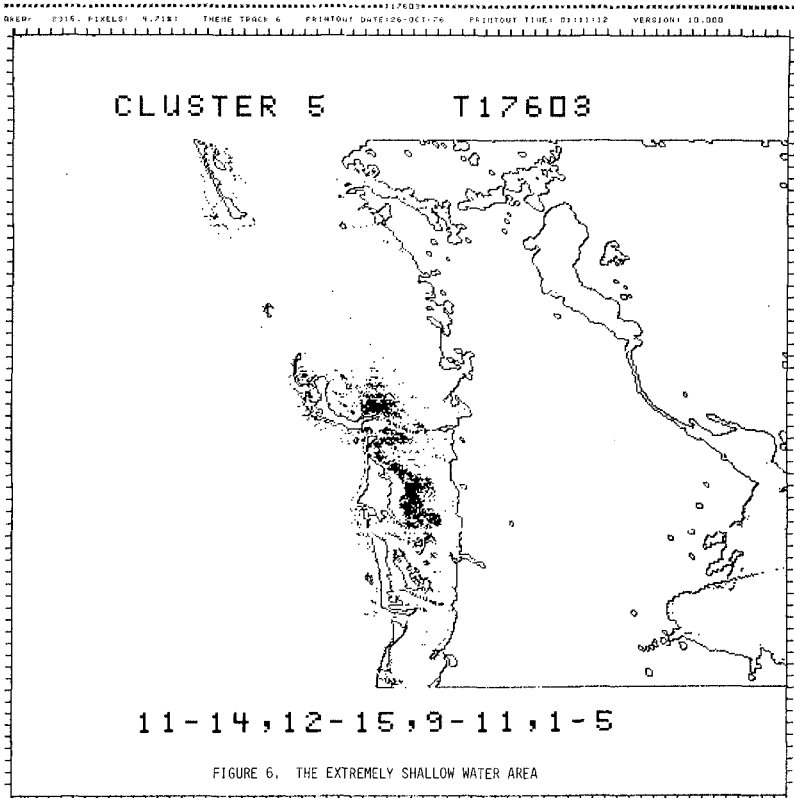

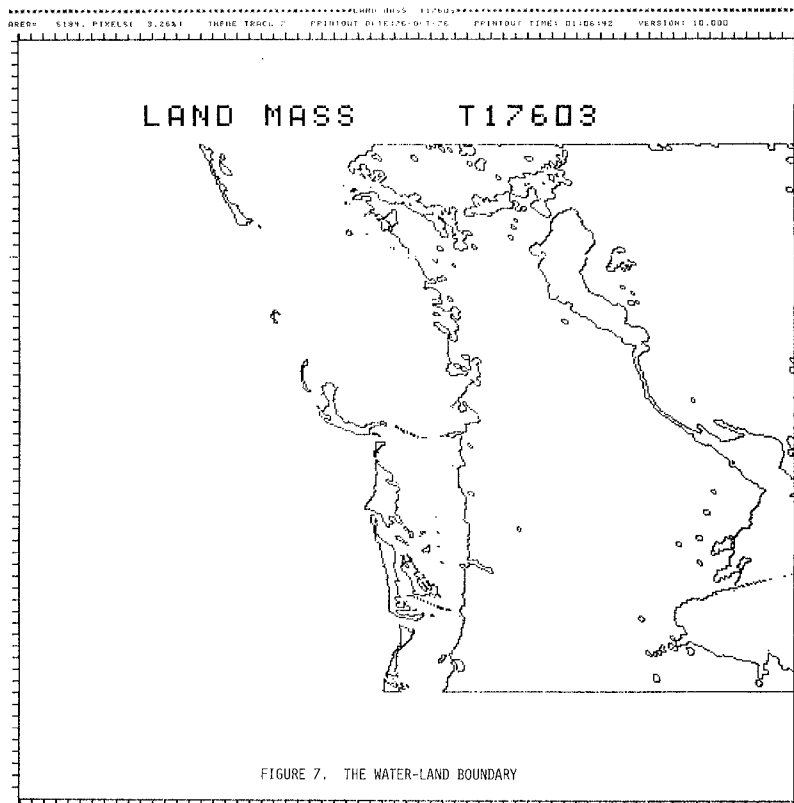

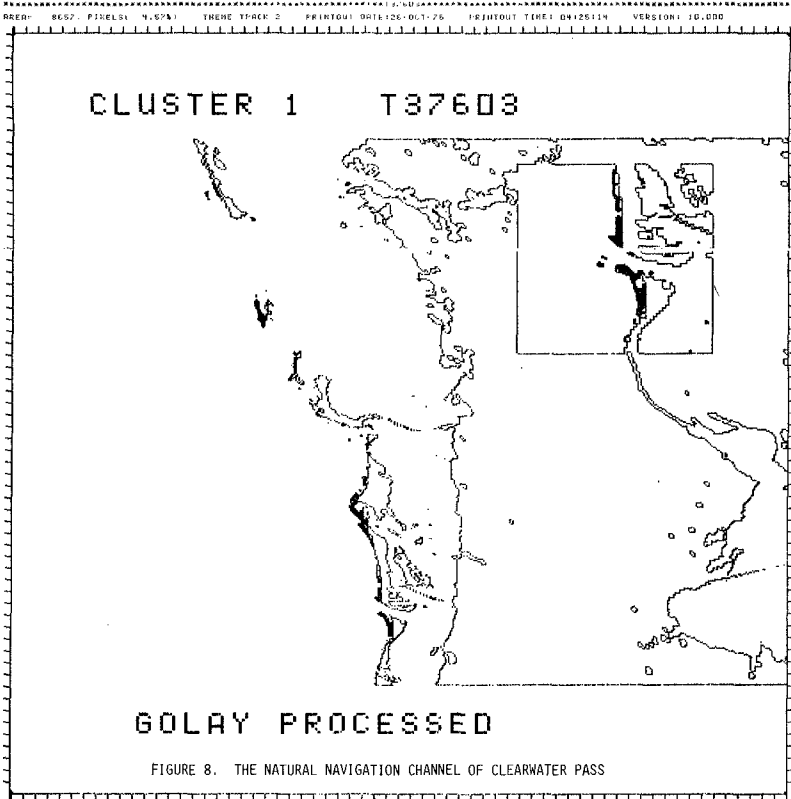

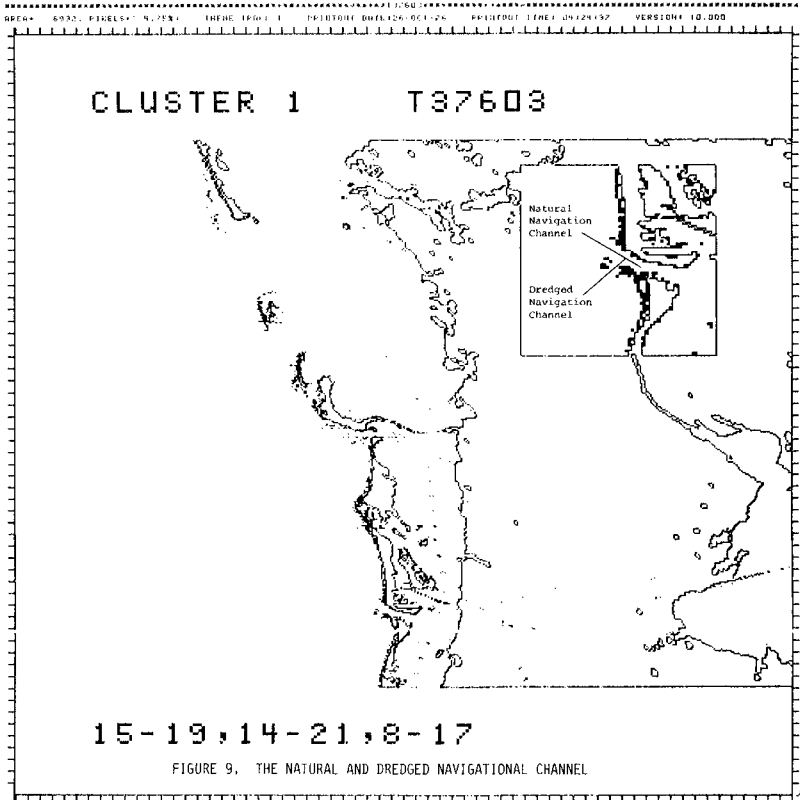

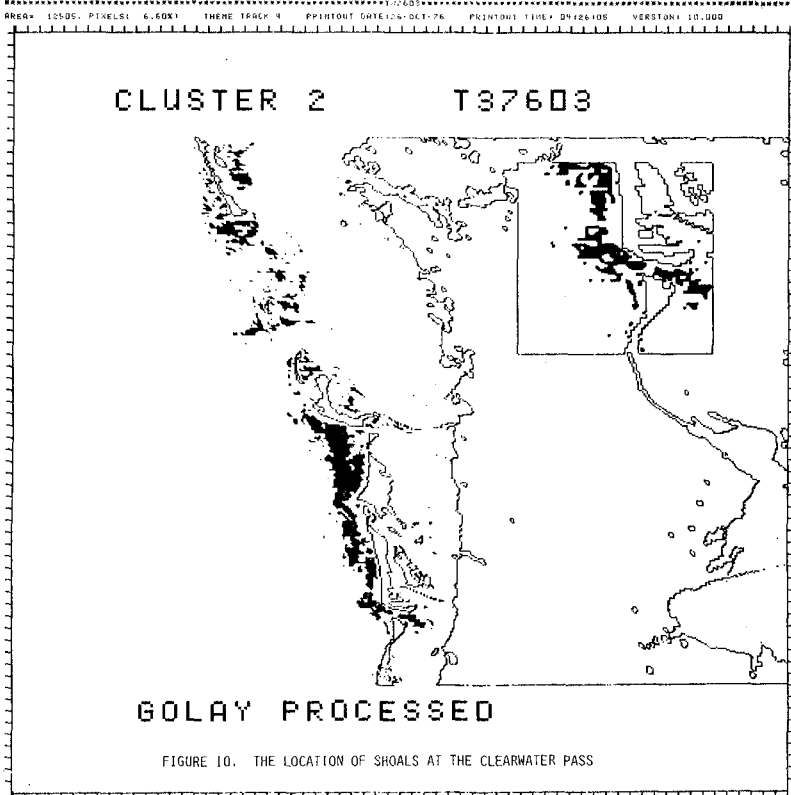

ENGINEERING ASSESSMENT FROM LANDSAT DATA

1. Identification of the pass's natural channel: Spectral analysis of the Landsat imagery (see Figures 8 and 9) has revealed the direction of the natural course of the inlet channel. The main stream (deep part) along the inlet has been eccentric and parallel to the north bank of the inlet. As a result, the beach erosion is likely to occur at south end of the Clearwater beach. It is also clear that the dredged navigation channel at the inlet mouth deviates from the inlet's natural channel course (see Figure 9).

2. Location of shoals:

A. Outer bars: The extremely shallow region and outer bars, such as the bathing zone and the second bar parallel to shoreline, are identifiable by the shaded regions in Figure 6. These regions correspond well with the area identified on the aerial photos. The identification of the bar location at the inlet mouth (Figure 9) has helped to reveal the need for realignment of the navigational channel for the following reasons: (i) the existing dredged navigation channel turned towards the outer bar and cut through the middle of the outer bar; this means the dredged channel may be filled with sand more rapidly and therefore will require more frequent dredging; (ii) the 35° turn that the channel made at the inlet mouth would create navigational hazards, since the current at the inlet mouth is strong and the wave field is variable there, particularly in bad weather; (iii) since the bar location is known the realignment of the navigational channel should be chosen in such a way that a straighter course cutting through the trough between two shoaling areas is possible.

B. Inner bars: The identification of the inner bar location in the bay area (see Figure 10) is important with regard to the future dredging practice in connection with the inlet stability problem. The inner bars slowed down the flow by increased bottom friction. As a result, the bay flow pattern was concentrated in two streams at the inlet throat. One was along the east bayshore where the navigation channel is maintained, the other was parallel to the west bayshore between the bridge and the toll booth. This flow concentration pattern focused its momentum on one part and was weakened in other regions of the inlet channel. Therefore, it was responsible for the scouring at the bridge pier and silting along the south jetty.

CONCLUDING REMARKS

This study has demonstrated the following:

1. The multi-spectral imagery, such as the Landsat imagery, can

be used to study many coastal phenomena and monitoring changes that take place. Navigation channel alignment, shoal locations and water depths are among the good examples.

2. Remote sensing by satellite should and can reduce cost and increase efficiency. It only needs a few training sites and ground truth measurements.

3. Formulation of engineering judgement and opinion from Landsat data are illustrated.

BOUNDARY CONDITIONS FOR ANALYSIS
OF FLOW IN TIDAL INLETST. C. Copalakrishnan¹ and J. L. Machemehl²

INTRODUCTION

One-dimensional gradually varied flow analysis of flood routing and inlet flows (Mahmood and Yevjevich, 1975; Amein, 1975 and Hinwood and Wallis, 1975) has been a subject of study in the last few decades and many mathematical models have been developed based on those studies. A common feature in all these models is that the boundary conditions at the ends of the channel reaches are supplied from measured values of stage, discharge or velocity. These boundary conditions form an integral part of the mathematical models. In the case of implicit schemes, without the supply of these boundary conditions there will be more unknowns than equations. Even though in the explicit schemes they are not required in order to supply sufficient equations, it is obvious that the flow will not be properly simulated without imposing proper end conditions of flow.

Normally two end conditions will be required, the upstream and downstream conditions, even though in a network of channels there will be more than two end conditions. Of these two the upstream condition is usually the forcing function and the downstream one is the result of the flow due to the forcing function. The downstream condition depends on what happens to the flow outside the system. In other words, it depends on the shallow water wave reflections from the continuation of the channel beyond the downstream end of the system considered. These reflections are characterized by the expansion or contraction of the channel, the rate of change of the side slopes and other channel characteristics. As mentioned earlier, the downstream end condition is supplied from measured values of flow parameters so that the channel features (outside the system) mentioned above are automatically simulated. However, if it is required to know the response for any given forcing function, the corresponding measured downstream values may not be available. This means that the downstream boundary condition cannot be imposed in the usual way. This paper describes a method by which the downstream boundary condition can be imposed in the absence of measured downstream response to a given forcing function. However, the method presupposes

¹Assistant Professor, Ocean Engineering Centre, Indian Institute of Technology, Madras, India 600 036.

²Associate Professor, Department of Marine Science and Engineering, North Carolina State University, Raleigh, N. C. 27650.

that measured values for at least one forcing function are known as part of the features of the channel or channel system.

FLOW PARAMETERS

The rate of change of velocity or stage at a point is a function of geometric and dynamic parameters. The geometric parameters include the shape of the channel cross section and the rate of change of that section beyond the point under consideration. The stage and velocity themselves at the point form the dynamic parameters, in addition, of course, to the acceleration due to gravity. However, when looking for the rate of change of velocity or stage at an end section, it should be recognized that such rates can be different for the same stage and velocity depending on whether the flow is accelerating or decelerating and whether the flow is inward or outward of the inlet. Thus, the following four situations are:

- 1) Flood tide - accelerating flow
- 2) Flood tide - decelerating flow
- 3) Ebb tide - accelerating flow
- 4) Ebb tide - decelerating flow

By grouping the geometric and dynamic parameters to form appropriate non-dimensional numbers that govern the flow, it is possible to predict with a degree of accuracy the time rate of change of velocity or stage at the end sections of a channel system. In the present study, the rate of change of velocity, $\partial U/\partial t$, has been used as the downstream boundary condition.

Application of the Π - Theorem

A functional relationship of the dynamic parameters involved can be written as follows, remembering that we are looking for, $\partial U/\partial t$:

$$F(\dot{U}, U, g, \eta) = 0$$

where, U , is the velocity, \dot{U} , is time-derivative, g , the acceleration due to the gravity and, η , the water level.

Using, η , and, g , as the repeating variables, the non-dimensional numbers, Π_1 , and, Π_2 , are:

$$\Pi_1 = \eta^a g^b \dot{U}$$

$$\Pi_2 = \eta^{a_1} g^{b_1} U$$

On applying the dimensional equations, it is found that $a = 0$, $b = -1$, $a_1 = -\frac{1}{2}$ and $b_1 = -\frac{1}{2}$. Therefore:

$$\Pi_1 = \dot{U}/g$$

$$\Pi_2 = U/\sqrt{gn}$$

As expected, the Froude number of flow is a governing factor.

Steps to Arrive at $\partial U/\partial t$

From a given set of velocity-stage relationship at a given end of a channel system a relationship between the two non-dimensional numbers, Π_1 , and, Π_2 , is obtained using a least squares fit of a fourth order polynomial. From this relationship one can compute, $\partial U/\partial t$, once the velocity and stage at the point for a given time is known. The, $\partial U/\partial t$, is then imposed as the downstream boundary condition. The steps involved in the procedure are shown in Figures 1 and 2.

APPLICATION TO THE CAROLINA BEACH INLET

The procedure mentioned was tested with the field data obtained for Carolina Beach Inlet, North Carolina, USA. The inlet (Fig. 3) has a small inlet-channel connecting the ocean to the Atlantic Intracoastal Waterway. That part of the channel system studied is shown in Fig. 3. The Galerkin finite element approach coupled with a Hermitian Cubic shape function (Zienkiewicz, 1971) was used to analyze the inlet. Details of this method have been reported independently. (However, the type of the numerical analysis is irrelevant at this point). The channel system requires the rate of change of velocity, i.e. $\partial U/\partial t$, at the two points Range 1 and Range 2. Independent relationships between Π_1 and Π_2 were obtained for these two points in order to impose the two downstream boundary conditions. The upstream boundary condition was the forcing function which is the tidal fluctuation at the mouth of the inlet.

The relationship between Π_1 , and Π_2 for flood tide at Range 2 and ebb tide at Range 1 for both accelerating and decelerating trends are shown in Figs. 4 and 5. The figures shown indicate a fairly smooth relationship in all cases. The inlet was analyzed using these relations for a complete tidal cycle. The best way to test the method would be to use two sets of tidal data, one to construct the relationship between Π_1 , and, Π_2 , and other to compare measured computed values. As two sets of data were not available for the inlet, a hypothetical tidal input was used as a second forcing function, the first one being from the records. Figs. 6 and 7 show the measured and computed tidal fluctuations at Ranges 1 and 2. The hypothetical forcing function was taken as 0.8 times the tide used for the first set of computations.

CONCLUSIONS

A method for supplying downstream boundary condition in the absence of measured data for any given forcing function has been developed. This method is based on non-dimensional numbers which govern the dynamics of flow. These numbers were determined by a simple application of the Π - Theorem to the dynamic parameters of flow.

The above method was applied to the Carolina Beach Inlet, N. C. analysis. As shown by Figs. 6 and 7 the method yield values which are in good agreement to the measured tide at the two points considered. This, no doubt, depends on the numerical method of analysis also. The non-dimensional numbers can be used to yield the downstream boundary conditions for any numerical method chosen to analyze the flow provided. $\partial U/\partial t$, is the downstream condition needed for all time. If it is, $\partial \eta/\partial t$, then a different set of non-dimensional numbers are required.

The advantage of the method developed here is that one can know the response of a channel system to a hypothetical but possible forcing function for which measured downstream values are not available. This situation is especially relevant to power canals and inlet channels where the flow is affected by man-made alterations in river discharge or construction, etc.

ACKNOWLEDCEMENT

This study was partly supported by the Center for Marine and Coastal Studies, North Carolina State University. The data for the analysis were obtained from the reports of the Army Corps of Engineers, Wilmington, North Carolina, USA.

APPENDIX II - Notation

The following symbols are used in this paper:

a, b, a_1, b_1 = powers of variables while applying the Π -Theorem

g = acceleration due to gravity

x = independent variable, space

t = independent variable, time

U = the one dimensional velocity in the x direction

$\dot{U} = \partial U / \partial t$

η = water level with regard to a horizontal datum

Π_1, Π_2 = the non-dimensional numbers \dot{U}/g and $U/\sqrt{g\eta}$ respectively.

MECHANISMS OPERATING AT A JETTIED RIVER ENTRANCE

Department of Public Works, State Office Block,
Phillip Street, Sydney, AUSTRALIA. 2000

ABSTRACT

Between October 1976 and July 1977 a northern rubble mound jetty was constructed at the mouth of the Hastings River, transforming the entrance from a single to a double jettied system. Prior to the jetty construction the entrance was characterised by the presence of a substantial swash bar (alternatively called an ebb delta marginal shoal) which was a continuous feature over 100 years of hydrographic survey records. However, construction of the northern jetty triggered an unprecedented onshore movement of the swash bar. This movement was well documented by a field monitoring programme incorporating hydro-surveys, aerial photographs, tidal gaugings, sediment sampling, float tracking and nearby wave rider buoy information.

A semi-quantitative model was developed to aid understanding and quantification of the macro sedimentary processes associated with this phenomenon. The model demonstrated that the sudden reduction of the swash bar was due to the disruption of a circulation of sand which had previously aided the dynamic stability of the bar. The quantitative predictions of the model agreed well with subsequent entrance behaviour. The philosophical development of the model and its findings are discussed in detail.

In the literature there is a general lack of attempts to quantify the sediment transport relationships between the gross morphologic features of tidal entrances. This paper presents a methodology for assessing the sedimentary process at tidal entrances.

1. INTRODUCTION

The coastline of New South Wales has over thirty jettied river entrances. Their physical setting varies from the sandy (albeit eroding) coastline of the north, characterised by relatively high littoral drift rates, to the southern coastline where pocket beaches and prominent rocky headlands extending into deep water testify to an impoverished littoral drift. Virtually all these entrances have river mouth bars and entrance jetties have been constructed to satisfy, to varying degrees, the navigational requirements of increased depth, safer navigation and/or stability of inlet location. This paper is a critical review of the response of the Hastings River, Port Macquarie, to recent entrance jetty construction.

Port Macquarie is located at the mouth of the Hastings River, in the mid-north coast of N.S.W. - See fig. 1. Tides are semi-diurnal

with a Mean Spring Tide range, at the entrance, of 1.26 m associated with a peak tidal discharge of 1600 cumecs. Fluvial flows are flashy but significant. The peak fluvial discharge is 7100 cumecs, estimated from height records spanning the last 50 years. The wave climate is moderate to high with offshore significant wave heights of 1.5 m being exceeded 50% of the time (Lawson and Abernathy 1975).

Since its discovery in 1819 by Captain John Oxley the Hastings River entrance has been hazardous

to navigate. Records are replete with accounts of vessels running aground on the bar or being swamped and even wrecked. Navigation of any entrance bar is never easy and the Hastings River bar can be treacherous because it is unusually wide, has a steep seaward face and a shifting channel.

2. HISTORY OF ENTRANCE WORKS AT PORT MACQUARIE

The first attempts to stabilise the entrance were made in 1897 when construction was started on the southern training wall and jetty - see fig. 2. These works proved to be largely ineffectual with the entrance varying in position over a distance of 1 km along the northern beach. The pattern was for floods to cut through the northern sandspit and the new entrance to migrate slowly southwards.

A northern training wall and jetty were completed in 1940 but the works were gradually out flanked by the prograding profiles of the adjacent beaches.

During the last decade the entrance has been host to a broad expanse of shoals through which the channel has shifted seasonally according to the prevailing wave pattern. The deterioration of the bar has had a deleterious effect on the local fishing and commercial fishing industries and prevented Port Macquarie from realising its full tourist and pleasure craft potential (Posford, et al 1974). Hence in October 1976 construction of a new northern jetty commenced with the objective of creating a more stable, safer bar for navigation.

Since the commencement of construction a field monitoring programme has been in operation and considerable data relating to the morphologic changes in the entrance area has been obtained.

3. SEDIMENTARY PROCESSES

To facilitate discussion of sedimentary processes the study area has been subdivided into a number of coastal cells - see fig. 3. The cells have been chosen because they comprise a number of discrete hydraulic processes and it is useful to discuss the interactions of these processes within relatively self-contained cells. Interactions between cells link them together as a complete dynamic system. The detailed discussion of data and the quantification of the processes is given by Druery and Nielsen (1979) and only the key findings will be discussed below.

Figure 3 Coastal Cells

3.1 Estuary Cell

This cell is defined as that part of the river upstream of the entrance throat and includes the inner bay shoals. An analysis of 14 hydrographic surveys, from 1881 to 1972, demonstrated that the inner shoals showed an early tendency towards accretion due to the high sand infill rates prior to the construction of the northern training wall in 1940. Since that time the inner shoals have tended to stabilise

and the contemporary growth rate was estimated at $50,000 \text{ m}^3$ per year.

Figure 4 shows the results of float tracking carried out in 1972. The flood tides promote accretion of the inner bay shoals due to the direct impingement of the flood tide velocities. The ebb velocities are basically parallel to the training wall and hence tend to interact little with the bulk of the inner shoals. This tendency for net flood tide accretion manifests itself as a growth of parallel, crescentic shaped shoals on the eastern edge of the inner shoals - see fig. 5. There appears to be a functional relationship between accretion and the throat shoal as seen by the close association of the more recent

Figure 4 Float Tracking Results

crescent (fig. 5) with sand coming from the throat shoal.

Tidal velocities and surface gradients, over a full ebb and flood tide cycle, were measured approx. 1 km upstream from the seaward tip of the southern jetty under conditions of Spring, Neap and intermediate tides. Using these measurements in the sediment transport formula of Ackers and White (1973), the annual transport of sediment by tidal action was estimated to be approximately 200,000 m³ p.a. for the flood tide and 150,000 m³ p.a. for the ebb. Similar sediment transport calculations in the entrance throat indicated a maximum tidal transport capacity of 500,000 m³ p.a. However analysis of bed sediments indicated that the sediments in the entrance throat were coarse and probably predisposed towards armouring. It was considered that because of the high likelihood of channel armouring, the annual transport in the throat would not differ greatly from that estimated for the upstream location. (i.e. there would be 100% throughput of sediment supplied to the throat).

Apart from the tidally active eastern edge of the inner shoals, the bulk of the shoals are relatively stable. Further inland on the shoals diver observations revealed active bioturbation and a surface growth of algae both of which are indicative of immobile sediments. The only note of instability associated with the inner shoals is scouring by floods which tend to remove portions of the crescentic shoals on the eastern margin.

Figure 5 Aerial Photographs showing growth of Inner Shoals.

3.2 River Mouth Cell

The dominant morphologic features of this cell (re: fig. 2) are the entrance bar, the offshore bar, the swash bar, the inshore gutter which separates the swash bar from the beach and the jettied entrance channel and throat shoal.

Current trackings carried out in 1972 (see fig. 4) are typical of the general current patterns which existed prior to the northern jetty construction. While the current trends would depend largely on the conditions pertaining to the particular day of measurement, discussion with the local navigation authority confirmed that fig. 4 is a fair representation of the persistent current features.

A significant feature of the ebb current pattern is the development of a large eddy centred about the swash bar. This is a common feature of tidal inlets, particularly when there is only one entrance jetty (Komar and Terich 1976, FitzGerald et al 1976, Dean and Walton 1975). At Port Macquarie it is considered that the eddy was produced by a combination of factors viz:

1. Viscous drag between the ebb tide jet stream and adjacent water (Dean and Walton 1975).
2. A strong current driving mechanism in the inshore gutter would have been created by the coupling of set down against the northern wall, due to superlevation of the main ebb flow as it was forced around the severe approach bend, and set up due to breaking waves on the swash bar.
3. Refraction of the dominant southeast waves around the swash bar would tend to produce an inlet directed longshore current (Hubbard 1976, Dean and Walton 1975).

During the flood tide the currents seawards of the entrance were generally 50% less.

Irrespective of the state of the tide the currents in the inshore gutter were inlet directed and showed a tendency to increase when the main entrance flow was ebbing. The commitment of the inshore gutter to flood tide currents produced a strong bias in favour of flood tide velocities and sediment transport against the northern training wall.

Figure 6 Horizontal Velocity Distribution at Entrance.

Fig. 6 shows portion of comprehensive tidal gaugings carried out in December 1966. Towards the end of the ebb tide the flood tide commenced two hours early against the northern training wall. During the commencement of the ebb tide it persisted for approx. one hour. Hence against the northern wall the flood flow had a duration of 8 hours thus indicating a strong potential for flood tide transport against the northern wall.

Sediment sampling and diver observation, during jetty construction, showed that the landward face of the bar was gravelly comprising well rounded and highly polished shell fragments and lithic pebbles. The surface was formed into symmetrical long crested ripples 7-10 cm in height and 0.3 - 0.6 m wavelength. There was no observed movement of the gravel during conditions of small swell. The seaward face of the bar, however, was composed of shell free quartzose sand and substantial movement of the sand took place (as sheet flow) in response to the orbital velocities of small swell.

The intrinsic difference between the surficial sediments of the inner and outer faces of the bar is intriguing. It is considered that it reflects possible differences in the ebb and flood sediment paths. The ebb tide would tend to jet most of its sediment onto the seaward face of the entrance bar, developing an armouring of the bed of the main channel in the process. During flood tides, the return of that sediment would take place by combined wave and current action on the swash bar and inshore gutter.

On a day to day basis the entrance bar and swash bar constitute a balance between the seaward movement of sediment by the ebb tide and landward transport by waves and the flood tide. The ebb tide would deposit sand on both the entrance bar and the swash bar. Shoaling of waves would induce sediment movement across the surface of the swash bar either onto North Beach or directly onshore and into the inshore gutter.

Figure 7

The inshore gutter would then feed sediment directly into the estuary at all states of the tide and during each ebb tide a significant portion of the inshore gutter sand feed would be carried back onto the swash bar and recycled.

3.3 Southern Coast Cell

This cell comprises small beaches which contain limited sand and are well pocketed between rocky cliffs - see fig. 7. Sedimentological studies identified a distinct northward fining of the beach sands and an absence of lithic minerals, setting them apart from the beach sands of the northern coast cell. All indications pointed to the existence of a weak, intermittent littoral transport which is probably associated with temporary development of offshore bars during major storms and is considered to be of the order of $20,000 \text{ m}^3 \text{ p.a.}$

3.4 Northern Coast Cell

North Beach is zeta shaped with a well developed offshore bar. Historical hydrosurveys revealed episodes of successive onshore and offshore movement of sediments. The offshore sediment movement, resulting from storm events, was of the order of $100-200 \text{ m}^3/\text{m}$ storm whereas onshore movement rates, during calmer periods, were much less and of the order of $30 \text{ m}^3/\text{m/year.}$

PERCENTAGE OCCURRENCE OF WAVE DIRECTION

DATA SOURCE: Wave Rider Buoy;
Coffs Harbour Jun.'75-Nov.'79

Wave refraction analyses were carried out with the aim of assessing longshore sediment transport rates at a number of locations on the beach. The direction of wave approach was divided into two directions; north easterly and south easterly. The percentage occurrence of waves from each direction was set at 19% and 81% respectively, based on four years of wave rider buoy data at Coffs Harbour - see fig. 8. For each direction, four classes of wave height were considered and a representative significant wave height was assigned to each class. From relationships of significant wave height and period derived from the wave rider buoy data a significant wave period was assigned to each representative significant wave height. These parameters are set out in Table 1.

Figure 8

TABLE 1. Representative Wave Statistics used in Refraction Analysis

Significant Wave Height Class	Hs (m)	Representative Wave Height Hs (m)	Wave Period Ts (s)
0 - 1		0.5	6.4
1 - 2		1.5	7.7
2 - 5		3.5	8.9
> 5		7.5	10.2

The occurrence of each representative wave height was determined from wave height exceedence curves presented by Lawson and Abernathy (1975).

The inshore wave breaking height obtained from the wave refraction analyses, the angle of shore break from aerial photographs and the values of % exceedance were used to estimate the littoral sediment transport. The CERC formula exhibited extreme sensitivity to the wave direction data but the overall result was one of zero net longshore drift on North Beach. However, historical aerial photographs showed that an occasional offshore bar forms around the northern headland of the beach (Point Plummer). This suggests that there is an intermittent northward leakage of sand from the compartment which is consistent with the zeta shape of the beach and the existence of rudimentary transgressive dunes in the far north of the beach. Hence it is considered that there is a weak net northerly longshore drift along North Beach.

Gross sediment transport rates calculated at a point on the northeastern edge of the swash bar indicated a strong net onshore transport, the amount of movement being on order of magnitude higher than that estimated for North Beach.

The gross sediment transport rates calculated using the CERC formula were unrealistically high. Gordon et al (1978) also found this to be the case in studies of other beaches along the New South Wales coastline. Hence, it was not considered valid to directly apply the CERC formula which has been empirically developed from measurements on USA beaches. Nevertheless, it was considered that the CERC formula would provide a reasonable indication of the relative magnitude of transport rates calculated at various locations within a littoral system. Hence the net sediment transport rates along North Beach and the northeastern edge of the swash bar were assigned values of "x" and "10x" respectively. The absolute values of the rates were then determined implicitly using the interaction equations of the sediment budget model (Section 7).

4. LONG TERM SEDIMENT DYNAMICS

On a day to day basis the entrance bar/swash bar appears to constitute a relatively stable dynamic system. However long term

Figure 9 Offshore Isopachs

data (hydrographic surveys and aerial photographs) indicated a cyclicality which can be attributed to the interplay of floods and waves.

Floyd and Druery (1976) found that the seaward face of an entrance bar undergoes movement largely as a result of deposition by floods. Floods deposit sediment on the seaward face in depths of 10 m and less. Hydrographic surveys of the Hastings River bar indicate that the volumes of deposition range from 400,000 m³ to 200,000 m³ for major and moderate floods respectively. Deposition by floods is sudden (i.e. 2 to 3 days). Initially the conditions for navigation on the bar would be good because major floods tend to gouge a gutter through the crest of the bar. This reduces the effective width of the bar and increases the ruling depth, making navigation less hazardous. However Floyd and Druery (1976) showed that any flood deposit, on the seaward face of the bar, would undergo reworking by waves and the pre-flood location of the seaward bar face would tend to be re-established. The onshore movement would be slow and therefore the improved bar conditions would persist for a time varying from six months to two years depending upon the magnitude of the flood. As the relatively slow onshore movement began to have effect, the bar channel would become infilled and conditions on the bar would noticeably deteriorate. The onshore movement would continue until the swash bar invaded the entrance channel. A new flood would restart the cycle.

On 20-23 March 1978 a flood occurred on the Hastings River. Figure 9 shows isopachs of hydrosurveys carried out before and after the flood. It can be seen that the flood deposited sediment on the seaward face of the bar (in depths less than 10 m). The total

offshore North Beach

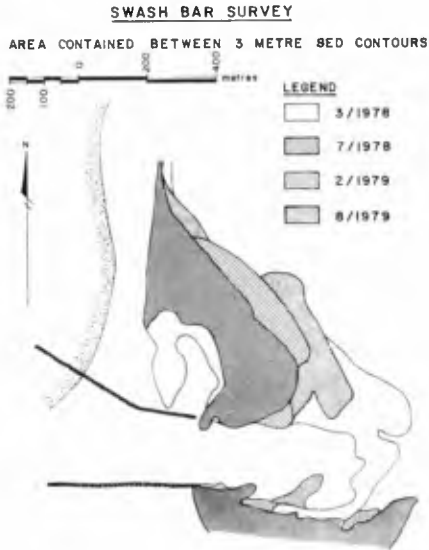

Figure 14

of the sand moving onshore from the swash bar had become attached to the jetty and North Beach as a fillet and the inshore gutter was becoming severely pinched between the tip of the jetty and the advancing slug of sand. The advancing slug of sand had shoaled and its surface was exposed at low water. By August (fig. 12) the slug of sand had completely inundated the inshore gutter and attached itself to North Beach. A portion had been intercepted by the end of the jetty causing the wave trap to be overwhelmed with sand. Spillage of sand from the wave trap had given birth to a fledgling throat shoal. By December (figure 13) the fillet of sand against the base of the jetty had been redistributed along North Beach in the form of a series of wave berms.

The onshore movement of sediment continued well after the completion of construction (viz. July 78) as shown by offshore surveys in figure 14. Between March 78 and August 79 the swash bar progressively reduced in size as a result of this onshore movement.

6. CONCEPTUAL MODEL OF SEDIMENTARY PROCESSES

The investigation of coastal processes in each cell led to the formulation of a conceptual model of the sedimentary processes of the

volume deposited was 280,000 m³ of which 60,000 m³ was derived from scouring of the inner face of the bar. The sequence of post flood surveys shows the seaward face of the bar undergoing reworking and moving slowly onshore as a series of sand slugs.

5. EFFECT OF NORTHERN JETTY

The construction of the northern jetty triggered rapid changes in the estuary mouth morphology - see Figures 10 - 13.

The jetty began to intrude into the surf zone in May 1977 at which time the swash bar occupied a substantial area and the throat shoal had been removed by a small fresh in early May. A month later further extension of the jetty had taken place and a portion of the swash bar had begun to move onshore. See fig. 10. During July (figure 11) some

entrance bar and its environs - see Figure 15. In order to test the coherence of the conceptualisation an attempt was made to quantify the various model elements.

6.1 Interaction Equations

Consideration of local sediment budget led to the following interaction equations:

- (1) Sediment moving onshore across the swash bar, Q(2), can either head towards the inshore gutter, Q(6), or travel along the offshore bar (i.e. the outer edge of the swash bar) to North Beach, Q(4).

Hence: $Q(2) = Q(4) + Q(6)$

- (2) Sediment is carried into the estuary, Q(12), by flood currents moving across the entrance bar, Q(3), and via the swash bar/inshore gutter complex, Q(8F).

Hence: $Q(8F) + Q(3) = Q(12)$

- (3) The quantity of sediment dumped on the entrance bar and swash bar each ebb tide, Q(14), is derived from the estuary, Q(11), and the recycled component of the inshore gutter sand feed, Q(8E).

Hence: $Q(14) = Q(8E) + Q(11)$

- (4) Within the estuary the flood tide, Q(12), produces some accretion of the eastern edge of the inner shoals, Q(9), and the rest remains in the active tidal sediment flux, Q(10).

Hence: $Q(12) = Q(9) + Q(10)$

Figure 15 Conceptual Model

- (5) The sediment moving directly onshore from the Swash Bar, Q(6) can split into longshore components Q(7) or Q(8) and Q(8) can be broken down into its ebb and flood constituents.

$$\text{Hence : } Q(6) = Q(7) + Q(8); Q(8) = Q(8E) + Q(8F)$$

- (6) Prior to jetty construction North Beach was relatively stable i.e. $Q(5) = Q(4) + Q(7)$.

6.2 Functional Relationships

- (1) It was assumed that 90% of the flood tide sediment transport took place via the swash bar and inshore gutter i.e. $Q(3) = 0.1 Q(8F)$.

- (2) The ebb and flood sediment transport potential against the inside of the northern training wall was calculated from tidal current measurements assuming transport potential was proportional to the cube of the velocity (Maddock 1969). This indicated that the recycled ebb tide constituent of the inshore gutter sand feed was approximately half the flood tide constituent, therefore

$$Q(8E) = 0.3 Q(8)$$

- (3) The application of the CERC formula to determine the net littoral transport along North Beach, Q(5), and the onshore transport on the Swash Bar, Q(2), was discussed in Section 3.4 where it was argued:

$$Q(2) = 10 Q(5)$$

6.3 Calculated Values

A number of the model elements were known or estimated viz:

- (1) $Q(1) = 20,000 \text{ m}^3 \text{ p.a.}$ (See section 3.3)
- (2) Because currents in the inshore gutter were always inlet directed (Section 3.2) it was assumed that all sand feed would be inlet directed i.e. $Q(7) = 0$
- (3) $Q(9) = 50,000 \text{ m}^3 \text{ p.a.}$ (Section 3.1)
- (4) $Q(12) = 200,000 \text{ m}^3 \text{ p.a.}$ (Section 3.1)
- (5) $Q(11) = 150,000 \text{ m}^3 \text{ p.a.}$ (Section 3.1)
- (6) $Q(13) = \text{Erosion during flood event only}$ (Section 3.1)
- (7) $Q(15) = \text{Deposition during flood events}$ (Section 4)

6.4 Effect of Northern Jetty Construction

The foregoing equations and relationships were adjusted so as to

represent the hydraulic impact of the northern jetty. The impact was divided into the "short term" (i.e. within the first 2-5 years say) and the "long term" (i.e. 10 years or more).

Short Term :

- (1) Because of the elimination of the inshore gutter the majority of sediment moving directly onshore from the swash bar, Q(6), would not find its way into the estuary.

$$\text{i.e. } Q(8) = Q(8F) = Q(8E) = 0$$

- (2) The jetty construction would greatly increase the flood tide velocities across the entrance bar and the tip of the northern jetty and hence the sediment transport capacity of Q(3) would greatly increase. It was considered that the net result would be a reduction in the infeed of sediment into the estuary and hence Q(12) was reduced from its pre-jetty value of 200,000 m³ p.a. to 150,000 m³ p.a.

$$\text{i.e. } Q(12) = 150,000 \text{ m}^3 \text{ p.a.}$$

- (3) It was assumed that initially accretion of the inner shoals would not change i.e. Q(9) = 50,000 m³ p.a.

Long Term :

- (1) After a long period of onshore movement the swash bar would tend to disappear and only an ebb delta bar would remain, similar in shape to other entrances in N.S.W. (Floyd 1968). The only throughput of sediment would be that necessary to bypass the net southerly drift.

$$\text{i.e. } Q(2) = Q(1) = 20,000 \text{ m}^3 \text{ p.a.}$$

- (2) Based on experience of the effects of entrance works at the mouths of other similar estuaries in N.S.W., it was considered that tidal propagation in the estuary would not change significantly and therefore the unusual estuary instability associated with entrance jetty construction at Forster (Gordon and Neilsen, 1980) would not occur.

It was considered that within the estuary a balance would be established but the general level of sediment movement would be less i.e.:

$$Q(10) = Q(11) = 100,000 \text{ m}^3 \text{ p.a.}$$

$$Q(9) = 0$$

Effects of Floods:

It needs to be stressed that the "long term" was considered within the context of no flooding. Floods will tend to place new deposits on the entrance bar (Section 4) which would have the effect of reversing the situation towards the immediate post construction condition.

7. RESULT OF CONCEPTUAL MODEL

All the various functional relationships and known values were applied to the interaction equations for each of the three cases i.e.

- (1) prior to construction
- (2) after construction in the short term
- (3) after construction in the long term

The results are shown in Table 2.

TABLE 2 - Quantification of Conceptual Model

Model Element	Prior to Jetty Const.	After Jetty Short Term	After Jetty Long Term
Q(1)	20,000	20,000	20,000
Q(2)	290,000	290,000	20,000
Q(3)	18,000	150,000	100,000
Q(4)	29,000	29,000	20,000
Q(5)	29,000	29,000	29,000
Q(6)	260,000	260,000	N.A.
Q(7)	0	260,000	N.A.
Q(8)	260,000	0	N.A.
Q(8E)	78,000	0	N.A.
Q(8F)	182,000	0	N.A.
Q(9)	50,000	50,000	0
Q(10)	150,000	150,000	100,000
Q(11)	150,000	100,000	100,000
Q(12)	200,000	150,000	100,000
Q(13)		EXTREME EVENT	
Q(14)	228,000	150,000	100,000
Q(15)		EXTREME EVENT	
Swash Bar Removal Rate i.e. $Q(2) + Q(3) - Q(14) - Q(1)$	60,000	270,000	N.A.
Sediment Feed to North Beach $Q(4) + Q(7)$	29,000	289,000	20,000

The main effect of the jetty construction was the elimination of the inshore gutter which used to drive a circulation of sand and therefore tended to perpetuate the swash bar. The recycled component of the inshore gutter sediment feed (i.e. Q(8E)) was of the order of 100,000 m³ p.a.

After jetty construction the swash bar removal rate increased dramatically. This would explain the unprecedented onshore movements observed during the jetty construction (Section 5).

The elimination of the inshore gutter greatly increased the quantities of sediment reaching North Beach and North Beach would therefore be expected to accrete markedly.

The model predicted long term erosion of North Beach viz.:

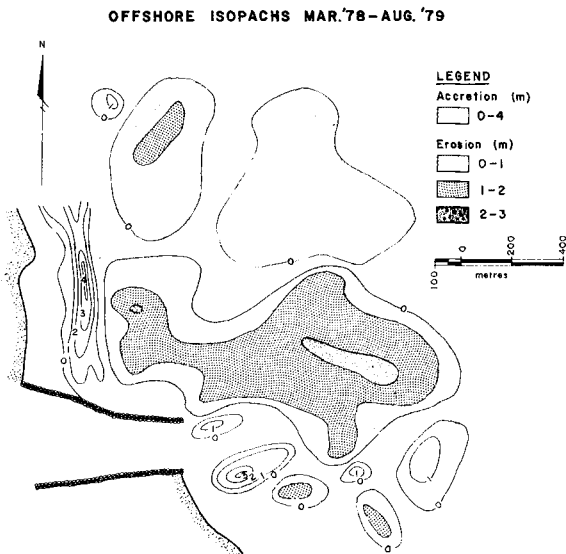

$$Q(5) - Q(4) = 9,000 \text{ m}^3 \text{ p.a.}$$

However, this would tend to be offset (to an unknown extent) by sediment injected into the system by fluvial floods i.e. $Q(15)$.

8. MODEL VERIFICATION

The conceptual model and its predictions were completed by the end of the jetty construction in July 1978. Hence the predictions of the model can be tested against the results of subsequent entrance monitoring.

The progressive decrease in areal extent of the swash bar has already been demonstrated in Figure 14. An Isopach plot between the March and August surveys is shown in figure 16. The broad area of erosion from the swash bar is directly related to pronounced accretionary structures on North Beach (viz. recent beach ridges). Volume calculations indicate a net erosion from the swash bar at a rate of $280,000 \text{ m}^3 \text{ p.a.}$ which compares remarkably well with the estimate of $270,000 \text{ m}^3 \text{ p.a.}$ obtained from the conceptual model.

The pronounced build up of North Beach is compatible with the predicted increase in the sediment supply to North Beach. Estimates of beach accretion were not possible because sediment was dispersed northwards beyond the control area of the beach surveys.

Recent monitoring of the entrance has indicated that the entrance bar has reduced in width and there has been an improvement in bar depth.

Figure 16 Swash Bar and Beach Isopachs

9. CONCLUSIONS

1. For over 40 years the entrance to the Hastings River was host to a large swash bar the presence of which created hazardous navigation conditions. The recent construction of a northern entrance jetty in, 1977-78, triggered an unprecedented onshore movement of the swash bar. The cause can be related to the elimination of a daily circulation of sand which had previously aided the dynamic stability of the swash bar.
2. Monitoring of post-construction changes has indicated that the swash bar will not return to its former size and there has been a substantial reduction in the width of the bar.
3. The long term configuration of the entrance bar and swash bar is linked to the occurrence of major floods. It was possible to discern past cycles of deposition by floods and subsequent slow onshore movement of the flood deposits.
4. It was possible to construct a conceptual model of entrance sedimentary processes which was suitable for predictions of morphological response. Although the model was based on elementary considerations of sediment budget, it was a highly effective tool for elucidating the subtleties of sediment transport relationships between the gross morphologic features of a tidal entrance.

Considerable fundamental research is necessary before full process understanding of tidal entrances will be achieved. Conceptual models as put forward in this paper are a useful interim step which combine the art and the science of coastal engineering and offer a means for assessing the impact of coastal works on macro coastal processes.

STABILITY OF ESTUARY MOUTHS IN THE RHINE-MEUSE DELTA

J. VAN DE KREEKE, Professor of Ocean Engineering, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, U.S.A.

JAC HARING, Research Engineer, Deltadienst, Rykswaterstaat, The Hague, Holland

1 GENERAL CHARACTERISTICS OF THE RHINE-MEUSE DELTA

The Rhine-Meuse Delta in the southwestern part of the Netherlands covers an area of approximately 60 x 60 km; see Fig. 1. The Delta consists of sediment deposits of the Rhine and the Meuse in which tides and river flow have scoured an intricate system of channels. The four major estuaries are from south to north Eastern Scheldt, Brouwershavense Gat, Haringvliet and Rotterdam Waterway. The connection between estuaries and rivers is formed by a system of branching channels, referred to as tidal rivers. The flow in the tidal rivers is constrained by dikes, revetments and groynes. It is in this region where most of the sand fraction of the sediments carried by the rivers Rhine and Meuse is deposited. Extensive maintenance dredging is required to maintain a sufficiently large cross-section for navigation. The mud fraction (all sediments with grain size $< 62 \mu$) of the river sediments is carried further seaward and is partly deposited in the estuaries and partly in the offshore underwater delta.

Average tidal ranges at the seaward boundary of the Delta decrease going from south to north and vary between 3.78 m at Flushing to 1.58 m at Hook of Holland. The ratio average tidal range to average spring tidal range is approximately 0.86. Tides are predominantly semi-diurnal. The average annual discharges of the Rhine and Meuse are respectively 2200 m³/sec and 250 m³/sec. Discharges of both rivers show seasonal fluctuations with a maximum in the winter and a minimum at the end of the summer. The river water is distributed over the estuaries in varying proportions. E.g. in 1959 the ratios of the average river volume to the average flood volume for the estuaries Eastern Scheldt, Brouwershavense Gat, Haringvliet and Rotterdam Waterway were respectively 0, 0, 0.25 and 0.53.

In the offshore region there exists a longshore sand motion to the north with a transport rate on the order of 50,000 m³/year. Associated with the longshore motion is a fining of the bottom sand when going from south to north. Typical values for the mean grain diameter of the sand are 200 μ for the mouth of the Eastern Scheldt and 150 μ for the mouth of the Haringvliet. Terwindt (1973).

The present shape of the Delta is to a large extent the result of man's interference with the natural sedimentation processes, the expansion of the port of Rotterdam, maintenance dredging and in particular the Delta project. The Delta project envisions the closure

Figure 1. Rhine-Meuse Delta prior to 1953.

of the Eastern Scheldt, Brouwershavense Gat and Haringvliet. To properly manage the Delta and in particular to minimize maintenance dredging and to prevent dike calamities it is important to be able to predict scour and shoaling associated with the various man-made modifications. For this purpose, empirical relations between characteristics of cross-section and flow are derived using observations in the Rhine-Meuse Delta, prior to the Delta project.

2 EQUILIBRIUM FLOW AREAS

The important parameters governing the cross-sectional area at the mouth of the estuaries are the sediment transport capacity of the tidal currents, Q_{tc} , and the littoral drift, Q_l . Assuming that during the major part of the tidal cycle the bottom shear stress is considerably larger than the critical shear stress for sediment motion, the sediment transport capacity of the tidal currents can be expressed as, Leliavsky (1966).

$$Q_{tc} = f(b, F, \rho_s, \rho_w, g, d) \left(\frac{Q}{A}\right)^n \quad (1)$$

in which

Q_{tc}	= sediment transport (m^3/sec)
b	= inlet width
F	= bottom friction
ρ_s	= density of sediment
ρ_w	= density of water
g	= gravity acceleration
d	= grain diameter
Q	= discharge
A	= cross-sectional area

Depending on the investigator, n varies between 3 and 5.

It is postulated that for long term equilibrium conditions

$$\overline{Q}_{tc} :: \overline{Q}_l \quad (2)$$

where the overbar denotes a long term (yearly) average, and thus,

$$\overline{\left(\frac{Q}{A}\right)^n} :: \frac{\overline{Q}_l}{f} \quad (3)$$

For tidal inlets with zero fresh water inflow $\overline{Q} = \text{const.}$
 \hat{Q} where \hat{Q} is the maximum discharge during the tidal cycle.
 Assuming a constant area $A = A_c$, Eq. (3) can be written as

$$\overline{\left(\frac{\hat{Q}}{A}\right)^n} :: \frac{\overline{Q}_l}{f} \quad (4)$$

From observations and restricting attention to inlets in the same geographical area, it follows $\hat{Q}/A_c \approx \text{constant}$, Jarrett (1976), Byrne et al. (1980). Thus, with regard to the long term equilibrium, the magnitude of the littoral drift and the sediment characteristics appear to be of secondary importance. Note that for $n = 3$ the left-hand side of Eq. (4) can be interpreted as the work done by the tidal currents on the inlet bottom per sec.

Similarly to the inlets an attempt is made to correlate the cross-sectional area at the mouth of the estuaries in the Rhine-Meuse Delta with the maximum tidal discharge \hat{Q} . Because in general estuaries have fresh water inflow, the tidal discharge follows from

$$Q(t) = Q_r + \hat{Q} \sin \omega t \quad (5)$$

$Q(t)$ = instantaneous discharge

Q_r = river discharge

$\omega = 2\pi/T$ = angular frequency of the tide

T = tidal period

In this study, the maximum tidal discharge, \hat{Q} , is computed from the measured value of the tidal volume (tidal volume is sum of flood volume and ebb volume) using the equation.

$$TV = \hat{Q} T \left[\frac{Q_r}{\hat{Q}} + \frac{2}{\pi} \sqrt{1 - \left(\frac{Q_r}{\hat{Q}}\right)^2} \right] \quad (6)$$

This equation assumes $Q_r < \hat{Q}$.

For the purpose of this discussion, the cross-section characterizing the estuary mouth is taken at the location where there exists a pronounced change in the rate of change of the cross-sectional area; see Fig. 2. It appears that at this location the characteristic velocity, \bar{v} , defined as the tidal volume divided by the tidal period is a maximum.

For the mouths of the estuaries values of cross-sectional area and maximum tidal discharge are plotted in Fig. 3. To a very good approximation

$$A_c = 1.17 \hat{Q} \quad (7)$$

Here the maximum discharge, \hat{Q} , in Eq. (7) refers to average tide conditions. The corresponding maximum tidal velocity for the estuary mouths is:

$$\hat{u} = 0.85 \text{ m/sec} \quad (8)$$

This value varies slightly for the different estuaries and ranges between 0.82 m/sec and 0.86 m/sec; see van de Kreeke and Haring (1979). For spring tide conditions, the corresponding maximum tidal

Figure 2. Variation in cross-sectional area and tidal velocity, \bar{v} , along longitudinal axis of estuaries.

Figure 3. Relation between equilibrium flow area and maximum tidal discharge for estuary mouths.

velocity in the estuary mouths is:

$$\hat{u} = 1 \text{ m/sec} \quad (9)$$

For the values encountered in the Rhine-Meuse Delta, $Q_r/\hat{Q} < 0.25$, the effect of the ratio Q_r/\hat{Q} on the equilibrium flow area appears to be negligible. This is somewhat unexpected as it is generally believed that for constant values of the maximum tidal discharge \hat{Q} , the equilibrium flow area increases with increasing values of the river discharge Q_r . A possible explanation is that the increased cleansing effect resulting from the increased ebb velocities is offset by the inward-directed density currents along the bottom.

It is shown in van de Kreeke and Haring (1979) that Eq. (7) implies that for the Rhine-Meuse Delta the cross-sectional areas at the mouths of the estuaries is proportional to the flood volume rather than the tidal volume.

3 STABILITY CONSIDERATIONS

Because of the time varying nature of the sediment transport capacity of the tidal currents, Q_{TC} , and the littoral drift, Q_d , it is to be expected that cross-sectional areas show variations in time about the long term equilibrium profile. As an example the observed variations in the cross-sectional area of Wachapreague Inlet, Virginia are presented in Fig. 4. The record clearly shows a yearly cycle. Variations are on the order of 10% of the yearly mean value of the cross-sectional area.

If as a result of the short term fluctuations, the cross-sectional area decreases below a certain value, the estuary mouth could conceivably close. This will be explained using Fig. 5 which is taken from Escoffier (1940).

In Fig. 5 the solid curve, further referred to as closure curve is analogous to the well-known relation between inlet velocity and cross-sectional area for bay-inlet systems. In principle, for estuary mouths the closure curve can be obtained by computing the tidal velocity for various values of the cross-sectional area at the mouth. E.g., see Dronkers (1964), chapter XII. The exact shape of the curve depends among other things on how the cross-sectional area is varied i.e., by a change in width or a change in depth. Here it will be assumed that the cross-sectional area, A_c , is gradually decreased by decreasing the water depth. In that case for larger values of A_c , a decrease in cross-sectional area leads to an increase in tidal velocity, \hat{u} . For smaller values of A_c frictional effects become increasingly important and a decrease in cross-sectional area will lead to a decrease in tidal velocity. The horizontal line in Fig. 5 represents Eq. (8), and will be further referred to as the sediment curve.

Figure 4. Variations in cross-sectional area for Wachapreague Inlet.

Figure 5. Escoffier diagram.

It follows from Fig. 5 that for values of the cross-sectional area are smaller than A_1 , tidal velocities are too small to maintain the cross-sectional area; the estuary mouth will shoal. For values larger than A_1 the tidal velocity is larger than the velocity required to maintain the cross-sectional area; the estuary mouth will enlarge until the cross-sectional area reaches the value A_2 . Estuary mouths with cross-sections larger than A_2 will shoal until the cross-section reaches the value A_2 . Thus the long-term equilibrium condition for an estuary mouth is represented by the second intersection of the closure and sediment curve.

The foregoing implies that a condition for an estuary mouth to remain open is that the closure curve and sediment curve intersect. As a measure of the degree of stability the ratio $(A_2 - A_1) / A_2$ is introduced. Multiplying by hundred this ratio yields the percentage by which the equilibrium flow area can be reduced before the estuary closes.

As an application of the concepts presented in the previous section variations in the cross-section of the mouth of the Rotterdam Waterway covering the period 1885-1958 are explained. Dredging activities and construction of new harbors during the period 1885-1958, have resulted in a considerable increase of the cross-section at the mouth of the Rotterdam Waterway. A time history of the cross-sectional area and the tidal velocity, u , at the mouth of the estuary, the tidal range at Rotterdam and the various construction activities is presented in Fig. 6. Two equilibrium periods can be identified. The first period between 1897 and 1909 shows a cross-sectional area of 3720 m². During the second period 1944-1958, the equilibrium flow area equals 5600 m².

Closure curves pertaining to the year 1885 and the previously mentioned equilibrium periods together with the sediment curve are indicated in Fig. 7. It is emphasized that the closure curves are not exact but rather show qualitatively the trend of the maximum tidal velocity when changing the cross-sectional area. In 1885 the cross-sectional area of 3000 m², in Fig. 7, was larger than the equilibrium cross-sectional area, a in Fig. 7. During the succeeding period the cross-section would have returned to the equilibrium value were it not for dredging upstream of the mouth. Dredging led to a change in closure curve and caused the cross-sectional area to increase until it reached an equilibrium value of 3720 m² in 1897, in Fig. 7. The cross-sectional area then remained constant until about 1909, when port expansion led to an increase in storage and a change in closure curve. The value of the tidal velocity became larger than the equilibrium value of 0.85 m/sec which led to scour at the mouth of the estuary. However, the process of natural adjustment could not keep pace with the increased storage associated with the construction of harbor basins. Only after 1923 when the pace of harbor construction and dredging reduced did the value of the tidal velocity decrease, in Fig. 7. With the additional help of dredging in the mouth, the cross-sectional area reached a new equilibrium value of 5600 m² in 1944, in Fig. 7. Because relatively little

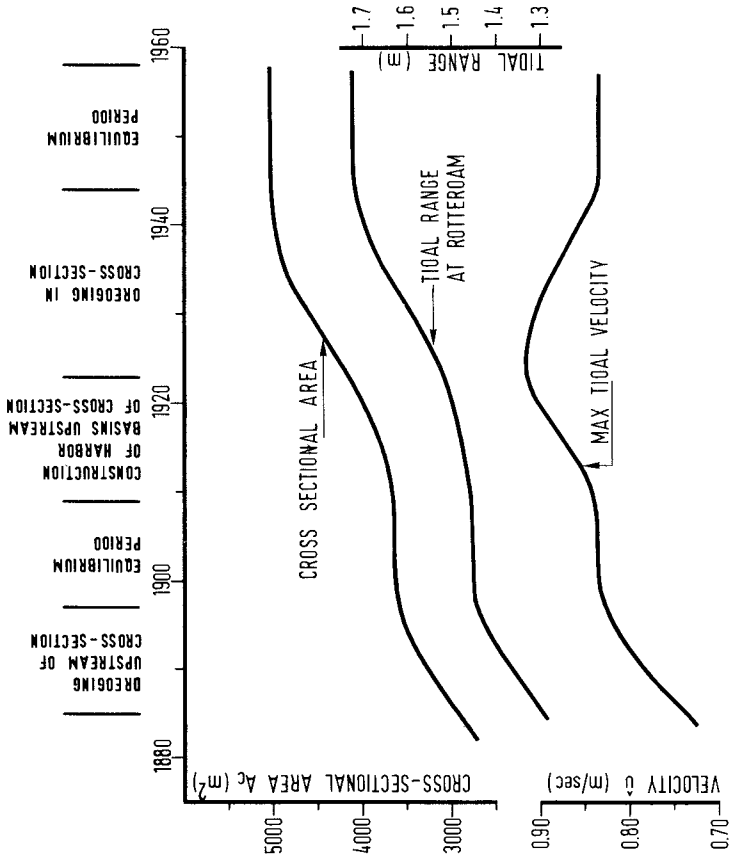

Figure 6. Mouth of Rotterdam Waterway; variations in cross-sectional area, tidal range and maximum tidal velocity during the period 1885-1958.

Figure 7. Mouth of Rotterdam Waterway; closure curves and sediment curve.

construction and dredging was carried out during the following period, stable conditions prevailed until 1958. Note that during the period 1885-1958 the stability index for the mouth had considerable increased.

5 CONCLUSIONS

For equilibrium conditions the maximum tidal velocity in the estuary mouths is constant and for average tide conditions equals 0.85 m/sec. For the estuaries with freshwater inflow this implies an approximately constant ratio between flood volume and cross-sectional area. For the estuaries with zero freshwater inflow the implication is a constant ratio between tidal prism and cross-sectional area.

Variations in the cross-sectional area at the mouth of the Rotterdam Waterway during the period 1885-1958 are explained using closure curves and a sediment curve (Escoffier diagram).

BARDEN INLET, N.C.
A CASE STUDY OF INLET MIGRATIONLimberios Vallianos, Chief, Coastal Engineering Studies Section
U. S. Army Engineer District Wilmington, Wilmington, N.C.ABSTRACT

The migratory pattern of a small coastal inlet was examined in terms of the factors generally acknowledged to control inlet behavior. That is, the tidal discharge which acts to flush the inlet and, on the other hand, the intrusive littoral materials depositing in the inlet environment. Specifically, a "flow conveyance index" was computed and compared to shoreline movements. The "flow conveyance index" was defined as the ratio of the mean distribution of the overall planform area of the throat of the inlet to the mean distribution of the planform areas of shoals within the throat of the inlet. High and low "flow conveyance index" values would correspond, respectively, to periods of relatively high and low inlet flushing conditions. A consistent pattern obtained from this analysis, wherein high and low index values corresponded with high and low shoreline movements. Additionally, the plot of rates of shore movements against rates of change of "flow conveyance index" was fitted with a simple linear regression line having a positive correlation coefficient of 0.85. Further analyses of the mean distribution of the shoals within the throat of the inlet demonstrated the cause of time-varying rates of movement of points along the spiriferous east shoreline of the inlet. Shoreline movement rates were plotted on a time-space plane and isolines of shore movement rates contoured. The result was a three-dimensional image of shore movement rates over time and distance. The position of the centroid of the inlet shoal distribution at different times was superimposed upon the three-dimensional image. This revealed that variations of shoreline movement rates along the shore at any point in time are dependent on the mean position of the inlet shoal distribution. Also, the direction of movement of the mean position of the inlet shoal distribution appeared to indicate the predominant direction of flushing action, that is, flood or ebb tides.

1 INTRODUCTION

Barden Inlet is located along the central portion of the North Carolina coastline and constitutes the physiographic juncture of Shackleford Banks and the south end of Core Banks, see figure 1. This inlet is characterized by an expansive shoal protruding into the inlet's throat from Shackleford Banks, and a resulting curvilinear main flow-conveyance channel juxtaposed with the east or Core Banks shore of the inlet. The effect of flow concentration on the east bank of the inlet has been to mold that shore into a spiraliform indenture. The continuous migration of the primary inlet channel (natural gorge) and concomitant erosion of the Core Banks shore is now threatening eventual damage and possible destruction of the historic Cape Lookout Lighthouse and related peripheral structures located near the inlet. On recognizing the hazard posed by the easterly migration of Barden Inlet, a study was undertaken

by the U.S. Army Corps of Engineers to determine the causative factors contributing to the problem and to develop appropriate corrective measures. This paper focuses on the evaluation of cause and effect relationships of the problem. It is remarked that prior to initiation of the study reported here, it was suggested by some parties having interest in the problem that the primary cause was the effects of dredging operations conducted in the maintenance of navigation channels approaching the throat of the inlet through its ebb and flood-tide deltas. Accordingly, the first steps in the problem evaluation involved a comparison of the pattern of movements of the shorelines adjacent to the inlet with the record of maintenance dredging in the channels approaching the inlet from its seaward and bay sides. This comparative analysis failed to demonstrate any relationship between dredging and shore movements or inlet migration. Therefore, the next phase of the evaluation examined those factors generally acknowledged to control inlet behavior on sandy shores, viz, sediment influx and tidal discharge. In this case, a very good correlation developed between the intensity and direction of shoreline movements, and an index value representing the relative magnitudes of sediment influx and tidal discharge. Further analyses of the distribution of shoal accumulations within the throat of the inlet demonstrated the cause of time-varying rates of movement of points along the eroding shore on the east side of the inlet.

2 EFFECTS - SHORELINE MOVEMENT HISTORY

The pattern of shoreline movements over time was established through the use of aerial photographs of the study area. The available record consisted of 21 photographic coverages during a 37.5-year period extending from October 1940 to April 1978, thus allowing for the evaluation of 20 discrete time spans. Standard methods of evaluating the shoreline movements were employed, that is, a measurement baseline or reference was selected and superimposed on each of the aerial photographs. The baseline was divided into stations at which measurements to the shorelines were made on the respective photographs and compared to determine shoreline movements and rates of movements during the time periods between successive photographs. The baseline passed through the center of the base of the Cape Lookout Lighthouse on a bearing of N 31° E which approximates the orientation of the longitudinal axis of the throat of Barden Inlet. A total of 35 baseline stations, numbered consecutively 1 through 35, were established at a spacing of 30.5 meters (100 feet), with station number 6 being located at the lighthouse. Distances to the shoreline(s) were measured at these stations along transects perpendicular to the baseline and extending toward the inlet. In the evaluation, stations 1 through 35 were utilized to obtain shoreline movement measurements pertaining to the overall Core Banks shoreline of the inlet, and measurements made at stations 4 through 8 were selected to represent conditions of the shoreline in the immediate vicinity of the Cape Lookout Lighthouse building complex, and the transects and related measurements at stations 20 through 27 were extended across the inlet to develop the general pattern of shoreline movement along the inlet's Shackelford Banks shoreline.

In terms of the single longest time span, that is October 1940-April 1978, the results of the photographic analysis were that: (a) the average movement of the entire east shore or Core Banks side of Barden Inlet had been eastward for a distance of 361 meters, giving an average rate of movement of 9.6 m/yr or 0.8 m/mo; (b) the segment of the inlet's east shore in the immediate vicinity of the Cape Lookout Lighthouse had moved easterly for a distance of 388 meters, resulting in an average movement rate of 10.3 m/yr or 0.9 m/mo and by April 1978, this segment of shoreline was within 49 meters of the lighthouse keeper's dwelling and 105 meters from the base of the lighthouse; and (c) the inlet's west shore or Shackleford Banks side had moved westward over a distance of 38 meters, giving an average rate of movement of 1 m/yr or approximately 0.1 m/mo. In regard to short time spans, the rates of shoreline movement deviated substantially from the long-term averages enumerated above. For example, the average movement rate of the east shore varied from as high as 4.4 m/mo in an easterly direction, to as much as 2.8 m/mo in a westerly direction. Additionally, in any given time span, there was great variability in the rates of shoreline movement experienced along the various station transects used in the analysis. In this connection, graphs of the cumulative movements of transect stations were plotted and superimposed, see figure 2. This superposition demonstrated that variations in shore movement rates, transect to transect, were generally occurring in the form of a gradual transition. This occurred because of the remarkably smooth planform curvature of the indentured east bank of Barden Inlet. Indeed, the major portion of this eroding shoreline at the various times that it was photographed could be precisely duplicated by the equation of a logarithmic or equiangular spiral, as illustrated by figure 3.

3 CAUSAL FACTORS

In search of a rational causal factor(s) resulting in the inlet channel migration and attendant erosion of the inlet's east bank, the first consideration was given to dredging activities associated with maintaining the seaward and bayward channels approaching the inlet gap. It is remarked that the primary inlet channel (gorge) flowing against the eroding east bank is naturally wide and deep and does not require dredging. With respect to dredging related to the inlet's approach channels through the ebb and flood-tide deltas, the existence, or lack thereof, of two primary trends was sought in terms of the comparison of dredging quantities and shoreline movements, namely: (a) high or low shoreline movement rates corresponding directly with high or low dredging quantities; and (b) high or low shoreline movement rates immediately following high or low dredging quantities. The first comparison to be made was the superposition of histograms of the shoreline movement rates and dredging quantities over time. This comparison failed to indicate any relationship between shoreline behavior and dredging. This was followed with simple linear regression analyses of shoreline movement rates and dredging quantities, considering both the overall indentured east bank of the inlet having a length of 1,036 meters, and a segment of that same shore having a length of 150 meters situated in the immediate vicinity of the Cape Lookout Lighthouse. With shoreline movement rates

FIGURE 2

FIGURE 3

and dredging quantities as the dependent and independent variables, respectively, the lines of regression fitted through the data points had correlation co-efficients of -0.03 for the overall east bank of the inlet and -0.24 for the small segment of east shore near the lighthouse, see figure 4. This demonstrated numerically that which was evident on inspection of the scatter diagrams, to wit, there was no apparent association between dredging operations in the approach channels and movement of the east bank of the inlet. This was not a particularly startling revelation inasmuch as many inlets on the coast of North Carolina at which there are no navigation channels through the ebb and flood deltas have experienced higher rates of primary inlet channel migration and attendant erosion of the downcoast inlet shoulders than has been experienced at Barden Inlet.

The next step in the evaluation was to examine the available data in terms of the factors generally acknowledged to control inlet behavior on sandy shores. That is, the tidal discharge which acts to flush the inlet and, on the other hand, the intrusive littoral materials depositing in the inlet environment. In the case of Barden Inlet, there was not sufficient data for a quantification of the relative magnitudes of the two opposing factors over the various time periods in which shoreline movements were determined. Accordingly, an implicit approach was taken in analyzing the relative magnitudes of the flushing and siltation factors as reflected in the shoaled and deeper water portions of the throat of Barden Inlet depicted by the available aerial photography. The aerial photographs selected for analysis were those dated 15 July 1960, 3 May 1962, 27 October 1965, 12 April 1968, 15 August 1971, 6 November 1972, 5 October 1973, 15 November 1974, 15 August 1976, 10 August 1977, and 22 April 1978. These particular photographs were selected due to their generally high resolution of submerged features. Moreover, the time spans between photographs were approximately in the range of 1 to 3 years, which should be sufficient time for the inlet to adjust to changed conditions but not so long as to miss important changes.

The analysis of inlet characteristics depicted on the selected photographs was performed on the basis of the geometric framework defined on figure 5, where the X-X and Y-Y axes are identical to those previously described. The longitudinal extent of the inlet was defined as the water area confined between the Y-Y axis and a line extending from and perpendicular to the X-X axis to the Core Banks shoreline through the point of maximum seaward protrusion of the platform shoal which projects into the throat of Barden Inlet from the Shackleford Banks side. The size and distribution of the overall inlet on a given photograph within this framework was characterized by its areal size, the X and Y distances to its centroid, and the first moments of the area taken about the X-X and Y-Y axes. Similarly, the size and distribution of the shoal areas within the inlet framework were defined by their combined areal size, centroidal distances, and first moments about the X-X and Y-Y axes. A measure of the flow conveyance of the inlet was established as the ratio of the first moment of the overall inlet area about the X-X axis to the first moment of the shoal areas about the X-X axis (M_{X-X} (inlet) / M_{X-X} (shoal)). This ratio is referred to here as the "flow

FIGURE 4

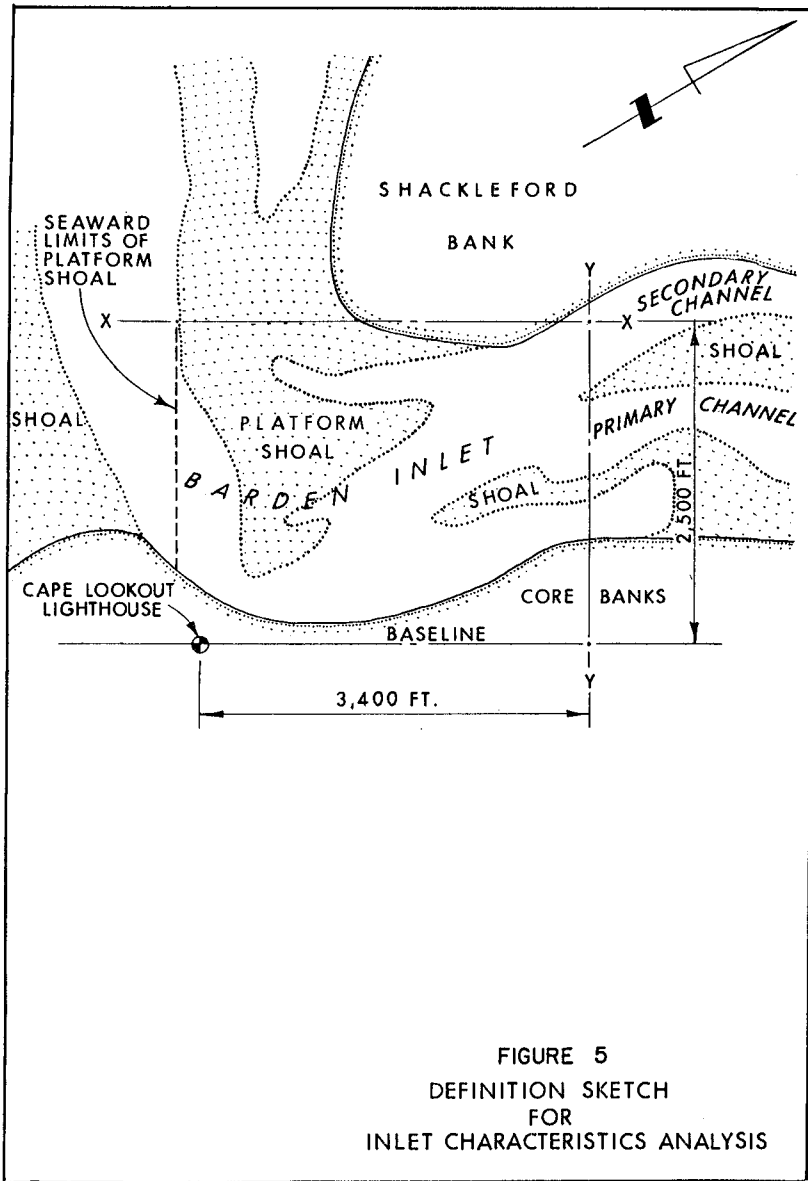

FIGURE 5
 DEFINITION SKETCH
 FOR
 INLET CHARACTERISTICS ANALYSIS

conveyance index." In other words, if the mean distribution of the overall inlet is large by comparison to the mean distribution of the shoal areas therein, it can be expected that the inlet's flow conveyance and flushing capability is high compared to a case where the flow conveyance index is relatively low. The values of inlet and shoal areas, centroidal coordinate distances, first moments about the X-X and Y-Y axes, flow conveyance indices, rates of change of flow conveyance indices, and the weighted average rates of shoreline movements between sequential photographs are listed in table 1. The reader will note the distinctly consistent pattern in which the rates of shoreline movement increase and decrease in accordance with increasing or decreasing flow conveyance indices. This trend is graphically displayed on figure 6 which is a scatter diagram and associated simple linear regression line for shoreline movement rates plotted against the rates of change of the conveyance indices. The linear correlation coefficient (R) has a value of 0.85. In view of the trends described above, it is concluded that the general shoreline behavior on the Core Banks side of Barden Inlet is basically dictated by changes in the tidal flow exchange through the inlet as controlled by increasing and decreasing littoral influx associated with changes in wave energy reaching Shackelford Banks, and increasing and decreasing flushing action which is primarily controlled by wind energy and attendant wind tides and wind drift (movement of water due to wind stress) over the estuarial waters comprised of Pamlico-Core Sounds and Bogue-Back Sounds.

Another important output of the inlet characteristics analysis was the evaluation of the changes in rates of movement of the spiriferous shoreline indenture on the Core Banks side of Barden Inlet generally confined between transect stations 4 and 32. Data plotted on figure 7 graphically display the influence of the longitudinal position of the inlet shoal distribution on the magnitudes of shoreline movement rates at specific points along the indentured shoreline. It will be noted that figure 7 provides a three-dimensional image consisting of a time-space plane on which isolines of shoreline movement rates are plotted. The isolines were contoured from shoreline movement rates of alternate transect station values plotted at the midpoints of the time periods for which the values were computed. Superimposed on the three-dimensional image are the positions (dots) of the centroids of the inlet shoal distributions with respect to the Y-Y axis as referenced to the transect station numbers. The influence of the longitudinal positions of the shoal distribution centroid on the magnitude of shoreline movement rates along the spiriferous shore indenture is clearly evident. During the 1960-1962 period, the shoal centroid position moved bayward with high shore movements being concentrated on the bayward end of the shore (transect stations 22 through 32). This was followed by a gradual seaward movement of the shoal distribution centroid over the period 1962-1972 during which the Core Banks shore retreated at a moderate rate, was stable, or in a state of accretion. This, in turn, was followed by a rapid seaward movement of the centroid in the 1972-1973 period, with concomitant high shore retreat rates concentrated along the seaward end of the shore near the lighthouse. Then, the centroid moved bayward with an accompanying stable or accreting state of the shoreline over the

 SHORELINE MOVEMENT RATE
 -vs-
 RATE OF CHANGE
 OF
 FLOW CONVEYANCE INDEX

1973-1974 time period. Again, in the period 1974-1976, the centroid moved seaward at a rapid rate with generally high erosion rates along the entire shoreline, followed by a bayward centroid movement in the 1976-1977 period with shore accretion developing. From 1977 to 1978, the centroid moved seaward with high rates of movement occurring along the lighthouse area at the seaward end of the shoreline. Thus, we see that the rates of shoreline movement along different points of the Core Banks side of the inlet are basically controlled by the position of the shoal distribution relative to the shoreline. This, of course, comes from the fact that the shoal distribution also relates to the major channel positions and orientations and, therefore, the points at which flows are concentrated.

The fundamental cause of the movement of the inlet shoal distribution can be attributed to the direction of the primary inlet flushing action. Major flushing occurs when strong perennial winds from the general northeasterly direction act over the expansive, shallow waters of Pamlico-Core Sounds. This wind action superelevates and forces water movement toward and through Barden Inlet, while concurrently suppressing onshore wave action and littoral materials transport along Shackleford Banks. Thus, the tidal ebb flows are highly efficient in flushing Barden Inlet when winds come from a general northeasterly direction. The results of this phenomenon are reflected in the general trend of seaward movement of the shoal-distribution centroid over the period 1962 to the present; see figure 7. The bayward movement of the shoal-distribution centroid from July 1960 to May 1962 as shown in figure 7 was, in all probability, caused by the high bayward flushing action generated by Hurricane Donna. This storm passed over the inlet on 12 September 1960 and was the last hurricane, to date, causing a significant ocean storm tide along the Shackleford Banks coastal zone. Indeed, it was not only the last significant ocean surge event, but was also the highest storm surge of record for that area. The Donna ocean storm tide reached an elevation of 3.3 meters above mean sea level. At the time of the recorded peak ocean tide, the bay water level was measured at 1.4 meters above mean sea level. Thus, a maximum water level differential of 1.9 meters existed between ocean and bay waters. The flood current velocity through Barden Inlet, as generated by this condition, was computed at 2.4 meters per second. Such a high flow would unquestionably flush the inlet shoal accumulations in a bayward direction. Moreover, as Hurricane Donna moved northward, its radius of maximum winds traversed a line coincident with the long axis of Pamlico Sound, thus tilting the water up at the north end of Pamlico Sound and depressing the water levels in Core Sound and the south end of Pamlico Sound. This resulted in an unusually long period of bayward flushing at Barden Inlet.

4 CONCLUSIONS

The investigation of Barden Inlet in reference to migration of the primary inlet channel (gorge) and the attendant erosion of the east bank demonstrates that one cannot, a priori, relate dredging operations through the ebb and flood-tide deltas of small coastal inlets with inlet migration in general nor with the rates of migration. The availability

ISOLINES OF RATE OF SHORELINE MOVEMENT IN FEET PER MONTH WITH RESPECT TO TIME AND SHORELINE STATIONING

FIGURE 7

of aerial photographs of Barden Inlet allowed for an implicit analysis of the causal factors associated with inlet processes at that site, resulting in findings consonant with the accepted concepts of factors influencing inlet behavior, namely, tidal discharge and the influx of littoral material.

STUDY ON VORTEX CURRENT IN STRAIT
WITH REMOTE-SENSING

by

INTRODUCTION

With rapid increases of industrial activity in present time, water pollution in the coastal environment has become an urgent problem to cope with. This problem is especially serious in enclosed bays or inland seas. Hydrodynamic character of the strait connecting the inland sea to the open ocean must be understood well in order to analyse the diffusion of pollutants in the inland sea, because its character determine boundary conditions in the mathematical models of the water pollution problem. So far however, it is seemed that the main efforts exerted by coastal engineers have concentrated mainly on the development of mathematical models, lacking satisfactory knowledge of the boundary conditions through field measurements. One reason of this state is resulted from the fact that the relating phenomena in the field are of too large scale, in general, to perform the field measurements.

Connecting with this point, the authors present in this paper, that remote-sensing technology is very useful to get information of the hydrodynamical phenomena occurring in the water body around the strait. To show the above, the authors selected as an object of the study, Naruto Strait in the Seto Inland Sea, which is world famous for the existence of rapid tidal currents and dynamic vortices. Remote-sensing data both from the airplanes and from a space satellite Landsat are analysed with the aid of theoretical considerations and hydraulic model tests to disclose the behavior of the vortices of various scales and the roles of them in the sea water mixing phenomena at the strait.

1. VORTEX DISTRIBUTION IN NARUTO STRAIT

Naruto Strait, being well known with the existence of dynamic vortices, is located between Shikoku and Awaji Island in Japan (Fig-1). Fig-2 is an aerophoto of the Naruto Strait. The left side on the figure is Harima Sea forming a part of the Seto Inland Sea and the right side is Kii Channel leading to the Pacific Ocean. The width of the Naruto Strait is, as shown in Fig-3 (a), contracted by shoals stretching out from both Oge Island in Shikoku and Tozaki Headland in Awaji Island. The most contracted section in the strait has V-shaped configuration as indicated in Fig-3 (b), in which the water surface is of 1,100m width, and the maximum depth is more than 80m. Each of the tidal levels in the Harima Sea and the Kii Cannel turns reversly with the period of 12hours,

(b) section view of the Naruto Strait

producing rapid tidal currents, the maximum velocity of which is about 10 knot, the dynamic vortices that are asserted roughly into coherent vortices along the free boundary layers leaving from both of the headlands, and vortex-pairs of large scale as schematically indicated in Fig-4. On the Fig-2, one can see the dynamic coherent vortices behind the headlands. Fig-5 shows the closer view of the coherent vortices. On the figure, one can see some aspects of the process through which rather smaller vortices amalgamate into the coherent vortices of larger size.

The authors investigated hydraulic character of these vortices through two different ways of field survey. The first of those is the remote-sensing with aero-photography, main purpose of which is to study the hydraulic character of the coherent vortices along the free boundary layer. The second way of the survey is the remote-sensing by Landsat, the purpose of which is to disclose the distribution of the larger scale vortex-pairs appearing as a result of amalgamation of the small scale coherent vortices.

(aerophoto from 300m altitude)

2. INVESTIGATION OF COHERENT VORTICES THROUGH SOLID AERO-PHOTOGRAPHY

2-1 Field observation

The aero-photographic surveys at Naruto Strait were done using a pair of airplanes at the altitude of 800m under the flood tide conditions of spring and autumn in 1978. Several series of aerophotos of the strait were synchronously obtained by the pair of airplanes at 3 sec time intervals and analysed through a stereoscope to map the hydraulic character of the strait such as unevenness of the water surface, direction of the tidal current, distribution of the vortices along the free boundary layers, upwelling currents and so on. Fig-6 is an example of the map gained. One of the interesting aspect is the existence of upwelling region, indicated by dotted line on the figure, on the water surface in the region opposite to the tidal current. Relations between the vortices and the upwelling current will be discussed in the paragraph 2-4 later.

Another example of the results obtained through the field survey is Fig-7 which represents the unevenness of the water surface. This figure was yielded through the solid aerophoto and will be used in the estimation of the vortex strength as described below.

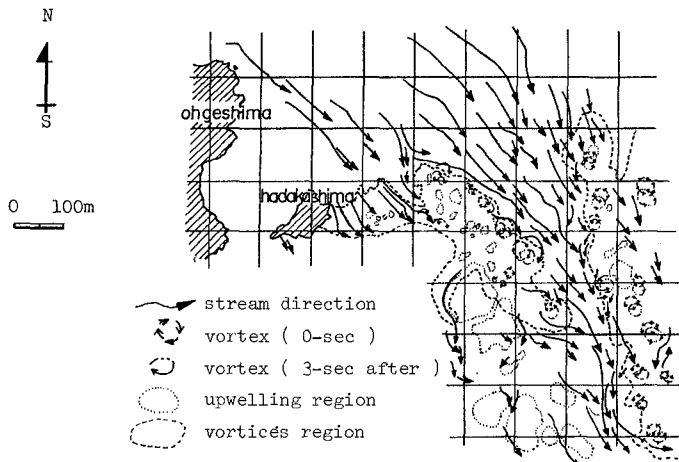

Fig-6 Distribution of tidal currents, coherent vortices and upwelling regions

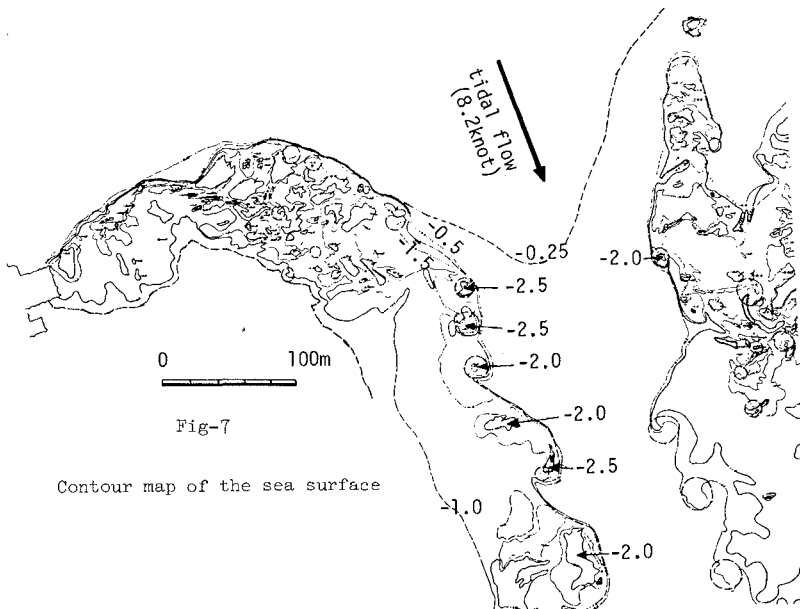

Fig-7

Contour map of the sea surface

2-2 Strength of the Coherent Vortices

From hydrodynamical view point, the vortex strength Γ in the practical sea water region with large scale such as the strait is quite an interesting subject to study. But, because of the unsteadiness as well as huge scale of the related hydraulic phenomena, the field measurement of the vortex strength by means of conventional instruments shall be considerably difficult. In this respect, the remote-sensing technology by the airplane and/or the satellite Landsat is quite useful. Here, authors present several ways to estimate the vortex strength with the data obtained through the remote-sensing.

(1) Estimation on the basis of " Rankine-Vortex " model

By applying the Rankine-vortex model to the individual vortex on the Fig-7, the vortex strength Γ_1 can be estimated by

$$\Gamma_1 = 2\pi R \sqrt{g \Delta h} \tag{1}$$

where R : vortex radius, g : acceleration of the gravity
 Δh : concavity of the water surface on the vortex axis

On the Fig-7, we can obtain Δh directly and R by the fact that the vortex radius is equal to the radius of the contourline of the concavity of $\Delta h/2$.

(2) Estimation on the basis of "Concept of vorticity flux conservation"

Referring to Fig-8 and assuming that the strength of vorticity generated at the point P will be preserved during transport to the downstream direction along the free boundary layer, the vorticity flux passing through the control section I in a unit time can be estimated as follows.

Volume flux of the fluid passing through an element of thickness dy in the unit time is $u dy$, where u is the velocity in the direction normal to the y -axis. The vorticity ω in the fluid of unit volume is

$$\omega = du / dy$$

therefore, the vorticity flux ω_{flux} passing through the control section I becomes

$$\omega_{flux} = \int_{-\infty}^{\infty} u \, dy = \int_{-\infty}^{\infty} \frac{du}{dy} u \, dy = \frac{1}{2} (U_1^2 - U_2^2) \quad (2)$$

where, U_1 and U_2 are the velocities above and below the boundary layer as shown in Fig-8 (a) respectively. With assumption that the free boundary layer consists of the group of coherent vortices, each of which is distributed in a constant space interval of b and possesses a shifting velocity of C as shown in Fig-8(b), the strength of each coherent vortex Γ_2 becomes

$$\Gamma_2 = \omega_{flux} \cdot \tau = \frac{1}{2} (U_1^2 - U_2^2) \frac{b}{C} \quad (3)$$

where, $\tau = b/C$ is the average shedding period of the vortices.

Fig-8 Concept of vorticity flux conservation

- (5) The sediment moving directly onshore from the Swash Bar, $Q(6)$ can split into longshore components $Q(7)$ or $Q(8)$ and $Q(8)$ can be broken down into its ebb and flood constituents.

$$\text{Hence : } Q(6) = Q(7) + Q(8); Q(8) = Q(8E) + Q(8F)$$

- (6) Prior to jetty construction North Beach was relatively stable i.e. $Q(5) = Q(4) + Q(7)$.

6.2 Functional Relationships

- (1) It was assumed that 90% of the flood tide sediment transport took place via the swash bar and inshore gutter i.e. $Q(3) = 0.1 Q(8F)$.

- (2) The ebb and flood sediment transport potential against the inside of the northern training wall was calculated from tidal current measurements assuming transport potential was proportional to the cube of the velocity (Maddock 1969). This indicated that the recycled ebb tide constituent of the inshore gutter sand feed was approximately half the flood tide constituent, therefore

$$Q(8E) = 0.3 Q(8)$$

- (3) The application of the CERC formula to determine the net littoral transport along North Beach, $Q(5)$, and the onshore transport on the Swash Bar, $Q(2)$, was discussed in Section 3.4 where it was argued:

$$Q(2) = 10 Q(5)$$

6.3 Calculated Values

A number of the model elements were known or estimated viz:

- (1) $Q(1) = 20,000 \text{ m}^3 \text{ p.a.}$ (See section 3.3)
- (2) Because currents in the inshore gutter were always inlet directed (Section 3.2) it was assumed that all sand feed would be inlet directed i.e. $Q(7) = 0$
- (3) $Q(9) = 50,000 \text{ m}^3 \text{ p.a.}$ (Section 3.1)
- (4) $Q(12) = 200,000 \text{ m}^3 \text{ p.a.}$ (Section 3.1)
- (5) $Q(11) = 150,000 \text{ m}^3 \text{ p.a.}$ (Section 3.1)
- (6) $Q(13) = \text{Erosion during flood event only}$ (Section 3.1)
- (7) $Q(15) = \text{Deposition during flood events}$ (Section 4)

6.4 Effect of Northern Jetty Construction

The foregoing equations and relationships were adjusted so as to

2-3 Strength of the Coherent Vortices in Naruto Strait

In order to estimate the strength of the coherent vortices in Naruto Strait, remote-sensing data from the airplanes were hydrodynamically interpreted using the above equations. On the Fig-7, one can estimate the surface concavity on the vortex axis to be $\Delta h = 1.0\text{m}$, the radius of the contourline of the concavity $\Delta h/2$ to be $R = 8\text{m}$. Putting these data into eq.(1), it is shown that the vortex strength amounts to about $160 \text{m}^2/\text{sec}$, when the velocity of the tidal current is 8.2 knot. The space interval of the vortices b , and the shifting velocity C were measured on the aerophotos to get the results presented in Table-2, where the velocity of the tidal current U was gained from the onsite data, and the velocity in the dead water region was considered to be negligible. The strength of the vortices on the basis of eq.(3) is estimated to be $50 \sim 100 \text{m}^2/\text{sec}$ in the case of the tidal flow velocity of 6.6 knots and $130 \sim 200 \text{m}^2/\text{sec}$ in the case of 10 knots, respectively. The vortex strength gained by eq.(1), (3) and (4) is considered to agree well each other.

2-4 Consideration of the Upwelling Current
Associated with the Coherent Vortices

Onsite field observations and analysis of the solid aerophotos disclosed the existence of strong upwelling regions adjacent to the coherent vortices as shown in Fig-6. Theoretical considerations²⁾ using tornado-model show that a single line vortex around a vertical axis terminating at the sea surface and at the sea bottom, induces strong upward flow from the bottom due to the friction along the bed surface. Deducing from these results of a single line vortex, the observed upwelling phenomena at the strait are considered to be strictly related to the coherent vortices along the free boundary layer.

In order to estimate the upward volume flux in Naruto Strait, hydraulic model tests were carried. In a test basin of 0.6m-width and 25m-length, a single line vortex was generated by putting suddenly a plate of 0.3m-width into the uniform flow with the velocity of 7.0cm/sec, keeping it standing still in a moment, and finally drawing out abruptly. Both of the strength and diameter of the vortex could be changed by controlling the degree of the small shifting motion of the plate toward the upstream. The vertical profiles of the water surface of the vortex were measured by a wave gauge set in the course of the vortex path. The vortex motion and the induced upwelling motion were coloured with respective different dyes and their side views as well as their plan views were photographed every one second. Experiments were carried under the two different conditions of bottom surface, that is, smooth surface and rough one with pasted sand of 1.7mm ~ 2.2mm diameter. The wave gauge was set at 0.5m downstream from the vortex generating point. Experimental conditions are presented in Table-3, in which H is water depth, C is shifting velocity of the vortex and Γ is the vortex strength estimated by eq.(1) with the surface concavity gained by the wave gauge.

Table-3 Experimental conditions

Fig-11
Upwelling due to
a line vortex
(Case 1)

Fig-12

Successive picture of
upwelling flow

Fig-13

Upwelling flux as a function
of vortex strength

When the vortex comes into the observation section, red colored dye set on the bottom surface moves along the bottom surface and turns its direction upward. In case of the vortices of weak strength, the upwelling flow concentrates near the vortex axis and breaks itself down before arriving at the water surface (Fig-11). According as the vortex strength increases, the downward flow along the vortex axis appears and increases its diameter, and the upwelling flow takes the shape of a ring. In the case of the rough bottom surface, the diameter of the upwelling flow becomes larger, and breaks down more easily because of the rotating energy consumption by the friction due to the bottom roughness.

Fig-12 shows the successive pictures of the upwelling flow mapped from a series of photos with the time interval of 1 sec. The upward volume flux associated with the upwelling motion was estimated from such figures gained respectively in each case of the experiments of Run 1~22 of Table-3. Fig-13 shows the relation of the upward volume flux to the vortex strength.

The upward volume flux at Naruto Strait was estimated by using these experimental data on the basis of the Froude similitude. In the experiments, the upward volume flux of $500\text{cm}^3/\text{sec}$ was observed to be induced by the vortex of 3cm-diameter, water surface concavity of 0.8cm and vortex strength of $500\text{cm}^2/\text{sec}$ in the case of water depth of 20cm. Basing on the Froude similitude, the upward volume flux of $280\text{m}^3/\text{sec}$ is expected to be induced by a vortex of 6m-diameter, 1.6m-concavity and $150\text{m}^2/\text{sec}$ strength in the case of water depth of 40m, which is of approximately equal scale to the coherent vortices in the free boundary layer generated at Naruto Strait in the flood tide condition. At Naruto, about a dozen of vortices are existing as shown in Fig-2, and then the total volume of upward flux is roughly estimated to be $3,000\text{m}^3/\text{sec}$. The total volume flux of the tidal current under the flood tide condition is about $100,000\text{m}^3/\text{sec}$. Therefore, at Naruto, the vertical sea water mixing caused by the upwelling motion induced by the coherent vortices is estimated to be a few percents of the total volume flux of the tidal current passing the strait.

3. LARGE SCALE VORTEX-PAIR OBSERVED BY LANDSAT

3-1 Remote-sensing by Landsat

As shown in Fig-4, the coherent vortices along the free boundary layers amalgamate into a pair of vortices of larger scale. This amalgamation phenomena have too large scale to observe from the airplane, but the satellite Landsat may present us these clearly. For example, Fig-14 shows a result of the analysis of the Landsat data obtained on August 1st, 1976. On this figure, one can see the vortex-pair of larger scale under the northward tidal current of the maximum velocity of 7.6 knot. Fig-15 is another example and shows the flow pattern on October 24th, 1972. In this case, the northward tidal flow maximum velocity of which is 10.2knot have just finished and the current is under the slack condition. The fully grown vortex-pair of large scale can be observed on this figure. Finally, Fig-16 obtained from the Landsat data on December 30th, 1975 shows the situation that the tidal current is flowing in the southward direction with about maximum velocity of 7.6knot while the vortex-pair left behind in the Harima Sea is still leaving away the strait with its self-induced velocity U_v , which is theoretically described by

$$U_v = \frac{\Gamma}{2\pi\ell} \quad (6)$$

where

$$\Gamma : \text{strength of each vortex} = \alpha \int_0^{6\text{hour}} \frac{1}{2} u^2(t) dt$$

ℓ : distance between each vortex

α : amalgamation efficiency factor

$u(t)$: velocity of the tidal current

Fig-14

at the maximum northward flow
condition

Fig-15

Final stage of the formation
process at the slack

Fig-16

Vortex-pair progressing into the
Harima Sea against surrounding
sea water at the maximum
southward flow condition

The above three different phases of large scale vortex-pair are summarized in the Fig-17. These Landsat data present clearly the various patterns of the vortex-pair formed by northward flow under each characteristic stage of the tidal cycle. On the other hand, patterns of vortex-pair formed by northward flow are not presented so clearly, although the vortex-pair can be vaguely recognized in Kii Channel in the case of Fig-16.

With the expectation to obtain more clear feature of the vortex-pair, the authors did measurements of thermal image of the flow from the air-plane at the altitude of 4,000m. Fig-18 shows the thermal image gained at 11:00 A.M. Aug. 23rd 1979, being 2 hours after the southward flow began. Again the existence of the vortex-pair in the Harima Sea can be definitely recognized. Fig-19 shows the situation at 12:00 A.M. on the same date. The tidal condition at this moment is southward maximum flow. On this figure, one can see the vortex-pair in Kii Channel as expected and strong water mixing proceeding at the strait.

Fig-18 Thermal image at 11:00

Fig-19 Thermal image at 12:00

3-2 Consideration of Tidal-Exchange by Vortex-Pair

The mechanism of the tidal-exchange through the narrow strait such as Naruto Strait is explained using vortex-pair model as shown in Fig-20, in which A-①~③ represent the growing process of the vortex-pair, each of which corresponds to the typical phase of the cyclic tidal current at the strait as shown as B-①~③.

- ① Tidal current is flowing with the maximum speed at the strait. The vortex-pair is being generated by the amalgamation process of the coherent vortices along the free boundary layer. At the same time, the vortex-pair advances forward with the self-induced propulsive force, pushing aside the surrounding water body.
- ② The first half of the tidal-cycle as well as the growing process of the vortex-pair are over.
- ③ Tidal current is running with the maximum speed in the reversal direction. Vortex-pair left behind is still leaving away the strait, with its self-induced velocity U_v defined by eq.(6). Under this situation, the water mass passing the strait, which has been pushed aside by the vortex-pair in the former processes, generates another vortex-pair in the opposite side of the strait.

Thus tidal-exchange is inspired by the self-propelling motion of the vortex-pair.

The water mass forming the vortex pair corresponds to the magnitude of the tidal-exchange during one tidal cycle, which is estimated to be 10^9 m^3 in Naruto Strait as the result of the analysis of the remote-sensing data and onsite data as well. The self-propelling motion, which plays an important role in the tidal-exchange process through the strait, is also expected to contribute to the mixing process in the open sea neighboring the strait. Analyses of the remote-sensing data from Landsat show that the self-induced velocity of the vortex-pair at Naruto-Strait is about 0.8 knot, from which the strength of the vortex is estimated to be $10^4 \text{ m}^2/\text{sec}$. Thus, about 10% of the vorticity generated at the strait is expected to amalgamate to the large scale vortex-pair via the form of the coherent vortices along the free boundary layer.

Fig-20 Schema of tidal-exchange mechanism

CONCLUSION

Usefulness of the remote-sensing from airplanes and Landsat in the study of tidal current in straits was discussed, choosing Naruto Strait as the object of the onsite study. Solid aerophoto provides various information of small scale hydrodynamical character of the tidal current including the distribution of the coherent vortices in the free boundary layer, surface concavity at the vortex axis and radius of the vortices, through which the strength of each coherent vortex can be estimated. Regarding the estimation of the vortex strength, the authors presented four formulas of eq.(1), (3), (4) and (5), of which fitness was studied by means of aerophotos. Among these, eq.(3) is considered to be most convenient in the case when we apply aerophotos in the study, because all variables in the equation can be obtained directly on the aerophotos.

The small scale coherent vortices amalgamate during a half of the tidal cycle, 6 hours, finally into a large scale vortex-pair, the self-propelling motion of which takes an important role in the tidal-exchange through the strait. The scale of the vortex-pair is generally too large to observe on the aerophotos. In that case, Landsat is quite useful as shown in Fig-14. The self-propelling motion of the vortex-pair is also considered to promote the mixing of the water from the inland sea with the water in the open sea. In the case of Naruto Strait, about 10% of the vorticity generated at the strait is expected to amalgamate in the vortex-pair via the form of small scale coherent vortices, and a few percents of total volume flux of the tidal current passing the strait is estimated to mix with the surrounding water body due to the upwelling current induced by the coherent vortices.

ABSTRACT

The discharges issued by OTEC plants, thermal power plants and other engineering devices, give rise to the transport of "foreign" properties and substances into the natural ocean environment. In order to predict the functioning of such structures and assess their environmental impact, physical modelling has already been utilized. Since the simultaneous fulfillment of both Reynolds and Froude criteria is impossible (in a conventional small scale model operating with the prototype fluid) in the models mentioned the transport phenomenon was reproduced on the basis of the densimetric Froude number (Fr) only, the influence of the Reynolds number (Re) being neglected. On the other hand, the identification of the scale of Fr (viz λ_{Fr}) with unity can lead to substantial differences between the model and prototype values of Re . (Because $\lambda_{Fr} = 1$ yields $\lambda_{Re} = \lambda_\ell^{3/2}$ where λ_ℓ is the linear model scale.) Yet many of the pertinent aspects of a turbulent diffusion (energy dissipation, thickness of mixing zones, separation processes, etc.) are strongly dependent on Re , and therefore an appreciable distortion of Re ($\lambda_\ell^{3/2} \ll 1$) can lead to some substantial errors with regard to the similarity of these aspects.

The central theme of the approach presented in this paper can be outlined as follows: Why should any of λ_{Fr} or λ_{Re} necessarily be identified with unity? If Π_A is the dimensionless version of a quantitative property A of the transport phenomenon, then $\Pi_A = \Phi_A(Re, Fr, \dots)$. The modelling of A means the approach of λ_{Π_A} to unity as close as possible. But, if so, then there should exist such (optimal) scales $\lambda_{Fr} = \alpha$ and $\lambda_{Re} = \beta$ (both $\neq 1$) which would yield

$$|\lambda_{\Pi_A} - 1| \rightarrow \text{minimum}$$

The proposed determination of α and β rests on experimental basis; it rests on the calibration of the model by adjusting the model velocity v so that the last equation becomes valid.

Since $\frac{\partial A}{\partial Re}$ cannot be expected to be the same for all the properties of the transport phenomenon each A will in general require "its own" scales α and β .

1. INTRODUCTION

Transport phenomena form a large class of problems whereby discharges from a source induce certain changes in the natural environment. The transported element may be matter (salinity) or temperature but may also refer to fluid properties such as momentum. The overall objective of this paper is to describe a method by which transport phenomena can be tested in a hydraulic model. In such phenomena both Froude number and Reynolds number play a role in their model simulation.

The method developed in this paper may also be useful in other hydraulic phenomena, in which both the Reynolds number and the Froude number play a role.

The reason to undertake this study was the present development of O.T.E.C. plants in the Hawaiian environment. In addition to the vast number of technological problems that have to be solved before O.T.E.C. plants can be operable and can deliver power to the network, the induced circulation and the effect of OTEC plants on the ocean environment have to be evaluated quantitatively. This is particularly important if one visualizes a large number of OTEC plants operating in the tropical oceans.

To the authors' opinion the environmental impact aspects of OTEC power plants have not been given adequate consideration in the research planning by the DOE and other agencies involved in OTEC developments.

Studies on environmental impact of these plants can be accomplished in three different ways:

- . by field studies on pilot plants
- . by laboratory investigations with hydraulic models
- . by mathematical modelling.

The question is often raised which of those methods would be preferable. In the authors' opinion all three are necessary in order to arrive at satisfactory and reliable answers.

Of these three methods a mathematical model is the most versatile tool. After the formulation of the model has been worked out and the algorithm has been developed, a large number of varying conditions can be investigated at a relatively low cost. There is no doubt that the mathematical model will be the ultimate method of analysis for the future. However such model utilizes physical concepts, parameters and constants, the values of which are only known for a limited degree of accuracy for a given situation. Of interest is the numerical model developed by Yamashita (Yamashita, 1979). This model has been developed for a shore-based OTEC plant at Keahole Point on the island of Hawaii, but can easily be extended into an offshore floating OTEC plant.

The answers that the mathematical model provides depend heavily on the numerical values of essential parameters and therefore verification is required. There is no doubt that the best way to verify the value

of physical constants is from the prototype. However, such verification requires a large number of points for the measurement of velocities, temperatures and salinities, both in the near field and in the far field.

Such program will be extremely costly, if at all feasible.

The scope of the field experiment can be strongly reduced if a combination of laboratory and field studies is employed to verify the physical constants. In the field, measurements can then be limited to observations in a number of strategically located points. The laboratory studies will provide the opportunity for taking a great number of detailed measurements in a controlled environment, whereby verification with the field conditions is possible from data obtained in corresponding points of prototype and model.

Having stated that hydraulic model experiments are an indispensable tool in the study of OTEC-related phenomena we will have to determine which scale relationships to apply to convert model data to prototype conditions. Before we discuss this matter in detail we will give a short description of the OTEC concept.

2. DESCRIPTION OF OTEC CONCEPT

Ocean Thermal Energy Conversion (OTEC) is presently one of the major development thrusts for energy extraction from the ocean. Other areas in which efforts may become fruitful are tides, currents, waves and salinity gradients.

In the OTEC concept the temperature difference between the warm surface water and the cold bottom water is utilized as a source of power generation.

The vast expanse of the oceans covers nearly three-quarters of the earth's surface and stores sufficient energy to fulfill the needs of everyone for many years to come (Richards and Vadus, 1980).

The study of OTEC-related problems in Hawaii has come to the forefront because Hawaii has been chosen for three major R&O OTEC research projects: the Mini-OTEC (50 kWe), OTEC-1 (1 MWe) and OTEC 10/40 MWe pilot plants.

Of these pilot projects the Mini-OTEC pilot project was in operation in Hawaiian waters during the summer and fall of 1979. It proved that the OTEC concept is workable.

Temperature, density and salinity profiles for offshore Hawaiian waters are summarized in Table 1. See also Bathen (1975).

Mini-OTEC was the world's first at-sea OTEC plant to produce net power.

Table 1. Density Profile (Offshore Hawaiian Waters)

Depth	Field Data		Computation with Constant Salinity (35‰)
	Temperature	Density	
0m	24.30°C	1.0236 (gm/liter)	1.0237
200	17.40	1.0254	1.0254
400	8.40	1.0267	1.0271
600	6.35	1.0270	1.0274

The system was developed by a private consortium of organizations including the University of Hawaii, Lockheed Missiles and Space Co., Oillingham Construction & Dredging Co., and Alfa-Laval.

An interesting feature of Mini-OTEC was that the cold water pipe (length 630m, diameter .6m and built of polyethelene), through which cold water is pumped from the deep to the plant, also serves as a part of a single mooring system.

As another step in the development, OTEC-1, a converted government-owned T-2 tanker, the Chepachet, will arrive at its test site off Keahole Point, westside of the island of Hawaii, in the summer of 1980.

The schematics of an OTEC seawater system is shown in Figure 1.

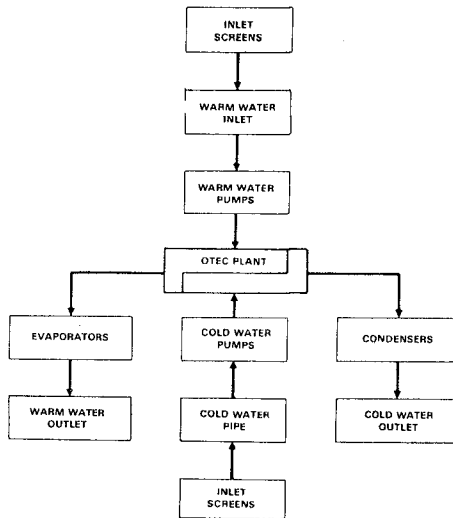

Figure 1. Schematics of OTEC Seawater System
(from Richards and Vadus, 1980)

Warm water of the surface layers of the ocean is used to evaporate a working fluid (ammonia) in an evaporator.

The vapor drives a turbogenerator, after which it passes through a condenser and a pressurizer. The condenser is cooled with the cold water pumped from the deep ocean layers.

The above-described system is the so-called closed cycle, which has been emphasized in ongoing research. Other cycles such as the open cycle, the hybrid cycle and the lift cycle offer other possibilities (Richards and Vadus, 1980).

When passing through the installation the warm water loses some of its heat, whereas the cold water gets warmer. Both are being discharged into the ambient ocean, either separately in two outlets or mixed in one discharge opening.

The location (depth) of the discharge jets is to be chosen in such a manner that no shortcuts in the circulation will develop; such short-cuts will necessarily lead to a reduction in the available potential.

The efficiency of an OTEC system is primarily determined by the difference in temperature between the warm and cold water. In Hawaiian waters this difference is about 20°C. The second law of thermodynamics specifies that the best efficiency of an OTEC system is of the order of 6%. If energy losses are taken into account (for pumping and other system components) the expected energy producing efficiency is 2-3%.

Despite the low efficiency the system may still be economically feasible, since no fuel is required for its operation.

Present research on OTEC systems is concentrated on the technological aspects of system components. Major problem areas are the bio-fouling of heat exchangers, and the design of the cold water pipe, and of the mooring system.

So far only little attention has been given to the aspects of induced ocean circulation and environmental impact, particularly if more than one plant will be built in a specified area. This area of study needs more attention in the near future. Laboratory studies can assist in providing the required information.

3. PHYSICAL MODELLING OF OTEC PLANTS

3.1. Objectives of Study

In the study of the functioning of OTEC plants by means of laboratory investigations (hydraulic models) two types of problems are particularly relevant:

problems concerned with the circulation near the plant (near-field) with the objective of determining the required distance between intake and discharge opening in order to avoid short

circuiting, having adverse effects on the available temperature potential.

problems of the flow field away from the plant (far-field) with the principal objective to determine the ocean area affected, and the required distance between plants if several plants are to be built in the same region.

Changes induced by the plants in the far field furthermore will be indicative of the effects, if any, on climatological conditions.

In order to achieve a reliable prediction from mathematical models it has been noted that the quantitative formulation of the phenomenon must be known. In the case of OTEC plants, it is the discharge flow, which manifests itself in the form of a turbulent jet, that is the main source of the flow phenomenon and its consequences.

At present the turbulent flow in general and the "free turbulence" (to which the jet flows belong) in particular have not yet been understood completely.

Consequently the mathematical formulation of the free turbulence is also far from being complete and thus reliable. This is especially so for the conditions presented by OTEC plants, where the fluid which constitutes the discharge flow has different temperature (and thus density and viscosity) in comparison to the ambient fluid and where the ambient fluid is not homogeneous (temperature decreases with the depth) and very often not even static (ocean currents). Considering this it will not be difficult to realize that mathematical modelling whose output accuracy is completely dependent on the knowledge and thus accuracy of the mathematical formulations forming the impact, cannot be regarded as more reliable than physical modelling which does not depend on the mathematical formulations, i.e. on the knowledge of the quantitative relations among the parameters involved but which is dependent only on the knowledge of the parameters themselves. Admittedly very often the knowledge of the parameters and thus of the criteria of similarity does also not mean that a reliable physical model can be immediately designed. Indeed, some criteria of similarity may turn out to be conflicting (and in the case of OTEC plants where both the densimetric Froude number (Fr) and the Reynolds number (Re) are involved this is just so), nonetheless to find a "way out" in such cases by means of a special research is considerably more feasible than the formulation of the free turbulence and its consequences for heterogeneous fluids; it should be sufficient to recall that the research on turbulence is being carried out since the beginning of the century and yet, with the exception of some very simple cases (parallel flows, rectilinear flow boundaries, homogeneous fluids, etc.), no generally accepted formulation of this elusive phenomenon has been found so far.

In view of the above it is not surprising that efforts dealing with the physical modelling of OTEC plants have been limited.

To the authors' opinion the work done by Jirka et al. (1977) has

been the only work of this kind, and in their view the approach used in their study is very innovative.

These authors have used an inverted model approach. The study was conducted at a scale 1:200, in which only the body of water above the thermocline was considered, giving the physical model a very shallow depth.

Results of their experiments agreed with those of a mathematical model. Because of the concerns expressed above there is no guarantee that the results also represent prototype conditions without further verification.

In the study by Jirka et al. (1977) the time averaged fields of temperature and velocities were measured and some pertinent aspects of these fields were determined.

In order to study the quantitative aspects of the phenomena in a physical model the authors believe that additional measurements are necessary.

It is recommended that the results of a small scale model (e.g. 1:50) be compared with the results of another, several times larger physical model (e.g. 1:10) and subsequently with the full scale (prototype).

The prototype in question could be the Mini-OTEC plant, when it will be back in operation for prototype testing, such as planned.

It is furthermore suggested to measure in the model the fields of some fluctuating properties of turbulence (viz of the root mean square values of the fluctuating velocities u' , v' and w' and also the Reynolds stresses $-\rho \overline{u'v'}$).

The overall picture of the phenomenon is characterized by its time average properties and therefore it is only reasonable to start the investigation of similarity by using the time average properties. It is perfectly possible that the rejection of the Reynolds criterion may not affect noticeably the similarity of the time average velocity fields in model and prototype but it may affect the similarity of the fluctuating velocities and thus the similarity of the internal structure of turbulence and its consequences (such as energy dissipation, diffusion, etc.).

3.2. Facilities For Proposed Research

Because of the large water depth involved model facilities need to be of large size in order to allow testing the phenomenon at a desirable scale.

Such facilities are limited on a worldwide basis. The new ocean tank of the Norwegian Hydrodynamic Laboratories in Trondheim, Norway (size 50 x 50 x 10m³) would be an excellent facility for such testing.

At the University of Hawaii's JKK Look Laboratory, the large steel circular model tank would be a suitable facility. The tank has an opening at the top and on the side.

The tank is 9.14m in diameter and 12.34m high. (See Figure 2.)

Figure 2. University of Hawaii's Large Circular Testing Tank

An analysis was made to determine if this tank could be made suitable for the testing of OTEC plants. The results were promising (Lee, 1978). Experiments can be carried out by using either the lower portion of the tank or by utilizing its full water depth.

The facility is considered suitable because it allows the simulation of ocean depths at a reasonable scale.

Heaters and coolers will have to be added for the establishment of a vertical temperature gradient in the tank and for the heating and cooling of the circulating fluid.

The circuits that provide the water circulation will be able to simulate the following conditions:

1. Skimming of "hot" water from the upper layers.
2. Discharging warm water at varying levels.
3. Pumping cold water from the deep portion of the tank.
4. Discharging cool water at varying levels.
5. Combining the warm water and cool water effluent into a single discharge arrangement at various levels. (Mini-OTEC arrangement)

4. THEORETICAL BASIS FOR MODEL SCALE DETERMINATION

From the pioneer work of Jirka et al., carried out in MIT in 1977, it is clear that the most relevant dimensionless variables determining the flow phenomenon around an OTEC plant are the densimetric Froude number Fr and the Reynolds number Re . If the geometry of the OTEC plant is specified then the velocity U which appears in both of these numbers can be any "typical velocity" of the system. If the undistorted model operates with the prototype fluid, that is with water having the same temperature, then, as is well known, a simultaneous fulfillment of both Froude and Reynolds criteria is impossible. Thus Jirka et al. made an attempt to achieve the dynamic similarity by identifying the model and prototype values of the Froude number only ($Fr'' = Fr'$), i.e. by identifying the scale of the Froude number with unity ($\lambda_{Fr} = 1$) and disregarding the Reynolds number completely (Re). This method of modelling is yet another example of the contemporary modelling convention, where a dimensionless variable, such as the Reynolds number, is rejected on the ground that its "influence on the phenomenon is negligible". This statement often is more a convenient justification of our conventional modelling methods than a reflection of truth. Indeed a physical phenomenon has an unlimited number of various properties which are different functions of the dimensionless variables defining that phenomenon. But if so then the influence of a certain variable, such as the Reynolds number, may indeed be irrelevant with regard to one set of the properties and yet it may turn out to be quite relevant with regard to another.

Notations.

For the analysis the following notations are utilized.

1. Model values are specified by ("), prototype values by (').
For example if α is a quantity to be studied then

α'' is the model value of α
 α' is the prototype value of α

and $\frac{\alpha''}{\alpha'} = \lambda_{\alpha}$ is the scale of α . (Yalin, 1971).

2. The ambient values (i.e. the values undisturbed by the OTEC plant) of any value of α is denoted by $\bar{\alpha}$. (See Figure 3.)

Figure 3. Schematics of OTEC Circulation and Ambient Ocean Conditions

Characteristic Parameters.

It is assumed that the model is undistorted and that it operates with the prototype fluid.

Since

$$\rho = f_1(T, S) \quad \text{and} \quad \mu = f_2(T, S) \quad (1)$$

the geometrically similar distribution of the ambient temperature and salinity in the model will yield the geometrically similar distributions of $\bar{\rho}''$ ($= \bar{\rho}'$) and $\bar{\mu}''$ ($= \bar{\mu}'$) [the same applies for ρ_0 and μ_0]. Accordingly, it is assumed, that the necessary distribution of the ambient temperature and thus of $\bar{\rho}''$ and $\bar{\mu}''$ is provided. Similarly, we assume that the model has the geometrically similar distribution of \bar{V}' (even if the scale λ_V' will be revealed later on).

If the ambient conditions are specified then the flow phenomenon in the region under investigation will be dependent only on the geometry of the plant and on the nature of its functioning, i.e. it will be dependent

- a) on the geometric parameters (lengths and angles) L_1, L_2, L_3, \dots
 $\theta_1, \theta_2, \dots$

- b) on the kinematic parameters (which in the steady state case under consideration are velocities only)
 $U_1, U_2, U_3, U_4, \dots$
- c) on the physical properties (ρ, μ) of "in" and "out" flows*
 $(\rho_1, \mu_1), (\rho_2, \mu_2), (\rho_3, \mu_3), \dots$

and

- d) on the acceleration due to gravity g .

Hence any quantitative property A of the present phenomenon must be expected to vary as a certain function of the position in space (x, y, z) and of the parameters above:

$$A = f_A(x, y, z, L_i, \theta_j, U_k, \rho_l, \mu_m)** \tag{2}$$

The subscript A in f_A indicates that the form of the function (2) depends on the quantity A under consideration: different properties A of a phenomenon are different functions of the same parameters (describing that phenomenon).

Let L, U, ρ, μ be some (single) parameters selected from the groups L_i, U_k, ρ_l, μ_m (as their "representatives"), e.g. one can identify L, U, ρ, μ with L_4, U_3, ρ_3, μ_3 respectively. In this case the (dimensional) relation (2) can be brought into the dimensionless form

$$\Pi_A = \phi_A \left[\frac{x}{L}, \frac{y}{L}, \frac{z}{L}, \frac{L_i}{L}, \frac{U_k}{U}, \frac{\rho_l}{\rho}, \frac{\mu_m}{\mu}, \frac{UL\rho}{\mu}, \frac{U}{\sqrt{gL}}, \theta_j \right] \tag{3}$$

Here Π_A is the "dimensionless version" of the property A under investigation

$$\Pi_A = \rho^\alpha L^\beta U^\gamma A \tag{4}$$

where depending on the dimension of A the exponents α, β, γ must be determined so that the power product (4) becomes dimensionless.

Dynamic Similarity, Model Scales

If all Π_A are identical in model and prototype, i.e. if

$$\Pi_A' = \Pi_A'' \quad \text{or} \quad \lambda_{\Pi_A} \equiv 1 \quad (\text{for any } A) \tag{5}$$

is valid then model and prototype are dynamically similar (and the predictions obtained from the model are reliable).

Since Π_A is given by the dimensionless variables shown in (3) the model and prototype identity of all Π_A [as implied by (5)] can certainly be achieved if the identify of all variables [on the right of (3)] is provided.

* T&S need not be included

** $i=1,2,\dots, N_L, j=1,2,\dots, N_\theta, \dots$ etc. where N_L, N_θ, \dots are the numbers of all the pertinent lengths, angles, ...etc.

Now, the identities

$$\left(\frac{L_i}{L}\right)' \equiv \left(\frac{L_i}{L}\right)'' \quad \text{and} \quad \theta_j' \equiv \theta_j'' \quad (6)$$

are provided: because model is geometrically similar.

The identities

$$\left(\frac{\rho_1}{\rho}\right)' \equiv \left(\frac{\rho_1}{\rho}\right)'' \quad \text{and} \quad \left(\frac{\mu_m}{\mu}\right)' \equiv \left(\frac{\mu_m}{\mu}\right)'' \quad (7)$$

are also provided, because model is supposed to operate with the prototype fluid and the similarity in the distribution of the ambient temperature and salinity is provided.

The identities

$$\left(\frac{x}{L}\right)' = \left(\frac{x}{L}\right)'', \quad \left(\frac{y}{L}\right)' = \left(\frac{y}{L}\right)'', \quad \left(\frac{z}{L}\right)' = \left(\frac{z}{L}\right)'' \quad (8)$$

are also valid, since the measurements and predictions will be carried out for corresponding points (of the space occupied by flow).

Since all velocities will be scaled down in the same proportion λ_U (whatever its value may be!) the identity

$$\left(\frac{U_k}{U}\right)' = \left(\frac{U_k}{U}\right)'' \quad (9)$$

is also satisfied. Thus the identity of all Π_A , i.e. the dynamic similarity depends entirely on the model and prototype identity of the Reynolds and Froude numbers

$$X = \frac{UL\rho}{\mu} \quad \text{and} \quad Y = \frac{U}{\sqrt{gL}} \quad (10)$$

At this state it should be mentioned that in the present phenomenon the free surface is not disturbed significantly and therefore the main role of the acceleration due to gravity g is not so much to reflect the influence of the free surface, but to reflect the influence of the gravity difference of the fluid layers having different densities. In other words the role of g consists of acting on various ρ_ℓ and generate various specific weights $g\rho_\ell$ and their differences such as

$$g\rho - g\rho_\ell = g(\rho - \rho_\ell) \quad (11)$$

Since g will thus appear in the expression of any Π_A in the form (11), one could consider the form (11) in the first place, i.e. one could take, say, $g(\rho - \rho_\ell)$, rather than simply g , (when writing d). In this physically more meaningful (and yet mathematically equivalent) approach we would have

$$Y_* = \frac{U}{\sqrt{gWL}} \quad (*) \quad (\text{with } W = 1 - \frac{\rho_1}{\rho}) \quad (12)$$

[rather than $Y = U/\sqrt{gL}$ in Eqs. (3) and (10)].

The mathematical equivalence with regard to model tests follows from the fact that

$$Y_* = Y \cdot (1 - \frac{\rho_1}{\rho})^{-\frac{1}{2}} \quad (13)$$

since in the present case the model and prototype values of ρ_1/ρ are identical. The model and prototype identity of Y -numbers implies automatically the model and prototype identity of Y_* -numbers and vice versa.

Hence in accordance with convention established in the field we replace consideration of (10) with that of

$$X = \frac{UL}{\nu} \quad Y_* = \frac{U}{\sqrt{gWL}} \quad (14)$$

As is well known the simultaneous identity of model and prototype values of X and Y_* (i.e. $\lambda_X = 1$ and $\lambda_{Y_*} = 1$) cannot be achieved (if the small scale model operates with the prototype fluid). Indeed

$$\lambda_X = 1 \quad \text{yields} \quad \lambda_U = \frac{1}{\lambda_L} \quad (15)$$

whereas

$$\lambda_{Y_*} = 1 \quad (\text{or } \lambda_Y = 1) \quad \text{gives} \quad \lambda_U = \sqrt{\lambda_L} \quad (16)$$

(e.g. if $\lambda_L = 1/16$ then Reynolds criterion requires $\lambda_U = 16$ whereas Froudian criterion demands $\lambda_U = 1/4$).

In the situations such as above the conventional approach is to ignore one of the criteria. Accordingly in the present field, one usually finds some justifications and states that "the influence of the Reynolds number X is negligible with regard to the present phenomenon and thus that it can be ignored". Accordingly, the condition $\lambda_X = 1$ and thus $\lambda_U = 1/\lambda_L$ are excluded and the flow velocities are scaled down according to $\lambda_Y = \lambda_{Y_*} = 1$, i.e. as $\lambda_U = \sqrt{\lambda_L}$. The weakness of this seemingly reasonable statement lies in the word "phenomenon", which is used as if it were a single entity. In fact, however, the term "phenomenon" stands for a multitude of the quantitative properties A

$$A_1, A_2, A_3, \dots, A_k, \dots \quad (17)$$

Indeed it is the sum total of these unlimited number of properties that constitute a physical phenomenon, e.g. A_1 may be the temperature at the space point m_1 , A_2 the temperature of a point m_2 , A_3 - root mean square value of the vertical component of the fluctuating velocity of turbulence at a point m_3 , A_4 the rate of energy dissipation at yet another location...etc. So, when saying that " X is unimportant"...which

* Referred to as "densimetric Froude Number"

property do we have in mind? A_1 or A_3 ...or which one?... Each of these properties A_n are different functions ϕ_{A_n} (of the same variables) and therefore some of them may vary indeed with X only in a feeble manner, but some others may vary with X strongly... It follows that the statement "X is unimportant" is rather sweeping and shallow. Being a different function of X , Y_* ,...etc. every property A has "its own degree of importance" with regard to the variables X , Y_* ...etc., the "measure" of the degree of importance of X , say, on any A_k can be reflected by the partial derivative of A_k with respect to X viz by

$$\frac{\partial A_k}{\partial X} \quad (18)$$

If $\frac{\partial A_k}{\partial X} \rightarrow 0$ then X can be neglected with respect to that A_k . If however $|\frac{\partial A_k}{\partial X}| \gg 0$ then the influence of X cannot be neglected (for that A_k).

Alternative Approach to Dynamic Similarity*

In the modelling of the present phenomenon all dimensionless variables, other than X and Y_* are identical in model and prototype. Thus any A_k can be regarded as a function of X and Y_* only:

$$\Pi_{A_k} = \phi_{A_k}(X, Y_*) \quad (19)$$

Consider the total differential $\delta \Pi_{A_k}$ implying the difference between the model and prototype values of Π_{A_k} :

$$\delta \Pi_{A_k} = \Pi_{A_k}'' - \Pi_{A_k}' = \Pi_{A_k}' (\lambda_{\Pi_{A_k}} - 1) \quad (20)$$

On the other hand

$$\delta \Pi_{A_k} = \frac{\partial \Pi_{A_k}}{\partial X} \cdot \delta X + \frac{\partial \Pi_{A_k}}{\partial Y_*} \cdot \delta Y_* \quad (21)$$

where

$$\begin{aligned} \delta X &= X'' - X' = X' (\lambda_X - 1) \\ \text{and} \quad \delta Y_* &= Y_*'' - Y_*' = Y_*' (\lambda_{Y_*} - 1) \end{aligned} \quad (22)$$

Hence

$$\Pi_{A_k}'' - \Pi_{A_k}' = \frac{\partial \Pi_{A_k}}{\partial X} X' (\lambda_X - 1) + \frac{\partial \Pi_{A_k}}{\partial Y_*} Y_*' (\lambda_{Y_*} - 1) \quad (23)$$

What is actually required is the identity of the model and prototype values of Π_{A_k} ; i.e. that $\Pi_{A_k}' \equiv \Pi_{A_k}''$ or that

* Outlined in the "invited opening lecture" by M.S. Yalin in the 15th International Congress of the IAHR-BadenBaden, Germany W., Aug. 1977

$$\Pi_{A_k}'' - \Pi_{A_k}' \equiv 0 \tag{24}$$

As seen from (23), the requirement (24) can be achieved if

$$\frac{\partial \Pi_{A_k}}{\partial X} \cdot X' (\lambda_X - 1) + \frac{\partial \Pi_{A_k}}{\partial Y_*} \cdot Y_*' (\lambda_{Y_*} - 1) = 0 \tag{25}$$

is provided.

Clearly if $\lambda_X = 1$ and $\lambda_{Y_*} = 1$ (i.e. if the model and prototype values of X and Y_* were identical) then (25) and thus (24) are satisfied and the dynamic similarity is achieved for any A_k . If, however, accordance with the usual practice $Y_*' = Y_*''$, i.e. $\lambda_{Y_*} = 1$ is provided but the equality of X numbers is ignored (i.e. if $X' \neq X''$ and $\lambda_X \neq 1$) then

$$\delta \Pi_{A_k} = \Pi_{A_k}'' - \Pi_{A_k}' = \frac{\partial \Pi_{A_k}}{\partial X} \cdot X' (\lambda_X - 1) \neq 0 \tag{26}$$

and

$$\Pi_{A_k}'' \neq \Pi_{A_k}' \tag{27}$$

In this case the dynamic similarity is violated, for the model and prototype values of Π_{A_k} are not identical and as seen from (26) the difference between Π_{A_k}'' and Π_{A_k}' (i.e. the error) increases in proportion to

$$\frac{\partial \Pi_{A_k}}{\partial X} \cdot X' \text{ and the deviation of } \lambda_X \text{ from unity.}$$

But why the requirement (24), reflecting the dynamic similarity of the property A_k , should necessarily be achieved by identifying one of the scales of the dimensionless variables (in our case λ_{Y_*}) with unity? If the purpose of the exercise is to fulfill the requirement (24) then this can be achieved by any pair $\lambda_{Y_*} = \alpha$ and $\lambda_X = \beta$ which constitute the solution of the equation (25):

$$\frac{\partial \Pi_{A_k}}{\partial X} X' (\beta - 1) + \frac{\partial \Pi_{A_k}}{\partial Y_*} Y_*' (\alpha - 1) = 0 \tag{28}$$

Clearly, in this case neither α nor β may be equal to unity ($\alpha \neq 1, \beta \neq 1$).

Denoting for brevity

$$\frac{\partial \Pi_{A_k}}{\partial X} = \Pi_X \text{ and } \frac{\partial \Pi_{A_k}}{\partial Y_*} = \Pi_Y \tag{29}$$

we determine from (28)

$$\frac{\beta - 1}{\alpha - 1} = \frac{\pi_y \cdot Y'}{\pi_x \cdot X'} \quad (30)$$

where X' and Y' are always positive ($X' > 0$, $Y' > 0$). It follows then

- (i) if π_y and π_x have different signs (i.e. if π_{A_k} is an increasing function of Y_x but is a decreasing function of X or vice versa) then $(\beta-1)$ and $(\alpha-1)$ have also different signs: i.e. one among α and β is larger than unity whereas another is smaller than unity, i.e.

$$\text{if } \pi_y = -\pi_x \text{ then } \left. \begin{array}{l} \text{either } \alpha > 1 \text{ while } \beta < 1 \\ \text{or } \alpha < 1 \text{ while } \beta > 1 \end{array} \right\} \quad (31)$$

- (ii) The Eq. (30) (which is in fact (28) and which thus implies (24) reflecting the similarity of the property A_k) does not have a unique solution. Indeed for the given values of π_x , π_y , X' and Y' and thus for the given value (C , say) of its right hand side, the Eq. (30) can be satisfied for an infinite number of pairs α and β :

$$\frac{\beta - 1}{\alpha - 1} = C \quad (32)$$

(as it is one equation for two unknowns). e.g. if $C = -2$ and thus (32) is

$$\frac{\beta - 1}{\alpha - 1} = -2$$

then any of the pairs:

$$\left. \begin{array}{l} \alpha_1 = 1/2, \beta_1 = 2 \\ \alpha_2 = 1/4, \beta_2 = 2.5 \\ \alpha_3 = 0.7, \beta_3 = 1.6 \\ \alpha_4 = 1.2, \beta_4 = 0.6 \dots \text{etc.} \end{array} \right\} \quad (33)$$

are the solutions [note, that since $C < 0$ (which means that $\pi_y = -\pi_x$), then when one of the scales (α & β) is larger than unity the other is smaller than unity, as predicted by (31)].

- (iii) Clearly the solution of (32) would be most elegant if α and β would deviate from unity as little as possible. This can be achieved with the aid of the straight-line diagram of α_j versus β_j e.g. the values (33), which correspond to $C = -2$, are forming the straight line shown in Figure 4. From this diagram it is clear that the solutions α_3 , β_3 and α_4 , β_4 should be regarded as more preferable than α_1 , β_1 and α_2 , β_2 .

Figure 4. Combinations of Model Scales

- (iv) The selection of scales can be based on the simultaneous consideration of several properties A_1, A_2, \dots, A_N . Consider e.g. only two A_1 and A_2 :

$$\frac{(\Pi_y)_1(Y')_1}{(\Pi_x)_1(X')_1} = C_1 \quad \text{and} \quad \frac{(\Pi_y)_2(Y')_2}{(\Pi_x)_2(X')_2} = C_2 \quad (34)$$

in this case

$$\frac{\beta - 1}{\alpha - 1} = C_1 \quad \frac{\beta - 1}{\alpha - 1} = C_2 \quad (35)$$

and we have two lines (intersecting at $\alpha=1; \beta=1$) which can be shown e.g. as in Figure 5

Figure 5. Intersecting Model Scales

As has been mentioned earlier each A_j requires "its own" scales α and β for its dynamically similar modelling. Hence A_1 and A_2 will require some pairs of α and β lying on their respective straight lines (C_1 and C_2 in the figure above). On the other hand if the

lines do not diverge from each other substantially and if the scales are selected in the neighborhood of the point $\alpha=1, \beta=1$ (shaded regions in figure above) then one can consider the α and β values of a point such as M somewhere in between. Admittedly, in this case neither A_1 nor A_2 will be rigorously reproduced. On the other hand the deviation from the rigor may be insignificant while the sacrifice of the rigor may be regarded as compensated by the advantage of studying both properties (A_1 & A_2) in the same model [or with regard to OTEC models "by the advantage of studying both A_1 and A_2 for the same model velocity u " (i.e. during the same run)"]

Clearly the idea above can be generalized to overall properties provided that their respective straight lines (e.g. C_1, C_2, C_3, C_4) do not diverge much from each other and/or the point M corresponding to common solution is reasonably close to the point $\alpha=1; \beta=1$

Figure 6. Intersecting Model Scales for Several Properties

- (v) All the considerations above rest on the assumption that the values of

$$X', Y', \frac{\partial \pi_{A_k}}{\partial X}, \frac{\partial \pi_{A_k}}{\partial Y}$$

corresponding to the property A_k are known (or estimated from some preliminary experiments) in the region X', Y' under investigation. If however this is not so then an "experimental model" should be adopted which is outlined in Figure 7.

1. Take prototype values X' and Y_{*}' and find the point M' (on the X, Y_{*} plane)
2. Let λ be the model scale. It is assumed that model is undistorted and that $\lambda_{\rho} = \lambda_{\mu} = 1$.
 - (i) if the model were Froudian: $\lambda_{Y_{*}} = 1 \rightarrow Y_{*}'' = Y_{*}'$ and $X'' \ll X'$ (point $M_{Y_{*}}$)
 - (ii) if it were a Reynolds model $\lambda_X = 1 \rightarrow X'' = X'$ and $Y_{*}'' \gg Y_{*}'$ (point M_X)

Figure 7. Graphical Presentation of Π_{A_k} as Function of X and Y_*

3. For a Froudian model $\lambda_u = \sqrt{\lambda}$ and thus $u'' = u'(\lambda)^{1/2}$
 For a Reynolds model $\lambda_u = \lambda^{-1}$ and thus $u'' = u'(\lambda)^{-1}$

i.e. the exponent ω of λ is distributed along the straight line interval $M_x M_y$ as in Figure 8

Figure 8. Variation of Exponent ω of λ

4. Now if $\frac{\partial \Pi_{A_k}}{\partial X}$ and $\frac{\partial \Pi_{A_k}}{\partial Y}$ have different signs, e.g. if Π_{A_k} increases with Y_* but decreases with X (which is likely to be the case) then

$$\overline{P_y M_y} > \overline{P' M'} \quad \text{while} \quad \overline{P_x M_x} < \overline{P' M'}$$

where $\overline{P' M'}$ signifies the prototype value $\Pi_{A'}$.

5. Now alter the model velocity u'' in the interval

$$(u' \lambda^{1/2}) < u'' < (u' \lambda^{-1}) \tag{36}$$

(and thus move along the straight line $\overline{M_x M_y}$) until such a point P_j is found where the ordinate $P_j P_j$, implying Π_A'' , becomes approximately equal to $P' M'$ implying (beforehand measured) prototype value Π_A' . Knowing thus "the solution point P_j " determine the corresponding exponent ω from Figure 8. The coordinates of P_j are model values X_j'' and Y_{*j}'' . Form the ratios X_j''/X' and Y_{*j}''/Y' ; these ratios are the scales β and α sought:

$$\alpha = \frac{Y_{*j}''}{Y'} \quad ; \quad \beta = \frac{X_j''}{X'} \quad (37)$$

5. CONCLUSIONS AND RECOMMENDATIONS

- 1) The potential effect of one or more large OTEC plants on the ocean environment requires further investigations.
- 2) In these investigations, field studies, laboratory investigations (physical modelling) and mathematical (numerical) modelling support each other and are all required to provide satisfactory answers.
- 3) In the physical modelling of OTEC plants special consideration has to be given to the similarity criteria to be used to convert model data to prototype values.
- 4) In the past the similarity criteria utilized can hardly be regarded as satisfactory. Since the simultaneous fulfillment of both Reynolds and Froude criteria is impossible (if the model is operated with prototype fluid), contemporary practice often uses one of these criteria as dominant, the other criterion being ignored. This practice may lead to erroneous results in model interpretation.
- 5) The present paper is intended as a step in improving the modelling technique. Rather than supposing that one of the parameters (e.g. the Reynolds number) is irrelevant and that similarity is based on the other parameter (the Froude number) a method is proposed in which the influence of both numbers is compromised.

MOORING FORCES INDUCED BY PASSING SHIPS

- MEASUREMENTS IN PROTOTYPE -

by

K. HAFFKE¹⁾

ABSTRACT

In the present study the mooring systems of four bulk carriers which were moored at a jetty located parallel to a navigable water were investigated with special regard to forces due to passing ships. The objective of this study was to verify in praxi the present knowledge of moored vessels berthed at more protected sites and to prove proposed models of forcing functions by passing ships as well as numerical models for the computation of ship mooring systems. For that purpose the mooring forces and also those data which characterized the properties of the mooring systems were recorded. On the basis of the also recorded wind and current data and the data of the passing ships with which the external forces could be estimated the mooring forces were computed. These computed forces are compared with the measured mooring forces.

1. INTRODUCTION

In recent years ship mooring problems arose at existing or projected berths located not only in exposed areas but also at comparatively protected sites. Among the more protected facilities also jetties rank which are located in close proximity and parallel to much frequented navigable waters (Laucht, 1976). For ships moored at these jetties in general not only forces due to wind and current and possibly due to waves have to be taken into account but also forces which are induced by passing ships. These forces can be of considerable significance when the passing distances of the ships are small or the velocities which are generally limited to a certain minimum to ensure sufficient manoeuvrability increase largely.

¹⁾ Research Assistant, Technische Universität Braunschweig, Federal Republic of Germany

The forces on moored ships due to wind and current can be estimated with sufficient accuracy, for instance with the data given by the Oil Companies International Marine Forum (1977) or by Remery and van Oortmerssen (1975), just as the behavior of moored ships in regular and irregular seas as well as in long waves (van Oortmerssen, 1976). Compared with this, the knowledge about those forces which are induced by passing ships is incomplete till now. One of the few theoretical works to this subject which provides more extensive results is that of Wang (1975), who replaces both vessels by idealised bodies with semicircular cross sections and a parabolic sectional-area distribution. Results of model investigations as well as of theoretical work are given by Remery (1974) and Muga and Fang (1975). Field investigations to this complex however are rare up to now. In 1972 measurements were carried out in Rotterdam at the Kalandkanal Quay by the Gemeendewerken Rotterdam and in 1976 the author performed measurements at the Kiel Canal (Haffke, 1976).

The behavior of moored ships can be described in general by a set of six simultaneous second order differential equations

$$\{M\} \{x\} + \{F_h\} + \{F_b\} + \{F_l\} + \{F_f\} + \{F_r\} = \{F_w\} + \{F_a\} + \{F_c\} + \{F_p\} \dots (1)$$

in which the mass forces $\{F_m\} = \{M\}\{x\}$, the hydrodynamic forces $\{F_h\}$, the hydrostatic forces $\{F_b\}$, the restoring forces due to the mooring and the fender system $\{F_l\}$ and $\{F_f\}$ and the fender friction forces $\{F_r\}$ face the external forces due to waves, wind, current and passing ships $\{F_w\}$, $\{F_a\}$, $\{F_c\}$ and $\{F_p\}$.

A comprehensive mathematical model of the non-linear oscillating system in which the hydrodynamic forces are frequency dependent functions of the accelerations and velocities in the six modes of motion was given by van Oortmerssen (1976) who investigated a moored ship in a quay-side position for various quai-distances and underkeel clearances due to wave excitation. In a similar manner Cuthbert and Seidl (1976) analysed the design layout of an offshore terminal mooring system. The time domain solution they used was, for the study of ship motions, originally formulated by Cummins (1962) and is based on the well known impulse response function technique.

Although a derivation of this technique is beyond the scope of this paper, some of the expressions may be given. Here for example the hydrodynamic force $F_{h,kj}$, the force in the k -th mode due to motion in the j -th mode

$$F_{h,kj} = m_{kj} \ddot{x}_j + \int_{-\infty}^t K_{kj} (t - \tau) \dot{x}_j(\tau) d\tau \quad \dots \dots \dots (2)$$

where: $K_{kj}(t) = \frac{2}{\pi} \int_0^{\infty} b_{kj}(\omega) \cos \omega t d\omega \quad \dots \dots \dots (3)$

with m_{kj} = a high frequency asymptotic value of the added mass

and b_{kj} = the frequency dependent damping coefficient

Substituting the hydrostatic forces as linear forces, equation (1) can be written

$$\sum_{j=1}^6 (M_{kj} + m_{kj}) \ddot{x}_j + c_{kj} \dot{x}_j + \int_{-\infty}^t K_{kj} (t - \tau) \dot{x}_j(\tau) d\tau + F_{1,k} + F_{f,k} + F_{r,k} = F_{w,k} + F_{a,k} + F_{c,k} + F_{p,k} \quad \dots \dots \dots (4)$$

$$k = 1, 2, \dots, 6$$

where the wave forces may also include drift forces. These equations can then be solved by a time stepping procedure. In those cases where the forces due to wind and current, which in a practical engineering approach can be considered as quasi-static forces, dominate or at locations where ship oscillations are not allowed a pure static analysis of the problem is sufficient.

The forces due to a passing ship are in general functions of the geometric properties of both ships and the waterway, the velocity and the distance of the passing ship and the properties of the fluid and may be

described as follows

$$\frac{1}{\rho (v - u)^2} \left\{ \frac{F_{p,1}}{B_1 T_1}, \frac{F_{p,2}}{L_1 T_1}, \frac{F_{p,3}}{L_1 B_1}, \frac{F_{p,4}}{L_1 T_1^2}, \frac{F_{p,5}}{L_1^2 B_1}, \frac{F_{p,6}}{L_1^2 T_1} \right\}$$

$$= \phi \left[\frac{B_1 T_1}{L_1^2}, \frac{B_1}{L_1}, r_1, \frac{L_2}{L_1}, \frac{B_2 T_2}{L_2^2}, \frac{B_2}{L_2}, r_2, \right.$$

$$\left. \frac{v}{v - u}, Fn, Rn, \frac{a}{B_1}, \frac{b}{L_1}, \frac{d}{L_1}, \frac{2c}{L_1 + L_2} \right] \dots \dots \dots (5)$$

where $F_{p,1}, F_{p,2} \dots F_{p,6}$ denote the forces and moments in the six modes of motion: surge, sway, heave, roll, pitch, yaw and L_1, B_1, T_1 and L_2, B_2, T_2 denote the length, the beam and the draught of the moored and the passing ship respectively. Further in this simplifying scheme the form parameter of both hulls are summarized by r_1 and r_2 , v denotes the velocity of the passing ship, u a characteristic current velocity in the navigable water, b the passing distance, c the distance of the transverse centerlines, a the distance from a vertical quay and d the water depth.

In nearly all practical cases the Froude numbers based on length of the passing ship are so small that the effect of the Kelvin-type wave pattern can be neglected and hence the influence of the Froude number too. A larger influence however is due to viscous effects especially cross-flow separation forces. Nevertheless approaches based on potential theory give good results when the geometric properties can be well approximated. Forces and moments i. e. their Euler numbers are therefore essentially functions of the geometric boundary conditions given by the ships and the navigable water. For engineering purposes simpler geometric models are possible.

For practical approaches the forces in surge, sway and yaw are the important ones. Due to the mostly large hydrostatic restoring forces and the small restoring forces of the mooring and the fender system in heave, roll and pitch the forces in these modes which are in a similar manner nearly even or odd functions of the normalized distance of the transverse centerlines of the ships can usually be ignored.

In the present study the mooring systems of four ships were investigated with special regard to forces induced by passing ships. The objective of this study was to verify and complete in praxi the present knowledge of moored vessels berthed at more protected sites and their mooring systems and to prove models of forcing functions by passing ships as well as numerical models for the computation of ship mooring systems.

2. FIELD INVESTIGATIONS

The investigations were performed at the "Asbestos Anleger" Nordenham, a jetty located in close proximity and parallel to the navigable water of the Weser near Bremerhaven (Figure 1). The structure has vertical quay walls and is equipped with mooring dolphins on both sides; the depth of the navigable water is SKN - 9,50 m. At this location forces due to passing ships, wind forces and distinct current forces have to be considered; due to the comparatively protected site wave forces have no influence.

Subject of the investigations were the mooring systems of four bulk carriers of conventional form and design which needed at this berth on an average six days to discharge their cargo (asbestos). The three ships of the first, the third and the fourth measuring period, the "Ouivendrecht", the "Deltadrecht" and the "Oordrecht" are sister ships with a loading capacity of 42 550 tdw (L = 187,00 m, B = 29,00 m, T = 11,90 m) the ship of the second measuring period, the "Scherpendrecht", has a loading capacity of 65 350 tdw (L = 224,00 m, B = 32,30 m, T = 13,60 m).

The ships were moored in the usual way with up to twenty mooring lines wire ropes with polyamid tails as well as fibre ropes, and in some cases the tension winch equipment was used. Figure 2 shows the bow mooring of the "Oordrecht" and Figure 3 the mooring at the stern.

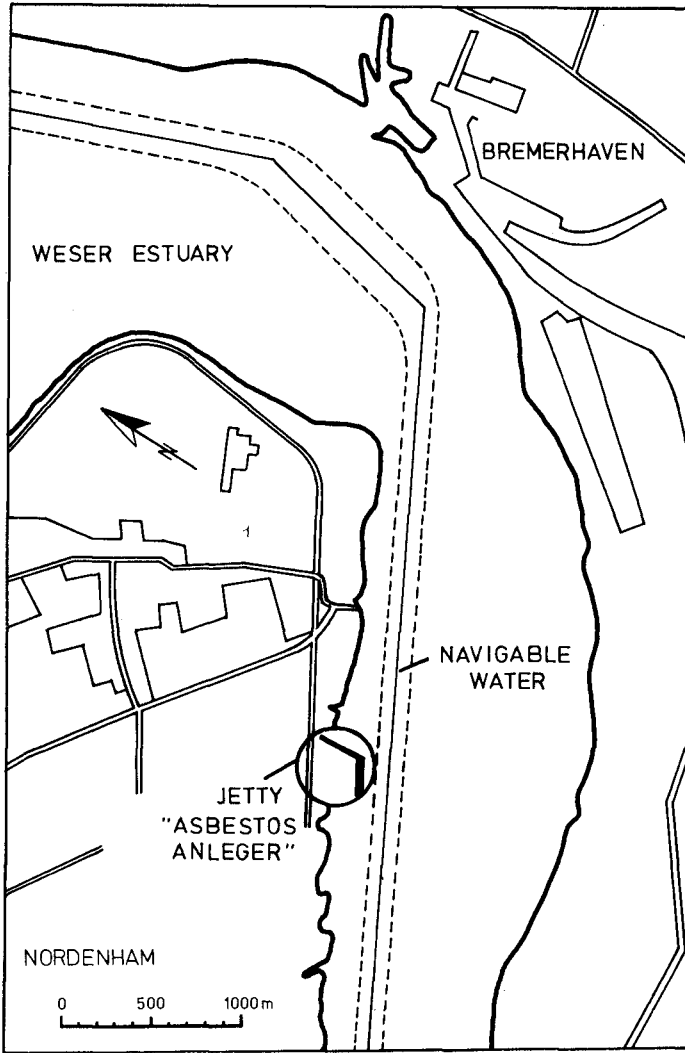

Fig. 1: Location of the "Asbestos Anleger"

Fig. 2: Bow mooring of the "Dordrecht" .

Fig. 3: "Dordrecht"-mooring at the stern

The mooring forces were measured by means of a special measuring equipment, strain gauge force transducers with a capacity of 750 kN which were connected to the mooring lines during the whole berthing time of each ship. In cases in which the number of mooring lines exceeded the number of transducers being available those lines were not connected which ran over mooring winches or which as reserve lines remained without effect. Consequently also in these cases, apart from some failures, the complete response of the mooring systems could be recorded since the forces adjusted at the tension winches were known. An example of a mooring line layout is given with Figure 4 with again the "Dordrecht". The mooring forces were recorded during the passage of ships just as in fixed intervals without a passing ship; in addition permanent measurements were performed in the first and in the second measuring period. For measurements only those passing ships were chosen by which larger forces could be expected. Velocity and distance of these ships whose main dimensions were known were recorded separately. Furthermore the geometric properties of the mooring systems, the draught of the moored ships and the waterlevel fluctuations were recorded as well as wind and current velocities at selected points. An example of a mooring force record is given in Figures 5 and 6.

In the first and second measuring period 56 passing ships were recorded, the number of ships recorded in the third and fourth measuring period was 51. The permanent measurements had a total length of 60 hours.

3. COMPUTATIONS

In the first stage of the study the described dynamic model was assigned for the computation of the mooring systems. In view of the relatively inaccurate hydrodynamic data being available for both ships however this model wasn't used since in all cases the oscillations of the ships and with that the mass and damping forces were negligible. Hence a static model was applied which includes also the reaction of tension winches, hydrostatic forces and fender friction forces which were approximated with a dynamical approach.

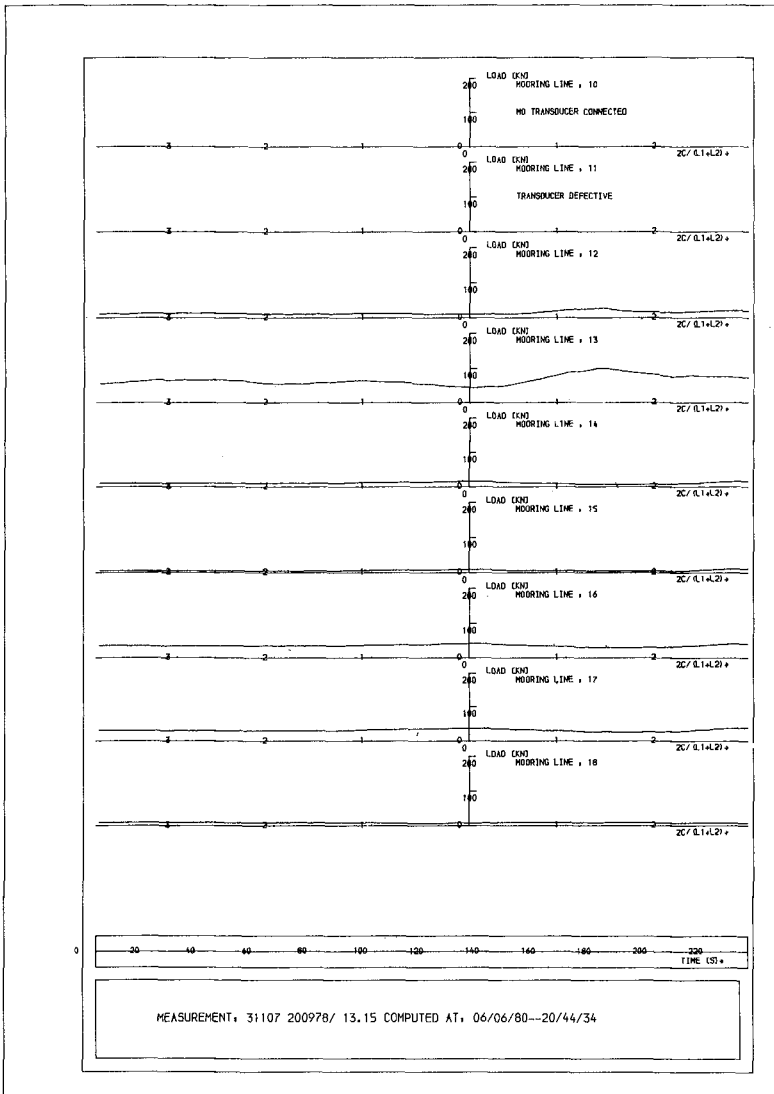

Fig. 6: Mooring forces - measurement No. 31107

For the determination of the forces due to passing ships only the data collection of Wang (1975) was used since these data provided the best approach with regard to the water depth - draught relation. In nearly all cases however it was also necessary here to extrapolate the data, since the given range of passing distances and water depths wasn't sufficient. The computations were performed for the overlapping position in which the force in sway reaches its maximum and the forces in surge and yaw become negligible. The wind and current forces were estimated with the data given by Remery and van Oortmerssen (1973).

The load-deflection curve of the installed tire fendering, a so called "Schweden Typ", which as well as the load-elongation characteristic of the mooring lines served as an input for the computations is shown in Figure 7. An other input of the computations was the initial static state of the mooring systems. This initial static state was estimated for each measuring period by some measurements at slack water and low wind velocities. Figure 8 and 12 give examples of such measurements.

4. RESULTS

As a result of the initial conditions, the fluctuating waterlevel and the varying draught and trim of the ships the pretension of the mooring systems differed widely between the measuring periods (see Figures 8 and 12) and within these periods between the various measurements too. In most cases the pretensions were moderate but in some however (periods 20, 21 and 22) they also reached considerable large values, corresponding to the magnitude of pretension fender friction forces gained importance.

During these measurements the spectrum of the passing ships was essentially determined by ships smaller than the moored ones; in most cases the velocities of the ships were in the upper part of the range characterising navigation in restricted waters. Due to the mostly large passing distances, which were not expected in this magnitude, however in most cases the response of the mooring systems was comparatively small.

Fig. 7: load-deflection characteristic of the installed tire fendering

In figures 9, 10, 11 and 13 the results of some measurements are compared with computed data. These figures show, representative of all investigations: 1. that the mooring forces due to wind and current action computed with the fore mentioned data agree pretty well with the measured forces and 2. that the computed response due to passing ships determined with the data given by Wang differ widely from the measured forces at which in most cases the computed forces exceed the measured ones. The good agreement between measured and computed forces in those cases in which only wind and current forces appeared is certainly the result of the only small external loads but also shows that the applied static model is quite useful in this special case. The large difference between the measured and computed response in measurements with passing ships however seems in the main to be the result of an inaccurate estimation of those forces which were induced by passing ships. Consequently these investigations with their restrictions by the given range of passing vessels, velocities and passing distances can not verify the used data given by Wang.

Moreover these investigations showed the difficulties involved in handling, measuring and computation of soft mooring systems which like here in most cases are used at more protected sites such as jetties located at navigable waters and harbors.

ACKNOWLEDGEMENTS

The present investigation was supported by the German Science Foundation. The author wishes to thank the Wasser- und Schifffahrtsamt Bremerhaven and the Asbestos Corporation GmbH, Nordenham for their generous aid during the field measurements.

Numerical Modelling of Nearshore Circulation

by

Bruce A. Ebersole¹ and Robert A. Dalrymple², M.ASCEINTRODUCTION

Waves impinging on beaches induce mean flows, such as longshore and rip currents. This nearshore circulation is of fundamental importance in the study of the transport of nearshore contaminants as well as littoral materials. Analytic models of this nearshore flow (see, e.g. 4, 9, 11, 12) have been constrained to be linear (in the governing equations) and simplistic in the bottom topography. Only recently have numerical models been developed to examine more complex situations. Steady state, finite difference models (1, 14), as well as a finite element model (10), have been proposed. The numerical model, developed by Birkemeier and Dalrymple (1), allowed for time dependency. Yet, in all of these cases, the governing equations have not included the nonlinear convective accelerations or lateral mixing terms.

In this study, a nonlinear numerical model is presented based on a leapfrog finite difference scheme, which includes time dependency and eddy viscosity terms. Results are shown for a planar beach showing a comparison with the analytical longshore current models (with and without lateral mixing) of Longuet-Higgins (11, 12). The longshore current over a prismatic beach profile including an offshore bar is presented next, showing the effects of the bar on the velocity profile. The circulation set-up by a rip channel inset into a plane beach is then computed. A comparison is made to the linear model of Birkemeier and Dalrymple. Finally the model is applied to the case of synchronous intersecting wave trains (4). An interesting result occurs when the waves are of different amplitudes, which could provide an explanation of the formation of finger bars on a beach.

GOVERNING EQUATIONS

The numerical model is formulated using the usual time-averaged (over one wave period) and depth-averaged conservation equations of mass and momentum, written in terms of the mean horizontal velocities (U , V) and the mean free surface displacement η . These are

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial}{\partial x}(UD) + \frac{\partial}{\partial y}(VD) = 0 \quad (1)$$

$$\frac{\partial}{\partial t}(UD) + \frac{\partial}{\partial x}(U^2D) + \frac{\partial}{\partial y}(UVD) = -gD \frac{\partial \bar{\eta}}{\partial x} - \frac{1}{\rho} \left[\tau_{bx} + \frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y} + D \frac{\partial \tau_l}{\partial y} \right] \quad (2)$$

¹U. S. Army Waterways Experiment Station, Vicksburg, MS.

²Associate Professor, Department of Civil Engineering, University of Delaware, Newark, DE.

$$\frac{\partial}{\partial t}(\text{VD}) + \frac{\partial}{\partial x}(\text{UVD}) + \frac{\partial}{\partial y}(\text{V}^2\text{D}) = -gD \frac{\partial \bar{\eta}}{\partial y} - \frac{1}{\rho} \left[\tau_{b_x} + \frac{\partial s_{xy}}{\partial x} + \frac{\partial s_{yy}}{\partial y} + D \frac{\partial \tau_{\ell}}{\partial x} \right] \quad (3)$$

where $D = h + \bar{\eta}$, the total depth, h is the local still water depth, τ_{b_x} and τ_{b_y} are the bottom frictions in the x and y directions, τ_{ℓ} is the lateral shear stress due to turbulent velocity fluctuations, and ρ is the water density. The radiation stress terms, introduced by Longuet-Higgins and Stewart (see 13, 15), are specified throughout the region of interest in terms of the local wave energy and direction, θ . This information is supplied independently using a coupled wave refraction procedure modified from Noda et al. (14), which includes wave-current interaction, and wave breaking (based on a breaking index model for wave heights within the surf zone).

The bottom shear stress in each direction is found by numerically integrating over a wave period the nonlinear stresses

$$\left. \begin{aligned} \tau_{b_x} &= \frac{1}{T} \int_0^T \frac{\rho f}{8} \left| \bar{U} + \bar{U}_w \right| (U + U_m \cos \theta \cos \sigma t) dt \\ \tau_{b_y} &= \frac{1}{T} \int_0^T \frac{\rho f}{8} \left| \bar{U} + \bar{U}_w \right| (V + U_m \sin \theta \cos \sigma t) dt \end{aligned} \right\} \quad (4)$$

where the vertical bars denote absolute value (to ensure that the shear stress acts counter to the total velocity vector $\bar{U} = (U, V)$) and $\bar{U}_w = (U_m \cos \theta \bar{i} + U_m \sin \theta \bar{j}) \cos \sigma t$, which is the wave orbital velocity vector at the bottom. Through experimentation, 16 terms in a Simpson's rule integration yielded bottom stress results with sufficient accuracy.

FINITE DIFFERENCE FORMULATION AND SOLUTION TECHNIQUE

In order to use a finite difference technique, the region of interest must first be discretized into a grid system as shown in Figure 1, with x positive offshore and y in the longshore direction. All the variables of interest except the velocities are defined at the center of each grid (the centers being separated by distances of Δx and Δy in the x and y directions). The horizontal velocities, on the other hand, are defined at the grid boundaries and are positive if they enter a grid in the positive coordinate direction.

To numerically solve the governing equations, they were approximated by their finite differenced forms. Following the methods of Lilly (8) and Blumberg (3), certain differencing and averaging operators are defined:

$$\delta_x [F(x, y, t)] = \frac{1}{\Delta x} \left[F\left(x + \frac{\Delta x}{2}, y, t\right) - F\left(x - \frac{\Delta x}{2}, y, t\right) \right] \quad (5)$$

$$\delta_x [F(x, y, t)]^x = \frac{1}{2\Delta x} [F(x + \Delta x, y, t) - F(x - \Delta x, y, t)] \quad (6)$$

¹ U_m given by linear wave theory.

Figure 1. Discretization of Nearshore Region and Detail of Grid.

$$\overline{F(x,y,t)}^x \equiv \frac{1}{2} \left[F\left(x + \frac{\Delta x}{2}, y, t\right) + F\left(x - \frac{\Delta x}{2}, y, t\right) \right] \quad (7)$$

$$\overline{F(x,y,t)}^{xy} \equiv \overline{\overline{F(x,y,t)}^x}^y \quad (8)$$

The first two operators are essentially central finite differences about the point (x,y) over one spacial grid step, or two. Equations (7) and (8) are horizontal spacial averages in the x direction first then in both the x and y directions. Note that $F(x,y,t)$ may be any function that varies in space and time and that similar operators exist for the variables y and t .

Using these operators the governing equations can be written in their differenced forms as,

$$\text{CONTINUITY: } \delta_t(\overline{\eta}^t) + \delta_x(\overline{D^x U}) + \delta_y(\overline{D^y V}) = 0 \quad (9)$$

$$\begin{aligned} \text{x-MOMENTUM: } \delta_t(\overline{D^x U}) + \delta_x(\overline{D^x U} \overline{U^x}) + \delta_y(\overline{D^y V} \overline{U^y}) = \\ - g \overline{D^x} \delta_x(\eta) - \frac{1}{\rho} \left\{ \overline{\tau_{bx}^x} + \delta_y(\overline{S_{xy}^{xy}}) + \delta_x(\overline{S_{xx}^{xx}}) \right\} \\ + \overline{D^x} \delta_y[\varepsilon_y \delta_y(U)] + \overline{D^x} \delta_y[\varepsilon_x^{xy} \delta_x(V)] \end{aligned} \quad (10)$$

$$\begin{aligned} \text{y-MOMENTUM: } \delta_t(\overline{D^y V}) + \delta_x(\overline{D^x U} \overline{V^y}) + \delta_y(\overline{D^y V} \overline{V^y}) = \\ - g \overline{D^y} \delta_y(\eta) - \frac{1}{\rho} \left\{ \overline{\tau_{by}^y} + \delta_y(\overline{S_{yy}^{yy}}) + \delta_x(\overline{S_{xy}^{xy}}) \right\} \\ + \overline{D^y} \delta_x[\varepsilon_y \delta_y(U)] + \overline{D^y} \delta_x[\varepsilon_x^{xy} \delta_x(V)] \end{aligned} \quad (11)$$

In converting these differenced equations into the i, j notation of Figure 1 it is important to note that the x, y coordinate is defined at the location where the variable of interest, to be solved for in a particular equation, is defined. For example, the x -momentum equation is used to solve for the horizontal velocity, U , so the x, y coordinate is defined to be at the grid edge where $U_{i,j}$ is defined. Also in the above equations the bottom friction and lateral mixing terms were lagged one step in time to increase the computational stability, (3) and (6).

Before the problem can be solved numerically, initial and boundary conditions must be specified. In all applications of the model the initial conditions were assumed to be the state of rest. The mean

velocity and mean free surface displacement fields were set to zero, a still water depth matrix was specified, and the wave characteristics were determined using the procedures of Noda *et al.* The boundary conditions are as follows: at the first dry grid row and at the offshore grid row, M, no flow conditions were imposed by setting the velocity components equal to zero. This choice of boundary condition essentially simulates a wall at the onshore and offshore extremities of the area of interest. The onshore condition provides that there is no flow into the beach while the offshore condition is valid if, as the model approaches a steady state, the circulation due to longshore and offshore flows is negligible at row M-1. In the y-direction periodic boundary conditions were invoked. Referring again to Figure 1 periodicity requires that, for a quantity Q,

$$\left. \begin{aligned} Q(i,1) &= Q(i,N) \\ Q(i,2) &= Q(i,N+1) \\ Q(i,3) &= Q(i,N+2) \end{aligned} \right\} \quad (12)$$

and so forth. Periodicity in the longshore direction was chosen because circulation patterns in nature are oftentimes periodic. Also if a particular stretch of beach, lacking periodicity, is being investigated, the boundaries in the model may be placed far enough away from this area of interest so that it does not affect the flow in this region, making the choice of periodic boundary conditions valid.

The differenced equations, (9) through (11), were derived using a central difference in time, for the time dependent terms, in which case they can be written as

$$\eta_{i,j}^{n+1} = \eta_{i,j}^{n-1} + 2\Delta t F_1^{n,n-1} \quad (13)$$

$$U_{i,j}^{n+1} = AU_{i,j}^{n-1} + 2\Delta t F_2^{n,n-1} \quad (14)$$

$$V_{i,j}^{n+1} = BV_{i,j}^{n-1} + 2\Delta t F_3^{n,n-1} \quad (15)$$

where A and B are functions of depth alone, F_1 , F_2 and F_3 are functions of all the variables in the problem, and $n+1$, $n-1$, and n denote time levels. These equations represent the leapfrog technique used to solve the problem in which updated values of η , U , and V are calculated using quantities defined at the previous two time levels. Everytime updated values of these three variables are computed, they are used to solve for the wave parameters at the same time level. In order to initiate the leapfrog scheme a forward difference in time using the initial conditions was implemented to establish variables defined at time levels 2 and 1. The leapfrog procedure was used for the duration of the computational steps. However, as the model approached a steady state, the solution diverged into two disjoint solutions, one following the even times steps and the other the odd. In order to correct this time-splitting problem, an Euler backward correction scheme (7) was used

every tenth iteration to "tie" the solutions back together. The following two equations describe the backward corrector,

$$h^* = h^{n-1} + 2\Delta t G \quad (16)$$

$$h^{n+1} = h^n + \Delta t G^* \quad (17)$$

Equation (16) is essentially any one of Equations (9) through (11) where "*" denotes the updated value of the variable of interest whether it be η , U or V . The function G is then computed using the new variable values and the new value at this time $n+1$, is computed. Equation (17) is a backward difference to the time step n from $n+1$. This correction scheme was chosen because it selectively damps the artificial computational mode of the solution, which can occur, while leaving the physical mode relatively unaffected. With the usage of this correction scheme the solution proceeded to reach a steady state with no further instability.

Due to the nonlinearities of the problem, an exact stability criterion for the choice of the time step, Δt , could not be established. Therefore, in applications of the model the time step was chosen to be significantly lower than the two-dimensional Courant stability criterion given by

$$\Delta t \leq \frac{\sqrt{(\Delta x)^2 + (\Delta y)^2}}{\sqrt{gh}_{\max}}$$

RESULTS

Prismatic Beaches--The model was first applied to the case of a single progressive wave train approaching a planar beach (slope of 0.025) at some angle to the beach normal. The following input data was used. The deep water wave characteristics were: (1) a period of 8.0 seconds; (2) an angle of 30.0 degrees; and (3) a height of 2.0 meters built up over 200 ($\Delta t = 0.5$ second) iterations to avoid "shock" loading the system. The region of interest was broken into a 6 x 30 grid mesh with spacings of 10.0 and 15.0 meters in the x and y directions, respectively. The bottom friction factor, f , was chosen to be 0.08 and the mixing coefficients N and ϵ_y were chosen to be 0.01 and 0.5 meters²/sec. The model was run for 1200 iterations which was nearly steady state.

The steady longshore current distributions both with and without mixing included are shown in Figure 2 along with the analytical results of Longuet-Higgins for the same input data. The major differences between the two profiles that exclude mixing are the sharpness of the discontinuity at the breaker line, and the difference in peak velocities. The numerical model shows less of a discontinuity in the breaker zone due to the fact that velocities just outside the surf zone are calculated using those from within the surf zone in the differenced form of the y-momentum equation, which results in a numerical "mixing". Also due to the use of a discrete grid size in the x-direction the exact location

Figure 2a. Analytical Models of Longshore Current, With and Without Mixing [Longuet-Higgins (11, 12)].

Figure 2b. Numerical Model Results for Longshore Current, With and Without Mixing.

of the breaker line is not adequately determined, resulting in a breaker line smoothing. As the grid size is decreased the location of the breaker line becomes better defined, making the discontinuity sharper as well as increasing the peak velocity. It must be noted that the peak velocities predicted by the model should not equal those resulting from Longuet-Higgins' theory due to the bottom friction formulation used in the model which was shown by Liu and Dalrymple (9) to decrease the analytical result by about 20% for the breaker angle and bottom slope found in this case.

In reality this strong discontinuity doesn't exist, and longshore current distributions tend to exhibit the properties shown by both the model and Longuet-Higgins results including mixing. These properties include: (1) a slight increase in velocities in the inner one-half of the surf zone; (2) a shift of the peak velocity from the breaker line shoreward; and (3) a slow decrease in the current to zero some distance beyond the breaker line.

Since in nature beach topographies often include longshore bars, the model was run on a bottom with an infinitely long longshore bar whose cross section is shown in Figure 3 in relation to a plane beach with slope 0.025. The remaining input into the model was identical to that used in the plane beach runs. The results for the model not including mixing are also shown in Figure 3. Notice the two distinct regions where a longshore current distribution exists. The velocity "spike" offshore is due to the waves breaking on the bar. As the wave height decreases, as a result of breaking, an onshore-offshore gradient of y-momentum flux is created which drives a longshore current. In the trough, however, the wave height starts to reform (no more breaking) resulting in the absence of a longshore current in this region. In reality a longshore current does exist in the trough, Allender et al. (1), due to the mechanisms of turbulent dissipation during breaking within a bore, lateral mixing which has been included in the model, and a set-up of water within the trough, Dalrymple (5). Figure 3b shows the velocity profile for the run including mixing. Note the reduction in current amplitude of the offshore "spike" and the smoothing of discontinuities resulting in the existence of a longshore current in the bar trough. Had the turbulent energy dissipation mechanism been included in the model the results would probably have approached those found in nature.

Periodic Bottom Topography Application--The model was next applied to the periodic bottom topography developed by Noda et al. (14) which is essentially a channel at some angle to the beach normal. The formulation for this bottom configuration is given in Appendix A. The model, including the effects of mixing, was compared to the linear model of Birkemeier and Dalrymple. The following wave characteristics were used in both instances: (1) deep water wave height of 1.0 meters; (2) wave period of 4.0 seconds; and (3) a deep water wave angle of 30.0 degrees to the beach normal. The bottom friction factor, f , was chosen to be 0.08, and the mixing coefficients, N and ϵ_y , were chosen to be 0.005 and 0.5 meters²/sec., respectively. In both runs the wave height was built up to its deep water value over 100 seconds.

Figure 3a. Beach Profile for Planar and Barred Beach.

Figure 3b. Longshore Current Profiles on Barred Beaches, With and Without Mixing.

Both models were run until they reached approximately a steady state, about 500 seconds. The wave-current interaction process was halted in the linear model after 150 seconds because the offshore velocity components grew too large for the refraction routines to handle (i.e. wave breaking occurred in the rip channel). In the nonlinear model, however, the wave-current interaction process was included for the duration of the run time. The circulation patterns after 500 seconds are shown in Figure 4 and 5.

Note the strength of the rip and its offshore extent in the linear model compared to the nonlinear model. The peak velocity in the linear model run is about 3.0 meters per second whereas in the nonlinear model it is about 0.8 meters per second. This large discrepancy is due to the inclusion of mixing in the nonlinear model. The mixing tends to spread the rip out and decrease its offshore velocity components thus causing the rip to turn more in the longshore direction as shown in Figure 5. The effects of the convective acceleration terms are not clearly visible because it seems as though the form of the rip itself is governed primarily by horizontal mixing in this case. It is reasonable to expect, however, that in nature the lateral mixing in the rip current is far less than used here.

Synchronous Intersecting Waves--The final application of the model was to the case of intersecting wave trains of a common frequency on a plane beach which Dalrymple (4) showed could generate rip currents. The purpose here was to show the effect of the convective acceleration terms in the model. Certain changes were made to the model, namely: (1) the refraction routines of Noda *et al.* were replaced with those using Snells' law without wave-current interaction; (2) lateral mixing was excluded; (3) the "exact" bottom friction formulation was made to include two waves; (4) the radiation stresses due to both intersecting wave trains were calculated analytically for use in the momentum equations.

The waves were of equal heights (0.25 meters) and of equal deep water angles on either side of the beach normal (30.0 degrees). The period was chosen to be 7.1594 seconds which resulted in periodic rip currents with a spacing of 80.0 meters. The plane beach (slope 0.025) was broken into a platform area of 25 grids in the x-direction with a Δx spacing of 5.0 meters, and 21 grids in the y-direction with a Δy spacing of 4.0 meters. The time step was chosen to be 0.2 seconds and the wave was built up for 500 of the 1500 iterations run. The friction factor, f , was selected as 0.12 to allow the system to reach steady state faster and to decrease the magnitude of the resultant currents.

The total free surface described by these two wave trains is in essence a normally incident wave with a periodically modulated height. This is the driving mechanism which produces the rip currents shown in Figure 6. Note the constricted width of the rip current in relation to the width of the inflow region. This is a result of the convective acceleration terms. Also note the weak rip head where the currents diverge from the rip axis and return towards shore.

When one wave is of greater height than the other, all other variables remain the same, then a longshore current is superimposed over the cellular circulation, Figure 7.

CONCLUSIONS

A model that can accurately predict currents and wave transformations in the nearshore zone is a necessary step in attempting to predict actual changes to our coastlines. From the results shown here it appears that the inclusion of the convective acceleration terms and lateral mixing terms in the horizontal momentum equations have important effects which must be included in models used to predict nearshore circulation. The terms become especially significant in attempts to model circulation over irregular bottom topographies which include bars and channels.

APPENDIX A - PERIODIC BOTTOM TOPOGRAPHY

The periodic bottom profile used in the model was developed by Noda et al. (14). The depths are given by

$$h = mx \left\{ 1 + A \exp \left[-3 \left(\frac{x}{20} \right)^{1/3} \right] \sin^{10} \frac{\pi}{\lambda} (y - x \tan \beta) \right\}$$

where m = beach slope = .025.

x, y are the coordinates of the depth location.

λ = length of periodic beach = 80 meters.

A = amplitude of bottom variation = 20.

β = angle of rip channel to beach normal = 30 degrees.

The grid spacing was chosen to be 5.0 and 4.0 meters in the x and y directions, respectively. There were 25 and 21 grids in the x and y directions. The last grid row and the "dry" grid rows were made planar with the slope being .025.

CHAPTER 164

MODELLING OF PLANFORM INFLUENCE ON CIRCULATION IN HARBOURS

by

ROGER A. FALCONER*

ABSTRACT

A two dimensional numerical model has been developed which is capable of predicting the tidal water elevations, depth averaged velocity components and horizontal concentration distributions in narrow entranced harbours and marinas. Particular attention has been paid to the numerical treatment of the convective accelerations where, as a result of narrow harbour entrances and the general nature of planform geometries, the resulting highly non-uniform flow fields can readily lead to non-linear instabilities and unstable numerical solutions.

In order to check the validity of the numerical results, a comprehensive study was carried out to compare, with scaled laboratory model studies, the predicted tidal velocity fields and flushing characteristics for a number of rectangular harbours of constant planform area but different length to breadth ratios. The experimentally measured average per cycle exchange coefficients and the observed mean water level pathlines agreed reasonably well with the corresponding numerically predicted exchange coefficients and depth averaged velocity fields.

The results of both the numerical and laboratory model studies confirmed conclusively that the maximum gross flushing characteristics occurred within a rectangular harbour when the length to breadth ratio was close to unity. Also, further tests showed that the insertion of impermeable barriers as a possible means of increasing the flushing efficiency proved to be unsatisfactory.

INTRODUCTION

In the past, harbours and marinas of various shapes and sizes have often been known to possess poor water quality characteristics, caused chiefly by internal stagnant regions known to dominate within the harbour. Historically though, the quality of water within harbours and marinas has been assumed, in part, to be dependent upon the basin's flushing rates and human activity on or adjacent to the basin. The natural engineering solution to this water quality problem is either to design the harbour initially such that the planform geometry produces a maximum flushing efficiency or, if the harbour has already been constructed, to alter the planform geometry favourably by modifying the boundary shape or inserting shear walls where appropriate.

Although a number of laboratory model studies have been carried

out for particular harbours and marinas (e.g. Nece and Richey (1,2)), where the main objective has been to determine the ideal boundary shape tending to produce a maximum overall flushing efficiency in the model, little use of numerical models appears to have been made in this type of analysis. This is possibly due to the generally complex nature of the velocity fields resulting from narrow entrances associated with harbours and marinas. The complexity of the velocity fields occurs in the form of separation streamlines around harbour entrances, and the resulting non-uniform properties of the flow, particularly on the incoming tide. This paper describes such a numerical model which has been specifically developed to predict the depth averaged velocities and concentrations in narrow entranced harbours and marinas.

The time dependent equations of mass, momentum and solute transport have been expressed in a two time level alternating direction implicit finite difference form, with the effects of bottom roughness and turbulent momentum transfer being included. The stability problems generally associated with the non-linear convective accelerative terms, particularly for the type of velocity fields being considered, have been overcome by time centring these terms with respect to the remaining velocity derivatives (3). The apparent favourable numerical properties of this difference scheme have been partially confirmed by applying the Fourier series stability method to a quasi-linearised one-dimensional form of the appropriate equations (4).

The numerical model has been applied to an idealised prototype rectangular harbour with an asymmetric entrance, a constant planform area and varying length to breadth ratios. The geometric dimensions of this harbour, together with the mean depth and tidal wave properties, were assumed to be similar to many existing and proposed basins in Puget Sound of the State of Washington. The resulting depth averaged velocity fields and mean concentration distributions, determined for each length to breadth ratio, were then compared to the corresponding observed path-lines and measured exchange coefficients for two independent hydraulic model studies (5,6). Also numerical and laboratory model tests and comparisons were carried out to determine the influence on the flushing efficiency of the insertion of impermeable barriers at selected locations within the harbour geometries considered.

GOVERNING DIFFERENTIAL EQUATIONS

The appropriate two-dimensional differential equations governing the tide induced fluid and concentration movements within harbours and marinas can be derived by integrating, over the depth, the standard equations of continuity, momentum and mass transport. For an incompressible turbulent fluid on a rotating earth, the depth averaged equations of horizontal motion can be expressed in Cartesian co-ordinate form as:

$$\frac{\partial U}{\partial t} + \frac{\alpha}{(h+\eta)} \left[\frac{\partial U^2(h+\eta)}{\partial x} + \frac{\partial UV(h+\eta)}{\partial y} \right] - fV + g \frac{\partial \eta}{\partial x} + \frac{gU\sqrt{U^2 + V^2}}{(h+\eta)C^2} - \epsilon \left[\frac{\partial^2 U}{\partial x^2} + \frac{\partial^2 U}{\partial y^2} \right] = 0 \quad \dots\dots\dots (1)$$

$$\frac{\partial V}{\partial t} + \frac{\alpha}{(h+\eta)} \left[\frac{\partial VU(h+\eta)}{\partial x} + \frac{\partial V^2(h+\eta)}{\partial y} \right] + fU + g \frac{\partial \eta}{\partial y} + \frac{gV \sqrt{U^2 + V^2}}{(h+\eta)C^2} - \epsilon \left[\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} \right] = 0 \quad \dots\dots\dots (2)$$

where U, V = depth average velocities in x, y directions respectively, α = velocity correction factor = 1.016 for seventh power law velocity distribution, h = mean depth, η = water surface elevation above or below mean depth, f = Coriolis parameter, g = gravitational acceleration, C = Chezy roughness coefficient and ϵ = depth mean eddy viscosity = $1.154 g(h+\eta) \sqrt{U^2 + V^2}/C^2$ for seventh power law velocity distribution. Similarly, the equations of continuity and mass transport can be written as, respectively:

$$\frac{\partial \eta}{\partial t} + \frac{\partial U(h+\eta)}{\partial x} + \frac{\partial V(h+\eta)}{\partial y} = 0 \quad \dots\dots\dots (3)$$

$$\frac{\partial S(h+\eta)}{\partial t} + \frac{\partial S(h+\eta)}{\partial x} + \frac{\partial S(h+\eta)}{\partial y} = \frac{\partial}{\partial x} \left[D_x(h+\eta) \frac{\partial S}{\partial x} \right] + \frac{\partial}{\partial y} \left[D_y(h+\eta) \frac{\partial S}{\partial y} \right] \quad \dots\dots\dots (4)$$

in which S = depth mean mass concentration and D_x, D_y = depth mean dispersion coefficients where, from Elder (7), it is assumed that $D_x = (5.93|U| + 0.23|V|) \sqrt{g(h+\eta)}/C$, and similarly for D_y where the U and V velocities are interchanged.

In addition to these differential equations, various boundary conditions had to be included in the numerical model. For the closed boundaries it was assumed that the normal velocity components and the advective and diffusive transport of concentrations were all zero. Likewise, for the open boundary conditions, it was assumed that the incoming tidal wave was sinusoidal in form, whereby:

$$\eta = a \cos(\omega t + \theta) \quad \dots\dots\dots (5)$$

with a = wave amplitude, ω = wave frequency, t = time and θ = phase lag; and that the velocity components at the harbour entrance, were given by the simplified form of the continuity equation:

$$U = A \frac{d\eta}{dt} / W(h+\eta) \quad \dots\dots\dots (6)$$

where A = harbour planform area and W = harbour entrance width. For the concentration values at the harbour entrance, these were assumed to be the same as those for the open sea on the incoming tide, whilst on the outgoing tide values were determined from those predicted within the harbour by linear interpolation.

FINITE DIFFERENCE EQUATIONS

The differential equations (1) - (4) were expressed in an alternating direction implicit finite difference form, with all terms being fully centred in both space and time, except for the pressure gradients in the momentum equations. Using the space staggered grid scheme shown in Fig. 1, then for the first half time-step η , U and S were implicitly solved for using the following finite difference forms of the continuity, x-direction momentum and mass transport equations respectively:

$$\eta_{j,k}^{n+\frac{1}{2}} = \eta_{j,k}^n - \frac{\Delta t}{2\Delta x} \left[(h+n)U \left|_{j+\frac{1}{2},k}^{n+\frac{1}{2}} - (h+n)U \left|_{j-\frac{1}{2},k}^{n+\frac{1}{2}} + (h+n)V \left|_{j,k+\frac{1}{2}}^{n-1} - (h+n)V \left|_{j,k-\frac{1}{2}}^{n-1} \right. \right] \dots\dots\dots (7)$$

$$U_{j+\frac{1}{2},k}^{n+\frac{1}{2}} = U_{j+\frac{1}{2},k}^{n-3/2} - \frac{2\alpha\Delta t}{\Delta x} \left[U^2 \left|_{j+1,k}^{n-\frac{1}{2}} - U^2 \left|_{j,k}^{n-\frac{1}{2}} + UV \left|_{j+\frac{1}{2},k+\frac{1}{2}}^{n-\frac{1}{2}} - UV \left|_{j+\frac{1}{2},k-\frac{1}{2}}^{n-\frac{1}{2}} \right. \right] - \frac{2\Delta t g}{\Delta x} \left(\eta_{j+1,k}^{n+\frac{1}{2}} - \eta_{j,k}^{n+\frac{1}{2}} \right) - \frac{\Delta t g (U^{n+\frac{1}{2}} + U^{n+3/2}) \sqrt{U^2 + V^2}}{(h+n)C^2} \left|_{j+\frac{1}{2},k}^{n-\frac{1}{2}} + \frac{2\epsilon\Delta t}{\Delta x^2} \left[U_{j+3/2,k}^{n-\frac{1}{2}} + U_{j+\frac{1}{2},k+\frac{1}{2}}^{n-\frac{1}{2}} - 2 \left(U_{j+\frac{1}{2},k}^{n+\frac{1}{2}} + U_{j+\frac{1}{2},k}^{n-3/2} \right) + U_{j+\frac{1}{2},k-\frac{1}{2}}^{n-\frac{1}{2}} + U_{j-\frac{1}{2},k}^{n-\frac{1}{2}} \right] \dots\dots\dots (8)$$

$$[S(h+n)]_{j,k}^{n+\frac{1}{2}} = [S(h+n)]_{j,k}^n - \frac{\Delta t}{2\Delta x} \left[S(h+n)U \left|_{j+\frac{1}{2},k}^{n+\frac{1}{2}} - S(h+n)U \left|_{j-\frac{1}{2},k}^{n+\frac{1}{2}} + S(h+n)V \left|_{j,k+\frac{1}{2}}^n - S(h+n)V \left|_{j,k-\frac{1}{2}}^n \right. \right] - \frac{\Delta t}{2\Delta x^2} \left[(S_{j+1,k} - S_{j,k})(h+n)D_x \left|_{j+\frac{1}{2},k}^{n+\frac{1}{2}} - (S_{j,k} - S_{j-1,k})(h+n)D_x \left|_{j-\frac{1}{2},k}^{n+\frac{1}{2}} + (S_{j,k+1} - S_{j,k})(h+n)D_y \left|_{j,k+\frac{1}{2}}^n - (S_{j,k} - S_{j,k-1})(h+n)D_y \left|_{j,k-\frac{1}{2}}^n \right. \right] \dots\dots\dots (9)$$

where j,k = finite difference grid co-ordinates in x,y directions respectively, and n = time-step level. For the second half time-step, from level $n+\frac{1}{2}$ to $n+1$, similar equations were formulated with η,V and S written and solved for in an implicit form, whilst terms involving U

were expressed explicitly.

This finite difference representation of the original differential equations has a truncation error of order $\Delta t, \Delta x^2$ and with the only stability constraint being introduced by the convective accelerative terms (4) as:

$$\frac{\alpha \Delta t}{\Delta x} |u_{\max}| \leq 1 \quad \dots\dots\dots (10)$$

For the type of velocity fields being considered, where the maximum velocity u_{\max} is relatively small, this stability constraint poses little restriction on the numerical model, particularly in comparison to the accuracy requirements suggested by Vreugdenhil and Voogt (8) as:

$$\frac{\Delta t}{\Delta x} \sqrt{gh} \leq 5 \quad \dots\dots\dots (11)$$

The finite difference equations were solved using the method of Gaussian elimination and back substitution and were found to give numerically stable results for all harbour configurations considered.

APPLICATION OF MODEL

In an attempt to check the reliability of the numerical model, comparisons were made with the results obtained from two laboratory model studies (5,6), carried out prior to the final development of the numerical model. In both of these experimental studies the main objectives were to compare the flushing characteristics and velocity fields for a number of different model rectangular harbour shapes. Each harbour shape had a different length to breadth ratio, but in all cases the harbour planform area remained constant. By comparing the flushing characteristics for the different shapes, it was possible to conclude which shape induced the maximum tidal flushing efficiency and hence, in general, resulted in the best overall water quality characteristics. Tests were also carried out to study the effects of inserting impermeable barriers at various locations within the different harbours, to investigate whether or not the flushing characteristics could be improved by altering the planform geometry accordingly.

The laboratory studies were treated as model studies of idealized harbour shapes, typical of many existing and proposed harbours and marinas in Puget Sound of the State of Washington. In the latter of the two laboratory studies in particular, where the experimental results were more directly comparable with the numerical model results, the prototype harbour was assumed to have a planform area of $4.0 \times 10^5 \text{ m}^2$, a mean depth of 6.0 m an asymmetric entrance of width 128.0 m. Also the prototype semi-diurnal tides, of period 12.4 hr., were assumed to be sinusoidal with an amplitude of 1.5 m. In the laboratory model the horizontal and vertical length scales were 1:1000 and 1:50 respectively, giving a vertical distortion of 20:1, with a Froude law scaling relationship being used to model the tidal period. The resulting physical model had a planform area of 0.4 m^2 , a mean depth of 120 mm, an entrance width

of 128 mm, a wave amplitude of 20 mm and a period of 10.52 min, see Fig. 2. The variable length to breadth ratios (L/B) considered ranged from 0.33 to 3.00, where the length L was defined as the harbour width in the plane of the entrance and the breadth B as the width perpendicular to the entrance plane.

Although vertically distorted hydraulic models do not properly scale diffusion and dispersion processes (9), the assumption was made that the dominant mode of water exchange was by convective, rather than diffusive or dispersive, transport. This allowed tracer dyes to be used in the model and for this purpose rhodamine B was used.

For the laboratory tests the harbour model, with adjustable side-walls, was inserted into a tidal tank in which an oscillating weir reproduced the required model tides (Fig. 2). With the harbour sidewalls set at the required length to breadth ratio, the tank and harbour were filled to the low tide water level and the harbour entrance temporarily sealed. Using a hypodermic syringe, 75 ml of rhodamine B (concentration 7.5 mg/l) was then thoroughly mixed with the harbour water and the average initial concentration recorded using a fluorimeter. The temporary entrance barrier was then removed and the tidal generator run for a period of three complete tidal cycles, at the end of which the harbour entrance was re-sealed. The fluid enclosed within the harbour was again thoroughly mixed and the average final concentration recorded as before. Knowing both the initial and final spatially averaged concentrations within the harbour, and the number of tidal cycles, then the average per cycle exchange coefficient was determined from the relationship given by Nece and Richey (2):

$$E = 1 - (C_i/C_0)^{1/i} \quad \dots\dots\dots (12)$$

where E = average per cycle exchange coefficient, C_0 = initial concentration and C_i = final concentration after i tidal cycles. The experimentally measured exchange coefficients for the various L/B ratios considered are given in Fig. 3, where it can be seen that the maximum value, resulting in the maximum flushing efficiency, occurs for an L/B ratio of unity i.e. a square harbour.

After measuring the exchange coefficient for each L/B ratio, the tide induced circulation patterns were determined using weighted drinking straws as drogues. The tidal generator was first run for two complete tidal cycles and on the third cycle the drogues were carefully inserted at fixed points, one minute before the flood and ebb mean tide water levels, and were then tracked for two minutes. The resulting pathlines were plotted to scale giving an indication of the corresponding velocity fields. Two sample results are shown for L/B ratios of 1.0 and 1.8 respectively, see Figs. 4 and 5.

In a similar procedure to that adopted for the laboratory model studies, the numerical model was applied to the prototype harbour with the planform area, mean depth and entrance width being as before, i.e. $4.0 \times 10^5 \text{ m}^2$, 6.0 m and 128.0 m respectively. Likewise the semi-diurnal sinusoidal tides had a period of 12.4 hr and an amplitude of 1.5 m. The model was started from the low water level, with an initial state of

rest being assumed within the harbour. Also at the start of the model, the initial concentration (C_0) at each grid point within the domain was assumed to be 50 ppm. As for laboratory model studies, varying L/B ratios were considered ranging from 0.25 to 4.0; the range of values being larger in this study since no restraints were imposed by physical space requirements.

For all the L/B ratios considered the numerical model was run for three tidal cycles with the spatially averaged concentration (C_i) being calculated at the end of this period. As for the experimental results, the average per cycle exchange coefficient was evaluated using Eq. (12), with the results being given in Fig. 3. The agreement between the numerical and experimental results is encouraging, with the general trends of the relationship between the exchange coefficient and the L/B ratio being almost identical. In both cases the maximum exchange coefficient occurs for a square harbour, indicating as before that this shape induces the best flushing characteristics.

Graphical representations of the numerically predicted velocity fields were reproduced at the mean flood and ebb tides, thus allowing a direct comparison with the experimental results for the third tidal cycle. Again the agreement between the numerical and experimental results proved encouraging, with the general features of the tide induced circulation being satisfactorily reproduced. As an example of the numerical model results, the velocity fields are shown for L/B ratios of 1.0 and 1.8 respectively, see Figs. 6 and 7. These examples correspond directly to the experimental results of Figs. 4 and 5.

A further feature of the numerical model was that the variation of concentration across the planform area of the harbour was determined at particular time levels. By evaluating the standard deviation of concentration, and dividing by the average concentration, the corresponding coefficient of concentration variation was obtained. The results determined for the various L/B ratios, with and without the inclusion of barriers in the model, can be seen in Fig. 8. The results have again confirmed that an L/B ratio of unity provides the best mixing characteristics. For this case the lowest coefficient of variation was obtained, which meant that the concentration was more uniformly mixed within the harbour than for the other L/B ratios.

Further tests were carried out, both for the laboratory and numerical models, to study the effects on the gross flushing characteristics of inserting impermeable barriers at various positions within the harbours. Although the results are not reproduced here, it has been confirmed from both the experimental and numerical results that barriers do not in any way improve the flushing characteristics. In fact, the results recorded clearly showed that the barriers had a detrimental effect on the flushing efficiency.

CONCLUSIONS

It has been shown that by representing the differential equations of continuity, momentum and mass transport in the finite difference form described, numerically stable solutions can be obtained for the

relatively complex flow fields considered. This representation includes time centring of the convective accelerations, a technique which appears to have overcome the problems generally associated with non-linear instabilities. In all of the comparisons made between the numerical model velocity field predictions and the experimentally observed path-lines, the results have agreed reasonably well with the essential characteristics of the flowfields having been adequately reproduced.

By determining the spatially averaged concentrations at the beginning and end of three tidal cycles, it has been possible to ascertain the average per cycle exchange coefficient for various L/B ratios in the laboratory and numerical models. Comparisons of the results again showed good agreement, with the peak exchange coefficient occurring for an L/B ratio of unity; thus indicating that a square harbour gives the maximum flushing efficiency for a constant planform area.

For the numerical model studies only, results were obtained for the concentration distributions across the harbour planform area. As before these results indicated that for a square harbour the plan variation of the concentration distribution was a minimum, thereby confirming that for this case the concentrate was more uniformly mixed within the basin.

Finally, velocity field predictions and exchange coefficients for both the laboratory and numerical model results, showed that the insertion of impermeable barriers within the harbours was detrimental to the improvement of the basin's flushing efficiency and overall water quality characteristics.

HYDRAULIC CIRCULATION PERFORMANCE
OF A CURVILINEAR MARINABY JEFFREY A. LAYTON, M.ASCE¹

INTRODUCTION

An innovative coastal engineering concept has been developed to maximize the hydraulic circulation and water quality of dredged backshore harbors and boat basins. The concept represents a radical departure from the hydraulic design of existing artificial boat basins in that the basin geometry and entrance channel are primarily sized for hydraulic purposes rather than navigational access. Specific elements of the concept are described below.

CONCEPT

Past design practice of backshore-dredged harbors, basins, and marinas has concentrated primarily on optimizing the dredged geometry to develop maximum maneuvering space and moorage area. Typically, little or no thought was given to water circulation and water quality within the artificial harbor. However, recent environmental studies have shown that rectangular dredged basins can have limited water circulation and flushing, resulting in the formation of stagnant zones throughout the harbor (Nece and Kroll, 1974, and Nece et al., 1976). Limited water circulation, in turn, can result in poor water quality levels in the harbor. Typically, water temperatures rise and dissolved oxygen levels decrease in basins with poor circulation. These changes can have profound effects on the flora and fauna inhabiting the harbor.

To overcome the above problems associated with limited hydraulic circulation, a new design concept was developed by the author in conjunction with Professors E. P. Richey and R. E. Nece of the University of Washington, Seattle.

The concept revolves around the use of a properly sized offset entrance coupled with a rounded basin shape. The curvilinear geometry allows "new" water entering the marina to move freely around the entire basin perimeter and mix with "old" basin water without forming isolated dead spots. Similarly, during ebb tide, the basin's shape minimizes restrictions to the potential flow field, eliminating stagnant zones. Specific elements of the concept are as follows:

- Conventional rectangular geometry of backshore-dredged basins is replaced with curvilinear

¹Principal, Layton and Associates, Consulting Coastal Engineers, 1611 - 116th Avenue NE, Bellevue, Washington 98004; formerly Senior Coastal Engineer, CH2M HILL NORTHWEST, Inc., Bellevue, Washington 98004.

geometry. Rounded corners of the basin reduce sideslope friction and eliminate stagnant zones common to sharp-edged rectangular corners.

- The rounded basin geometry is coupled with a single narrow entrance channel. This channel is hydraulically designed to produce a flooding tidal jet that possesses sufficient momentum to create large-scale rotating vortex systems within the curvilinear basin.

Through the above process a strong tidally driven basin circulation current system can be created. This current system is capable of maintaining water quality levels within enclosed harbors at near-ambient open water levels. Physical hydraulic model testing and post-construction prototype monitoring have verified the concept (discussed below).

THEORY

Figure 1 illustrates a plan view of a typical small-craft harbor. The principal elements of the harbor's geometry consist of a wide entrance channel coupled to a large square or rectangular moorage basin. The efficiency at which the interior "old" basin water mixes with "new" incoming offshore water is directly affected by the velocity of the flooding tidal jet as it flows through the harbor entrance. For weak entrance channel currents, which are characteristic of wide channels, the flooding tidal jet may not possess sufficient momentum to allow the incoming water to penetrate to the farthest reaches of the basin. This can result in the formation of hydraulically stagnant zones in the harbor. For harbors with linear geometry, the stagnant zones commonly form in corner areas. This poor mixing action of tidal water can result in degradation of water quality as previously described.

To improve the circulation and mixing action of a harbor, two basic approaches are available:

1. Induce artificial circulation in stagnant zones with mechanical devices such as pumps or ducted propellers (Dunham, and Finn, 1974).
2. Redesign the geometry of the harbor basin and entrance channel to allow natural tidal action to improve hydraulic circulation and mixing.

The first method described above is a remedial solution. Reliance on mechanical devices (and the human personnel required to operate them) to work continually in a marine environment is questionable at best. Typically, mechanical systems corrode, become biofouled, and experience general electrical and mechanical problems such that they cannot be relied upon 100 percent. As an example, if a mechanical system used to induce circulation in a harbor fails at a critical period, such as during a prolonged hot spell in the summer season, solar heating of the stagnant basin water

**FIGURE 1
CONVENTIONAL
RECTANGULAR BASIN**

**FIGURE 2
CURVILINEAR BASIN**

could increase ambient temperatures to levels that are lethal to resident and migratory fish populations.

Because of poor reliability of mechanical systems, most governmental agencies responsible for issuing permits related to marine water quality are extremely reluctant to approve artificial circulation devices. The agencies prefer natural systems that do not require constant monitoring and maintenance. Thus, the use of artificial circulation systems in harbors to maintain water quality is generally not an acceptable solution.

As an alternative to mechanical systems, harbor geometry can be modified to allow nature, through the action of the tides, to produce sufficient hydraulic circulation to eliminate or minimize potential water quality problems. Such a modification of a conventional harbor is shown in Figure 2. The linear geometry of the square basin of Figure 1 has been replaced with curvilinear geometry to eliminate sharp corner areas. In addition, the entrance channel has been reduced in size and offset along one side of the basin. These simple changes in geometry result in the formation of a strong flooding tidal jet that now possesses sufficient angular momentum to carry new incoming offshore water throughout the entire volume of the basin. This naturally induced momentum results in excellent internal circulation and mixing within the harbor. To illustrate the angular momentum concept, an example problem is provided below.

DESIGN EXAMPLE

It is desired to dredge a small-boat harbor and entrance channel in a low-lying area landward of an existing shoreline (see Figure 2). To be economically justifiable, the basin must have sufficient area for 1,000 moorage berths, and the entrance channel should be wide enough to safely allow two-way boat traffic. Also, property boundary constraints require the entrance to be positioned to the right side of the basin. Environmental restrictions placed on the site to protect migrating salmon fry limit increases in basin water temperature to no more than 1-1/2 degrees C above ambient offshore waters. Also, the use of artificial circulation devices is prohibited. The mean tide range is 6 feet, and the mean tide level is 6 feet above mean lower low water (MLLW = 0). Size the basin and entrance channel to meet the above conditions.

Basin Size

Through the use of standard marina berth layout parameters (Dunham and Finn, 1974) and the use of a curvilinear boat basin geometry (Figure 2), it is determined that a circular basin with a radius of 600 feet will provide sufficient space for 1,000 small craft. Similarly, calculations of solar-heated basin water mixing with ambient offshore water over a tidal cycle show that basin temperatures will not exceed the 1-1/2 degrees C increase limit if the boat basin is well mixed. A complete rotation of the entire basin's water mass

over the flooding cycle is calculated to provide the necessary mixing. The problem now becomes to size the entrance channel such that the flooding tidal jet will produce the desired rotation of the basin water.

Entrance Channel Size

To size the entrance channel, consider the water within the circular basin of Figure 2 as a cylinder. Allow this water body to be given sufficient angular momentum to move with "solid-body" rotation, overcoming frictional resistance of the basin's bottom and sides. From the discussion above, assume that one complete revolution of the water body during a flooding tide period (approximately 6 hours) is sufficient to induce the necessary circulation. To produce this rotation, the entrance channel must be sized to transmit sufficient tidal jet momentum to the basin waters. The following describes procedures to calculate the required tidal jet energy.

Treat the basin as a cylindrical body with a 600-foot radius. Assume a uniform friction coefficient of 0.005 for all boundaries (Nece and Richey, 1975). The problem now becomes one of estimating the required torque of the solid-body water mass to overcome the bottom and sidewall frictional resistance of the basin. To calculate the resisting frictional torque exerted on the rotating water mass by the bottom, Nece and Richey (1975) suggest the following:

$$T_b = \int_0^{r_0} c_{f \frac{\rho}{2}} (\omega r)^2 2 \pi r r d_r \quad (1)$$

$$= c_{f \frac{\rho}{2}} \omega^2 2 \pi r_0^5 \frac{1}{5} \quad (2)$$

where T_b = bottom torque (ft-lb)

c_f = friction coefficient = 0.005

ρ = mass density (2 slugs/ft³ for seawater)

ω = angular velocity for one rotation
of boat basin water during one-half tidal
cycle

$$= \frac{2 \pi}{(6.2)(3600)} \quad \frac{\text{radians}}{\text{sec}}$$

r_0 = radius of basin = 600 feet

For the example problem a friction bottom torque of 38,600 foot-pounds is calculated.

For the sidewall torque, Nece and Richey (1975) suggest treating the basin perimeter as a cylindrical surface of revolution. The resulting peripheral torque is calculated as follows:

$$T_p = c_f \frac{\rho}{2} (\omega r_o)^2 2\pi r_o h r_o \quad (3)$$

where T_p = peripheral torque (ft-lb)

h = water depth corresponding to distance from mean tidal level to basin bottom. (For example, basin dredged to -10 with mean tide of 6 feet, $h = 16$ feet)

For the example problem a peripheral torque of 5,150 foot-pounds is calculated.

Combining the bottom and peripheral torque results in a net torque to be overcome by the entrance jet of approximately 43,750 foot-pounds. Startup, or inertial, effects have been neglected and are considered minor because of long tidal periods. Also, the current deflecting effects of the Coriolis force have been neglected because of the overriding influence of basin geometry on current direction. (It should be noted, however, that, if harbor geometry allows placement of the entrance channel on either side of the basin, it is preferable to place the entrance on the left side in the Northern Hemisphere. This will allow the Coriolis force to help augment the resulting clockwise circulation. For the Southern Hemisphere, a right-hand entrance is preferred.)

Assuming that all of the torque to overcome the net frictional torque of 43,750 foot-pounds is provided by an entrance channel hydraulic jet offset a distance of r_o to the side of the boat basin, the required entrance momentum can be calculated as follows:

$$QVr_o = T_b + T_p \quad (4)$$

where the entrance channel provides a volumetric flow rate of Q (ft³/sec) with a jet velocity of V (ft/sec).

For the example problem, a momentum flow of $QV = 36.5$ is required. To determine both Q and V , the following procedure is used:

$$\text{Average } Q = \frac{\text{basin tidal prism volume for mean tide level}}{\text{half-tidal cycle time period}} \quad (5)$$

$$= \frac{(6.0)(\pi)(600)^2}{(6.2)(3600)}$$

$$= 304 \text{ cubic feet per second}$$

The required average velocity of the entrance jet can then be calculated as follows:

$$v = \frac{36.5}{Q} = \frac{36.5}{304} = 0.12 \text{ foot per second} \quad (6)$$

Thus, the entrance channel must be designed to provide an average flooding entrance channel velocity of 0.12 foot per second. It should be noted that the actual entrance channel velocity will vary as a function of time and tidal height

such that peak velocities are two to four times higher than the average velocity and minimum velocities approach zero. However, the average velocity of 0.12 foot per second represents the same net momentum input to the basin when peak and minimum velocities are combined.

To estimate the required cross-sectional area of the channel, the continuity equation is employed:

$$Q = VA \quad (7)$$

where V = average tidal velocity (feet per second)

A = average area of entrance channel (square feet)

$$\text{Therefore, } A = \frac{Q}{V} = \frac{304}{0.12} = 2,500 \text{ square feet}$$

Thus, for the example problem, the entrance channel must have a cross-sectional area less than or equal to about 2,500 square feet.

Figures 3 and 4 illustrate two entrance channel configurations that are sized to produce an average tidal jet velocity of 0.12 foot per second. Both channel types are sufficiently wide to allow two-way vessel traffic into and out of the harbor.

Factor of Safety

To account for possible inaccuracies in the procedures described above (e.g., selection of friction coefficient, neglecting inertial forces), it is recommended that for design purposes the calculated minimum entrance channel velocity be increased by at least a factor of 1.35. This results in a reduction of the required entrance channel area by about 25 percent.

HYDRODYNAMIC ASYMMETRY

Angular momentum within a harbor basin will persist for some time after flooding stops and ebbing tide begins. This sets up a flow condition where rotating basin eddies encounter the potential flow regime of the ebbing tide. Thus, two different flow conditions occur at the same instance, producing hydrodynamic asymmetry. This is advantageous because it helps to further increase mixing action within the basin.

PROTOTYPE EXAMPLE

The concept described above was developed as a result of the design of a large marina located in northern Puget Sound at Point Roberts, Washington. Analytical studies, field measurements, and physical modeling efforts were all utilized in the hydraulic design of the marina's basin and entrance channel. Calculations presented in the example problem were based, in part, on the design of the marina. A brief description of the marina is provided below.

ENTRANCE CHANNEL

Point Roberts Marina

The 1,000-berth Point Roberts Marina is one of the largest privately owned coastal engineering developments on the Pacific coast of the United States. Construction of the marine portions of the \$6 million marina began in November 1976 and were completed in August 1978. The marina is located on the south shore of Point Roberts, a small peninsula politically part of the State of Washington, USA, but physically connected to British Columbia, Canada. The marina site encompasses approximately 140 acres and includes nearly 8,000 linear feet of marine shoreline (Layton, 1979).

Figures 5 and 6 present aerial views of the completed marina showing the relationship of the entrance channel to the back-shore curvilinear boat basin. This configuration was found to maximize hydraulic circulation within the marina's 40-acre boat basin, which in turn resulted in acceptable water quality levels. Construction of this marina represents the first application of the above-described concept and is representative of the state of the art in marina and harbor basin hydraulic design.

Hydraulic Model Study

Prior to construction of Point Roberts Marina, a hydraulic model of the proposed marina was constructed and a series of tracer dye tests conducted to predict the circulation performance (CH2M HILL, 1976, and Nece, 1976). Results showed that the marina would have excellent internal hydraulic circulation. A large counterclockwise rotating vortex system was found to occur in the boat basin during all ranges of flood tides. No stagnant zones were observed and the basin was found to be well mixed. Figures 7 and 8 illustrate typical circulation patterns of the boat basin and offshore waters during ebb and flood tide conditions.

Prototype Studies

After construction of the marina, several hydraulic and water quality studies have been conducted to determine the overall performance of the design concept. Figure 9 illustrates the results of one test where a drogue was used to trace the path of water mass movement in the basin during a typical flood tide. Of importance to note is that the drogue traveled from the entrance channel over 2,000 feet to the head of the boat basin. This verified the hydraulic model tests and demonstrated that the concept of curvilinear boat basin geometry coupled with a hydraulically designed entrance channel is effective in producing strong internal circulation.

Remote aerial sensing studies conducted by the U.S. Environmental Protection Agency in June 1978 also showed that the Point Roberts Marina basin has excellent thermal mixing. Comparison of thermal imagery of other conventional rectangular marina basins in Puget Sound clearly illustrated the superior mixing action of the curvilinear basin.

ON OCTOBER 13, 1978

In addition to the above prototype studies, a water quality monitoring program was conducted at the marina during 1978. Table 1 presents a typical set of water temperature measurements recorded in the constructed boat basin. The results indicate that the interior of the boat basin has a fairly uniform temperature distribution with basically very little variation from ambient water temperature conditions in the Strait of Georgia.

* See Figure 9 for station locations.

CONCLUSIONS

A new concept in the design of dredged backshore basins for maximizing hydraulic circulation and water quality has been described. The concept employs the use of curvilinear basin geometry coupled with a single offset entrance channel. This combination produces a flooding tidal jet that can have sufficient momentum to penetrate all portions of the basin, producing a well-mixed, stagnant-free water mass. The concept was employed in the design of a large marina, and subsequent post-construction monitoring has verified the concept.

ACKNOWLEDGEMENT

The author wishes to thank Mr. Roger Lindquist of CH2M HILL, Corvallis, Oregon, for presenting this paper for the author at the 17th International Conference on Coastal Engineering.

THE EFFECT OF BREAKING WAVES ON THE MIXING
OF LIQUID POLLUTANTS INTO THE SEA.

by

Dr.ing. Arvid Naess,
The Norwegian Hydrodynamic Laboratories,
Trondheim, Norway.

ABSTRACT.

Experience gathered during the last few years shows that a serious problem when fighting oil spills out in open waters, is the mixing of the oil into the sea by breaking waves. In this paper we propose a theoretical model that we believe represent a fruitful approach to the problem of determining the amount of oil mixed into the sea by breaking waves. Our model is based primarily on probabilistic methods, but with experimental observations and data as an essential foundation.

1. INTRODUCTION.

We shall in this paper consider the mixing of an oil spill into the sea caused by breaking waves, and the main topic will be a stochastic model for estimating the oil distribution with depth caused by this mixing. The answer to the question - How much oil can you expect to have left on the sea surface in a given sea state? - is rather crucial to planning and organizing oil pollution control. The reason is that oil being mixed into the sea is very difficult to recover.

The phenomenon that is the primary cause of dispersion is turbulence in the upper layers of the ocean. Now, the sea states of most immediate concern to us, are characterized by rather strong wind and breaking waves, which we shortly describe as rough seas. Under conditions as these, there are two mechanisms that completely dominate the generation of turbulence in the surface layers. One is breaking waves, the other is wind induced shear currents.

It is only in recent years that people have really begun to study breaking waves and their role in generating turbulence in the ocean. Of special interest to us would be a connection between sea state and turbulence level together with the penetration depth of the turbulent layer

beneath a breaking wave. However, in the literature there are no available data or analyses of a connection between sea state on the one hand and turbulence level and penetration depth on the other. In passing let me mention that some simple experiments we have done, indicated that the maximum penetration depth of the turbulence beneath a breaking wave is of the same order of magnitude as the wave height.

During conditions of rough seas, the strong down-welling turbulent water masses beneath breaking waves will constitute the main driving mechanism behind the dispersion of an oil slick into the sea. Generally speaking, we may say that breaking waves are two orders of magnitude more effective in dispersing surface oil than turbulence due to wind induced shear currents. This conclusion has also been drawn by other workers in this field, see reference 1.

However, it is not legitimate to conclude that turbulence due to dynamically instable shear currents in the surface region have little or no effect on dispersion when breaking waves dominate. While the turbulence generated by breaking waves is characterized by being highly non-stationary, i.e. the energy in the turbulence beneath a breaking wave dissipates rather quickly, we may with some confidence assert that the turbulence generated by wind induced shear currents has an approximately stationary character. This means that when the strong turbulence beneath the breaking waves dies out, a certain turbulence level is still present. How this turbulence will affect oil already being dispersed, is not well known. However, there is strong reason to believe that the residence time of an oil globule within the water column will depend significantly on this turbulence level.

When a breaking wave hits an oil slick, it will tear up part of it and drive a cloud of oil globules down into the sea. As long as the turbulent water motions beneath the breaker continues, the positions of the globules are mainly determined by this. But as soon as the turbulence has lost its energy, the buoyancy of the globules will drive them towards the surface. The rise velocity will certainly depend on globule size, but also probably on the background level of turbulence in the surface layers as we just mentioned.

How fast the amount of oil being mixed into the water will rise towards the surface again depend on how the amount of oil is distributed over different globule sizes, or more precisely, over different rise velocities and on how deep down into the water the oil globules are mixed. Every serious effort to estimate the dispersion of oil in open waters will consequently have to find estimates of rise velocity distribution and mixing depth due to breaking waves. And for this information to be of practical use, it has to be related to sea states by some suitable method.

In the first part of our paper we will describe the method or model chosen as a starting point in dealing with this problem. In the latter part a description of experiments and analyses we have done in order to estimate rise velocity distribution and mixing depth will be given.

However, before we enter the details of our paper, we shall list some excellent reports and papers dealing with the dispersion of oil. In reference 1 is presented a mathematical model of dispersion. In reference 2, detailed discussions of most of the phenomena playing a part in the dispersion of oil are given, and theoretical models for some of these are presented. This report is a highly valuable addition to the literature. A short presentation of some of the work contained in reference 2 is given in reference 3. Reports on work having a strong bearing on the experimental part of this paper are given in references 4 and 5.

2. THEORETICAL MODEL.

2.1 Basic assumptions.

In order to construct a manageable theoretical model to estimate the vertical distribution of oil in the sea due to the mixing induced by breaking waves, it is obvious that quite a few simplifying assumptions have to be made.

The basic assumptions on which we build our model, are as follows: Firstly, we shall assume that the time points when breaking waves pass a fixed location on the sea surface are randomly distributed according to some probability law that may, in principle, be determined for each environmental condition.

Assume then that initially we have an oil slick of surface density σ at our fixed location. With each passing of a breaking wave, a mixing of the oil into the sea will occur. In agreement with experimental observations, we will assume this mixing process to be instantaneous, i.e. relative to the time intervals between passing breakers. Further, we assume that with each breaking wave we may associate a quantity, called the "mixing depth", which gives a measure of the depth to which oil is carried by the mixing created by the breaking wave, and that this quantity is a random variable whose probability distribution may, in principle, be determined for each environmental condition. From our experimental observations, we may conclude that the "mixing depth" is largely determined by the depth to which the more or less turbulent water motion created by the breaking wave extends, and much less on the type of oil present. We shall, accordingly, assume that the probability distribution of "mixing depth" is independent of the particular type of oil present.

A few more simplifying assumptions are needed to avoid an intractable model.

To be precise, we neglect the horizontal motion of the oil due to waves and current, so that the vertical distribution of the oil always adds up to σ at our fixed point. If on the average the oil slick is moving with a uniform velocity, we may introduce a reference frame moving with the same velocity and relate our analyses to this. The probability distribution must then, of course, be determined relative to this frame. The next simplification is to neglect the variation of the vertical distance between specific water particles caused by the wave motion.

We shall also neglect the influence of the oil on the breaking waves. Now it is a fact that oil under some conditions does have an influence on breaking waves, but what limitations that put on our model is hard to say at present. For instance, observations in connection with the blow-out on the Ixtoc 1 field in the Gulf of Mexico, seem to indicate that strongly emulgated oil have no or very little effect on breaking waves. The main reason for neglecting this effect is, however, that the state of knowledge in this field is such as to allow no quantitative conclusion.

2.2 Probabilistic model.

With the simplifying assumptions made above in mind, we shall now construct our theoretical model. Starting with the occurrence of breaking waves, we then have a sequence of random time points

$$\dots, T_1, T_2, T_3, \dots, T_n, \dots$$

describing each passing of a breaking wave past a fixed location. With each T_k there is associated a random variable D_k , called the "mixing depth", and we assume that all the D_k 's are mutually independent and identically distributed with probability density f_D . The D_k 's are also assumed to be independent of the timepoints T_k . The last assumption is not essential.

Due to the mixing process, the oil will be broken up into droplets of different sizes, which we characterize by the parameter u equal to the terminal rise velocity of a droplet through calm water, cfr. section 4. For the present discussion, we will neglect the influence on the vertical distribution of oil of all but the last breaking wave. More precisely, we assume that the vertical distribution at an arbitrary time is determined by the last breaking wave to pass before that time. This approximation seems satisfactory if the ratio of "mixing depth" to the time interval between breakers is "small enough". It is clear that when this ratio increases the need to include the effect of earlier breakers will sooner or later become mandatory. Now, there is nothing in our model that prevents us from taking into consideration the effect of any number of preceding breakers, the only limitation being the unwieldiness of the expressions obtained.

To get on with our present model, assume that the density of droplets with rise velocity u as a function of depth z immediately after a breaker has passed, i.e. at time T_k for some k , is given by the function $\phi(D_k, z; u)$. For each definite value of the random variable D_k , this is an ordinary function of the real variable z . Letting $C(t; z, u)$ denote the density of droplets with rise velocity u at depth z at an arbitrary time t , we may write

$$C(T_k; z, u) = \phi(D_k, z; u) \text{ for every } k \dots\dots\dots(1)$$

and

$$C(t; z, u) = \phi(D_k, z + u(t - T_k); u); T_k \leq t < T_{k+1} \dots\dots\dots(2)$$

for every k.

We now want to determine the probability density of $C(t; z, u)$ for an arbitrary fixed time t . To this effect, let f_W denote the probability density function of the time interval W between t and the time of the last preceding breaker. Having fixed t, z and u , we suppress the variables from $C(t; z, u)$ and write simply C . We now have

$$C = \phi(D, z + uW; u) \dots\dots\dots(3)$$

As the next step, we shall exploit our experimental observations which indicate that the mixing created by the breaking wave gives a nearly uniform distribution down to a rather well defined depth, which we have called the "mixing depth". Accordingly, we shall assume that we may write

$$\phi(D, z; u) = \frac{p(u)}{D}, \text{ for } 0 \leq z \leq D \text{ (= 0 elsewhere)} \dots\dots\dots(4)$$

Here $p(u)$ denotes the fraction of droplets with rise velocity u , cfr. section 4. For simplicity, we shall assume $\sigma = 1$ so that

$$\int_0^{u_{\max}} p(u) du = 1 \dots\dots\dots(5)$$

From the above we may proceed to calculate the probability distribution function F_C of the random $C = C(t; z, u)$. Instead of entering the details of this calculation, we refer the interested reader to reference 6 where the details may be found. Here we shall just give the final answer, which is:

$$F_C(c) = \int_0^Z f_D(x) dx + \int_Z^\infty \int_{\frac{x-Z}{u}}^\infty f_W(w) f_D(x) dw dx + \int_0^\infty \int_0^{\frac{x-Z}{u}} f_W(w) f_D(x) dw dx \dots\dots\dots(6)$$

for $0 \leq c \leq \frac{p(u)}{Z}$ (the singular point $c = 0$ causes no difficulty here) while for c outside this interval:

$$F_C(c) = 0 \dots\dots\dots(7)$$

Before we continue to make specific assumptions about the probability laws, a few words on the probability density function f_W are appropriate. Now, it is obvious that to determine the probability law of W directly from observations of passing breakers is a rather cumbersome process. In trying to connect W to a random variable more easily determined, it is natural to investigate the connection between

W and the time intervals between passing breakers. Define, then, the random variables $Y_k = T_k - T_{k-1}$, which we assume to be identically distributed with probability density f_Y . It turns out that for most practical purposes we have the following connection between f_W and f_Y .

$$f_W(w) = \frac{1}{E(Y)} \int_w^\infty f_Y(y) dy; w \geq 0 \quad (=0; w < 0) \dots\dots\dots(8)$$

Consequently, an estimate of f_Y , which we may obtain directly from the observational data (with the proper assumptions), allow us quite easily to estimate f_W .

From our experimental data, we are able to give estimates of $p(u)$ as a function of u , cfr. section 4. By taking this into consideration, we see from (6) that the remaining unknown factors are the probability density functions f_W and f_D . At present, however, there is no information available regarding these probability laws. In passing we mention that we intend to carry out research aiming at providing this necessary information.

Using (6) and (7) and writing $C = C(z, u)$ since the probability structure of C is independent of t , as it should be, we shall have

$$E(C(z, u)) = \int_0^{p(u)/z} \{1 - F_C(c)\} dc \dots\dots\dots(9)$$

(9) gives the expected density at depth z of droplets with rise velocity u . To find the expected density of oil at depth z , we just integrate (11) over u (expectation commutes with integration) to find

$$E(C(z)) = \int_0^{u_{max}} E(C(z, u)) du \dots\dots\dots(10)$$

where $C(z)$ denotes the density of oil at depth z .

Denoting by $M(z)$ the amount of oil below the depth z , we find that

$$E(M(z)) = \int_z^\infty E(C(x)) dx \dots\dots\dots(11)$$

If, initially, the surface density is σ , then we just multiply (12) and (13) by σ to obtain the appropriate answers.

A quantity of special interest for oil recovery operations is the mean amount of oil left on the sea surface under given weather conditions. Expressed in per cent of total amount, we denote it by P_S . It is now easy to see that P_S will be given as follows:

$$P_S = 100 \cdot \{1 - E(M(0))\} \dots\dots\dots(12)$$

3. EXPERIMENTS.

This section is an adaption of the work reported in reference 7.

3.1 Test conditions and instrumentation.

In order to analyze the break-up and turbulent mixing into the sea of an oil slick on the surface caused by a spilling breaker passing the slick, a series of experiments were carried out in a towing tank of main dimensions 25 x 2.5 x 1.5 meters (length x width x depth). The principal aims were to find an estimate of the droplet size distribution, which is caused by the break-up of the oil slick, and to determine the "mixing depth" produced by each breaker.

After some preliminary experimentation, it was decided to apply the following testing procedure:

To produce the breaking waves, the technique of impulse waves was applied. An impulse wave is brought about by the dispersive properties of deep water waves. By decelerating the wave maker in a proper manner a wave train is produced that will converge at a preassigned location in the test tank. For details, see for instance reference 8. Using this technique, it was possible to produce a rather well defined spilling breaker in a given region in the middle of an oil slick with a thickness of about 5-7 mm. The height of the breaking impulse wave was varied by changing the amplitude of the wave maker. During the test programme, a wave height of approximately 0.4 metres was used.

To get a measure of the amount of oil at different depths as a function of time after the breaker had passed, an apparatus as sketched in Fig. 1 was used. (Tables and figures are placed at the end of the paper). It consisted of six thin glass tubes of different length, each inserted into a larger reservoir pipe, as shown in Fig. 1. The six reservoir pipes ended in a common suction chamber, which was connected to a vacuum tank by a flexible suction hose. A manually operated magnetic valve was used to open and close this connection. The suction chamber with its six protruding glass tubes was secured to an aluminium frame on the top of two light float elements in such a manner that the length of the submerged part of the glass tubes were 2, 4, 7, 10, 15 and 20 cm, respectively, when the assembled rig was floating on calm water. With this floating rig it was desired to take a sample of the oil/water mixture at the depths given above and at different times after the breaker had passed. In order to obtain this, it is obvious that the wave riding properties of the rig had to be very good. By trial and error, float elements were found that gave a wave rider that followed the wave forms nicely. The rig was kept in an upright vertical position by long nylon strings, as shown in Fig. 2. The strings were made sufficiently long to ensure unhampered vertical motion of the rig.

The sample of the oil/water mixture was taken by opening the connection between the suction chamber and the vacuum tank for a few tenths of a second. By allowing the oil to settle in each reservoir pipe, the fraction of oil in the sampled mixture could be measured, as illustrated in Fig. 1.

The tests were performed with a pure mineral oil both in fresh and emulgated state, i.e. oil that had been on the water for several weeks. In the non-emulgated state, the oil has properties similar to those of fresh crude oil from the Norwegian Continental Shelf. The properties of the oil in the two states are given in Table 1. As we mentioned above, during all the tests there was a mean oil film thickness of about 5 - 7 mm in the test tank.

The test programme we refer to in this report is detailed in Table 2. Explanatory comments to the tests are given in the table.

3.2 Presentation of results.

We shall present the experimental results in the form of diagrams giving the arithmetical mean and standard deviation of the measurements for each condition.

Fig. 3 to 7 show the percentage of emulgated oil in the sample as a function of time after the breaker had passed the rig. During these tests the wave started to break about 1.5 meters ahead of the rig.

Fig. 8 to 11 show the percentage of fresh oil in the sample as a function of time after the breaker had passed the rig. The wave started to break about 1.5 meters ahead of the rig.

3.3 Discussion of results.

In order to assess the errors we may commit in using the described sampling procedure to estimate the "mixing depth" and distribution of the oil, we need to consider what happens when a breaking wave hits the oil slick. During the first second after the breaker has passed, there is a mixing of the oil into the water which gradually reaches its maximum depth. Then, immediately, the oil droplets will start to rise towards the surface and, for instance, during three tenths of a second the fastest droplets may have risen as much as 4 cm. From this it is clear that sampling at time intervals of one second leads to the following conclusion: The deeper the sample is taken, the more we are in error when using the sample to estimate the initial density of oil. Consequently, the applied sampling procedure will not allow a proper estimate of the "mixing depth". However, the measured evolution with time of the density at the different sampling depths will be approximately correct, except for the first second after the breaker has passed. Therefore, if by some other means we are able to give a reasonably correct estimate of the initial distribution with depth of the density of oil, we shall also be able to estimate the droplet size distribution.

To obtain an estimate of the density distribution, we shall exploit the visual observations made of the mixing process. These observations did indicate a rather well-defined depth to which the mixing of oil extends and also a nearly uniform distribution of oil droplets with depth. The corresponding assumption of a uniform distribution down to a well-defined depth, called the "mixing depth", has already been used in section 2 in constructing our theoretical model. We shall also apply it in the next section in order to determine the droplet size distribution. From both visual observations and later experiments (cfr. reference 9) we have estimated the "mixing depth" to be approximately 0.2 meters.

4. DROPLET SIZE DISTRIBUTION.

Exploiting the experimental data given in section 3 and with the assumptions of section 2 still effective, we now want to find an estimate for the distribution of droplet sizes $p(u)$ characterized by the parameter u , which is the terminal rise velocity of a droplet through calm water. According to the assumptions we made in section 2, each passing breaker produce the same distribution $p(u)$ and a uniform depth distribution from the sea surface down to the "mixing depth". Assuming a unit surface density and letting $K_D(t, z; u)$ denote the density of droplets with rise velocity u at depth z as a function of time t after the breaker has passed, given the associated "mixing depth" D , we then have

$$K_D(0, z; u) = \frac{p(u)}{D}; D < z \leq D \dots\dots\dots(13)$$

Under the given conditions there will be an upper bound to the rise velocities. We shall consequently assume a fixed upper limit u_{max} to the rise velocities u , so that $p(u) = 0$ for $u > u_{max}$. u_{max} will generally depend on the type of oil present. A more detailed discussion of u_{max} is deferred to the end of this section.

We define $K_D(t, z)$ by

$$K_D(t, z) = \int_0^{u_{max}} K_D(t, z; u) du; 0 < z \leq D \dots\dots\dots(14)$$

$K_D(t, z)$ is then the density of oil at depth z at time t after the breaker has passed. From (13) and (14) we get

$$K_D(D, z) = \int_0^{u_{max}} K_D(D, z; u) du = \frac{1}{D}; D < z \leq D \dots\dots\dots(15)$$

At a time t after the breaker has passed, all droplets with a rise velocity $u > (D-z)/t$ will have passed the depth z on their way to the

surface. This, of course, presupposes that $t \geq (D-z)/u_{\max}$. Accordingly, we shall have

$$K_D(t,z) = K_D(0,z), \quad 0 \leq t < \frac{D-z}{u_{\max}}, \dots\dots\dots(16)$$

$$K_D(t,z) = \int_0^{\frac{D-z}{t}} \frac{p(u)}{D} du ; \quad t \geq \frac{D-z}{u_{\max}} \dots\dots\dots(17)$$

The experimental results for $K_D(t, z)$ show an exponential decrease with time. In agreement with our assumptions, we therefore expect to find that

$$K_D(t,z) = \frac{1}{D} e^{-\kappa(D,z)(t-t_{\min})} ; \quad t \geq t_{\min} \dots\dots\dots(18)$$

where $t_{\min} = (D-z)/u_{\max}$ and $\kappa(D,z)$ is constant for each D and z . To determine the dependence of κ on D and z , we apply the following one-to-one correspondence between the rise velocity and time

$$u = \frac{D-z}{t} ; \quad t \geq t_{\min} \dots\dots\dots(19)$$

Differentiating (17) and (18) with respect to time, by direct comparison we obtain, using (19):

$$p(u) = \kappa(D,z)(D-z)u^{-2} e^{-\kappa(D,z)(D-z)\left(\frac{1}{u} - \frac{1}{u_{\max}}\right)} \dots\dots\dots(20)$$

Our assumptions imply that $p(u)$ should not exhibit any dependence on D and z , which lead to the following equality

$$\kappa(D, z) = \frac{\kappa}{D-z} \dots\dots\dots(21)$$

where κ should depend only on the properties of the oil. Substituting (21) into (18) we obtain

$$K_D(t,z) = \frac{1}{D} e^{-\frac{\kappa}{D-z}(t-t_{\min})} ; \quad t \geq t_{\min} \dots\dots\dots(22)$$

Inserting (21) into (20) we get

$$p(u) = \kappa u^{-2} e^{-\kappa \left(\frac{1}{u} - \frac{1}{u_{\max}} \right)}, \quad 0 < u \leq u_{\max} \dots\dots\dots(23)$$

In order to test out the relations we have obtained on the basis of our assumptions, we plotted $K_D(t, z)$ taken from Fig. 4 -7 and 9 - 11. As mentioned at the end of the previous section, the "mixing depth" was estimated to be approximately 0.2 m. For fresh oil we found $\kappa = 0.17$ from Fig. 9, $\kappa = 0.20$ from Fig. 10 and $\kappa = 0.22$ from Fig. 11. This supports our assumptions rather well, and by putting $\kappa = 0.2$ in (22) we shall find that this expression fits the experimental results nicely. Similarly, we find that (22) with $\kappa = 0.02$ agrees tolerably well with the experimental results for the emulgated oil.

The distribution $p(u)$ that we have determined above is the result of one breaking wave. In reality, however, it is clear that the appropriate rise velocity distribution induced by a passing breaker is not determined solely by that wave, but also by preceding breakers. The reason for this is that the smaller oil globules may not have resurfaced when the next breaker comes along. The "equilibrium" rise velocity distribution will therefore contain a larger portion of small rise velocities than the $p(u)$ determined previously. In order to obtain a better approximation to the correct distribution, we shall assume a constant frequency of passing breakers and a constant mixing depth. It is natural to choose the corresponding mean values \bar{Y} and \bar{D} , respectively. We then have a limit velocity $u_1 = \bar{D}/\bar{Y}$, because all the oil with rise velocity greater than u_1 will have resurfaced before the next breaker comes. However, in many cases u_{\max} is smaller than u_1 , and as this simplifies the analysis below, we shall assume this to be the case.

Let us now study the effect of a sequence of breaking waves, equidistant in time, passing a fixed location with an initial surface density of oil $\sigma_0 = 1$. The rise velocity distribution induced by the first passing breaker we have already determined to be given by $p(u)$ as in (23).

With the assumption $u_{\max} \leq u_1$ in mind, we find that the amount of oil of rise velocity u having surfaced when the second breaker passes, i.e. after a time \bar{Y} , is given by

$$\sigma_1(u) = p(u) \frac{u}{u_1}; \quad 0 < u \leq u_{\max} \dots\dots\dots(24)$$

The surface density at that instant is given by

$$\sigma_1 = \int_0^{u_{\max}} \sigma_1(u) du \dots\dots\dots(25)$$

The distribution over rise velocity due to surface oil induced by the second breaker is $\sigma_1 p(u)$. The distribution due to oil being

in the water column will be $p(u) - \sigma_1(u)$. The rise velocity distribution, $p_1(u)$, due to the second breaker will then be given by

$$p_1(u) = (1 + \sigma_1) p(u) - \sigma_1(u) \text{ or } (\sigma_0 + \sigma_1)p(u) - \sigma_1(u) \dots\dots\dots(26)$$

We have, of course, tacitly assumed a uniform distribution with depth, as implied by the considerations of section 2.

The amount of oil of rise velocity u having surfaced when the third breaker passes, is given by

$$\sigma_2(u) = p_1(u) \frac{u}{u_1} = [(\sigma_0 + \sigma_1)p(u) - \sigma_1(u)] \frac{u}{u_1} \dots\dots\dots(27)$$

The corresponding surface density is

$$\sigma_2 = \int_0^{u_{\max}} \sigma_2(u) du \dots\dots\dots(28)$$

Similarly as above, we find that the rise velocity distribution $p_2(u)$, due to the third breaker is given by

$$\begin{aligned} p_2(u) &= \sigma_2 p(u) + p_1(u) - \sigma_2(u) \\ &= (\sigma_0 + \sigma_1 + \sigma_2)p(u) - (\sigma_1(u) + \sigma_2(u)) \dots\dots\dots(29) \end{aligned}$$

Continuing this process, we shall find generally for every $n = 1, 2, 3, \dots$

$$\sigma_n(u) = \left[\sum_{i=0}^{n-1} \sigma_i p(u) - \sum_{i=1}^{n-1} \sigma_i(u) \right] \frac{u}{u_1} \dots\dots\dots(30)$$

$$\sigma_n = \int_0^{u_{\max}} \sigma_n(u) du \dots\dots\dots(31)$$

$$p_n(u) = \sum_{i=0}^n \sigma_i p(u) - \sum_{i=0}^n \sigma_i(u) \dots\dots\dots(32)$$

Here $\sigma_n(u)$ denotes the surface density of oil of rise velocity u having surfaced just prior to the $(n+1)$ th breaker, σ_n is the total density of surfaced oil at that instant and $p_n(u)$ is the rise velocity distribution induced by the $(n+1)$ th breaker.

From (30) we easily establish the following recursion relation valid for every $n = 1, 2, \dots$

$$\sigma_{n+1}(u) = \sigma_n p(u) \frac{u}{u_1} + \left(1 - \frac{u}{u_1}\right) \sigma_n(u) \dots\dots\dots(33)$$

Using this recursion relation, we find that for $n = 1, 2, \dots$

$$\sigma_{n+1}(u) = p(u) \frac{u}{u_1} \sum_{i=0}^n \sigma_{n-i} \left(1 - \frac{u}{u_1}\right)^i \dots\dots\dots(34)$$

We have for every $n = 1, 2, \dots$

$$\sigma_{n+1}(u) = p_n(u) \frac{u}{u_1} \dots\dots\dots(35)$$

Combining (34) and (35), we get

$$p_n(u) = p(u) \sum_{i=0}^n \sigma_{n-i} \left(1 - \frac{u}{u_1}\right)^i \dots\dots\dots(36)$$

The appropriate rise velocity distribution to use in the model developed in section 2 would be $\lim_{n \rightarrow \infty} p_n(u)$ provided, of course, that

this limit exists. It turns out that with $p(u)$ as given by (23), $p_n(u)$ converges very fast for all relevant values on u_1 , and we may assume a stationary situation after just a few waves (~ 10).

To know $p(u)$ we see that we also need to know u_{max} . Unfortunately, we are not able to estimate u_{max} from our experiments, as is easily realized by recollecting the discussion in section 3.3. According to reference 10, the maximum rise velocity through calm water for oil droplets of fresh crude oil with properties similar to our mineral oil is approximately 0.1 m/sec. This corresponds to droplets with diameter about 2 - 3 mm. A further increase of the diameter leads to a decrease of the rise velocity. As we have nothing else to rely on at the present, we shall assume $u_{max} = 0.1$ m/sec. in the next section, where we try to illustrate our theory by some numerical examples. The value of u_{max} that enters the distribution $p(u)$ cannot be expected constant for each type of oil. For instance, u_{max} will most certainly depend on the surface density σ and the intensity of the mixing process. The assumptions $u_{max} = 0.1$ m/sec. may therefore prove to be a rather crude one.

For the sake of completeness we mention that some simple experiments we performed did corroborate a maximum rise velocity of the mineral oil of about 0.1 m/sec. More precisely, we found a maximum rise velocity of 0.13 - 0.15 m/sec, and there was no significant difference between fresh and emulgated oil.

Regarding the maximum rise velocity for emulgated oil, it turns out not to be easily accessible. This is due to the fact that the interfacial tension between the water phase and the emulgated phase is a key parameter in the mechanism that determines the maximum rise velocity, and this interfacial tension is almost impossible to measure.

5. CONCLUDING REMARKS.

In this paper we have constructed a theoretical framework which we believe will enable us to determine with reasonable accuracy the vertical distribution of oil in the sea under given environmental conditions. But this, of course, depends on the availability of sufficiently accurate input data. These, however, do not exist today.

At the Ship and Ocean Laboratory in Trondheim we are at present engaged in research aiming at developing suitable experimental methods that will allow us to establish the correct input data to our model by full scale measurements out at sea. Especially, we want to establish the statistical laws of breaking frequency and "mixing depth" which are the two most important inputs to the model.

The importance to pollution control of the problem we have considered in this paper should warrant a considerable effort towards the establishing of a reasonably correct solution.

ACKNOWLEDGEMENTS.

The author would like to express his appreciation of the many helpful discussions with Prof. E. Huse of the Ship and Ocean Laboratory. I also stress my debt to Mr. S. Eggen and Mr. E.G. Kringeland for supplying the experimental data given in this paper.

7. NOMENCLATURE.

- t - arbitrary, fixed time point
- T_k - random time points of passing breakers
- Y_k - $Y_k \stackrel{\text{def.}}{=} T_k - T_{k-1}$
- f_Y - probability density function of the random variables Y_k
- W - random variable equal to the time interval between t and time of the last preceding breaker
- f_W - probability density function of the random variable W (W_1)
- D_k, D - random "mixing depth" as induced by passing breakers
- f_D - probability density function of the random variables D_k and D
- u - rise velocity of an oil droplet
- $p(u)$ - fraction of droplets with rise velocity u
- $p_n(u)$ - fraction of droplets with rise velocity u just prior to (n+1)th breaker (section 4)

- $\sigma_n(u)$ - Surface density due to oil of rise velocity u just prior to $(n + 1)$ th breaker (section 4)
- δ_n - Surface density of oil just prior to $(n + 1)$ th breaker (section 4)
- z - Depth below the water surface
- $\phi(D,z;u)$ - Density of droplets with rise velocity u as a function of depth z immediately after a breaker inducing a "mixing depth" D has passed
- $C(t;z,u)$ - Density of droplets with rise velocity u at depth z at an arbitrary time t
- F_C - Probability distribution function of the random variables $C(t;z,u)$
- $M(z)$ - Amount of oil below depth z
- $K_D(t,z;u)$ - Density of droplets with rise velocity u at depth z as a function of time t after the breaking impulse wave has passed (section 4)
- $K_D(t, z)$ - Density of oil at depth z at time t after the breaking impulse wave has passed (section 4)
- P_S - Defined by $P_S = 100(1-E(M(D)))$, i.e. $P_S\%$ of the oil is expected on the surface
- κ - Parameter entering $p(u)$

ON A ROLE OF THE INTERFACIAL FROUDE NUMBER

by

Masakazu Kashiwamura*

ABSTRACT

As already stated in the previous conference, the fresh-water flow which passes through a river mouth horizontally into the sea, exhibits a special characteristic due to the effect of buoyancy. Its dynamics belongs, essentially to the same category with the transonic flow in aerodynamics. The interfacial Froude number plays a dominant role in this case, as well as the Mach number does in the transonic gas flow. The supercritical zone, in which the interfacial Froude number exceeds unity, occupies the sea surface with some area, in response to a degree of the discharge amount of the fresh water. This zone begins at the river mouth and stretches in the offshore directions over the sea, accompanied with a lateral growth.

As is well known, on the other hand, supersonic zones are sometimes formed partially along an airfoil, or in a tube with a varying cross-section, if they are placed in a subsonic gas flow. Those two different phenomena have been proved to be identical dynamically with each other [KASHIWAMURA and YOSHIDA 1978], [KASHIWAMURA 1979]. There have been a great number of researches in order to obtain an analytical solution of the transonic flow, in the past several decades, but there seem still many difficulties to attain a complete solution, except some particular cases such as a stream-lined approximation of immersed bodies being possible.

Considering such circumstances, it may also be difficult for the present problem to be solved completely, although it has not been decided yet to be impossible. The present author describes the process of his efforts for obtaining an analytical solution and its results, from a view point of the inspection on an applicability of the hodograph method, and its modification to this problem. In spite of incompleteness, they provide us several findings which are useful to understand the dynamics of the outflow of the fresh water. In addition to those, a few examples of field data concerning the horizontal distribution of the interfacial Froude number around a river mouth, and some experimental results are presented.

INTRODUCTION

Not only a river water, which flows into the sea, but also other types of flow, such as a thermal discharge of cooling water from a power plant, a drainage of waste water from human lives, etc. are dynamically in the same category of the density current. Studies on those topics seem to have been extensively carried on, all over the world, nowadays, based on an enhancement of the environmental assessment. A vast quantity of papers have been issued concerning those problems every year. However, in the opinion of the present author, studies related to the mixing mechanism have been too much highly weighted, judging from the trend of issued papers, compared with the buoyancy effect which is the essential origin of the density current.

The inertia of a fluid mass accelerated by the buoyant force, sometimes, causes unstable circumstances along the interface, which frequently lead to the occurrence of internal waves, interfacial unstable vortices, and their breaking and finally mixing. Although studies on mixing are surely very important from a view point of the dilution of water temperature and waste water, the essential solution of those problems seems not to be possible, unless the basic buoyancy effects are evaluated correctly.

Based on this conception, the present author started a series of theoretical studies on an idealized density current without mixing. Such a situation corresponds to the treatment of the transonic gas flow without viscosity effects and thermodynamical changes accompanied with a heat loss. The first thing to be dealt with, along this line, was an inspection of the fundamental equations related to the idealized two-layered flow. As a result, a certain type of equation was derived, with regard to the velocity potential, under the assumption of a steady, irrotational, inviscid and immiscible flow. This equation coincides in form with that of the transonic gas flow, except one point that the Mach number is replaced by the interfacial Froude number [KASHIWAMURA and YOSHIDA 1978].

Such a coincidence implies that the river water has a flow pattern which is dynamically similar to the transonic flow. As is well known, supersonic zones are sometimes formed in part around an airfoil which is placed in a uniform subsonic flow. The same trend can also be seen in a pipe flow with a varying cross-section. Those instances predict the existence of a supercritical zone in which the interfacial Froude number exceeds unity, over the sea surface, around a river mouth. The prediction was proved quite right from field observations which were already shown in the previous conference.

Since the above-mentioned equation is a mixed type of a partial differential equation of the second order, it is difficult to obtain an analytical solution with usual methods. The author shows developed processes of an analytical approach in this problem mainly with the hodograph method, although they are incomplete yet.

FUNDAMENTAL EQUATIONS AND THEIR TRANSFORMATION

Extremely idealized equations of motion will be followed, in regard to the two-layered flow, under the assumption of steadiness, inviscidity and immiscibility. Since it means that there is no entrainment from the sea water below, the fresh water maintains its density to be unchanged, and the lower sea water should be stagnant. Therefore, only the fresh-water flow may be taken into consideration, as follows.

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + \epsilon g \frac{\partial h}{\partial x} = 0 \quad (1)$$

$$u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + \epsilon g \frac{\partial h}{\partial y} = 0 \quad (2)$$

$$\frac{\partial}{\partial x} (hu) + \frac{\partial}{\partial y} (hv) = 0 \quad (3)$$

Eqs. (1) and (2) are equations of motion, and Eq. (3) is a continuity equation. All symbols employed here, are listed in the last section.

As the fresh water is considered to have a uniform velocity at a distance sufficiently upstream from the river mouth, the flow may be regarded to be irrotational everywhere. Then,

$$\frac{\partial v}{\partial x} = \frac{\partial u}{\partial y} \quad (4)$$

and this is satisfied by

$$u = \frac{\partial \phi}{\partial x}, \quad v = \frac{\partial \phi}{\partial y} \quad (5)$$

Thus, the velocity potential ϕ exists. Combination of Eqs. (1), (2) and (3) produces the following equation, which was already presented in the previous conference.

$$\left(1 - \frac{u^2}{\epsilon gh} \right) \frac{\partial^2 \phi}{\partial x^2} - 2 \frac{uv}{\epsilon gh} \frac{\partial^2 \phi}{\partial x \partial y} + \left(1 - \frac{v^2}{\epsilon gh} \right) \frac{\partial^2 \phi}{\partial y^2} = 0 \quad (6)$$

Eq. (6) is of much significance, because of its mathematical form, showing that the fresh-water flow is dynamically the same with the transonic gas flow.

If the term $\sqrt{\epsilon gh}$ is replaced by the local sound velocity, Eq. (6) coincides with a two-dimensional equation of the transonic flow with a velocity potential. But this type of equation is extremely difficult to obtain a solution due to not only its non-linear form but also its mixed type with elliptic, parabolic and hyperbolic characters in response to numerical values of the dominant parameter, such as the Mach number, or the interfacial Froude number.

In the subsonic flow, however, immersed bodies are usually thin and stream-lined in shape, that some approximations have been adoptable to obtain a practically useful solution. On the other hand, in the present case, any river extends its width discontinuously from finite to infinite at its mouth, and the surrounding boundary cannot be changed into any convenient shape which is regarded as stream-lined.

Considering such a difference of both circumstances, the fresh-water flow seems to be more difficult than the transonic flow, in order to obtain a solution around a river mouth. Nevertheless, it will not be meaningless, to try to solve it, even with those methods already adopted in the transonic flow, since it may bring us something useful to understand this phenomenon deeply.

First, an attempt to transform the fundamental equations will be described. The stream function of some kind can be defined from Eq. (4), as follows.

$$hu = \frac{\partial \psi}{\partial y}, \quad hv = -\frac{\partial \psi}{\partial x} \quad (7)$$

Thus, Eqs. (1) and (2) are transformed into,

$$u \frac{\partial u}{\partial x} + v \frac{\partial v}{\partial x} - v \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right) + \epsilon g \frac{\partial h}{\partial x} = 0 \quad (8)$$

$$u \frac{\partial u}{\partial y} + v \frac{\partial v}{\partial y} + u \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right) + \epsilon g \frac{\partial h}{\partial y} = 0 \quad (9)$$

Those equations are rearranged by substituting Eq. (7), as follows.

$$\frac{\partial}{\partial x} \left(\frac{1}{2} q^2 + \epsilon gh \right) + \frac{\Gamma}{h} \frac{\partial \psi}{\partial x} = 0 \quad (10)$$

$$\frac{\partial}{\partial y} \left(\frac{1}{2} q^2 + \epsilon gh \right) + \frac{\Gamma}{h} \frac{\partial \psi}{\partial y} = 0 \quad (11)$$

where,

$$\Gamma = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} = - \left\{ \frac{\partial}{\partial x} \left(\frac{1}{h} \frac{\partial \psi}{\partial x} \right) + \frac{\partial}{\partial y} \left(\frac{1}{h} \frac{\partial \psi}{\partial y} \right) \right\} \quad (12)$$

Therefore, the following form is derivable.

$$\frac{1}{2} q^2 + \epsilon gh + \int \frac{\Gamma}{h} d\psi = C \quad (13)$$

where C is an integral constant. Differentiation of Eq. (13) with regard to ψ , leads to,

$$\frac{dH}{d\psi} + \frac{\Gamma}{h} = 0 \quad (14)$$

or

$$\frac{1}{h} \left\{ \frac{\partial}{\partial x} \left(\frac{1}{h} \frac{\partial \psi}{\partial x} \right) + \frac{\partial}{\partial y} \left(\frac{1}{h} \frac{\partial \psi}{\partial y} \right) \right\} = \frac{dH}{d\psi} \quad (15)$$

where $H = q^2/2 + \epsilon gh$, which is a modified Bernoulli's term.

When the flow is assumed to be irrotational, Eqs. (4) and (5) can be employed, and Eq. (15) is divided into two parts.

$$H = \frac{1}{2} q^2 + \epsilon gh = \text{const.} \quad (16)$$

$$\frac{\partial}{\partial x} \left(\frac{1}{h} \frac{\partial \psi}{\partial x} \right) + \frac{\partial}{\partial y} \left(\frac{1}{h} \frac{\partial \psi}{\partial y} \right) = 0 \quad (17)$$

Eq. (17) is another expression of Eq. (4).

HODOGRAPH METHOD

It seems so difficult to eliminate h from both equations (16) and (17), that a derivation of the equation concerning ψ only may be hopeless. Then it is necessary to seek another approach. In such a case, the hodograph method has been sometimes effective, as is well known of some examples in aerodynamics. The following set arises from Eqs. (5) and (7).

$$u = \frac{\partial \phi}{\partial x} = \frac{1}{h} \frac{\partial \psi}{\partial y} \quad (18)$$

$$v = \frac{\partial \phi}{\partial y} = -\frac{1}{h} \frac{\partial \psi}{\partial x} \quad (19)$$

The existence of h makes it impossible to apply the conformal representation, since the Cauchy-Riemann's equation is not realized, though there is a little resemblance, in form, between them.

From both equations, the followings are derived.

$$d\phi = u dx + v dy \quad (20)$$

$$\frac{1}{h} d\psi = -v dx + u dy \quad (21)$$

Combining those two, with the latter being multiplied by the imaginary unit i , the complex equation can be formed as follows.

$$d\phi + i \frac{1}{h} d\psi = (u - iv)(dx + idy) = q e^{-i\theta} dz \quad (22)$$

Therefore,

$$\frac{\partial z}{\partial q} = q^{-1} e^{i\theta} \frac{\partial \phi}{\partial q} + i \frac{1}{hq} e^{i\theta} \frac{\partial \psi}{\partial q} \quad (23)$$

$$\frac{\partial z}{\partial \theta} = q^{-1} e^{i\theta} \frac{\partial \phi}{\partial \theta} + i \frac{1}{hq} e^{i\theta} \frac{\partial \psi}{\partial \theta} \quad (24)$$

are obtained. Differentiating the upper with respect to θ and the lower q , and putting them to be equal, two equations are obtainable from the real part and the imaginary part respectively, as follows.

$$\frac{\partial \phi}{\partial q} = q \frac{\partial}{\partial q} \left(\frac{1}{hq} \right) \frac{\partial \psi}{\partial \theta} \quad (25)$$

$$\frac{\partial \phi}{\partial \theta} = \frac{q}{h} \frac{\partial \psi}{\partial q} \quad (26)$$

Now, the transformation is made in the following manner.

$$t = \int \frac{h}{q} dq \quad (27)$$

Eqs. (25) and (26) are rearranged with respect to t and θ , by taking Eq. (16), which represents a conservation of the modified Bernoulli's term, into consideration, as follows.

$$\frac{\partial \phi}{\partial t} = - \Lambda \frac{\partial \psi}{\partial \theta} \tag{28}$$

$$\frac{\partial \phi}{\partial \theta} = \frac{\partial \psi}{\partial t} \tag{29}$$

where Λ is defined by,

$$\Lambda = \frac{1}{h^2} \left(1 - \frac{q^2}{\epsilon gh} \right) = \frac{1}{h^2} \left(1 - F_1^2 \right) \tag{30}$$

Eliminating ϕ from Eqs. (28) and (29), the following equation is obtained.

$$\frac{\partial^2 \psi}{\partial t^2} + \Lambda \frac{\partial^2 \psi}{\partial \theta^2} = 0 \tag{31}$$

Since the symbol Λ includes F_1 in itself, this equation shouldn't be linear in a strict sense, but if Λ can be replaced by any adequate function with respect to t and θ , this equation is regarded as a linear one, and there may be a possibility of obtaining an approximate solution.

The parameter Λ changes from positive to negative, while F_1 grows from a value smaller than unity to a value which exceeds unity. This means that Eq. (31) is also a partial differential equation of the mixed type. Therefore, it is the most important, in this case, to find a function which has a good agreement to the characteristic of Λ . Such a situation has already been experienced else, in the past, with several proposals of functional forms in the field of the two-dimensional transonic flow.

ANOTHER APPROACH

A great interest is centered on a knowledge of the interfacial Froude number, in particular, how it to distribute horizontally over the sea off a river mouth. It may be effective for this purpose, to employ the interfacial Froude number F_1 , as an independent variable in the governing equation of the fresh-water flow. It may be considered also as one of the modified hodograph methods. Let F be a newly defined variable, as $F = F_1^2$, that is,

$$F = F_1^2 = q^2 / \epsilon gh \tag{32}$$

If Eq. (16), that is, $(1/2)q^2 + \epsilon gh = C$, is employed simultaneously, the followings are obtainable.

$$h = 2C / \epsilon g (F + 2) \tag{33}$$

$$q = \sqrt{ 2CF / (F + 2) } \tag{34}$$

By the use of those two relationships, Eqs. (25) and (26) can be transformed into,

$$\frac{\partial \psi}{\partial F} = \frac{2C}{\epsilon_g F(F+2)^2} \frac{\partial \phi}{\partial \theta} \quad (35)$$

$$\frac{\partial \psi}{\partial \theta} = \frac{2CF}{\epsilon_g (F-1)} \frac{\partial \phi}{\partial F} \quad (36)$$

Cross-differentiation of both equations with respect to F and θ , leads to,

$$\frac{\partial^2 \psi}{\partial F^2} + \frac{3F+2}{F(F+2)} \frac{\partial \psi}{\partial F} + \frac{1-F}{F^2(F+2)^2} \frac{\partial^2 \psi}{\partial \theta^2} = 0 \quad (37)$$

$$\frac{\partial^2 \phi}{\partial F^2} + \frac{1}{F(1-F)} \frac{\partial \phi}{\partial F} + \frac{1-F}{F^2(F+2)^2} \frac{\partial^2 \phi}{\partial \theta^2} = 0 \quad (38)$$

Those are both linear partial differential equations of the second order, and it may be possible to obtain each solution, although there is a difficulty in transforming boundary conditions from the physical plane to the hodograph plane.

Let Eq. (37) only be treated with here. The solution is assumed to be in the form of

$$\psi = \int_{-\infty}^{\infty} f(F, n) e^{in\theta} dn \quad (39)$$

By substituting Eq. (39) into Eq. (37), an ordinary differential equation of the second order, with respect to the new function f , is obtained, as follows.

$$\frac{d^2 f}{dF^2} + \frac{3F+2}{F(F+2)} \frac{df}{dF} - n^2 \frac{1-F}{F^2(F+2)^2} f = 0 \quad (40)$$

This is the equation of the Fuchs' type, in which three regular singular points exist, at $F = 0$, $F = -2$ and $F = \infty$. From the indicial equation at each point, two roots, viz., the exponents can be obtained as follows, respectively.

$$\lambda_1 = \frac{n}{2}, \quad \lambda_2 = -\frac{n}{2} \quad \text{for } F = 0 \quad (41)$$

$$\mu_1 = \frac{1}{2}(-1 + \sqrt{1+3n^2}), \quad \mu_2 = \frac{1}{2}(-1 - \sqrt{1+3n^2}) \quad \text{for } F = -2 \quad (42)$$

$$\nu_1 = 2, \quad \nu_2 = 0 \quad \text{for } F = \infty \quad (43)$$

Therefore, the function f can be determined with the Riemann's P-function, as shown in the followings.

$$f = P \left\{ \begin{array}{ccc|c} 0 & -2 & \infty & \\ \frac{n}{2} & \frac{-1 + \sqrt{1+3n^2}}{2} & 2 & F \\ -\frac{n}{2} & \frac{-1 - \sqrt{1+3n^2}}{2} & 0 & \end{array} \right\} \quad (44)$$

Since the P-function is not concrete in a mathematical form, for a practical application, it is possible to transform the expression into a hypergeometric series with regard to the regular singular

points, if necessary. Thus, anyhow, the general solution of Eq. (37) can be obtained in the form;

$$\psi = \int_{-\infty}^{\infty} C(n) P \begin{pmatrix} 0 & -2 & \infty \\ \frac{n}{2} & \frac{-1+\sqrt{1+3n^2}}{2} & 2 \\ -\frac{n}{2} & \frac{-1-\sqrt{1+3n^2}}{2} & 0 \end{pmatrix} F e^{in\theta} dn \quad (45)$$

where $C(n)$ denotes a function of n , which must be determined by the boundary conditions.

On this stage, the determination of a functional form of $C(n)$ comes up to be a troublesome task in order to satisfy the boundary conditions. At the present, it prevents a further development for obtaining a satisfactory solution which is applicable for practical use. Although, unfortunately unsuccessful yet it is, those two kinds of mathematical approach strongly impress us again, that the outflow dynamics of the fresh-water flow belongs to a category which is quite the same with that of the transonic flow, from both dynamical and mathematical view points.

Numerical computations are in progress, in parallel with such analytical approaches, but they need a little more time to overcome the singularity which appears at a river mouth, where the equation changes its characteristic from elliptic to hyperbolic.

The present author has continued a series of studies on the density current which appears in the neighborhood of a river mouth, for more than twenty years, and has, just recently, reached a finding of this interesting problem. Since he has little knowledge about the progress at the present situation in aerodynamics, he desires earnestly to receive any advices and comments, kindly offered by those who have much experience in the field of the two-dimensional transonic flow.

FIELD EXAMPLES AND DISCUSSIONS

A supercritical zone, in which the interfacial Froude number F_i exceeds unity, extends over the sea surface, from a river mouth into offshore directions, as well as a supersonic zone in which the Mach number M exceeds unity, is formed partially along an airfoil which is placed in a subsonic flow. It has already become a common understanding that the interfacial Froude number must be unity at the river mouth, if a salt wedge lies along the river bed, beneath the fresh water. This condition is very important, in particular, to calculate a shape of the salt wedge. It is also widely accepted that the interfacial Froude number decreases its numerical value smaller and smaller with the distance upstream from the mouth. Outside the mouth, in contrast with it, the number grows larger than unity, as has been revealed in the field measurements made by the author and his collaborators [KASHIWAMURA and YOSHIDA 1978].

The trend of such a longitudinal change of the interfacial Froude number was, hitherto, sometimes treated by some researchers but usually only one-dimensionally, along the stream line. According to the present author, however, it must be considered horizontally. This paper neglects mixing from the fundamental equations intentionally, because of an attempt to put emphasis on the buoyancy characteristic of the fresh-water flow. However, needless to say, this type of flow is always accompanied with mixing, and therefore, some differences between theoretical and practical are expected at some points, for instance, a figure and a size of the supercritical zone, or a spatial distribution of the interfacial Froude number.

It is well known that the mixing grows intensively with an increase of the numerical value of the interfacial Froude number. Accordingly, the upper fresh water and the lower sea water must be mixed violently with each other, within the supercritical zone. This fact has also been examined in field measurements, in which salinity concentration in the fresh water abruptly grows in this zone. The mixing mechanism of this kind has been studied with a very careful observation in laboratory experiments, by Dr. Yoshida [YOSHIDA 1980].

Figs. 1, 2 and 3 show three field examples of the supercritical zone and a horizontal distribution of the interfacial Froude number, in the vicinity of the mouth of the Ishikari River, which flows by Sapporo City. The amount of the river discharge, in Fig. 1, is the greatest among three cases, and in Fig. 3, smallest. In every case, the salt wedge stretched inward, beneath the fresh water along the river, though its length differed. Judging from those figures, the area occupied by the supercritical zone seems to depend on the amount of the river discharge. From a theoretical view point, the numerical value of the interfacial Froude number at the front of the salt wedge should be a dominant parameter for determining the whole area occupied by the supercritical zone.

We can find a small zone in which $F_i > 3$, in Fig. 1, but on the other hand, the maximum of F_i doesn't reach 2, in Fig. 3. Thus, the area of the supercritical zone is also dependent on the maximum value of F_i itself within it. The inshore end of the zone is always located approximately at the river mouth in each case, and it must correspond to the control condition which has been believed to hold true that $F_i = 1$ at the river mouth. Another small supercritical zone is found locally at the end of the left sand spit in Figs. 2 and 3. It may perhaps be caused by a rapid flow based on a potential flow.

Fig. 4 shows a longitudinal change of the interfacial Froude number F_i along the main stream of the fresh-water flow, where F_i grows rapidly in the vicinity of the river mouth and exceeds unity. In this figure, since the distance is limited within 600 m offshore, the further trend of F_i cannot be seen, but it decays down again at some point beyond 600 m, undoubtedly, as shown in Fig. 3. The symbol E denotes a coefficient of entrainment which takes place from the lower sea water into the upper fresh water. Numerical values of E are obtainable from an equation which has been proposed, as Eq. (5), in

Fig. 1 The supercritical zone formed in the neighborhood of the mouth of the Ishikari River.

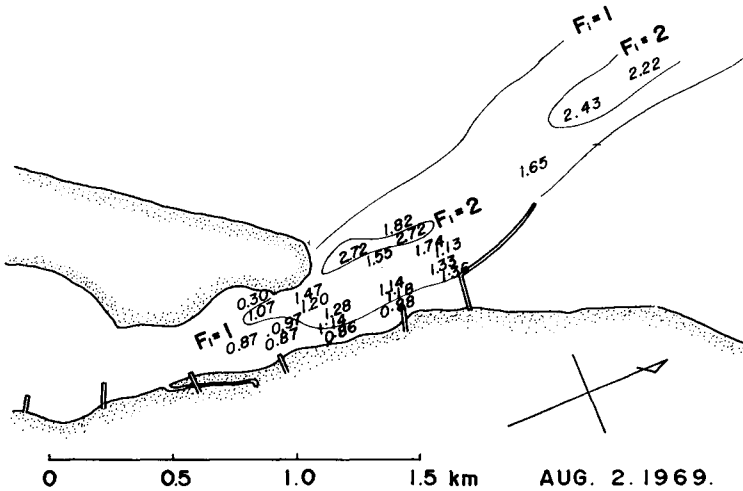

Fig. 2 Another example of the supercritical zone at the Ishikari River

Fig. 3 The third example of the supercritical zone at the Ishikari River.

Fig. 4 Longitudinal change of the interfacial Froude number F_i and the entrainment coefficient E .

the previous proceedings. The entrainment coefficient E grows rapidly with an increase of F_i , but it is interesting that E decays soon much earlier than F_i . The relationship between E and F_i should be a theme which is necessary to reveal in the near future.

Figs. 5 and 6 show another field examples which have been obtained in the neighborhood of the mouth of the Teshio River, which is situated on the north-western district of Hokkaido. Since the observed points are much less than the previous examples at the Ishikari River, the extension of the supercritical zone cannot be determined in shape exactly, but the zone evidently exists just from the river mouth to offshore directions, as well as in each case of the Ishikari River. In both cases, in Figs. 5 and 6, the salt wedge was formed over a distance more than 10 km along the river bed. The longitudinal change of F_i is also shown in Fig. 7, whose data are based on the observation shown in Fig. 5. The trend resembles that of the Ishikari River, but it shows that there is a decaying stage after the distance of 200 m off the mouth. The symbol \bar{u}_1 is a velocity of the fresh-water flow, and its highest value is found at a little distance off from the mouth. This phenomenon has usually been believed to be peculiar to the two-layered flow at a river mouth, as has already been published by the present author [KASHIWAMURA 1972]. In this manner, the field examples have confirmed an existence of the supercritical zone, as already predicted by the theory.

If the discharge amount of the river water grows up beyond a certain limit, the salt wedge is pushed out from the river mouth into the sea, as is frequently experienced in a flood season. In such a case, as the interfacial Froude number F_i exceeds unity even inside the river, the dynamical situation is similar to a flow around an airfoil which is placed in a supersonic flow, and then, the supercritical zone may occupy a much larger area over the sea. A thermal discharge of cooling water from a power plant is also belonging to the same category with those cases.

As is well known, shock waves and thermodynamical changes are accompanying to the formation of the supersonic zone in aerodynamics. In our cases, the mixing between the fresh water and the sea water may correspond to those phenomena. Studies on a fine mechanism of the mixing seem to be very important from this view point.

Finally, an example in model experiments is shown in Fig. 8. This is one of the recent works which have been done by Mr. Nishida, graduate student of our laboratory. This shows a horizontal distribution of F_i and the supercritical zone which extends from the outlet of the channel into offshore directions, and it gives approximately the same trend with the field examples. Thus, the laboratory experiment and the field measurements have proved together, the existence of the supercritical zone, as the present author predicted from the theoretical consideration.

CONCLUSION

First, the equation of motion was treated, with regard to the fresh-water flow, which flows out from a river mouth, horizontally into the sea. Emphasis was placed on the buoyancy only, and then viscosity and mixing were neglected. As the result, the dominant equation agreed, in form, with the equation of a transonic gas flow. The interfacial Froude number plays a dominant part, in the place of the Mach number, which is dominant in the transonic flow.

Next, the governing equation was studied, with the hodograph method and its modification, in order to obtain a solution. Although unsuccessful yet they were, the coincidence between the fresh-water flow and the transonic flow, was still more confirmed, in dynamical and mathematical meanings. As the present author had predicted an existence of the supercritical zone outside a river mouth, by analogy of the existence of a supersonic zone in the transonic flow, several examples of the field observation were illustrated, in order to prove that the prediction was correct. Mixing takes place intensively in the supercritical zone, since the interfacial Froude number exceeds unity there.

Throughout the description, the author has put emphasis on the importance of the buoyancy effect of the fresh-water flow, so as to attract attentions to the singular characteristic of the two-layered density current, which resembles the transonic flow, and also to a significant role of the interfacial Froude number which dominates the entire flow characteristics even including the mixing between the fresh water and the salt water.

The author expresses his sincere thanks to all the collaborators in his laboratory for their helps of many kinds, in particular, to Mr. Nishida, who kindly offered an unpublished experimental result, for the present paper.

NOTATIONS

- x, y: Longitudinal and lateral coordinates.
- u, v: Velocity components referred to x and y.
- q: Absolute value of velocity, $q = \sqrt{u^2 + v^2}$.
- ϕ : Velocity potential.
- ψ : Modified stream function.
- F_1 : Interfacial Froude number, $F_1 = q/\sqrt{\epsilon gh}$.
- F: $F = F_1^2$.
- ϵ : Parameter of density difference, $\epsilon = 1 - (\rho_1/\rho_2)$.
- ρ_1, ρ_2 : Densities of fresh water and salt water.
- g: Gravitational acceleration.
- h: Depth of fresh water.
- M: Mach number.
- z: Complex number, $z = x + iy$.
- θ : Argument of velocity vector.
- Γ : $\Gamma = (\partial v/\partial x) - (\partial u/\partial y)$.

H: Modified Bernoulli's term, $H = (1/2)q^2 + \epsilon gh$.
t: $t = \int (h/q) dq$
 $\Lambda: \Lambda = (1 - F_1^2)/h^2$.
n: Arbitrary variable defined within $-\infty < n < \infty$.

DISPERSION OF COOLING WATER FROM A COASTAL LNG PLANT.

P. ACKERS,* J.D. PITT,* G.THOMPSON,* AND K.G. RIPPIN+

ABSTRACT

The object of this case study was to predict the likely degree of pollution resulting from the discharge of heated water from a proposed LNG plant into the sea (Figure 1). The expected thermal loading was 40 m³/s at a temperature of 10°C above the natural ambient sea water temperature. The investigation was required to provide data for an ecological study to determine the possible impact of the plant on the coastal and marine environment.

Information on tide levels, tidal currents, salinity, sea temperature, wind strength and direction was obtained in a general survey programme which had already been commissioned. These data provided vital information on seasonal variations in marine conditions and further local information was obtained from short intensive hydrographic surveys. The data were analysed to yield a simplified description of the tidal and wind induced currents and suitable values of mixing parameters for use in two numerical models. The first dealt with the "near field" processes of the spread of a buoyant layer of heated water under the convecting influence of the tidal currents. The second model simulated the "far field" processes which give rise to a general increase in the temperature of the sea in the region.

1. INTRODUCTION

Objectives

1.1 The main object of the study was to obtain approximate indications of the extent of the spread of heated effluent from the proposed LNG plant, together with the probable range of temperature increase at locations which were environmentally sensitive. The methods used relate equally well to other conservative and non-conservative pollutants, and so an ancillary purpose of the work was to assess the spread and concentration of chemical pollutants, for example anti-fouling additives, that might be present at significant concentrations in the plant effluent. However, only the temperature aspects are described here. This information was required for a range of tidal and seasonal weather patterns, to enable other specialists to assess the impact of thermal and other pollution on the marine and coastal ecology. To this end, liaison between the ecologists and hydraulicians was necessary to identify sensitive areas requiring particular scrutiny.

1.2 In the time scale available and within the budget that appeared reasonable for an environmental study, physical modelling was inappropriate. In any case, there are severe limitations in making scale models of the relevant processes. Consequently the chosen method of study was by computer simulation. Within the time and budget constraints many approximations and simplifications were needed but it is believed that the predictions made were of appropriate detail and accuracy for the purposes of an environmental impact appraisal.

1.3 Two numerical models were used, one of which dealt with the "near field" processes of the spread of a buoyant layer of heated water under the convecting influence of the tidal currents. The second model simulated the "far field" processes which give rise to a general increase in the temperature of the sea in the region. In each case, output was presented as the increase above ambient temperature so absolute temperatures were derived by super-position of output data on existing conditions.

The Proposed Scheme

1.4 Woodside Petroleum Development Pty Ltd. are proposing to abstract natural gas from the North Rankin gas field located some 130 km offshore from Dampier in 125 m depth of water. The gas will be brought ashore through a single pipeline to the onshore terminal at Withnell Bay, approximately 12 km north-east of the town of Dampier (Figure 1). Here some of the gas will be piped directly to local markets and to the city of Perth through a proposed 1,500 km long gas pipeline, and some will be liquified to be exported in LNG tankers. It is expected that something like half of the total output from the North Rankin field will be liquified, for export, at Withnell Bay.

1.5 The proposed facilities at Withnell Bay include a gas inlet station, LNG loading jetty, service jetty, LNG storage tanks, offices, and the gas liquifaction plant. It is envisaged that the liquifaction plant will be divided into three equal sized modules (trains), each with a capacity of about 11 mill. m³ per day. To liquify gas it must be cooled

down to -160°C . This is achieved by compressing the gas in large steam driven compressors, typically of 20,000 hp or more each. The enormous amount of heat given off during the liquifaction process is dissipated through heat exchangers into the cooling water system, the heat load being of similar order of magnitude to a nuclear power station.

The Cooling Water System

1.6 Neither fresh water cooling nor air cooling is possible in the hot arid climate of the north-west. The only cooling medium readily available to the site is sea water. Optimisation studies carried out on the LNG complex as a whole indicated an optimum rise in the cooling water temperature of about 10°C , corresponding to a once-through sea water requirement of about $150,000\text{ m}^3$ per hour, i.e. $40\text{ m}^3/\text{s}$ approximately.

1.7 It is proposed that the water will be drawn from near the sea bed several hundred metres off the coast north of the plant site. The heated water will be discharged into a watercourse known as "No Name Creek" south of the plant site. From here the hot water will travel down the watercourse into "No Name Bay" and thence to the open sea. The proposed arrangement for the cooling water system is shown in Figure 2.

2. METHODOLOGY

Physical principles

2.1 The prediction of thermal pollution relies upon a detailed understanding of the mechanism by which the heat from the discharge will spread through the receiving body of water and overlying air. The heat absorbed by the seabed adjacent to hot water outfalls has been shown to be negligible in similar situations elsewhere (1) and so was not considered further.

2.2 As the heated water travels down No Name Creek a distance of 750 m, it will lose a small amount of heat by evaporation and radiation. On entering No Name Bay the heated water will mix with the relatively small body of water in the bay and it may form a surface layer in the deeper part of the bay, depending upon the tidal conditions. The total heat losses in the creek and bay were calculated to give a maximum temperature reduction of less than 1°C . Therefore in the rest of the analysis it was assumed that the nominal 10°C temperature rise through the plant applied at the outfall from No Name Bay into Mermaid Sound.

2.3 At the exit from No Name Bay, the heated water will spread out over the surface of the sea under the influence of buoyancy, momentum and shear stresses between the two layers. In this "near field", the water will be vertically stratified with the hot water forming a plume on the surface of the cooler sea water. This plume will be convected up and down the coast by the currents whilst being gradually dispersed by vertical and horizontal mixing. The temperature concentration will thus reduce and the edge of the plume will become indistinct. The degree of mixing occurring will be a function of the variability of the velocity, which in turn will depend upon tidal and wind conditions as well as local sea bed topography.

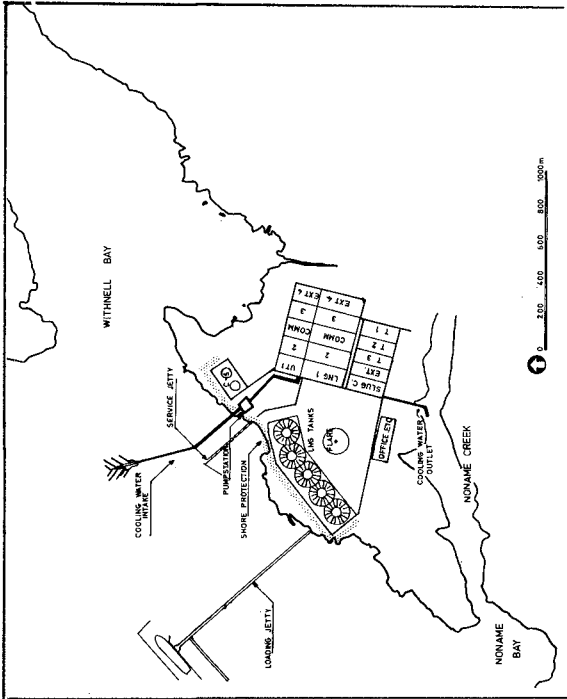

FIGURE 2 COOLING WATER OUTFALL ARRANGEMENT

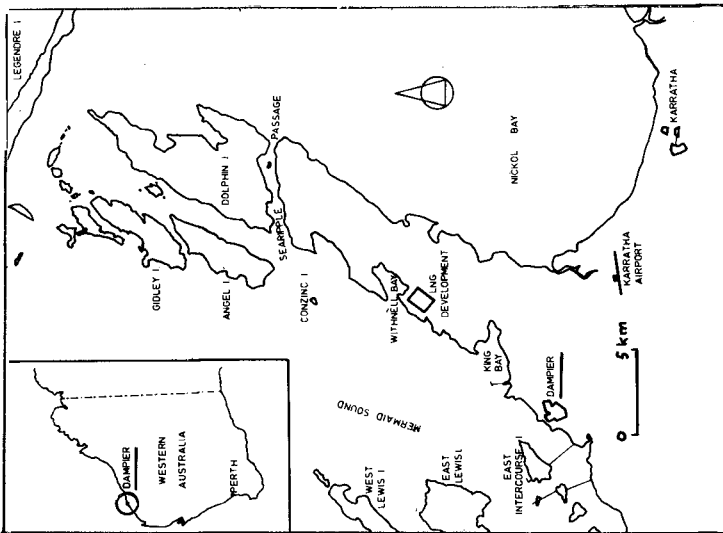

FIGURE 1 GENERAL LOCATION MAP

2.4 The hot water discharge can travel up to one tidal excursion from No Name Bay in the first tidal period after release; however, to travel further, it must rely upon net tidal and wind induced drifts and mixing. These are slower processes than inter-tidal convection. Outside a range of one tidal excursion from No Name Bay, the maximum temperature rise caused by the hot water discharge will be much reduced. The vertical stratification will also diminish progressively until mixing over the water depth is complete.

2.5 The continuous release of heat through No Name Bay will raise the general water temperatures above their natural levels over a large area of Mermaid Sound. The new temperature distribution will depend upon:

- the heat input by the LNG plant.
- the distribution of the cooling water by tidal drift and wind induced currents.
- the mixing of the cooling water with the water in the sound in both horizontal and vertical directions.
- the heat losses through the water surface into the atmosphere.

2.6 The computer programs which model the two main phases of cooling water dispersal are based on different assumptions. The "near field" model indicates the conditions in the intertidal zone close to the outlet at No Name Bay, in the surface layer generated by thermal stratification. The "far field" model looks at a much larger sea area beyond the zone of strong stratification assuming the heat to be distributed through the water depth and to be dissipated by surface cooling and spread by drift currents induced by wind and tides. In practice the "near field" and "far field" processes merge but they are commonly considered separately for simplicity.

Near field model

2.7 The "near field" model considers the initial spread of a buoyant plume entering Mermaid Sound via No Name Bay. It traces the change in shape of the plume and derives the temperature rise at various points within the plume for a variety of wind and tidal conditions.

2.8 The plan shape of the plume was determined by monitoring the movement of discrete labelled patches of hot water in a calculated velocity field over two or more tidal cycles. The velocity of a labelled patch in the surface layer was obtained as the vector addition of the ambient time-varying water velocity and the imposed velocity due to the source (2). The source has significant width compared to the tidal excursion, and was therefore treated as the summation of a large number of closely spaced point sources. The imposed velocity is then given by:-

$$U_x = \frac{Q}{4 \pi Da} \log \left\{ \frac{y^2 + (x+a)^2}{y^2 + (x-a)^2} \right\}$$

$$U_y = \frac{Q}{2 \pi Da} \left\{ \tan^{-1} \left(\frac{x+a}{y} \right) - \tan^{-1} \left(\frac{x-a}{y} \right) \right\} \quad \text{Equ.1.}$$

where a = half width of the line source.
 D = assumed depth of surface layer
 x,y = co-ordinates of the point relative to the centre of the line source.
 Q = volumetric discharge rate
 U_x, U_y = velocities in the x and y directions.

2.9 Random eddy motions and the non-uniformity of current patterns are inevitable components of any turbulent flow. Such motions will mix the cooling water discharge with the ambient water, and can be described by using a Fickian analogy in writing a steady-state two-dimensional diffusion convection equation. Taking into account a simple description of surface cooling based on temperature increment above an ambient equilibrium condition, the full cooling expression becomes:-

$$\frac{\partial}{\partial y} \left\{ -D_y \frac{\partial T}{\partial y} \right\} + U \cdot \frac{\partial T}{\partial x} + \frac{kT}{h} = 0 \quad \text{Equ. 2}$$

where T = temperature
 x,y = the local plan co-ordinates within the plume
 U = water velocity in the plume in the x direction
 D_y = instantaneous lateral dispersion coefficient
 k = surface heat loss coefficient
 h = plume depth

In the above, the dispersive flux in the direction of water movement has been ignored because it is generally much less than the convective flux due to the velocity U.

2.10 The solution of equation 2 has been treated by Brooks (3). Although his analysis was restricted to an unidirectional current, it is informative in that it gives an estimate of the likely dilution during either the ebb or flood tide and is therefore appropriate to the early life of the plume. In the equation, the mixing of the plume and the local water is described by a lateral dispersion coefficient which has to be assessed. It is a function of many physical phenomenon, including vertical density gradients, wind effects, tidal currents and local topography, but field and laboratory work has shown that a reasonable first estimate of the dispersive processes is given by:-

$$D_y = 0.01 L^{4/3} \quad (\text{in CGS units}) \quad \text{Equ. 3}$$

where L = plume width
 D_y = lateral dispersion coefficient.

Substituting into equation 2 and solving gives the centreline temperature of the plume (3) as:-

$$N_d = T/T_o = \exp \left\{ \frac{-kt}{h} \right\} \operatorname{erf} \left\{ \frac{3/2}{(L/b)^2 - 1} \right\}^{1/2} \quad \text{Equ. 4}$$

where b = initial plume width
 L = instantaneous plume width, where

$$L = b \left\{ 1 + \frac{2}{3} \beta \frac{x}{b} \right\}^{3/2} \quad \text{Equ. 5}$$

$$\beta = \frac{12 D_0}{U b} \quad \text{or} \quad \frac{12 D_0 t}{b x} \quad \text{Equ. 6}$$

D_0	=	initial dispersion coefficient
N_d	=	dilution at centreline
t	=	time since particle was released at source
x	=	distance travelled by particle since leaving the source
T	=	temperature of cooling water discharge
T_0	=	initial temperature of cooling water discharge

The initial plume width, b , was assessed from the spread of the plume during its first hour out of No Name Bay and this value was used to derive an initial dispersion coefficient from equation 3. Equation 4 was then used to derive the temperatures at various points in the plume.

The Far Field (background) Model

2.11 Cooling water from the LNG plant will be transported away from No Name Bay by tidal and wind induced currents. Turbulent mixing and dispersion will act to spread the heat horizontally and vertically, so that after the first one or two tidal cycles, the hot water from the LNG plant will have mixed with ambient water over the full depth. Eventually the heat content of the cooling water discharge is lost to the atmosphere by exchange across the water surface at a rate proportioned to the difference between the water temperature and the equilibrium temperature. The actual water temperatures change diurnally and seasonally, and strive to follow the changes in the instantaneous values of the equilibrium temperature, by heat transfer across the water surface. The LNG plant will increase the actual temperature and hence increase surface losses close to the outfall. The far field model calculates the distribution of this increase in the vertically averaged water temperature.

2.12 No Name Bay is situated on a relatively straight coastline. Therefore in order to maintain continuity of mass, the depth average current, in the nearshore zone, must be parallel to the coast. These currents were assumed to be made up of two parts; a steady predominantly wind induced longshore drift, and a periodic current with a tidal average value of zero. During the tide, water moves back and forth along the coast and hence the cooling water passes from No Name Bay into an oscillating tidal plug of water, of length equal to one tidal excursion along the shoreline.

2.13 The time scale associated with significant cooling by surface heat exchange can be shown to be at least an order of magnitude greater than a tidal period. Therefore the temperature distribution which results from this surface exchange can be represented by the tidal averaged equation:-

$$U \frac{\partial T'}{\partial x} - D_x \frac{\partial^2 T'}{\partial x^2} - D_y \frac{\partial^2 T'}{\partial y^2} + \frac{K}{h} T' = 0 \quad \text{Equ. 7}$$

where T' = vertically averaged temperature rise
 x, y = horizontal co-ordinates on the moving axis
 within the tidal plug.
 U = longshore drift velocity
 D_x, D_y = Tidal average dispersion coefficients in the
 x and y directions.
 h = water depth
 K = surface heat loss coefficient.

2.14 The solution to equation 7 for a shore-based outfall into a body of water of constant depth was derived from work by Atkins and Diver (4) to be:-

$$T'(x, y) = \frac{q T_o}{\pi h \sqrt{D_x D_y}} \exp\left(\frac{xU}{2D_x}\right) Ko(z) \quad \text{Equ. 8}$$

where $z = \left\{ \left(\frac{x^2}{D_x} + \frac{y^2}{D_y} \right) \left(\frac{u^2}{4D_x} + \frac{K}{h} \right) \right\}^{1/2}$

$T'(x, y)$ = the temperature at point, x, y
 T_o = the temperature at the outfall, above ambient
 q = the outfall discharge
 $Ko()$ = is the modified Bessels function of the second
 kind of order zero.

2.15 Equation 8 represents the solution for one point source at the origin, i.e. staying at the centre of the moving tidal plug. The solution in the present case must represent the movement of the plug past the outfall during each tide. In the tidal average solution this was done by considering the heat distributed over a length of the coastline equal to one tidal excursion centred on No Name Bay. The source was therefore divided into several point sources distributed over the tidal excursion. The solution is linear and therefore the temperature rises due to each of these sources were added directly to give the final solution.

2.16 As a point of interest, equation 8 was compared with a similar solution given by McQueen (5), and was found to agree well at all points except close to the source, where the assumptions on which the two solutions were based differed slightly.

2.17 Equation 8 indicates that the temperature distribution is dependent upon the tidal average dispersion coefficients which are themselves highly variable. The coefficients represent the overall effect of many physical phenomenon including local seabed topography, the variability of wind and tidal currents in time, the variability of velocities over depth and in plan, and the buoyancy of the cooling water itself. According to Talbot (6), a realistic value of the longitudinal dispersion coefficient is given by:-

$$D_x = 3.6 U_{\max} H \quad \text{Equ. 9}$$

where U_{\max} = the maximum tidal velocity
 H = mean tidal depth.

2.18 For effective temperature reduction, the heated water should dis-

perse offshore to mix with the main body of water in Mermaid Sound. It is generally found that such lateral dispersion is less than longitudinal dispersion. 0.1 is a typical ratio for the lateral to longitudinal dispersion coefficients, although this value could increase markedly with onshore/offshore wind activity. In modelling the seasonal changes of water temperature, the 14 day average drift velocity was used with typical dispersion coefficients of $D_x = 5.0 \text{ m}^2/\text{s}$ and $D_y = 0.26 \text{ m}^2/\text{s}$. The basic lateral dispersion coefficient was multiplied by a factor of between 1 and 20 depending on the onshore/offshore wind conditions in the preceding 14 days.

2.20 The loss of heat to the atmosphere is a much slower process than the convective and dispersive processes and is therefore not dominant in determining the plan distribution of the excess heat. In general a coefficient of 6 cm/hr was used. This value is typical of that used in recent similar studies (7,8,9). Sensitivity tests with the loss coefficient varying from 3 to 30 cm/hr did change the temperatures noticeably, but did not significantly change the general results. A greater change in the results could be obtained by relatively small changes in dispersion coefficients or drift velocities.

Data Synthesis

2.21 The data required for the models outlined above relate mainly to two basic parameters: the current pattern which determines overall movement, and dispersion coefficients which determine the degree of mixing. However both of these are dependent on many factors and a general understanding of the marine environment is required before suitable input data can be formulated. In particular the influence of winds and tides must be understood to define conditions appropriate to different seasonal or tidal conditions. Furthermore uncommon conditions, and the probability of their occurrence, must be considered.

2.22 As already explained dispersion coefficients were based on values obtained from relevant references adjusted by the application of appropriate empirical rules. Dye tests or similar field work to estimate dispersion coefficients in the Mermaid Sound area were not considered appropriate for this broad-brush study. A large number of tests in a variety of weather and sea conditions would have been necessary and neither funds nor time were available for such detailed work. Having assessed what were considered appropriate values, the sensitivity of the analysis to changes in dispersion coefficient was tested.

2.23 The distribution (spatial and temporal) of currents was required in two forms. For the near field and far field models respectively these were:

As variations over a tidal cycle for surface water in the nearshore zone. These data were required to predict the movement of the surface plume of recently released hot water and therefore could be restricted to a zone close to No Name Bay, about 6 km long and within 2 km of the shore.

As vertically-integrated residual velocities over a tidal cycle, so that the long term exchange of hot water with

the surrounding sea water could be evaluated. The area of interest is dependent on the smallest temperature rise considered significant, which was considered here to be 20 km by 10 km.

2.24 The following approach was adopted in formulating input data on currents for the models:-

- A general appreciation of tidal currents in Mermaid Sound and identification of principle flow patterns in spring and neap tides.
- Analysis of the effect of wind on surface currents and on depth integrated currents and hence the deduction of empirical relations between wind speed and current speed. A comparison was also made between observed data and available theory. (10,11).
- Analysis of long term wind records to deduce typical seasonal wind patterns and the duration of particular events, in particular calm periods which may be critical in the dispersion of cooling water.
- Formulation of alternative current patterns both nearshore e.g. tidal excursion etc. and in the far field zone e.g. residual drift, for use in the heat dispersion models.
- Sensitivity tests to determine where critical values of input data occur and where necessary to refine these.

2.25 Results of these analyses are presented in the following section.

3. MARINE ENVIRONMENT (Refs 12-20)

Available data

3.1 The main source of data used in the study were long-term recordings collected by E.G. & G, the principal survey contractor engaged on the project. An extensive programme had been organised to provide criteria for design of pipeline, the harbour, jetties and other coastal facilities: instrumentation to record data on wind, waves, tides, currents, salinity and temperature was installed over a wide area. However, many of the instruments were located offshore and were beyond the zone of interest so far as cooling water dispersion was concerned. It was therefore necessary to supplement the main programme with subsidiary data collection exercises specifically aimed at obtaining data on near shore conditions. Three exercises were mounted by Binnie International, in the periods 23-24 November 1978, 16-19 December 1978 and 16-22 January 1979.

Winds

3.2 Winds have a significant effect on the marine environment through the generation of waves, which increase mixing, and through the creation of currents, which change the pattern of advection. Two dominant wind patterns are evident (Figure 3):

FIGURE 4 MERMAID SOUND

FIGURE 3 TYPICAL SUMMER AND WINTER WIND PATTERNS

- The summer pattern consists of a prevailing westerly wind, acted upon by the night and early morning south-easterly land breeze and by the afternoon north-westerly sea breeze.
- The winter pattern consists of a prevailing easterly wind, again acted upon by the night and early morning south-easterly land breeze and by the afternoon north-westerly sea breeze.

3.3 Cyclones can occur in the summer months between November and March, accompanied by sea surges and by severe wave action: however so far as the study of cooling water dispersion is concerned these are of little importance since they can only improve the mixing. Of greater concern are the possible calm periods in which there is relatively little mixing by wave action and significantly less convection in the absence of wind induced currents.

Currents

3.4 Tidal streams are summarised in Figure 4 and are given as depth averaged values deduced from the long-term current observations. The pattern is similar to that of a closed bay, with very little tidal flow near East Intercourse Island. The main flood flow is towards the south but is directed southwest along the coastline in the area near Withnell Bay. Ebb currents are generally of comparable magnitude and flow in the opposite direction. An exception to this is in the area southwest of Angel Island where water flowing through Boat Passage creates an ebb dominant flow with nett movement to the North West.

3.5 Tidal velocities along the shoreline between Phillip Point and Withnell Bay are significantly lower than those in the centre of Mermaid Sound and reach a maximum of only 15 cm/s. The tidal excursions corresponding to spring and neap tides in this area are 2.0 km and 0.6 km respectively, and it follows that tidal mixing is significantly less than in many other regions where tidal excursions may be in the range 15 to 25 km.

3.6 Whilst observed data are broadly consistent with the above pattern, the majority of cases are affected by winds. The vertical velocity profiles are complex, particularly where the local topography is irregular and when wind induced currents are generated at an angle to the tidal component. A further complication arises from the duration dependence of the velocity profile. The depth affected by wind stress increases with time. Surface currents were observed to respond within about an hour of changes in wind conditions and the whole depth was affected within 12 hours. However steady state conditions did not appear to be established for considerably longer.

3.7 A simple approach to generating input conditions for the near field model was provided by the observation that surface currents were about 1.5% of the wind speed (recorded 10 m above sea level) and were in line with the wind. This result is consistent with previously published data relating to open sea conditions, although in such cases the Coriolis effect is often significant, causing currents to deviate to the left of

the wind direction (to the right in the Northern hemisphere). It follows that the typical daily wind patterns (Fig. 3) can be used to derive surface currents, typical values being in the range 3-12 cm/s. Wind induced currents and tidal components were superimposed to formulate conditions under different tide and seasonal wind patterns.

3.8 Current data for the far field model was derived by relating residual movement of water in Mermaid Sound to longer term wind patterns, the tidal residual movement being small in comparison. Residual drift velocities induced by winds are governed partly by the direct action of the wind and partly by larger scale effects which control water movement outside Mermaid Sound. Typical net movements of water in summer and winter are shown in Figure 5. The summer pattern is governed by dominant westerly winds which force water through Mermaid Strait and then North-East into the Sound. In the winter months, South-Easterly winds cause high water levels along the North-West boundary of Nickol Bay and result in strong currents flowing Westwards through Boat Passage, which induce South-Westerly currents along the shoreline near Withnell Bay. It is the longshore residual drift which is of importance in the far field model and depends mainly on the longshore component of wind velocity. In addition the offshore component of wind velocity induces south westerly longshore currents. A simple model was proposed in which

$$u = 0.015 U - 0.010 V \quad (V > 0)$$

$$u = 0.015 U \quad (V < 0)$$

where u is the longshore drift current (north east)
 U is the longshore component of wind velocity (north east)
 V is the offshore component of wind velocity (north west).

Values of u ranged from -10 to +10 cm/s.

Temperature

3.9 Water temperatures were available from the long term records obtained from E.G. & G. They are fairly uniform over the area of Mermaid Sound and show an annual variation from 19°C in July or August to 32°C in February or March (Figure 6). Variation over the vertical is generally small though anomalies may occur giving temperature differences of about 2°C or more.

3.10 Variation through the tide is only significant in the area south-west of Angel Island, and results from warmer water in Nickol Bay passing through Boat Passage on the ebb tide: here temperature fluctuations of 1-2°C are common over the tidal cycle. Elsewhere the variation is less than 0.5°C over a tide but the effect is detected in variations over the two-week cycle between spring and neap tides. The greater quantity of warm water exchanged during spring tides increases general ambient temperatures by 1-3°C over the whole of Mermaid Sound. This effect is not always apparent when seasonal changes of temperature during the same spring/neap cycle are large.

3.11 Temperature variations in the shallow water of the bays along the coast are sometimes quite pronounced, and diurnal fluctuations of 5°C or more have been reported.

FIGURE 6 ANNUAL VARIATION OF SEAWATER TEMPERATURE IN MERMAID SOUND

4. RESULTS

The buoyant plume

4.1 Output of the near field model is in the form of age-contours and for each of these a temperature dilution factor can be estimated based on the turbulent mixing of the plume with its surroundings, with a minor additional effect due to surface cooling. Typical "plume" shapes are shown on Figure 7. By considering the plume movement over a period of 24 hours, envelopes of areas which reach specified temperature rises at any stage in that time can be plotted. Figure 8 shows conditions for a typical winter day when winds are offshore. In this case, shoreline temperature rises are negligible but in summer conditions when winds are onshore, temperature rises of up to 5°C were shown to occur near the entrance to Withnell Bay.

Background temperatures

4.2 The simulation used the weather pattern of 1978-1979 as 14-day averages to deduce the background temperature field on a tide average basis. The results were related to the environmental issues by extracting the variation of average background temperature at Withnell Bay, 3 km north-east of the cooling water outfall, and at Kings Bay, 4 km south-west of the outfall (Figure 9). Typical isotherm plots are presented in Figure 10.

4.3 The background temperature field has been considered by assuming the water to be fully mixed in the vertical. In practice, there is much overlap between the area swept by the buoyant plume and the background (far field) model. The background temperature results may be considered as applying to the main body of sea water underlying the buoyant surface layer.

4.4 Wherever there is an elevated background temperature beneath the surface plume, the plume temperatures quoted will be increased by a varying proportion of the background rise. There is no available method of combining plume temperature results with background temperature results. The problem is complicated by time and space variation and interaction between the models but for present purposes an adjusted surface temperature may be calculated from:

$$T_{\text{adjusted}} = T_{\text{plume}} + \left(\frac{1 - T_{\text{plume}}}{10} \right) \times T_{\text{background}}$$

This represents a rough upper limit, and is based on application of the estimated plume dilution factor with a warmed dilutant.

CONCLUSIONS

The framework of this study was the need to provide ecologists and environmental scientists with approximate forecasts of the temperature rises to be expected in the area and an indication of the extent of the main thermal impact, so that they could assess the effect on the marine environment should the project proceed.

In the time scale available and within the budget that appeared

FIGURE 7 TYPICAL PLUME PATTERNS FOR OFFSHORE WIND

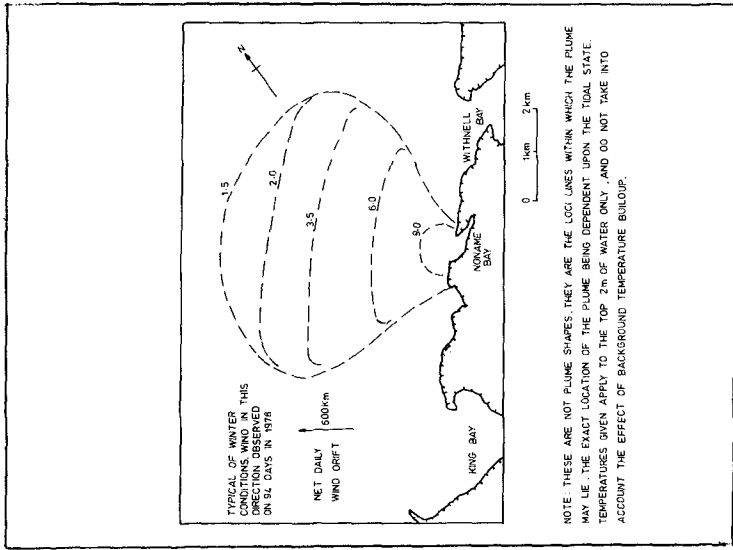

FIGURE 8 ENVELOPE OF MAXIMUM INSTANTANEOUS SURFACE TEMPERATURE RISES

FIGURE 9 ANNUAL VARIATION IN TEMPERATURE RISE AT WITHNELL AND KING BAYS

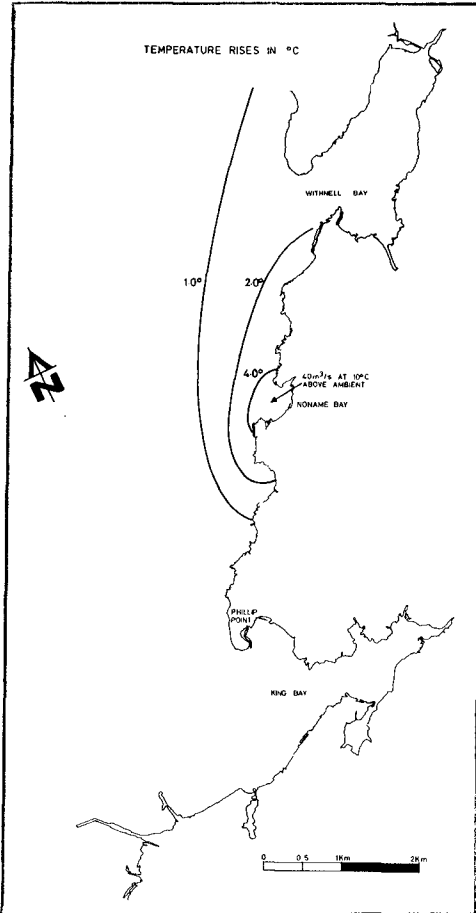

FIGURE 10 TIDAL AVERAGE TEMPERATURE RISE
LATE DECEMBER 1978

reasonable for an environmental study, physical modelling was inappropriate. In any case, there are severe limitations in making scale models of the relevant processes. Consequently the chosen method of study was by computer simulation.

Two numerical models were used, one of which dealt with the "near field" processes of the spread of a buoyant layer of heated water under the convecting influence of the tidal currents. The second model simulated the "far field" processes which gives rise to a general increase in the temperature of the sea in the region.

The simulations of the spread of pollutants, mainly hot water, from the outfall of the cooling water system provided indications of the likely range of temperatures and the extent of the spread of effluent in the environmentally sensitive coastal zone either side of No Name Bay.

The pattern of spread is strongly seasonal, being much influenced by wind induced drift of the tidal waters. The careful analysis of weather patterns and their effect on water movements is an essential part of any investigation of the spread of effluents. The study established the range of likely patterns and indicated the likely persistence at various points along the coast and elsewhere of temperature rises of several degrees Celsius.

ACKNOWLEDGEMENTS

This study was carried out in association with Maunsells (Perth) on behalf of Woodside Petroleum Limited, operator for the North West Shelf Joint Venture. Participants in the Venture are Woodside Petroleum Limited 50%, and North West Shelf Development Pty. Ltd., B.P. Petroleum Development Australia Pty. Ltd., and California Asiatic Oil Company, each with 16.2/3%. The authors are grateful to them, and also to E.G. and G Ltd. and to staff of HRS, Wallingford, for their ready co-operation and guidance. Development work on computer programs was carried out by M.C. Allen of Binnie and Partners London.

EXPERIMENTAL STUDY OF THE BUOYANT SURFACE JET
WITH THE PRESENCE OF BOTTOM BOUNDARY
AND CROSS CURRENT.

B. SAFAIE, Ph.D., A.M. ASCE
KUWAIT INSTITUTE FOR SCIENTIFIC RESEARCH

I. INTRODUCTION:

The problem of buoyant surface jet (BSJ) is relevant from the practical standpoint to the discharge of cooling water of power plants into the receiving water bodies. The buoyant surface jet has extensively been studied by numerous investigators both theoretically and experimentally. Most studies have been concerned with the problems of BSJ discharged horizontally into a surface of a deep ambient water with or without cross current.

From a practical standpoint, however, the design engineers are often confronted with the design of thermal outfalls in the coastal regions which are frequently shallow and have the boundary effects. Few investigators have studied the problem of BSJ discharged horizontally over slopping bottom into quiescent receiving water (1), (2), (4), (5), (6), and (7). However, no information on the foregoing problem with moving ambient water is available. The purpose of this paper is (a) to present the experimental results of BSJ which is discharged over slopping bottom into moving ambient water, and (b) to see the degree of error which is introduced by applying the deep water integral models to the case of a buoyant surface jet with a bottom boundary.

II. DIMENSIONAL ANALYSIS:

The BSJ is characterized by the following source parameters

1. Volume flux, $Q_o = U_o A_o (L^3 T^{-1})$;
2. Momentum flux, $M_o = U_o^2 A_o (L^4 T^{-2})$;
3. Buoyancy or kinematic mass deficiency. flux
 $B_o = \frac{\Delta \rho_o}{\rho_a} g U_o A_o (L^4 T^{-3})$;
4. Aspect ratio, $A_s = h_o/b_o$;

The subscript -o refers to source parameters and the subscript -a to ambient conditions (receiving water); U is velocity, A is area, h_o is discharge height, b is width, ρ is density, $\Delta \rho$ is $\rho_a - \rho$, and g is gravitational acceleration.

The bottom boundary is characterized by the bottom slope and the bottom friction. However, only the effect of bottom slope is considered in the present investigation.

In the present study, the direction of ambient current is assumed to be parallel to the shore line. Therefore the ambient current is characterized by current speed U_a .

By dimensional analysis one can show that the independent dimensionless numbers are

1. Source Densimetric Froude number,

$$F_o (A) = \frac{M_o^{5/4}}{B_o^{1/2} Q_o} = \frac{U_o}{(g'_o A_o^{1/2})^{1/2}}$$

where $g'_o = (\Delta\rho/\rho_a) g$

2. Discharge Aspect Ratio, $A_s = h_o/b_o$
3. Bottom slope, S
4. Current ratio, $U_r = U_a/U_o$

In this experimental study the range of values of the abovementioned dimensionless numbers have been chosen to be close to the typical range of values commonly encountered in the design of outfalls.

The range of the variation of the above dimensionless parameters in this experimental study are as follows:

1. $2 < F_o (A) < 13$
2. $A_s = 1.5$
3. $0 < S < 0.04$
4. $0.2 < U_r < 0.7$

It should be noted that in developing the foregoing dimensionless parameters, it is assumed implicitly that the Reynolds number is high enough so that viscous effects are negligible, the heat loss to the atmosphere is insignificant, and since we are mainly concerned with the near field the effect of ambient turbulence is negligible.

III. EXPERIMENTAL ARRANGEMENT:

The experimental arrangement is designed in such a way that the preceding dimensionless parameters could be varied systematically and their effect on temperature field could be studied. The main feature of the experimental arrangement is shown in figures 1 and 2.

The experimental set up consisted of three major systems:

1. Receiving water system;
2. Warm water discharge system;
3. Data acquisition system.

These are described briefly in the following:

III.1 The Receiving Water System:

The main components of the receiving water system consisted of (a) a wind wave tank, 45.7m x 2.4m x 1.5m. In the middle section of this tank there was a 3.6m x 1.2m glass window on one of the side walls. Thus the flow pattern could be visualized from the side as well as from the top. (b) A circulating pipe and pump, which could generate a maximum current of 15cm/sec., was used to simulate the off-shore currents. (c) The bottom boundary consisted of a plywood "beach" 2.4m x 4.6 m with a supporting frame. The "beach" slope and the direction of the slope was adjustable. The direction of the "beach" slope was adjusted so that the ambient current was parallel to the shore. It should be noted that since the "beach" was installed in the tank in such a way that there was minimum obstruction to the ambient current, an excellent uniform and parallel ambient current could be obtained. In other words the "beach" was acting as a "flat plat" in the uniform flow field.

III.2 The Warm Water Discharge System:

The main components of this system consisted of (a) the main insulated tank with the dimensions 1.2m x 0.91m X 0.91m. This tank was insulated and was used to mix the warm and cold water to obtain the desired temperature of the Warm water discharge in the main tank. During the mixing process and during the experimental run a stirrer was used to assure temperature homogeneity of the water in the main tank. During the mixing of warm and cold water, water was continuously pumped through a bypass to the drain. By this procedure it was possible to warm the pipeline to the temperature of the warm water to be discharged. Also, using a continuous discharge, the water temperature could be monitored by the use of a digital thermometer which was placed in the line. Thus, proper adjustments could be made of the flow rate of the warm and cold water supply to expedite

Fig.1 Schematic of the experimental set-up (Plan View)

Fig.2 Schematic of the experimental set-up (Side View)
3a

achievement of the desired temperature.

b) The line from the main insulated tank to the discharge point: this "pipeline", most of which was a flexible hose, had an orifice meter installed in it which was used to measure the flow rate. It also had a dye injection assembly installed in it, which was used for the injection of dye into the discharge. Warm water was discharged from the side using a flexible hose (see figures 1 and 2).

c) Dye injection assembly: this consisted of a stainless steel tank for the dye supply in which dye could be stored and be kept under constant pressure. A needle valve was used to give the desired dye flow rate.

III.3 Data Acquisition System:

The data acquisition system can be divided into two main subsystems as follows:

III.3.1 The photographic system: consisted of a remotely controlled camera and four stroke lights which were mounted on a four adjustable arms. The camera and floodlight assembly were mounted under a moveable base which in turn was mounted on a rail, located just under the roof. The rail was above the longitudinal centerline of the tank (see figure 2).

III.3.2 The temperature measuring system: consisted of a number of thermistor probes, a moving carriage on which thermistor probes were mounted, electronic boxes for the thermistor probes, shielded cables, five channels of digital to analog (DA) for control and operation of experiments and 256 channels of analog to digital (AD) convertors, a 16K Nova mini-computer, 2 floppy disk systems, an acoustic coupler for data transfer to the computer of UCB, and ± 15 volt power supply.

A more detailed descriptions of the experimental arrangements, the experimental procedure, and the methodology for data analysis are given in Ref. (4).

IV. AN OVERVIEW OF THE FLOW AND CIRCULATION PATTERN:

Figures 3 to 10 show the photographs of a typical flow pattern generated by the discharge of a BSJ over a slopping bottom into an ambient water with cross current. In these photographs the squares are 30.48cm x 30.48cm and are on the the beach. Figure 3 shows the start of the discharge. Note that the nucleus of a circulating cell is forming at the tips. Figure 4 shows the flow pattern

Fig.3 Photo of the Flow Pattern

Fig.4 Photo of the Flow Pattern

Fig.5 Photo of the Flow Pattern

Fig.6 Photo of the Flow Pattern

Fig.7 Photo of the Flow Pattern

Fig.8 Photo of the Flow Pattern

Fig.9 Photo of the Flow Pattern

Fig.10 Photo Of the Flow Pattern

at a later time. As can be seen the BSJ is bent due to the cross current (parallel to the shore line). The circulating cell is still under development and have moved approximately 0.5m from the shore line. Figures 5 and 6 indicate that the circulating cell is reaching the equilibrium condition and has initiated the reentrainment of the warm water. Note the dye streaks from dye crystals is developing and showing the bottom flow pattern.

Figures 7 and 8 clearly show the recirculation pattern. As can be seen from these photographs the circulating cell has a two-dimensional character. Also to be noticed in these photographs is the interesting deflection pattern of the ambient current which was parallel to the shore line before discharging the BSJ. Figures 9 and 10 show the final equilibrium stage at which the reentrained warm water has completely filled the area between shore line and the BSJ. The bottom current pattern is also clearly shown by the developed dye streaks. Again note the interesting deflection pattern of the ambient current and the circulating cell in these photographs.

Based on these observations the flow field can be schematized as shown in figure 11. It was found that the location of the center of the circulating cell is mainly a function of the source Densimetric Froude number and the ambient current ratio.

V. PRESENTATION OF EXPERIMENTAL DATA:

The effect of the systematic variations of the independent dimensionless numbers on the centerline temperature and the jet trajectory is investigated experimentally. In this section the experimental results are presented.

Figure 12 shows the effect of the variation of the source Densimetric Froude number on the centerline temperature decay other parameters being constant. In this figure normalized centerline temperature, $\Delta T_m / \Delta T_0$ is plotted Vs. normalized distance, $S_c / \sqrt{A_0}$, for different values of the source Densimetric Froude number. Here $\Delta T_m = T_m - T_a$, $\Delta T_0 = T_0 - T_a$, T_m is maximum temperature at a given section, T_a is ambient temperature and T_0 is source temperature along the curvilinear co-ordinate as shown in figure 11. As can be seen for all practical purposes, within the experimental range, the centerline temperature decay does not vary with the source Densimetric Froude number.

The effect of the ambient current ratio on the centerline temperature can be seen in figure 13. The other parameters being constant, an increase in the cross-current

Fig.11 Schematic of the Flow Pattern

Fig.12 Normalized Centerline Temperature vs Normalized Curvilinear Distance (effect of F_0)

ratio will cause the centerline temperature to increase. The normalized centerline temperature is 26% higher for high ambient current ratio as compared to the one for low ambient current ratio, for $S_C/\sqrt{A_0} > 40$. The reason for this trend may be attributed to the increased recirculation, on the shore side, due to increase in the ambient current ratio, as well as the characteristics of the circulating cell which causes the warmer water to reentrain at a farther distance from the source. Shown in figure 14 is the effect of bottom slope on the centerline temperature decay. As can be seen increasing the bottom slope causes a decrease in the centerline temperature.

The effect of the important parameters on the centerline trajectory of a BSJ (i.e., the locus of the centerline temperature in the x-y plane) is depicted in figures 15 to 17. Figure 15 indicates that other parameters being constant an increase in the source Densimetric Froude number will cause a decrease in the radius of curvature of the jet trajectory. In other words the higher the Densimetric Froude number the closer is the jet trajectory to the shore line. This may be attributed to the high ambient pressure drag force at high Densimetric Froude numbers due to the jet attachment and the blockage of the ambient current. Figure 16 indicates that the higher the ambient current ratio the closer is the jet trajectory to the shore line. Finally figure 17 shows that, surprisingly, the reduction in bottom slope will cause the jet trajectory to move offshore, i.e., the jet trajectory assumes larger radius of curvature.

Realizing the unavailability of satisfactory numerical model for buoyant surface jet over slopping bottom with ambient cross current, it is desirable for practical purposes to know the degree of error in predicting the centerline temperature and the trajectory of a buoyant surface jet discharged over slopping bottom into moving ambient flow, by applying the simple integral models which have been developed for BSJs discharged into deep water. For this purpose, the Prych's model (3) was selected. An example of the results is shown in Figures 18 and 19. As can be seen from Figure 18, Prych's model overestimated the centerline temperature. Such overestimation was generally observed for other conditions as well. It was observed that in general Prych's model overestimates the centerline temperature by 10 to 36 percent. However, the predicted jet trajectory shows considerably less deflection than the observed jet trajectory. This can be seen in Figure 19. The comparison for additional conditions is reported in Ref. (4). In general, based on these results, one may conclude that the application of the simple integral models for the prediction of the characteristics of the

BSJ discharged over slopping bottom into moving ambient water, will result in conservative estimates.

VI. SUMMARY AND CONCLUSIONS:

The effect of important dimensionless parameters on the characteristics of a BSJ discharged over a slopping bottom into moving ambient water is investigated experimentally. The main results are presented in Figures 12 to 17 and are summarized in Table 1.

TABLE 1. Summary of the Experimental Results.

Increase in →	F_o	S	U_R
Centerline Temperature	No effect	Decrease	Increase
Jet Trajectory	Deflect further	Deflect further	Deflect further

The obtained results are expected to be helpful as general guidelines in the design of thermal outfall in the coastal regions.

The comparison between the experimental results and the predictions by Prych's model reveals that the integral models for BSJs discharged into deep water, generally overestimate the centerline temperature and jet trajectory of a BSJ discharged over slopping bottom into moving ambient water.

VII. LIST OF SYMBOLS:

A_o	Discharge Area
A_s	Discharge Aspect ratio, $A_s = h_o/b_o$
B_o	Discharge Buoyancy flux, $B_o = g'_o Q_o$
$F_o(A)$	Source Densimetric Froude number based on area
	$F_o(A) = M_o^{5/4} / B_o^{1/2} Q_o$
M_o	Kinematic momentum flux, $M_o = U_o^2 A_o$
Q_o	Volume flux, $Q_o = U_o A_o$
S	Bottom slope
S_c	Curvilinear co-ordinate (along trajectory)
S_n	Normalized curvilinear co-ordinate, $S_n = S_c / \sqrt{A_o}$
T	Fluid temperature in °C.
U_o	Magnitude of discharge velocity
U_a	Magnitude of ambient cross current
U_r	Dimensionless velocity ratio for ambient current,
	$U_r = U_a / U_o$
b_o	Discharge width
g	gravitational acceleration
g'_o	Modified gravitational acceleration, $g'_o = (\Delta\rho_o/\rho_a)g$
h_o	Discharge depth
x	Longitudinal cartesian co-ordinate axis
y	Transverse cartesian co-ordinate axis
ΔT	Excess temperature, $\Delta T = T - T_a$
$\Delta\rho$	Water density defficiency, $\Delta\rho = \rho_a - \rho$
ρ	Fluid density

DESIGN OF AN INTERMITTENTLY
OPERATED OUTFALL

By Roger W. Lindquist, M.ASCE¹
and George J. Murphy, F.ASCE²

INTRODUCTION

The City of San Francisco, California, has a combined sewer system that presently overflows into the bay or ocean when it rains. Under the current wastewater management program being implemented, this combined flow of storm and sanitary wastes will be treated and discharged into the Pacific Ocean through a three-pipe outfall system. The system will dispose of the treated sanitary wastewater (dry weather flow) through a 2740-millimetre-(mm)-diameter, 6-kilometre (km) ocean outfall, and the mixture of sanitary wastewater and storm-water (wet weather flow) will be disposed of through two 2740-mm-diameter outfalls, 4 km long. The depth of the dry weather diffuser is approximately 24 m and the depth of the wet weather diffuser is approximately 17 m. The wet weather outfall will operate only when the rain exceeds 0.5 mm per hour. Rain exceeds this intensity about 4 percent of the time, or 350 hours per year. The peak wet weather flow is approximately 1800 megalitres per day (Ml/day)³. The average dry weather flow is 400 Ml/day and the peak dry weather flow is approximately 700 Ml/day.

This paper reviews the unique problems of an intermittently operated outfall located in an area of shallow water with loose bottom sediments on a coast subjected to high wave energy. The circulation of seawater through the dormant diffuser and the resulting reduction in hydraulic capacity by sediment intrusion and biofouling are identified as the most severe problems for the intermittently operated outfall. The features incorporated to reduce these problems are bottom-exiting risers, diffuser ports elevated above the seabed, four ports per riser with a dual valve system, and use of antifouling materials and a flushing system.

³1 Ml/day = 1,000 cubic metres per/day (m³/day) = 11.6 litres per second (lps)

BACKGROUND

San Francisco is undertaking an extensive wastewater management program to upgrade treatment and reduce the volume and frequency with which untreated effluent is discharged into both San Francisco Bay and the Pacific Ocean. This program involves construction of two secondary treatment plants for dry weather flow, and one chemically assisted primary treatment plant for the wet weather flow, several large storage and transmission facilities, and an ocean outfall system consisting of one dry weather and two wet weather outfall pipes. Figure 1 shows the basic configuration of the major elements of the wastewater treatment and disposal system.

The storage and transmission facilities will have the capacity to store excess combined sewage during most storms, thus limiting the number of overflows onto the beaches of the San Francisco peninsula. The chemically assisted primary plant will treat combined sewage in excess of that receiving secondary treatment. The combined sewage in storage will be processed as the storm flows subside. Once the transport and storage system is empty, the wet weather outfalls will be dormant until the next storm.

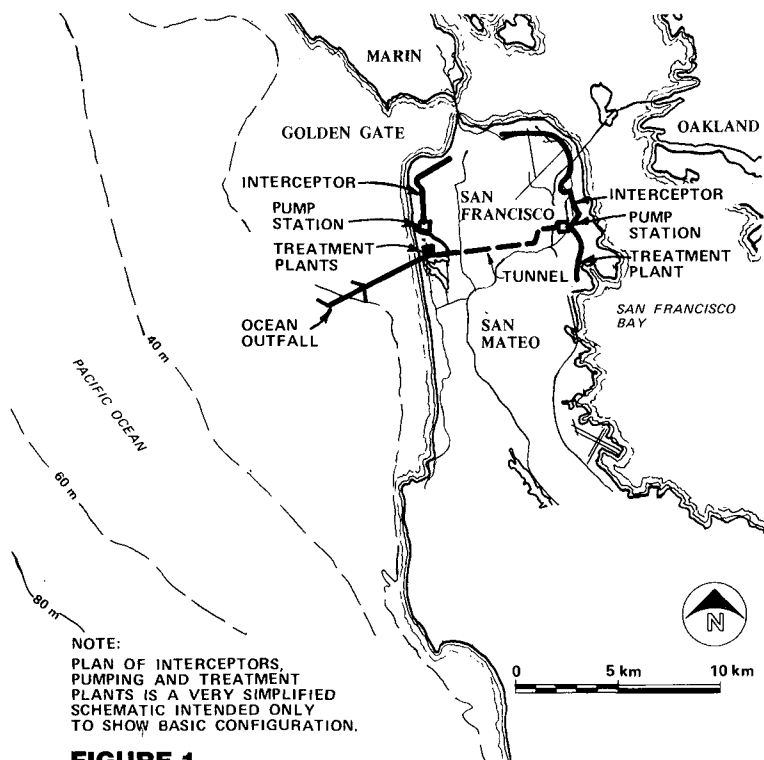

CONSTRAINTS

San Francisco's operating and site conditions make the design of the wet weather outfall considerably different from continuously flowing deep ocean outfalls. These constraints are reviewed below.

Dilution Requirements

The ocean outfall system must meet the requirements of the amended California Ocean Plan, which contains discharge regulations set by the California State Water Resources Control Board. These regulations do not contain specific requirements for dilution nor effluent criteria for biochemical oxygen demand (BOD) or coliform levels. The major provisions of the Ocean Plan include:

- Establish limits of receiving water quality, which the discharge does not violate
- Require that waste systems that discharge to the ocean will maintain the indigenous marine life
- Establish requirements for wastes that are discharged to the ocean

NOTE:
 PLAN OF INTERCEPTORS,
 PUMPING AND TREATMENT
 PLANTS IS A VERY SIMPLIFIED
 SCHEMATIC INTENDED ONLY

FIGURE 1
SAN FRANCISCO
WASTEWATER PROGRAM MASTER PLAN

The limitations on wastewater characteristics include 75-percent removal of suspended solids and limits on discharge of grease and oil, settleable solids, turbidity, pH, toxicity concentration, and toxic materials. There are receiving water limits on heavy metals, floating particulates, organics, dissolved oxygen, and radioactive and toxic substances. Maximum coliform concentrations are specified for beach and shellfish areas.

The discharge requirements for effluent concentration include a 6-month median as well as a daily maximum and an instantaneous maximum limit. Thus, by using the 6-month median, the wet weather dilution requirements are considerably less than the dry weather dilution. The target established for the dry weather diffuser is for better than 100:1 average initial dilution at least 80 percent of the time. The target for the wet weather diffuser is for greater than 25:1 average initial dilution at peak discharges. The relatively low target dilution for the wet weather discharge can be obtained in shallow water.

Operation Constraints

The wet weather outfall will operate about 350 hours per year during the wet season (December through April) and remain dormant during the rest of the year. Both dry weather and wet weather outfalls will operate at their maximum design flows several times each year. Whenever the wet weather outfall is not discharging, wave pumping through the diffuser ports will occur. Wave pumping, as used here, is the circulation of seawater through the diffuser with water entering the ports under the wave crest and exiting through the wave trough. If allowed to occur, this circulating seawater will introduce fouling organisms and sediment into the diffuser.

Site Constraints

The ocean floor, in the vicinity of the outfall, has a relatively flat slope for over 45 km from shore. Thus, no significant advantage can be gained by extending the outfall beyond the minimum depth required to obtain the dilution. The location of the outfall, 8 km south of the Golden Gate, is subject to intense winter storms as well as continuous wave action throughout most of the year. The ocean floor in the outfall area consists of loose sediments to a depth of up to 3 m; also an abundance of fine-grained sediment is discharged through the Golden Gate from the Sacramento and San Joaquin Rivers. The shallow water and the high wave energy cause sediments to be suspended except during the calmest days.

Over the life of the project, the elevation of the sea floor is predicted to vary from approximately 1 m above to 2 m below the present floor.

The low elevation of the onshore treatment site limits the head available for gravity flow to 7 m during high tide and high flow conditions.

Structural Constraints

The outfall is designed to account for wave and seismic forces and soil liquefaction. To protect it, the outfall will be buried in a trench, with approximately 3 m of backfill materials and armor cover over the pipes. Along the San Andreas Fault, which the outfall crosses approximately 3 km from shore, movement perpendicular to the pipe of up to 20 feet is possible. Special joints that provide for some movement and are easily replaced were designed for the fault zone.

ANALYSIS

The analysis and design of the outfall required close coordination between many engineering and scientific disciplines. No single solution was completely satisfactory to each discipline; judgment and compromises were required to fully develop the design. The analysis of several major elements is described below.

Dilution

The results of the dilution analysis indicated that the wet weather diffusers should each be approximately 420 m long, have 96 ports with a nominal diameter of 200 mm, and discharge with approximately 15 m of water above the port. Figures 2, 3, and 4 show the configuration of the outfall, diffuser, and risers.

Wave Pumping

Various methods of analysis and levels of refinement were made to estimate the volume of water that would enter the ports due to wave pumping. It was determined that large volumes of water would enter each riser under each wave crest. For instance, by using a simple orifice equation and an average head of the wave crest over the still water level, it can be found that over 1 cubic metre (m^3) of water will enter a riser under a relatively small wave.

FIGURE 2
SCHEMATIC OUTFALL CONFIGURATION

TOTAL NUMBER OF PORTS = 96

FIGURE 3
WET WEATHER DIFFUSER CONFIGURATION

FIGURE 4
TYPICAL SECTION OF WET WEATHER RISER

Sediment Intrusion

The volume of sediment that enters the diffuser depends upon the concentration of sediment in suspension. This concentration in turn depends upon the bottom currents, the wave conditions, and the height of the port above the seabed. The trapping efficiency of the port and riser also affect the volume of sediment entering the diffuser. The trapping efficiency is defined as the percent of sediment entering the ports that is deposited in the diffuser. Various assumptions on concentration were made using sediment trap and water sample data. With the high trapping efficiency it was found that the diffuser could fill with sediment during a single storm.

Biofouling

Biofouling organisms were identified and methods of controlling them were examined. It was concluded that the diffuser would be an ideal habitat for certain organisms if seawater circulated through the diffuser. Unless circulation of seawater could be eliminated, fouling growth several inches thick could be expected inside the outfall. Other methods of control that were investigated included washing the newly settled, but poorly attached, fouling organisms off the structures with high velocity flushing water, use of antifouling materials, or discharge of small quantities of freshwater in the diffuser. None of these methods appeared satisfactory on close examination.

Various types of antifouling materials, including NOFOUL¹ rubber, various copper-nickel alloys, and aluminum bronze alloys were studied. Coupons of these materials were placed in the seawater at Monterey Bay, in bay water in the San Francisco Bay, and alternated between bay water and treated sewage effluent. These test coupons provided information on the rate of leaching of these compounds when alternately exposed to treated sewage effluent and seawater.

Flushing

Removal of sediments from the diffuser by flushing was analyzed. The diameter and length of the outfalls require a large volume of water for minimum flushing. There is no source of freshwater for flushing other than secondary treated sewage effluent. Various storage facilities were examined for storing the treated effluent flushing water,

¹ Manufactured by B.F. Goodrich, Akron, Ohio

including the tunnel storage system, the primary sedimentation basins at the wet weather treatment plantsite, and a separate storage reservoir built above the plantsite. The use of the sedimentation basins in the primary treatment system located near the headworks provides the most economical storage for flushing water. Samples of sediments, in suspension in the water column, were trapped in a nest of sediment traps, located near the wet weather diffuser. The sediments in suspension are a nonplastic silty fine sand with a mean diameter of 0.16 mm. This material is finer than the fine sand on the seafloor.

For the sediment flushing system to be effective, the flushing water must have sufficient velocity and volume to erode and transport the deposited sediment. Very little information is available that is applicable to large diameter outfalls and diffusers. A relationship of shear intensity parameters and transport parameters based on conduit data, flume data, and river data presented by Graf-Acaroglu(1) was used as a guide in developing a method of predicting the amount of sediment that could be flushed from the diffuser pipe. Using parameters for the outfall pipe diameter and Manning's flow equation, the Graf-Acaroglu relationship reduces to:

$$C = 1.03 \times 10^{-5} d^{-1.02} D^{-1.84} v^{4.04}$$

Where D = the diameter of the diffuser pipe in feet
 d = the grain size in millimetres
 V = velocity in the diffuser pipe in feet per second
 C = sediment concentration by volume

This equation was used to estimate the flushing characteristics in the outfall diffusers as a function of the sediment grain size and the effluent velocity through the diffusers. The analysis and computations are complicated because of the continually changing effluent velocity as it is discharged through the diffuser ports and it is transported through the tapered sections of the diffuser. A computer program was written to perform the calculations for flushing the diffuser and record the mathematical calculations.

This analysis indicates the upstream end of each tapered section would be the first to scour clean. Part of the sediment removed from these upstream sections would be discharged out of the first riser pipe, and part of it would be deposited in the downstream sections. After the upstream section was clean, the cleaning process would progress downstream. A very simple hydraulic model was used to

verify the concepts developed from the Graf-Acaroglu relationship. The results of this model study gave reasonable verification to this method of predicting the success of the flushing process.

Flushing with the end gate open and end gate closed were analyzed with the computerized hydraulic model. With the end gate open, a 90-minute flushing period will remove 0.6 m^3 of sediment per metre of diffuser, or approximately 240 m^3 . With the end gate closed, a 90-minute flushing period will remove less than half of this amount of sediment from the diffusers. With the end gate closed, the first sections of diffuser will be cleaned out, but the remainder of the sediment will be transported to the end of the diffuser, plugging the last few sections.

DESIGN FEATURES

The design features that were incorporated into the diffuser to protect it from the seawater circulation problems caused by wave pumping are discussed below. A double check valve system is considered the primary defense against seawater circulation. However, because of the severe site and operating conditions, the diffuser was designed with several safety features in case the check valve system does not work properly.

Double Valve System

After it was concluded that some sort of valve system was necessary to reduce wave pumping, many ideas were evaluated. These ideas varied from using manufacturers' standard check valves to complicated, remote-controlled valves that could be opened when the wet weather flow began and closed when it stopped. Because of the harsh environment, it was decided that the valve should be as simple as possible with few moving parts.

The final system consisted of a "poppet" valve over the riser and rubber flap valves over the ports, as shown on Figures 5 and 6. The poppet valve consists of a flat copper nickel plate, centered over the riser pipe with four guide legs. This plate rises when the outfall is flowing and closes under its own weight when the flow has stopped. It is provided with rubber gate seats. Each port is covered with a heavy rubber flap valve that is reinforced with a metal plate, which opens under flow and closes when the flow stops.

HORIZONTAL SECTION AT CENTERLINE OF PORTS

VERTICAL SECTION AT CENTERLINE OF RISER

FIGURE 5
WET WEATHER RISER CAP AND VALVES

FIGURE 6
ISOMETRIC DETAIL OF WET WEATHER RISER CAP

Four hydraulic models were used as tools to develop and refine the design. The wave tank facilities at Oregon State University, Corvallis, Oregon, were used to study a 4:1 scale model of the riser cap and valves under wave action. While the combination of the flap and poppet valve greatly reduces the flow of seawater into the riser, waves cause some fluttering of the valve, which may allow some backflow of seawater. This fluttering is caused by wave forces, orbital velocities, and differential pressure on each flap valve. The fluttering can be reduced or eliminated by adding weights to the flap valves, but this increases the headloss across the valves. The headloss across the riser cap and valve system was 0.9 m under the maximum design flow of 1800 Ml/day.

Bottom-Exiting Risers

The wet weather risers are designed to exit from the invert of the diffuser pipe as shown on Figure 4. The main purpose of this configuration is to improve the effectiveness of flushing to remove sediments.

Multiport Riser

Normally, the diffuser ports are simply holes located in the sides of the diffuser pipe. However, with the buried diffuser, a riser pipe had to be used to bring the effluent from the buried pipe to about 1500 mm above the sea floor. Since the risers are exposed to damage by wave forces, anchors, and fishing gear, they must be structurally designed to resist these forces. The structural requirements control the external shape and size of each riser, regardless of the riser diameter. Such a riser is expensive and difficult to construct. In order to reduce the number of risers, two, three, and four ports per riser were studied and tested. In the final design, four ports were designed for each riser as shown on Figure 4.

Hydraulic modeling of the plume behavior was performed at the California Institute of Technology, Pasadena, California. Modeling consisted of comparisons of two, three, four, or eight ports per riser. Confirming tests were performed on the four-port-per-riser system, as finally designed. The four ports are located close together, in one quadrant, and positioned to discharge offshore, as shown in Figure 5.

Antifouling Materials

To reduce fouling, the riser cap was lined with copper nickel; the metal parts of the valves are copper nickel. The rubber valve seals, gaskets, and valve hinge are NOFOUL rubber. NOFOUL rubber is a chloroprene rubber impregnated with tributyltin oxide.

Height Above the Seabed

The highest concentration of suspended sediments occurs near the bottom. In order to reduce the concentration of sediment in suspension around the ports and to provide some protection from port burial caused by the fluctuating elevation of the seabed, the ports were located approximately 1500 mm above the seabed.

Flushing System

The sedimentation tanks for the proposed primary treatment system furnish storage for approximately 72,000 m³ of effluent for flushing the outfall. These tanks will be filled with secondary treated effluent and then discharged through the outfall. To be effective, the velocity of the flushing water must be at least 2 metres per second. It is estimated that this water, when flushed through the diffuser with the end gate open, will remove approximately 240 m³ of sediment.

ACKNOWLEDGEMENTS

The work on which this paper is based was performed for the City and County of San Francisco. PBQ&D, Inc. is the prime consultant on the Southwest Ocean Outfall Project (SWOOP). Woodward-Clyde Consultants is the principal subconsultant for oceanographic and geotechnical study. CH2M HILL is the principal subconsultant for the hydraulic and sanitary design of the project.

EXPERIMENTAL EVALUATION OF HEAT EXCHANGE
BETWEEN WATER SURFACE AND ATMOSPHERE

by

ABSTRACT

The heat balance of a water body mainly depends upon the heat exchange processes at the water surface. An experimental method has been developed for determining the heat exchange, the exchange coefficient and the equilibrium temperature. The measuring equipment consists of two similar, well insulated pools which are exposed to the meteorological conditions of the Lower Weser River, Germany. The water temperature of the first pool (T_1) is artificially adjusted to the actual river temperature either by cooling or heating. The temperature of the second pool (T_2) is held constant above the temperature T_1 . The difference in power inputs required $W_2 - W_1$ is equivalent to the net rate of heat exchange due to the increase of temperature to ΔT above the river temperature.

1. INTRODUCTION

In order to protect the ecological system of a river the thermal load caused by heat discharge of power plants must be predicted and controlled. In many cases there is a mutual influence and superposition of several heat discharges.

In brackish zones of tidal rivers the ecology is especially sensitive. Therefore the permissible heating range in German tidal rivers is limited to 2°K. This limitation is relevant during periods with little heat exchange.

After the heated effluent is completely mixed with the receiving water, the decrease of water temperature mainly depends upon heat exchange processes between the water surface and atmosphere. Especially in tidal rivers, where a body of water repeatedly receives artificial heat and remains inside the region of discharge influence for a long time, the knowl-

edge of the heat exchange at the water surface is fundamental for determining the cooling rate.

In a previous comprehensive study Kuhn (1972) established a heat exchange coefficient which is proportional to the cooling rate and computed as a function of water temperature and meteorological variables. But past experience has demonstrated that the computation of heat exchange coefficients on the basis of meteorological variables becomes efficient only when extensive and very exact measurements of these parameters are available. Therefore an experimental method has been developed by the Franzius-Institut measuring the rate of heat exchange directly.

2. BASIC THEORY

The net rate of heat exchange at the water surface consists of the following components (Kuhn, 1972):

$$H = H_W + H_G + H_S + H_V + H_K + H_N \quad (1)$$

in which

H_W = net rate of heat exchange due to back radiation from the water to the atmosphere

H_G = net rate of heat exchange due to absorbed atmospheric radiation

H_S = net rate of heat exchange due to absorbed solar radiation

H_V = net rate of heat exchange due to evaporation and condensation at the water surface

H_K = net rate of heat exchange due to conduction at the water surface

H_N = net rate of heat exchange due to rainfall

Under the assumption that a body of water is well mixed the variation of temperature with time is determined by

$$\frac{dT}{dt} = \frac{H}{H \cdot \rho \cdot c} \quad (2)$$

in which

h = water depths

ρ = water density

c = specific heat of water

Neglecting heat exchange due to rainfall, only the terms H_W , H_V and H_K are changing due to heating up by artificial heat. The atmospheric radiation and the solar radiation are not influenced by increasing water temperatures.

If the net heat flux directed into the water body is defined to be positive, an increase of water temperatures due to artificial heat will cause a decreasing net heat flux at

the water surface, because back radiation from the water body and evaporation are increasing with higher temperature.

If there is a positive heat flux at a starting point, the temperature of the water will increase until the heat flux is equal to zero. This water temperature is defined as equilibrium temperature T^+ . The equilibrium temperature is that temperature, a body of water exposed to a constant set of meteorological conditions would approach.

The equilibrium temperature only depends on meteorological conditions, not on water depth. A change in meteorological conditions leads to another curve, describing the relationship between heat flux and temperature. Kuhn established a heat exchange coefficient A , which is the derivation of that curve in the point of non heat flux. The coefficient is proportional to the cooling rate and can be calculated as a function of water temperature and wind velocity. Kuhn expressed the net rate of heat exchange at the water surface as

$$H = \frac{\partial H}{\partial T} \cdot (T - T^+) = A (T^+ - T) \quad (3)$$

in which A = total heat exchange coefficient
 T^+ = equilibrium temperature
 T = water surface temperature

This equation shows, that the net rate of heat exchange is equal to the product of the heat exchange coefficient and the difference between the equilibrium temperature and the water surface temperature.

Combining Equation 2 and 3 gives

$$\frac{dT}{dt} = - \frac{A}{h \cdot \rho \cdot c} (T - T^+) \quad (4)$$

Assuming constant meteorological conditions, this equation is soluble and the solution shows the wellknown exponential course of temperature until reaching the equilibrium temperature.

$$T - T^+ = (T_0 - T^+) \cdot \exp \left(- \frac{A}{g \cdot \rho \cdot c} t \right) \quad (5)$$

Besides the heat exchange coefficient, water depth is the essential parameter of the range of temperature variation with time. For example, in case of wind velocity of 2 m/s and water depths of 5 m the half-life-period amounts to 8 days. Normally constant meteorological conditions can not be expected throughout such long periods.

Furthermore an applicable computation of heat exchange coefficients is only possible, if wellknown data about evaporation and condensation are available. This is one diffi-

culty when using the exchange coefficient for computation of heat exchange between water surface and the atmosphere.

Another problem is the determination of the equilibrium temperature, because generally the actual water temperature is not equal to the equilibrium temperature. There may occur large differences between actual temperatures and equilibrium temperatures with time of a day or under consideration of daily averaged values all the year round.

Considering a period of one day, normally the maximum of the equilibrium temperature will occur at noon due to solar radiation and the minimum at night. The temperature T_w of a water body will follow the variation of the equilibrium temperature T^* with a phase lag.

Considering the variation of temperature throughout a year there are similar curves with maximum in summer and minimum in winter. In spring and early summer the actual water temperatures are normally lower than the equilibrium temperatures, whereas in autumn and winter the relation is contrary.

If the equilibrium temperature is higher than the temperature of a water body including already artificial heat water temperature will continue to increase and the artificial heat will even remain in the water body.

The application of the heat exchange coefficient under the assumption that water temperature without any artificial heat is equal to the equilibrium temperature leads to an easy calculation. This assumption, however, will only casually agree with real conditions. Therefore it was thought desirable to determine the heat exchange between water surface and atmosphere by experimental evaluations.

3. EXPERIMENTAL PROCEDURE

3.1 Measuring Equipment

The measuring equipment consists of two similar plastic pools with a free water surface, 2.00 m in diameter and 30 cm deep. They are well insulated on the sides and bottom and generally filled to the same depths to within 3 cm of the top of the pool sides. Water loss by evaporation is refilled automatically. Identical stirring devices placed in each pool keep the water well mixed.

The pools are placed on a platform above the water surface of the river. They are directly exposed to the climate of the river region investigated.

The measuring equipment further consists of thermo-couples for temperature sensing, water level gauges, a flowmeter, electrical heating elements, a refrigerator, heat exchangers and a 12-point recorder. The arrangement of the measuring equipment is shown in Fig. 1.

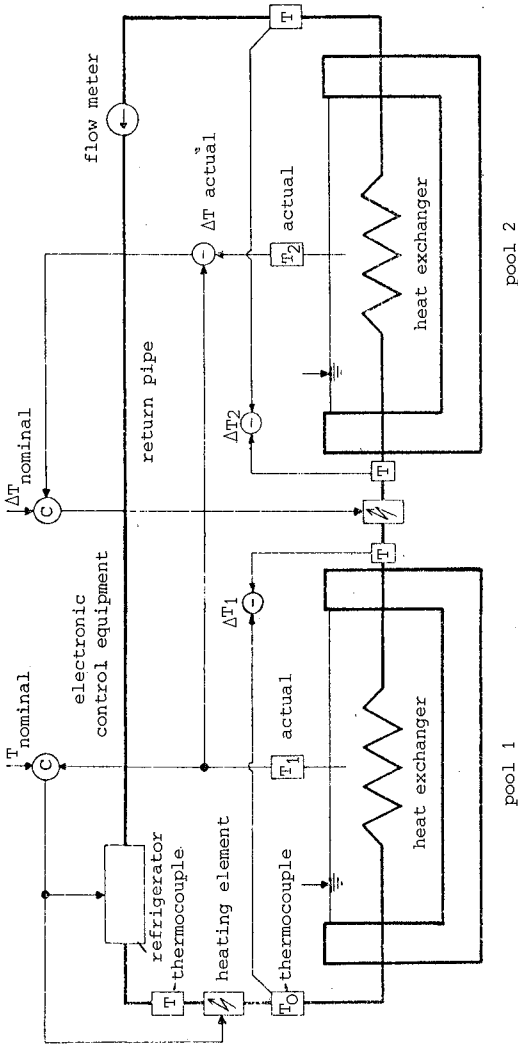

Fig. 1
Scheme of the Measuring Equipment

Additionally all relevant meteorological data are registered on the platform and recorded.

The principle of the measuring equipment is that both pools have equal dimensions and that they are exposed to the same meteorological conditions.

By means of an electronic control unit the water of the first pool is cooled or heated corresponding to the actual river temperature T_1 . The water of the second pool is also cooled or heated, but is controlled by a constant difference of temperature $\Delta T = 2.00^\circ\text{C}$ above the temperature of the first pool (tolerance 0.01°C). Water temperatures T_1 , T_2 , and the difference of temperatures ΔT are measured and recorded. The power inputs W_1 and W_2 are determined by measurements of initial and return temperatures at the heat exchangers and quantity of flow.

The difference of input $W_2 - W_1$, which is necessary to maintain the range of $\Delta T = 2.00^\circ\text{C}$ is equivalent to the net rate of the heat exchange between the water surface of a river artificially heated by 2.00°C and the atmosphere.

In analogy to Kuhn the heat flux can be expressed as the difference between equilibrium temperature and water temperature multiplied with the heat exchange coefficient, now called α , because it is evaluated experimentally.

$$H_1 = \alpha_1 (T^+ - T_1) + W_1 \quad H_2 = \alpha_2 (T^+ - T_2) + W_2 \quad (6)$$

in which

W_1 = power input to pool 1
 W_2 = power input to pool 2) (heating +, cooling -)
 α_1, α_2 = experimental heat exchange coefficient
 T^+ = equilibrium temperature

The constant difference of temperature implies, that the variation of temperature in pool 1 is equal to that of pool 2

$$\frac{dT_1}{dt} = \frac{dT_2}{dt} \quad (7)$$

and it follows, that the heat flux of pool 1 is equal to that of pool 2.

Assuming that for a low difference of temperature $\Delta T = 2.00^\circ\text{C}$ $\alpha_1 \approx \alpha_2 = \alpha$ Equation 6 produces

$$W_2 - W_1 = \alpha (T_2 - T_1) \quad (8)$$

and the heat exchange coefficient is

$$\alpha = \frac{W_2 - W_1}{T_2 - T_1} = \frac{W_2 - W_1}{\Delta T} \quad (9)$$

The equilibrium temperature can be determined by Equation 2 and 6:

$$H_1 = h \cdot \rho \cdot c \cdot \frac{dT_1}{dt} \stackrel{!}{=} \alpha (T^+ - T_1) + W_1 \quad (10)$$

$$T^+ = \frac{1}{\alpha} (h \cdot \rho \cdot c \cdot \frac{dT_1}{dt} - W_1) + T_1 \quad (11)$$

So the complex processes of heat exchange between water surface and atmosphere can be determined by measurements of temperature and power input.

3.3 Results of Measurements

The prototype of the measuring equipment described was installed on a platform above the water surface of the Lower Weser River, Germany, near by a nuclear power plant. The equipment was put into operation in April 1979 in connection with an already existing system of control points for water temperature in order to determine the cooling rate of river water artificially heated up by the discharge of cooling water.

Results of measurements are shown in Fig. 2 and 3, demonstrating the operation method of the measuring equipment. The water temperature of the first pool was controlled on the level of 18.30°C corresponding to the actual river temperature. For that purpose it was necessary to heat the pools during the night and to cool it in the day-time.

The net rate of heat flux can be determined separately for each of the pools by the difference between the temperatures of forward and return flow (ΔT_1 , ΔT_2) and quantity of flow in the heat exchanges. Furthermore the distance between the curves of ΔT_1 and ΔT_2 is proportional to the heat exchange coefficient α . Fig. 3 shows important meteorological data.

The results of the measurements have been compared with results of heat exchange computations which are conducted on the basis of meteorological measurements. This comparison yielded differences of a certain tendency, which requires further research. For example, measurements conducted during the night obtained better correspondence to the computations than those conducted in the day time.

4. CONCLUSIONS

The surface heat coefficient and equilibrium temperature can be evaluated using the experimental method described here. An advantage of this method consists in determining the complex processes of heat exchange at the water surface by simple measurements of temperature and power input.

Fig. 2
Meteorological Measurements on 28.7.1979

Fig. 3
Measurements of Heat Exchange on 28.7.1979

Because the physical actions of heat exchange at the pools are in principle similar to those at the river surface, different results are only imaginable as a consequence of different boundary conditions (wind,waves). Thus it is important to expose the pools as near the water surface of the river as possible.

Finally, a functional relation has to be found which allows to apply the results of pool measurements to the actual exchange at the river water surface.

DYNAMICS OF SILT IN ESTUARY, RESIDUAL CURRENT

OR FLOCCULATION WHICH PREVAILS ?

by
J.P. LEPETIT and M. DAVESNE¹

ABSTRACT

The transport of fine suspended sediment in a partly-mixed estuary has been simulated on a physical model of a schematic estuary reproducing the main geometrical and hydrodynamical characteristics of the Gironde Estuary (France). The natural sediment consisting of silt and clay is simulated using a light and fine material, gilsonite, and the flocculation processes in salt water and under turbulence induced by tidal currents have been reproduced by adding in salt water a flocculating salt solution (sodium pyrophosphate). Then the formation of the turbidity maximum surveyed in the field and its upstream-downstream migration in response to varying river discharge have been successfully simulated and the results of different series of tests lead to the following conclusions :

- flocculation processes - which are responsible of the variation of the settling velocity with salinity and turbulence-have to be reproduced to explain the formation of the turbidity maximum ;
- after high river discharges the convergence of bottom residual currents (null point) due to the salinity intrusion creates a trap for suspended sediments supplied by the river flood which accumulate in the form of the turbidity maximum. Without salinity intrusion, a large amount of sediment would escape out of the estuary to the sea ;
- during low river flows, a part of the suspended sediment migrates upstream but the amplitude of this migration is small compared with the displacement of the upstream limit of the salinity intrusion ;
- the upstream migration of the turbidity maximum is increased when a transverse bottom morphology (existence of a deeper navigation channel) is represented.

1. INTRODUCTION

Transport of fine suspended sediment in partly-mixed estuaries is generally characterised by the existence of an accumulation zone with high turbidities migrating with the season ; this maximum of concentrations occurs in the lower part of the estuary after high river flows and part of it progressively migrates upstream during low river flows. This mechanism has been attributed to various processes,

¹ Division Hydraulique Maritime. Laboratoire National d'Hydraulique. Electricité de France. Chatou. France.

e.g. flocculation, tidal resuspension of bottom sediment, convergence of bottom residual currents depending on the salt intrusion, river flow and estuary geometry. The contrasting results from different estuaries indicate that the question of defining the process controlling the transport has no general solution at the present stage of progress.

In order to study these phenomena in laboratory, a fixed-bed small scale model of a schematic estuary has been developed. The beginning of the study consisted in reproducing salinity intrusion for different tidal amplitudes and river flows, and extracting residual currents from flow velocity measurements with an optic fiber laser anemometer.

Then the simulation of suspended sediment transport has been undertaken ; the extreme complexity of the factors involved in suspended transport and their simulation on a very small scale model raised many difficulties but interesting results have been obtained which are presented in this report.

2. DESCRIPTION OF THE SCHEMATIC ESTUARY MOEEL

The geometrical and hydrodynamical characteristics of the schematic estuary are those of the Gironde estuary, France. This estuary has been chosen because of the smooth and monotonic longitudinal variation rate of both its width and cross sections and also because of the availability of numerous field measurements although most of them are located in the navigation deep channel.

The Gironde estuary (cf fig. 1) is formed by the junction of the Garonne and Oordogne rivers. The navigation channel is about 7 m deep (below LWL) upstream PK 80 (distance in kilometers from Bordeaux) where a break in slope occurs. Downstream the depths increase and reach 30 m at the mouth. The north channel is wider and shallower (3-5 m) and is also marked by a slope break at PK 80 with increasing depths downstream ; the two channels merge in the mouth. The upper estuary, extending from the Bec d'Ambès to about PK 50, is characterized by numerous banks, shoals and islands. The lower estuary exhibits a simpler morphology consisting of two channel systems separated by a succession of sandy banks.

The monthly averaged river discharge varies from 200 m³/s in summer to 1 500 m³/s in winter with a mean of 800 m³/s. During river floods the instantaneous discharge can often exceed 3 000 m³/s. The tidal amplitudes in the inlet vary from 2 m during neap tides to 5 m during spring tides. In spring tides, the tidally averaged ebb or flood discharges vary from 12 000 m³/s (15 times larger than the annual averaged river discharge) at the Bec d'Ambès to 100 000 m³/s (125 times larger than the mean river discharge) at the mouth. These figures show that the velocities of the tidal currents are not significantly influenced by the river discharge in the lower part of the estuary.

Fig. 1 : THE GIRONDE ESTUARY (France)

Fig. 2 : DESCRIPTION OF THE SCHEMATIC ESTUARY MOEEL

The silt and clay presently accumulating in the estuary are mainly supplied by the rivers. This influx of suspended sediment has been evaluated at about 2×10^6 tons/year.

The schematic estuary model presented in figure 2 reproduces the entire tidal part of the Gironde estuary.

It is a fixed-bed, distorted scale model with length scales of 1/200 vertically and 1/5000 horizontally with rectangular cross sections ; the longitudinal rate of variation of cross sections of the Gironde estuary is fitted by an exponential law.

The variation rate of its width is also exponential except near the mouth where the width is supposed to be constant between PK 76 and PK 96. The depth is constant transversely and equal to the cross sectional area divided by the width.

The experimental equipment allows to reproduce the following mechanisms :

- fortnightly variation of the tidal amplitude at the sea boundary ;
- annual variation of the river flow, as shown in figure 2 ;
- annual variation of sediment input introduced at river source with a turbidity proportional to the river flow ; in the experiments suspended sediments are supposed to be supplied only by the river ;
- variation of salinity intrusion with the tidal amplitude and river flow ;
- flocculation of sediment in salt water.

The natural sediment is simulated using a light and fine material, gilsonite, with a density of 1.035, an average grain size of 45 μm and a mean settling velocity of 0.04 mm/s in freshwater. The flocculation processes in salt water have been reproduced by adding in salt water a flocculating salt solution (sodium pyrophosphate). The flocculating solution induces formation of large flocks which entrap gilsonite particles (cf fig. 3).

This mechanism seems to be mainly linked with the value of the PH of the solution. So, the settling velocities of gilsonite flocks depend on both salinity and concentrations of pyrophosphate as shown in figure 4.

The concentrations of flocculating salt solution influence the characteristics of flocks - size and shear strength and consequently those of deposits - especially the critical shear stress of resuspension.

Fig. 3 : FLOCCULATION OF GILSONITE

Fig. 4 : SETTLING VELOCITIES OF GILSONITE FLOCKS IN STILL WATER (initial concentration of gilsonite : 2 g/l)

This condition has been respected using a concentration of pyrophosphate of about 0,6 g/l for the salinity 20 ‰. If we suppose that the longitudinal gradients of salinities and pyrophosphate concentrations are identical in the model, the settling velocity of gilsonite flocks varies from about 0,3 mm/s to 0,5 mm/s (ten times more than the settling velocity of gilsonite without flocculation) when the salinity increases from 5 ‰ to 20 ‰. But in the model the size of flocks depends on turbulence ; so the settling velocity is a function of the flow velocity.

Gilsonite flocks represent the behavior of natural silt and clay much better than individual particles of constant size. Nevertheless it is doubtful that the extreme complexity of depositional and erosional behavior of cohesive sediments is reproduced in detail. For example the rates of deposition, which probably depend on the distributions of flocks shear strengths and the value of bed shear stress, have not precisely compared to their values in nature. So the experimental results must be considered as more qualitative than quantitative.

3. SALT INTRUSION AND RESIDUAL CURRENTS

In a first part of the study the model has been calibrated to reproduce water surface elevations, current velocities along the estuary and the mixing of salt and freshwater for different tidal ranges at the mouth of the estuary and different river discharges. Then the vertical profiles of residual currents¹ have been extracted from flow velocity measurements with an optic fiber laser anemometer. These results presented in detail in [1] lead to the following conclusions :

- salinity intrusion creates a zone of upstream bottom residual currents in the lower part of the estuary ;
- the point of convergence of the bottom residual currents (null point) depends on the tidal range (cf fig. 5) ;
- the migration of the null point with the river discharge is small in the range 500-2 500 m³/s for a fixed mean tidal amplitude, as shown in figure 6. So the zone of convergence of bottom residual flow does not follow the migration of the upstream limit of the salinity intrusion.

In nature the bottom residual flow field measured in the navigation channel is more complicated due to the influence of bottom topography, which creates successive zones of convergence and divergence (fig. 9). Nevertheless the measurements show the same influence of the tidal elevation as is pointed out by the results of the physical model : the residual velocities in spring tides are directed seaward for any river flow except at PK 89 near the bottom.

¹ It is the Eulerian residual velocity equal to the time average of the flow velocity within a tidal period calculated at a fixed point.

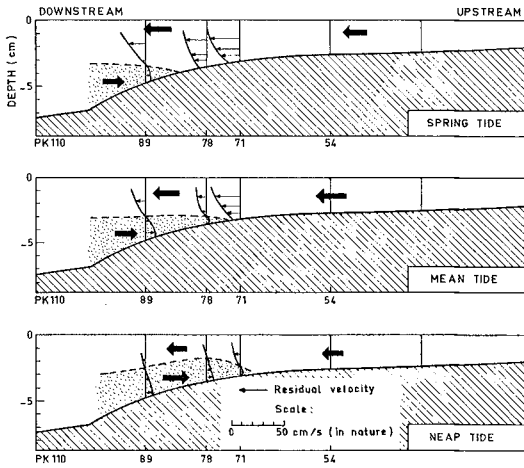

Fig. 5 : RESIDUAL VELOCITIES MEASURED IN THE MDEL (results for a mean river flow)

Fig. 6 : RESIDUAL VELOCITIES AND SALINITIES MEASURED IN THE MDEL (results for a mean tidal amplitude)

4. SUSPENDED TRANSPORT TESTS

4.1. Description of tests

At the beginning of a test, the model is operated with low river discharge until salinity concentrations throughout the model has become stabilized. Once stability has been obtained without sediment injection, the river discharge and suspended sediment influx cycles, as shown in figure 2, are initiated. The annual cycle is about one day long on the model. Salinity and suspended sediment concentration measurements are made continuously during the following cycle using an electro-optical system based on colorimetry method (colorimeter) and recorded on a magnetic tape.

Three series of experiments have been conducted : the first without reproducing flocculation processes. In this case the settling velocity of gilsonite particles is equal to 0,04 mm/s in fresh water and diminishes a little when moving from the fresh water to the salt water areas (for a salinity of 20 ‰ the settling velocity is about 0,02 mm/s). The following tests have been made with reproduction of flocculation. In that case the settling velocity increases from 0,04 mm/s to a maximum of about 0,5 mm/s when moving from the fresh water to the salt water areas. Other tests have been made in the same conditions but without upstream bottom residual currents (no salt but the flocculating zone is reproduced).

4.2. Principal results of tests

4.2.1. Without flocculation

The results show that the tidally-averaged concentration of suspended sediment diminishes seaward by dilution and settling out and there is no formation of a turbidity maximum. In the lower part of the estuary, a large amount of suspended material escapes out of the estuary by downstream advection. In the upper part of the estuary there are deposits of coarser gilsonite which are badly resuspended during spring tides.

4.2.2. With flocculation

The results obtained through the experiments taking into account flocculation processes can be summarized as follows :

- the tidal amplitude has a very important influence on the gilsonite flocks transport : after neap tides, the flocks deposit on the bottom and the turbidity decreases whereas after spring tides the deposits are resuspended and the turbidity increases ;

- the tidally averaged concentrations measured in spring tides depend on the river flow according to the following sequence described in figure 8 : at the maximum of flood the sediment input is large and the turbidity is high in the whole estuary ; when the river flow decreases, the development of a turbidity maximum is observed in the lower part of the estuary and the maximum is located near PK 85 at the end of the flood. During low river flows, the maximum diminishes and shifts upstream but the amplitude of this migration is small, the maximum being located near PK 71 at the end of low river flows ;
- different deposits can be observed : in the upper part of the estuary there are deposits of coarse non flocculated gilsonite which are badly resuspended during spring tides ; in the same way in the lower part of the estuary near the sea boundary there is an accumulation of flocculated gilsonite on the bottom ; except these two particular zones, the formation of deposits, only after neap tides, is linked to the turbidity maximum ; the upstream limit of the flocculated deposits is located near PK 75 after flood and near PK 54 after low river flow but several small deposits can be observed up to PK 30 ;
- the location of turbidity maximum seems to be linked to the convergence of bottom residual currents and not to the upstream limit of flocculating zone.

4.2.3. Without residual currents

The preceding conclusion has been confirmed by other tests carried out without residual circulation ; the results of these tests have shown no formation of turbidity maximum in spite of the reproduction of flocculation.

5. EFFECT OF TRANSVERSE BOTTOM MORPHOLOGY

In a last serie of experiments, the rectangular cross sections of the schematic estuary have been modified in order to study the influence of a deep navigation channel ; this channel was reproduced with the same depths as in nature without changing the cross sectional areas ; of course the lateral curvatures of the Gironde estuary are not still simulated. The measurements of tidally-averaged suspended sediment concentrations in spring tides and in the deep channel (fig. 8) show that the turbidities are higher in the channel than in the preceding tests with rectangular cross sections and that the upstream migration of the turbidity maximum is more important during low river flows.

So the transverse topography plays an important complementary role ; this influence is probably due to an enhanced density generated flow in the deeper channel but the results of velocities measurements are not yet available to confirm this hypothesis.

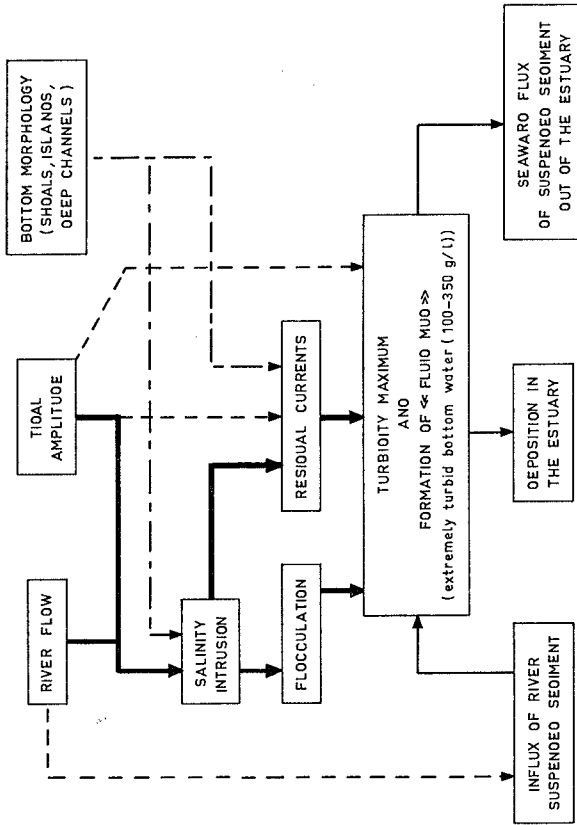

Fig. 11 : PRINCIPAL PHENOMENAE INVOLVED IN SUSPENDED SEDIMENT TRANSPORT IN ESTUARIES

6. CONCLUSION

The figure 11 summarizes the principal mechanisms involved in transport of fine sediments in estuaries. All these mechanisms or part of them have been simulated on a schematic physical model of the Gironde estuary. The formation of the turbidity maximum surveyed in the field has been successfully simulated by reproducing both the density generated residual currents and the flocculation processes when fresh water mixes with salt water. Gilsonite (density : 1.035, mean grain diameter : 45 μm) has been used for simulating natural sediment consisting of silt and clay and the addition of sodium pyrophosphate in salt water allows the reproduction of flocculation processes. The concentrations of sodium pyrophosphate have been adjusted to have a satisfactory reproduction of the fortnightly erosion-deposition cycle of the sediment in response to varying tidal amplitudes at the mouth of the estuary. With these concentrations the gilsonite flocks have a settling velocity of about 0,4 mm/s in still water (ten times more than the settling velocity of gilsonite without flocculation) but the observation of gilsonite flocks behavior in the model shows clearly that the settling velocity depends on the tidal current velocities.

In spite of some scale effects and the fact that the experimental approach is more qualitative than quantitative the results obtained on the schematic estuary show a sufficient likeness to field measurements (cf fig. 10) to let us suppose that the mechanisms reproduced in the model (flocculation and residual currents) are those which play an important role in the Gironde estuary. So we may conclude that residual velocities and flocculation are both responsible for the development of high turbidity zones in a partly-mixed estuary with hydrodynamical characteristics near those of the Gironde estuary.

The lateral geometry (effect of a deep channel) plays also an important role in the behavior of the turbidity maximum.

Abstract

Construction of the Jebel Ali Port complex, 35 km southwest of Dubai, in the United Arab Emirates, has included the disposal of 110 Million cubic metres of excavated spoil.

Disposal of dredged carbonaceous breccia raised particular problems due to the high proportion of fines generated and which, unless properly controlled, could cause wide scale environmental damage in the coastal zone. At the same time it was necessary that acceptable reclamation should be created. An extensive data collection exercise was carried out in order to monitor the geotechnical, hydraulic, meteorological, marine climate and marine biology aspects of the operation.

Introduction

The new port of Jebel Ali, situated on the Emirates coast 35 km south west of Dubai, consists of two very large basins constructed inland of the line of coastal dunes. These basins are connected to deep water in the Arabian Gulf by a dredged navigation channel 17 km in length with a bottom width of 235 m at 16 m below LAT. The inner basin is 3750 m long and 420 m wide, excavated to a depth of 11.5 m below LAT. The outer basin is 2500 m long and 600 m wide, excavated to a depth of 14 m below LAT. The basic layout, shown in Figure 1, provides 17 berths approximately 300 m long and 49 berths approximately 200 m long. In addition the harbour entrance channel is flanked by a tanker berth, with 15 m of water depth, and 2200 m of wharfage dredged to 5.5 m below LAT.

The Excavations involved in construction of the port were:

- Inner Basin : 31 million cu.m. of dry excavation from which the spoil was used to raise ground levels in the proposed industrial area to the south of the port.
- Outer Basin and Harbour Channel : 58 million cu.m. of dredging, the spoil being used to raise the levels and reclaim a total area of 700 hectares as indicated on Figure 1.
- Approach Channel : 21 million cu.m. of dredging, the spoil being mostly conveyed in barges to an offshore dump area.

Ground Conditions and Excavation

Ground Conditions

At the beginning of the project soils investigations revealed the presence of a variety of carbonate breccias overlain by sand and sandstone across the entire site. Sand in dunes just behind the original shoreline was up to 10 m thick, but this reduced rapidly to a thin layer at two to three hundred metres offshore. Underlying this sand was a layer of caprock varying in thickness up to 2 m. The four basic material types can be described as follows:-

- (i) Loose sand.
- (ii) Caprock, described as bioclastic limestone, containing numerous small solution features up to gravel size.
- (iii) Sandstone, fine to medium grained, occasionally laminated, with point load indeces averaging 2 MN/m^2 .
- (iv) Breccia, classified into five main types, the poorest of which consisted primarily of carbonate limestone containing attapulgate clay.

Samples taken from large diameter boreholes showed that, whilst the breccia would not present difficulties when excavated dry, when wetted a large portion tended to disintegrate into very finely divided material forming a soft slurry. This indicated that problems could arise in disposal of such material contained in a considerable volume of water after excavation by cutter suction dredgers. Even when cutting more uniform soils the process of disposal from a dredger pipeline inevitably involves fine material remaining in suspension when the excess water runs off.

With the exception of the Approach Channel and part of the Entrance Channel, the bulk of the excavation lay inland of the original shoreline and this presented the possibility of reducing the disposal problem by adopting dry excavation methods using conventional plant. The decision as to how much, if any, should be carried out in this way was dependent on a number of factors as follows:-

- (i) The availability of different types of plant required to carry out excavations entirely in the wet or partly in the dry.
- (ii) The method of construction of the blockwork quay walls.
- (iii) The phasing requirements for utilisation of completed parts of the port at the earliest possible opportunity.
- (iv) The suitability of the excavated material for backfilling, ground level raising and general reclamation.
- (v) The extent of dewatering required for such large excavations in the dry.
- (vi) The relative economics of each method of excavation.
- (vii) The quality and quantity of material resulting from each type of excavation.

Considering all of these factors it was decided that the combination of both dry excavation and dredging in the proportions given in the Introduction would satisfy the majority of the requirements.

Dry Excavation

The material in the areas scheduled for dry excavation comprised primarily sand and breccia. Excavation of the former was carried out with scrapers whilst the breccia in its dry state was quite hard and required blasting for removal by hydraulic excavators.

Wet Excavation

In the Entrance Channel and Outer Basin all the major dredging was to be carried out using four large cutter suction dredgers (2000 h.p. at the cutter head) and two smaller dredgers (1200 h.p. at the cutter head) together with booster pumps as required. All of the spoil was to be used for reclamation or was to be pumped to stockpiles for use as fill behind quay walls etc.

In the Approach Channel material was initially dredged using one cutter suction dredger and two dipper dredgers. The fleet was later supplemented by the worlds first self elevating cutter suction dredger (2). The majority of this material was loaded directly into barges for disposal offshore.

Disposal Methods

Disposal at Sea

The 21 million cubic metres of caprock and sandstone excavated from the Approach Channel was to be barge loaded and dumped offshore. Initially the disposal site was 21 km offshore in over 20 m depth of water. However, this was found to be unmanagable and the dump area was moved closer inshore, to an area in approximately 10 m of water as shown in Figure 2. This area is 5 km by 5 km so that the average depth of dumped material would be about one metre, although there were no rigorous controls on the dumping pattern. Barge loading was generally limited to between 50 and 75% of the theoretical full capacity in order to reduce overflow losses and re-sedimentation, while maintaining a high level of operational efficiency.

Disposal to raise existing land levels

Some areas of subkah flats around the port basins were low lying, much of it no higher than highest tide level. The area to the SE in particular required up to 4 m of fill to achieve an acceptable level for the proposed industrial development. This was achieved with spoil from dry excavations in the inner basin, and did not involve problems of fines disposal.

However, to the SW and NE of the port it was necessary to use considerable volumes of spoil arising from dredging the entrance channel and outer basin to fill the low areas (See Figure 1).

Discharge from the cutter suction dredger to be used would contain particles of all sizes from cobbles down to fine clays in view of the extent of breccia in these areas. A typical grading curve of actual discharge is given in Figure 3. This shows 30% silt and fines and immediately raised the questions, firstly, of how the fines were to be incorporated into the fill so as to provide land in an acceptable condition and secondly, how to control the flow into the sea of the calcareous fines suspended in the run-off water.

The initial wet filling was on the SW side of the port and it was anticipated that up to three of the large cutter suction dredgers could be discharging at any one time. Return of the potentially large quantity of water to the sea required a substantial channel excavated through the coastal dunes as shown on Figure 1.

In a second area to the north west of Quay 1 (See Figure 1) filling had to be done early in the Contract to provide areas for contractors depots and construction offices. Dry fill together with dredged sandstone was generally used for this. The eastern half of this area was also used for stockpiling dredged sandstone for re-use as selected fill behind quay walls etc.

Although not a serious problem, the run-off water from the area contained some calcareous fines arising from breakdown of the cementing material in the sandstone. The discharge was initially into the very large lagoon formed by the East Breakwater and the East Reclamation Bund shown in Figure 1.

A third area of land to be raised in level was to the east of Quay 2, and it was planned to fill this with spoil arising from dredging the east end of the outer basin. This was commenced late in the programme and the same procedure was adopted as that for the western area. In this case the water was returned to the sea via a long drainage channel down the east side of the site to discharge at the root of the East Breakwater.

Disposal to Reclamation

As originally planned in 1976 the east breakwater followed a conventional form on the lea side, being normal to the coast out to the harbour entrance. However, the problem of disposal of the carbonate breccias was appreciated immediately the results of the preliminary investigation began to come in. As a consequence, the breakwater was realigned to enclose together with the East Reclamation Bund a much larger area of approximately 320 hectares, so as to provide a disposal lagoon, as shown in Figure 1, in which the fines could be allowed to settle.

It was intended that this should be an area into which would be dumped material not suitable either for immediate use for raising land levels or stockpiling for use as backfill, and especially material in which the fines remaining in suspension would create environmental hazards if discharged directly into the sea. It was looked upon as a disposal area in which the ground conditions would improve over a long period and the land would be available for use in the later stages of port development. However, even before filling commenced proposals were being made for the land use for industry and consequently efforts had to be made to achieve the best ground conditions economically possible.

Disposal Problems

While it was anticipated that disposal from dry excavations would not present problems, the main concern in disposal of the breccias from wet excavations was the large amount of fines which were likely to remain in suspension. Little was known about the hydraulic disposal of carbonate breccia of the type to be encountered and literature on the subject, e.g. slurring for the cement industry, was of little assistance. There were no fixed guidelines to the quantity of carrier water to be expected due to the number of variables involved in the dredging process, but the ratio of water to solid matter pumped was expected to be about 10:1.

Without special care it was obvious that environmental problems could arise if the large proportion of fines that was anticipated remained in suspension when the discharge water returned to the sea. To indicate the scale of the problem, the quantity of water to be returned would be of the order of 450 million cu.m. which could contain up to 3.6 million tonnes of carbonate fines (i.e. equivalent to 2.3 million cubic metres of in situ rock at a dry density of 1.54).

Following early field trials the major problems could be identified:

- (i) It would be difficult to provide conditions in which an acceptable proportion of the fine material could settle out of suspension within a manageable retention period for the water. The bulking factors for breccia fines could remain very high for long periods of time before consolidation and meanwhile the fines would be sensitive to resuspension.
- (ii) When settled in the reclamation areas the fine material could create poor ground conditions.
- (iii) Disposal of the fines remaining in suspension in the vast quantities of overflow water which must eventually go into the Arabian Gulf, could damage the existing environment.
- (iv) Evaporation rates were not high enough to consider pumping all the material inland. In any case the distances involved would incur unacceptable costs and still involve environmental problems.

Of all the problems listed above the possibility of wide scale environmental damage was considered to be the most serious. If no special precautions were taken an average of 1500 cu.m. of soil would enter the sea in suspension each day for three years, with uncertain characteristics for settling in the turbulent open sea conditions. The cost of treating this amount of material, contained in about 100 times its volume of carrier water, was not economically feasible either by use of extracting equipment, such as cyclones or filters, or by flocculation.

Early experiments indicated that initial settlement of sediment from a fully mixed column of water achieved 50% clear water in a 2 m column within 24 hours, while further settlement was very slow indeed. It was hoped that this initial rate of settlement could be utilised in the field in a series of settling lagoons, the capacity of each lagoon being sufficient to take the 24 hour discharge from one of the larger dredgers. For example, there was sufficient area to provide six rows of four lagoons and to allocate two rows to each of three dredgers. The head lagoon could be filled and drained into the second one and similarly into the third lagoon and so on. The initially decanted water could contain fairly high concentrations of sediment, but this would reduce as the discharge progressed down the lagoons before eventually being allowed to seep through the breakwater into the sea. As the head lagoon filled the bunds, could be raised until filling reached the final level plus an allowance for settlement and the second lagoon would become the head lagoon.

This appeared to be a very attractive solution, but a number of problems were foreseen:

- (i) Bund building would have to be with dry material, otherwise material from a dredger discharge would flow out and considerably reduce the lagoon capacities. This would be an expensive operation and use material needed for fill elsewhere.
- (ii) Wet bund building would also produce its own problems with fines disposal.
- (iii) The fines might be so easily disturbed that it was quite possible that even the turbulence caused by bed shear as the flow crossed the lagoons to the decanting outlets would bring it back into suspension, especially as the discharge tends to form erosion channels through the fill.
- (iv) The front of coarser fill materials, as it progressed over the settled fine material would push it forward and upward against the opposite bund, but it was not known whether it would then dry out sufficiently to be rehandled or to incorporate it in the bunds once it rose above water level. Rehandling could be very expensive.

It was decided to obtain further information on behaviour of the fines by forming experimental lagoons, firstly to the west of the port to determine the settling and drying characteristics of the fines and secondly, when construction had progressed sufficiently to achieve protection from the breakwaters, in the coastal disposal area. The results of these experiments are given later

Experimental Lagoons

Preliminary Lagoon Studies

Before the four specially built, large cutter suction dredgers arrived on the site, it was decided to do test dredging of breccia with the discharge into an experimental lagoon on the west side of the site, (See Figure 1), where future development had a low priority. The aims of these tests were to determine:

- (i) The percentage of the breccia which would become fines in suspension when pumped through a representative length of pipe line.
- (ii) The settling characteristics of the total solids discharged into the lagoon.
- (iii) Quantities remaining in suspension when the carrier water was returned to the sea and diffusion characteristics of the suspended solids.
- (iv) Guidance as to areas likely to be affected by abnormal settlement of fine material and how soon the concentration of solids would reach acceptable levels.

The lagoon was divided into three sections.

Section 1 into which the pump mixture was discharged.

Section 2 into which the carrier water would overflow and where settlement of some of the fine material would take place.

Section 3 to take the discharge of sandstone and gravel when the dredger encountered these as they represented better fill material outside interest in carbonate fines.

Excess water from the two latter sections discharged through water boxes into the main discharge channel leading to the beach.

The lagoon bunds were raised as necessary to maintain a 2 m depth of water, with overflow water box having an initial invert level of 3.5 m above LAT. At the discharge end of the lagoon the ground was brought up to + 6.5 m and allowed to advance at this level. Silt was carried away towards the water box. The settled silt was so soft that it appeared to be entirely moved forward by the advancing face. However,

the characteristics changed once it heaved above water level and the advancing fill spilled over it. When this happened a fairly well mixed material could be achieved.

Based on resources available to undertake data collection within the short time available, a testing programme was devised, aimed at determining the best method to utilise this ability to trap the breccia fines and the effect this would have on early ground conditions.

The programme included:

- (a) Permeability tests on breccia fines situated above water level.
- (b) Durability tests on samples of each type of in situ breccia by agitating them in vessels containing sea water so as to simulate pumping and pipeline conditions.
- (c) Permeability tests on the rock fill breakwaters to determine their ability to filter out the fines from dredger discharge water.
- (d) Flocculation tests using polymer flocculants.
- (e) Analyses of particle size and shape of the material remaining in the lagoons.
- (f) Degree of trapping of fines beneath advancing coarse material.
- (g) Determination of bulking factors.
- (h) Determination of bearing capacity and consolidation characteristics of reclamation.

A complete review was also made of the location of breccia deposits in the areas to be dredged and the most likely areas to which they would be pumped.

To increase the retention of fines, stub bunds were built within the lagoon in order to increase the path of the discharge water while still controlling the flow to a low velocity on its way to the water-box.

Even so the discharge into the sea contained about 0.5% carbonate solids. It was of interest to note, however, that the flow, on entering the sea, hugged the coast towards the main west breakwater and most of the material in suspension was initially deposited near the beaches. Further, as sand was moved shorewards in calm to moderate seas, the beaches acquired a layered condition of silts and sand and, as this is an area of accretion, some of the fines were stabilised.

The deposition and accretion of the sediment in the lagoon was complex, but from the testing programme it appeared that the optimum settlement must be related not only to the percentage of clay size particles in the discharge, but also to time needed by the discharge to produce a suspended sediment concentration above an equilibrium value. The tests

using polymer flocculants which had indicated an initial improvement in settlement characteristics were not pursued as after about two hours in still water this advantage was lost and no difference in rate of settlement could subsequently be detected.

It was soon established that fairly substantial quantities of fine carbonate cementing material was released when the sandstone was broken down by dredger cutting and pumping operations.

By the time the large cutter suction dredgers arrived on site, (late 1977 early 1978) the evidence collected tended to indicate that small lagoons were unlikely to be satisfactory and three further experimental lagoons were established in the coastal disposal area as shown in Figure 4.

Trial Area No 1

The first of the experimental lagoons had an area of only some $1\frac{3}{4}$ hectares, and pumping was continuous with height of fill carried up from a bed level of about 3 m above LAT to about 7.5 m above LAT in six days. This meant that as the front advanced, time for discharge water to reach the fixed overflow was reduced and the concentration of fines carried into the main lagoon gradually increased. Over 50% of the fines were lost in this way and the lagoon size and method of filling were obviously inadequate.

The volume of material dredged was 50,000 cu.m. comprising primarily breccia with approximately 15% sandstone. The trial was monitored by sampling the dredger discharge and overflow water to determine quantities of fines entering and leaving the trial area. In addition pre and post fill surveys were carried out to determine the quantity of material retained in the area.

The scale of the trial was too small to create any significant pockets of silt, but it did enable sampling techniques to be tried out and confirmed the degree to which breccia would break down to form slurry.

Trial Area No.2.

The second experimental lagoon had a larger area and in this case pumping was intermittent over a period of six weeks. This produced a layered effect of coarser and finer fractions of the fines with a total thickness of about 3 to 4 m. and topped by 2 to 3 m of coarse material which had been dozed ahead over the finer material as filling proceeded. On completion of fill the lagoon contained entirely soft silty sand ahead of the final front of coarse material, overlying up to 1 m of very fine soft silt.

Float tracking showed that flow across a lagoon varies in a random manner, depending upon erosion channels leaving the point of discharge. However, loss of fines in the overflow water was found to be reasonably steady until the water in the lagoon was reduced to a critical depth.

From that point the velocity of flow was sufficient to carry most of the fines over the overflow and filling was stopped. It was possible to draw the immediate conclusions that:

- (a) Even using intermittent discharge the larger the lagoon the greater percentage of fines would be retained;
- (b) It would be possible to raise the overflow level by using coarse material to increase bund height and to have a water box in which the weir level could be raised to maintain sufficient depth of water for optimum settlement of fines in the lagoon;
- (c) The original proposals to create twenty four small settling lagoons within the coastal reclamation area would not be very efficient in trapping the fines.

A final survey of the lagoon and the dredged areas indicated that 390,000 cu.m. of in-situ material had been pumped to the lagoon. The volume of bulked material retained was 278,000 cu.m. indicating a considerable loss of material from a lagoon with an area of only 50,000 sq.m.

On completion of filling trial pits were excavated and boreholes sunk to examine and collect samples of the various strata within the reclaimed ground. Settlement pads and piezometers were installed and surveys were carried out before, during and after the filling. Samples of slurry which had settled in the lagoon were collected and analysed for bulk density, moisture content, grading, Atterberg limits and specific gravity of solids.

As a result of these trials it was decided to use large settling lagoons by dividing the coastal reclamation area into four quadrants and a programme for monitoring these was established.

Trial Area No.3.

This consisted of monitoring the reclamation in the SW quadrant of the Coastal Reclamation Area from September 1978 to April 1979 and included a soils investigation of the completed reclamation as for Trial Area No.2. The results in general supported those from Trial Area No.2. and as anticipated, the percentage of fines deposited increased with size and depth of the lagoon.

A summary of silt losses for the three trial areas is given in Table 1.

Trial Area No	1	2	3
Area (m ²)	17,000	60,000	390,000
Av.Depth (m)	1.0	3.0	4.0
% Silt loss	60%	33%	18%

Table 1 Summary of Lagoon Disposal Trials

Study of Marine Conditions

Hydrographic studies

A parallel programme of studies being undertaken on the project was the comprehensive collection and analysis of data on the marine climate, in order to predict sediment transport and hence maintenance dredging potential, as well as local coastline disruption that may be caused by the port works. This included standard meteorological data, regular hydrographic and topographic surveys, two wave height recording instruments, two wave direction recording instruments, float tracking, five automatic recording current meters, and extensive water/sediment sampling. The location of these instruments and limits of surveys are shown in Figure 2. The data gave good coverage of long term trends with respect to waves, currents and existing background suspended sediment concentrations.

Before it became necessary for any outflow of dredge run-off water from the coastal reclamation area to be discharged into the sea, an uncontained breccia disposal trial was carried out. This involved discharging a limited quantity of dredged breccia directly into the sea over the outer arm of the East Breakwater. The progress of the plume so produced was monitored by float tracking and pumped suspended sediment sampling. Contrary to expectations the breccia laden plume displayed relatively little mixing and was observed to run close to the breakwater, in an easterly direction, until it reached the knuckle of the breakwater and there separated.

Aerial photographs were also taken during the exercise and on two occasions after completion. The latter covered a 60 km length of coastline during both rough and calm conditions and the photos were processed so as to enhance underwater features. The photographs taken under rough sea conditions enabled an assessment of the general levels of turbidity along the adjacent shorelines to be made and any increases in the Jebel Ali area noted. The photographs taken under calm sea conditions enabled the areas of deposition of breccia fines to be broadly identified.

The photographic survey was intended also to monitor the behaviour of sediment already released into the sea from the offshore dredging in the Approach Channel and the first trial lagoon. The extent, nature and thickness of these, and subsequent, silt deposits were regularly estimated by diving surveys. Although a dual frequency echo sounder was used for the hydrographic survey work capable of giving broad indications of soft and hard deposits, it was found that there was no satisfactory way of calibrating the instrument to detect the interface between the original seabed and the overlying silt. However, successive silt surveys by diver, together with measurements of bulk densities allowed estimates to be made of volumes of material accumulating on the sea bed. Once all the dredger water discharge points were being monitored it was then possible to record concentrations of suspended material in the outflows and compare these with the volumes deposited in the survey areas.

Further records included regular chemical analyses of the dredge run-off water, the water in the lagoons and the sea water, close to and far from the port to determine whether there were any changes in the salinity levels or chemical changes in the sea due to disposal practices.

Marine Biology Study

The enclosed waters of the Arabian gulf are poor in marine organisms compared to the Red Sea and Indian Ocean. This is probably due to a combination of low nutrient levels, high salinities, (up to 40%) and high temperatures (30°C). As a result there are fewer species of coral forming reefs and less associated marine life where these conditions approach the limits of their tolerance.

In the Jebel Ali area the most abundant of the corals is *Acropora* (Staghorn coral) a genus with high salinity and temperature tolerance, but very sensitive to sediment in the water column. Other types of coral which are found to be less sensitive are *Seriatopora* (antler horn coral) *Meandrina* (Brain Coral), *Goniopora* and others. The approximate ratios by species are 50%, 10%, 20% and 20%. *Acropora* and *Seriatopora*, of all the corals, provide the biggest area of shelter with their flat table top and overhang effect. The largest of the fish associated with these corals were Groupers, Parrotfish, Perch, Angel Fish, Captain's Daughter, Sergeant Major, Clown Fish, Damsel Fish, Pampano, Sauge and Wrasse. These fish are not apparently seasonal. Demersal fish, however, appear to be seasonal and include Barracuda, Garfish, Spanish Mackerel, Yellow Tail Tuna, Yellow Jack and Sardines.

It is important to ascertain what damage the suspended fines might cause to various types of marine organisms. Marine life is dependent on the phytoplankton - microscopic floating green plants - which is marginally seasonal in tropical waters.

Zooplankton consists of minute animals both mature and larval forms living directly off the phytoplankton and serving in their turn as food for larger predators. This continuous dependence forms the food chain of the marine ecosystem. Fisheries are an important local industry and are vulnerable to changes in the environment especially if they are persistent over a long period.

Early in 1977 a fisheries expert was engaged to study the effect of the breccia fines in the sea and advise on the possible consequences of pollution.

Laboratory tests were performed to assess the chemical and physical tolerance to the fines by a range of marine organisms. These included microscopic plankton and larger organisms representing stages in the interdependent food chains.

The conclusions were that toxicity of the fines in suspension was negligible. This was confirmed quite dramatically in Nov.1978 when the last lagoon of the series of 4 had been relatively undisturbed for about 4 months. The lagoon had about 1.5 metre depth of water over about 1 metre of settled sediment. At this period a survey was carried out and it was found that the lagoon had developed into a clearly balanced environment with fish and young fry evidently hatched there. The breccia had been flocculated by the combined activity of microorganisms, bacteria and algae and considerable invertebrate fauna was present.

The physical laboratory tests showed, however, that some zooplankton species were vulnerable to sediment concentrations of more than 500 ppm. This figure provided the key to the control needed at the sea outfalls and also to the consequent problem should the fines remain in suspension or become disturbed by storm waves. If a cloud of suspended material covered a large area of the Gulf, the reduction in zooplankton would cause extensive damage to the pelagic fishing industry.

The two limiting factors then were the effect of concentration of suspended breccia on the microscopic fauna and the direct effect of settled sediment on the major coral species *Acropora*. Both of these could affect the fishing, the former especially the pelagic and the latter especially the coral fish, the former being the most important commercially.

The control of the outfall was established and continuous monitoring was maintained at fixed points on the coral reefs. Regular sampling of the plankton also was carried out.

Results

Offshore Reclamation Area

It is not the intention of this paper to rigorously discuss the geotechnical aspects of the completed reclamation. The proportions of fines trapped for different lagoon sizes are given in Table 1 and a typical grading envelope for spoil at the discharge point is shown in Figure 3. Figures 5, 6 and 7 show typical grading envelopes for material sampled as trapped fines, untrapped slurry in the lagoon and that material which found its way onto the sea bed. It can be seen that as the material progressed and was deposited through the system the proportion of very fine material increased, the coarser end of the grading having been retained.

Comparison of grading of the dredge discharge, concentration of suspended sediment in the lagoon, and the lagoon water level showed that the correlation between these three aspects was generally weak. There was a notable drop in concentrations when the lagoon water level was raised, but generally peak concentration levels appeared to correspond more with strong winds which maintained the material in suspension by way of the turbulence generated. It was also found that once the material had a chance to settle and form attractive bonds during a cessation in the dredge discharge it took a considerable flow to resuspend material below the water level. Table 3 gives a chronological account of the values of

material dredged, volumes lost in suspension, volumes of trapped fines and respective bulking factors. All volumes are expressed in millions of cubic metres and the volumes of discharge water include run-off from stockpiles of sandstone provided outside the reclamation area.

Date	Vol. of dredging to date	Vol. of discharge water direct to sea	Vol. of reclamation to date	Vol. of soil lost in suspension	Vol. of un-trapped slurry	Average bulking factor of slurry	Vol. of trapped fines	Average bulking factor
Nov 78	11	20	15.4	0.07	5.2	3.1	Small	-
Feb 79	13	20	17.8	0.20	5.9	3.1	Small	1.35
May 79	16	58	21.7	0.28	7.7	3.0	0.9	1.35
Sept 79	20	108	25.1	0.46	6.8	2.9	2.7	1.34
Jan 80	21	147	27.4	0.66	8.9	2.6	2.9	1.33
July 80*	26	187	29.9	1.32	3.5	2.3	8.0	1.3
Sept 80*	27	200	30.7	1.54	nil	-	10.2	1.3

*These quantities are predicted

Table 2: Chronological Summary of Dredged and Trapped Fines

The surveys of the offshore reclamation area showed that actual quantities compared well with predicted quantities as shown typically in Table 3. The predictions for Feb.1979 were based on borehole data from the early experimental lagoons, whereas the Jan.1980 predictions were based on all the information available in March 1979.

	Predicted		Actual from survey	
	Feb 79	Jan 80	Feb 79	Jan 80
Total volume dredged soil	12.5	21.3	13.2	21.3
Total volume of fill	18.4	28.6	17.8	27.4
Overall bulking factor	1.47	1.38	1.35	1.33
Volume of coarse fill	11.2	16.7	11.9	15.5
Volume of soft slurry	7.2	11.8	5.7	11.9
Percentage of soil as coarse fill	75	85	86	82
Percentage of soil as slurry	25	11	14	14
Percentage silt lost (Balance)	Trace	4	Trace	4

Table 3. Comparison between Predicted and Measured Quantities.

It can be seen that the actual volumes compare very well with the predicted volumes particularly with respect to silt losses.

Seabed Deposits

The unconfined breccia disposal trial did not lead to any firm conclusions with respect to levels of fines remaining in suspension near the discharge point. It did lead to the general conclusion that the plume of heavily concentrated sediment was very localised indicating that the majority of material found its way rapidly to the sea bed in the form of a density current. However, as a result of this trial it was decided that the reclamation area outfall should be a little way inshore of the knuckle on the East Breakwater as shown in Figure 1. on the grounds that the majority of the material would tend to deposit in this relatively sheltered area.

The development of the silt bank each side of the port was monitored as previously described. Figure 8 shows the extent of the area over which 100% coverage by silt occurred at various stages in time. It would appear that on the east side of the port the silt bank reached a sensibly stable limit beyond which further migration was extremely slow. On the west side of the port the silt bank was very much more spread out and was relatively more mobile. In fact, after an initial period of discharge from the western drainage outfall there was a long period over which there was no discharge. During this period it was noted that large areas of seabed naturally cleared and benthic communities began to re-establish themselves.

Tests on undisturbed core samples from the silt bank next to the East Breakwater revealed a sensibly linear relationship between bulk density and depth below surface, at least for the upper layers. It appeared that at the early stages of deposition bulking factors can be as high as 5 or more. Continual sampling of sediment concentrations and the dimensions of the silt bank enabled estimates of volume of fines which remained on the seabed in the immediate vicinity of the port and that which dispersed elsewhere to be made. This confirmed that most of the fines carried into the sea in suspension remained in the silt bank. Also the deposits on the east side were relatively stable, whilst those on the west side had a greater tendency to migrate, due to the higher degree of turbulence on the weather side of the port entrance breakwater. Without carrying out tracer studies it is difficult to be definitive as to the exact patterns of sediment movement. However, the extensive current measurements from the self recording current meters and float tracking enabled qualitative estimates of general movement to be made. From these it was evident that the material from the west silt bank migrated both to the west and around the breakwaters to the east to supplement the east silt bank. Migration from the east silt bank was limited and predominantly in a northerly direction.

Marine Life

The Plankton samples were collected for more than a year on a fortnightly basis. These did not reveal any particular seasonal trends and hence did not indicate that dredge run-off should be curtailed during any potentially sensitive periods.

Careful long term observations of specific monitoring areas close to and remote from the run-off discharge points were made. It was found that the sea bed in the immediate vicinity of the outfalls and over which there was complete coverage by silt, became completely sterile as predicted. The bank on the east side were more stable than anticipated partly due to the formation of an algae carpet over the surface of the bank. This helped to prevent the movement of the upper layers of fluid mud which might otherwise have occurred.

In January 1980 the situation was as shown in Figure 8. This shows an area outside the silt banks in which there was up to 10% mortality of *Goniopora* and *Meandrina* type corals. Further out as shown pollution resulted in 15% mortality of *Acropora* type corals, but no deterioration of the hardier species. These zones were not extensive and the area was soon reached where young corals were found re-colonising where the silt lay only sparsely in troughs and deterioration of coral was reduced to background levels in response to normal prevailing conditions.

Conclusions

The problems involved in dredged spoil disposal have attracted an increasing amount of attention during recent years particularly with respect to achieving acceptable reclamation with difficult spoil³, optimising disposal area dimensions and outfall arrangements^{4,5} and avoiding environmental problems^{6,7}. In the situation described in this paper the disposal area was under water so that assisted drainage techniques such as trenching etc, could not be employed. Pumping distances were too great to contemplate drying by evaporation and in any case the quantities involved were too large.

An ongoing monitoring and testing programme enabled timely measures to be taken so that silt losses to the sea were reduced to a minimum and an acceptable reclamation area was created within the economic constraints of the project. It was estimated that if no measures had been taken between 10 and 15% of the fines would have entered the marine environment. By optimising lagoon size, bund levels and water box controls it is predicted that this will be reduced to between 2 and 5%, a quantity that could be and was retained within an acceptably small area adjacent to the breakwater.

It appears that the major bank of silt created in the port area will remain quite stable due to the combination of shadow effects of the breakwater, high cohesion and consolidation of the sediment, the intermittent formation of an algal carpet and the damping effects on waves passing over a fluid mud bottom. Further the concentrations of suspended sediments measured in the sea never seriously exceeded the harmful levels established from laboratory experiments.

It was found that the corals, especially the more sensitive species, were excellent monitoring agents. Deterioration, initially identifiable by the bleached appearance at the centre of the branches was not a rapid process. Since *Acropora* are already living outside their temperature and salinity optima, further stress due to siltation of the fine coral polyps,

removal of adequate substrate for larval settlement and higher light attenuation due to silt turbidity could be readily detected.

In order to replace the reefs, in the immediate area of the port that have been unavoidably destroyed an experimental programme of installing artificial tyre reefs has been initiated. Several different pilot schemes have been implemented according to past practices. but it is too early to report whether these will be effective.

Acknowledgements

The authors gratefully acknowledge the contribution to the project of Mr M M Deas, who enthusiastically carried out all of the underwater survey and monitoring work. Also, to Mrs A J Summers for her contribution on marine biology.

CHAPTER 174

An Experiment on Clay Suspension under Water Waves

by

Prida Thimakorn

Associate Research Professor, Asian Institute of Technology

Bangkok, Thailand

SUMMARY

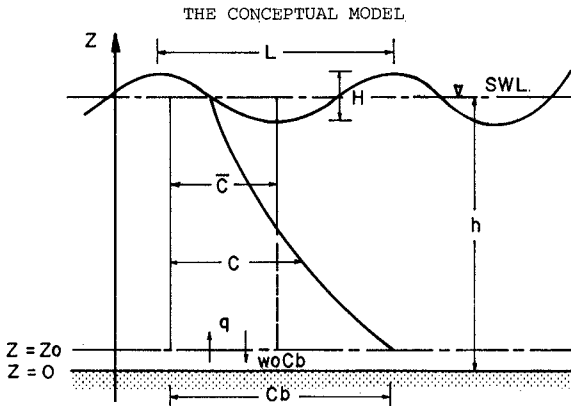

The physical behaviour of water waves upon the suspension of fine cohesive clay was explored experimentally in a wave channel. Results obtained from the experiment show that equilibrium concentration is reached in the wave field some time about five hours after the initiation of waves. The ratio between the mean bottom concentration and the vertical average is constant and yields almost the same value within the range 1.17 and 1.34 at equilibrium and the bottom concentration at equilibrium is linearly proportioning to the maximum bottom velocity of waves. The dimensionless transient concentration possesses a relationship also with the bottom velocity and the bottom shear stress can be related to the maximum value of the ratio between the bottom concentration and the vertical average value found within a short time after the initiation of waves.

INTRODUCTION

Tidal current, river flow, waves, longshore current and wind drifted current are those dynamic factors affecting sediment transport in a coastal region. Two kinds of the sediment; sand and clay exposed themselves to those forces differently. The loosened particles and larger densities of sand show its transport as bed load, suspended bed material load and suspended load while the cohesive property of clay and small density besides its chemical interactions shows its transport only in the form of suspension. Within the complex physico-chemical system in a coastal region various investigations were carried out under field conditions to quantify the coastal transport and relate it with the acting forces and the sediment properties.

In order to understand in particular the behaviour of waves on coastal sediment, studies were and are actively conducted also in the laboratories and theories are being developed. However, the majority of the works are concentrated on the behaviour of granular materials and sand, MONOHAR (1955) set up on oscillating plate with sand on top to investigate the vertical motion of sand under simulated water waves. Flume experiments were carried out by many investigators for example HOMMA and HORIKAWA (1963), HORIKAWA and WATANABE (1970), HATTORI (1971) and others to examine the behavior of waves on sand con-

centration. Emphasis have been made with respect to formation of ripples and evaluation of the diffusion coefficient affected by ripple dimensions. Researches on transportation of cohesive clay are mainly carried out under the two forces namely; the current and the settling. In the current system KRONE (1963) introduced a flume study to demonstrate the rheological properties of clay in the transport process METHA and PARTHENIADES (1974) clarified the physico-chemical properties of clay and the resisting shear stress in a rotating annular channel. LEE (1974) obtained the depositional characteristics of clay in different salinities. WATANABE et al (1979) showed that clay transport by tidal current can be simulated in a simplified experiment. Settling studies of clay were done for example by MALIK (1974). Information about the effect of waves upon clay were mentioned by ALLERSMA et al (1965). It is the objective of this study to determine the interaction between waves and the cohesive materials by means of an experiment

The concentration field under wave motion is shown in Fig.1. From the figure a level $z = z_0$ is defined as an active layer where the sediments at rest in the bottom, $z = 0$, are disturbed and entrain at the rate q into the upper layer, C_b is the concentration at this level. C is the concentration profile and \bar{C} is the vertical average concentration. The wave field possesses the depth at still water level (SWL) equals to h having the wave height H with the wave length L and the period T . The settling velocity of the sediment is w_0 ,

By definition, the average concentration is:

$$\bar{C} = \frac{1}{h} \int_0^h C dz \quad (1)$$

The total concentration is:

$$\hat{C} = \int_0^h C dz \quad (2)$$

Introducing a parameter β , the dimensionless concentration as:

$$\beta = \frac{C_b}{C} \quad (3)$$

THE EXPERIMENT

The experiment was carried out in a glass walled wave channel of 40 cm wide 60 cm deep and 45 m long. It has the horizontal steel bottom. A paddle type wave generator with hinge at the bottom is incorporated at the upper end of the channel. At the lower end, the perforated sloping wave absorber is located. To minimize the under current due to rise of water level at the stagnant lee end, a 15 cm diameter pipe connected the fore bay and the far bay of the channel. Waves were measured by a capacitance type wave gauge. Samples of clay water mixture were extracted through the mine siphons of 2 mm hole. The concentration of each sample was obtained from a calibrated photo-transistor sediment meter. Fig.2 shows the definition sketch of the general set-up of the experiment.

Clay sample taken from the Samut Sakhon river mouth, an estuary in central Thailand was used in the experiment. The sizes of the particles obtained from the hydrometer analysis are between 0.001 mm and 1.0 mm with the apparent densities of 1.21-1.64 kg/lit. Prior to placing the clay into the flume, the sample was washed through the U.S. standard sieve No.200 having the opening of 0.074 mm to ensure the uniformity of the particles and to eliminate the small fraction of the non-cohesive materials. The sample was rinsed through fresh water to remove the original high saline content of the clay so that effect of flocculation is reduced. The mixture was evenly filled over the length of the channel so that after two weeks settling it showed an approximate 2.5 cm clay layer above the steel bottom with a low concentration mixture of 30 cm depth above.

Waves in the experiment are confined within the intermediate range having $1/2 > h/L > 1/20$. The reason is that effect of turbulence due to breaking waves and the strong fluctuating shear stress within a wave period are not encountered. Twenty two runs were conducted and within each test run samples were siphoned and analysed simultaneously as shown in the time steps below.

Time Step	0	1	2	3	4	5	6	7	8	9
Time Interval (min)	0	5	5	10	20	30	30	60	60	120
Elapse Time (min)	0	5	10	20	40	70	100	160	220	340

Fig. 2 The Wave Channel

Fig.3 shows the flow diagram of the experimental procedure.

THE RESULTS

The results obtained from the experiment are presented in the following manners:

i) Concentration Profiles Fig.4 shows an example of the concentration profiles which demonstrates the vertical exchanges of clay at successive time steps. It shows that there is a significant increase of the bottom concentration some time after waves were generated while the concentration in the upper layer remains unchanged. This means that the bottom clay are disturbed and entrain into the near bottom layer. At longer time concentration in the upper layer increases which shows that the sediment from the near bottom layer diffuses into the wave field.

ii) Equilibrium Concentration Time variation of the total concentration is shown in Fig.5. It shows some fluctuations at the early stages and becomes asymptote with time at a longer time period. Hence equilibrium condition is existed.

iii) The Normalized Concentration Fig.6 shows some plots of the normalized concentration, β , against time, t . Interpretation of this parameter is similar to (ii), however, with more physical emphasis. It shows the effect of bottom entrainment during the rising limb of β until it reaches the maxima (β). Follows by the diffusion process as shown by the gradual fall of β and consequently equilibrium when β is asymptotic with t . It also shows that at equilibrium β is nearly constant for all cases.

iv) Transient Concentration The characteristics of changes in the concentration can be obtained from the integrated diffusion equation which is derived from the mass conservation in the concentration field as:

$$(h - z_o) \frac{d\bar{C}}{dt} = -w_o C_b + q \quad (4)$$

and the boundary conditions at $t = 0$ when:

$$\beta_{eq} = \frac{(C_b)_{eq}}{\bar{C}} = \text{constant};$$

$$\bar{C} = \bar{C}_{(eq)}; \text{ and } \frac{d\bar{C}}{dt} = 0$$

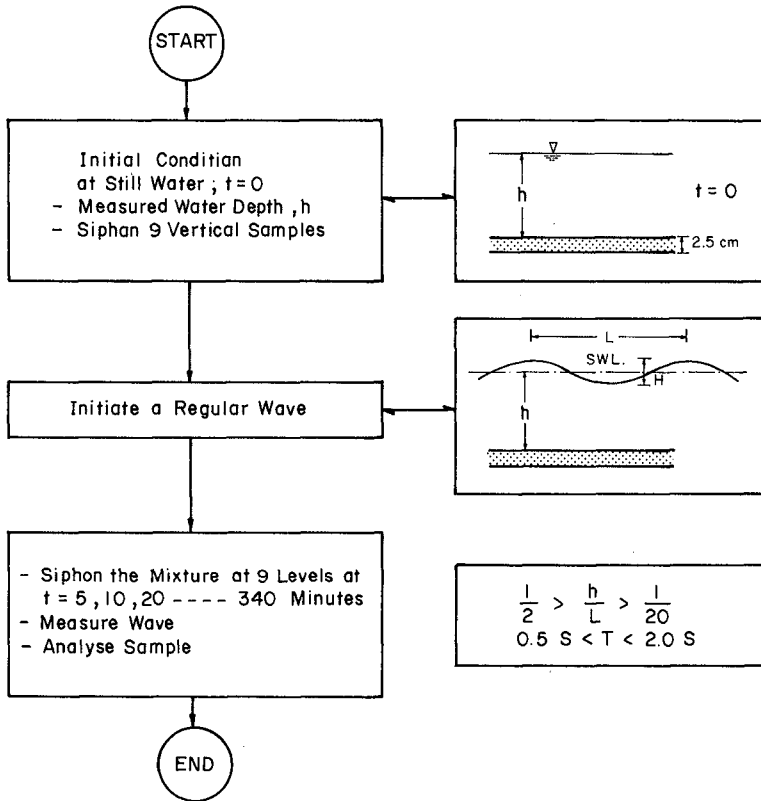

Fig. 3 Flow Diagram Showing the Procedure of the Experiment

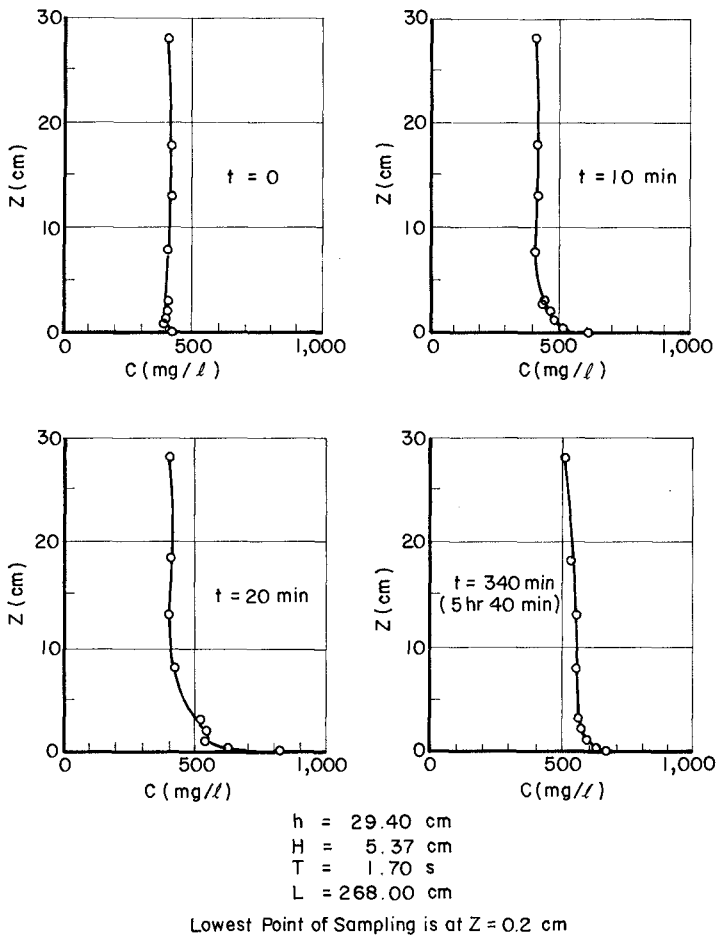

Fig. 4 An Example of Concentration Profiles

Fig. 5 Time Variation of Total Concentration

Fig. 6 The Normalized Concentration, β

At $t = 0$; $\bar{c} = \bar{c}_0$

The solution is:

$$\frac{\bar{c}_{(eq)} - \bar{c}_i}{\bar{c}_{(eq)} - \bar{c}_0} = e^{-\beta' t} \quad (5)$$

when $\beta' = \frac{\beta w_0}{h-z_0}$ (6)

Plotting $\frac{\bar{c}_{(eq)} - \bar{c}_i}{\bar{c}_{(eq)} - \bar{c}_0}$ with t the slope β' can be evaluated from the

known value of β of each run the average value of the terminal fall velocity, w_0 , is obtained which is equal to 2.15 mm/s.

v) Wave Effect on the Concentration This effect can be demonstrated by the maximum bottom velocity, \hat{U} , from:

$$\hat{U} = \frac{\pi H/T}{\sinh 2\pi h/L} \quad (7)$$

of the small amplitude wave theory and the bottom concentration at equilibrium, $C_{b(eq)}$. It was found that the two parameters give a relationship:

$$C_{b(eq)} = 191 + 47\hat{U} \quad (8)$$

Fig.7 shows the graphical relationship plotted from the data. The value 191 at the intercept is the bias concentration.

The effect of the bottom velocity can be demonstrated also by correlating it with the parameter $-\beta'$ which characterizes the transient concentration. Fig.8 shows the relationship between $-\beta'$ and \hat{U} as:

$$-\beta' = 3.59(10)^{-3} \hat{U}^{-0.12} \quad (9)$$

Fig. 7 Effect of Bottom Velocity, \hat{U} , upon the Equilibrium Concentration at Bed, $C_b(\text{eq})$

Fig. 8 Variation of Transient Concentration Parameter β' and the Bottom Velocity, \hat{U}

Fig. 9 Relationship between the Bottom Shear Stress $\hat{\tau}_w$, and the Maximum Normalized Concentration, $\hat{\beta}$

vi) Effect of the Bottom Shear Stress The bottom shear stress under intermediate waves is calculated using:

$$\hat{\tau}_w = f_w \frac{1}{2} \rho \hat{U}^2 \quad (10)$$

where $\hat{\tau}_w$ is the maximum bottom shear stress, f_w is the fiction factor, ρ is the water density and \hat{U} is the maximum oscillating velocity. It was found that the bottom shear stress can be correlated with the maximum value of the normalized concentration, $\hat{\beta}$, which indicates then the effect of shear force in disturbing the bottom clay into the active layer near the bottom. Fig.9 shows that:

$$\hat{\beta} = 1.227 \hat{\tau}_w^{0.575} \quad (11)$$

CONCLUSIONS

This experiment was conducted as a preliminary stage of the investigation to determine the effect of waves on the concentration of cohesive clay. The main part of the knowledge is to identify the parameters of the acting forces, eg velocity and shear stress effecting the concentration field. Physical natures of the two regions; one in the immediate vicinity of the bed and the other in the upper region of the wave field in the disturbing process are identified. Field application cannot yet be recommended until further theoretical back up with, if possible confirmation by field data will be made.

CONSIDERATIONS IN THE DESIGN OF AN
OFFSHORE DATA COLLECTION PROGRAMCortis Cooper¹ and Germán Febres²

1. INTRODUCTION

In-situ data collection in the ocean is costly and unpredictable even when the program is relatively well planned and executed. Despite these inherent difficulties, designers of a data collection program will find little guidance in the literature to assist them in the planning and organizational stages. Some papers have been published discussing particular aspects of a program such as instrumentation, and others have described some of the general experiences of various programs. However, there has been no attempt to conceptualize the process of design of an offshore data collection program and this is one of the purposes of the discussion which follows. The various steps involved in design are identified, ordered, and discussed in some detail. Specific examples are drawn from the authors' experiences with several offshore monitoring programs.

The work presented is most applicable to the collection of oceanographic and meteorological (O/M) data since the authors' experience is essentially restricted to this particular type of data collection. However, it is suspected that a significant portion of the aspects considered would apply to offshore programs involving the collection of other types of data such as geotechnical.

Many of the ideas presented originate from experience with two large O/M programs conducted by Instituto Tecnológico Venezolano del Petróleo (INTEVEP). One of the studies extended over the Orinoco Delta region of Venezuela with an area of roughly 150 x 150 kms. The program began in late 1977 and ended in the spring of 1979. O/M data were taken at nine stations in the region. Figure 1 shows the region and the location of the stations involved in the study.

The second INTEVEP program was started in the summer of 1979 and covers the contiguous coastline of Venezuela, approximately 1200 x 100 kms. O/M data are being taken at nine stations during the three year life of the program. Figure 2 shows the coast of Venezuela and the station locations.

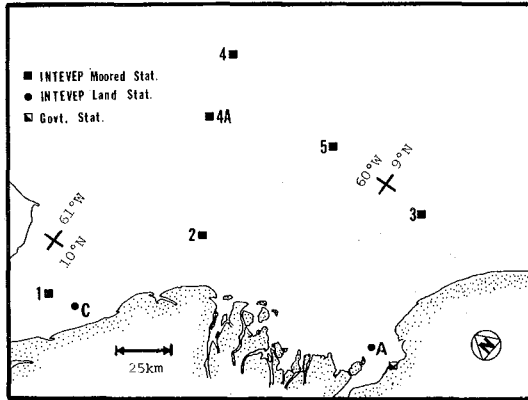

Figure 1: Locations of the oceanographic and meteorological stations in the Orinoco Delta region of Venezuela.

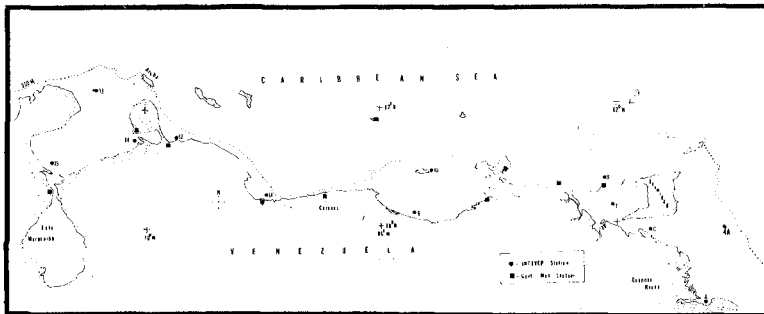

Figure 2: Locations of the oceanographic and meteorologic stations in the Integral Program along the coast of Venezuela.

The primary objective of these studies is to gather the information needed for design and operation of offshore petroleum facilities. The Orinoco program cost approximately \$3 million (U.S.) and the Integral Program is expected to cost about \$5 million (U.S.). Justification for these expenditures was based on the absence of historical data in the region and the high likelihood of petroleum deposits and subsequent development.

2. MAJOR STEPS IN DESIGN AND IMPLEMENTATION

An offshore data collection program can be conceptualized into six major steps: (1) identification of the objectives of the program; (2) identification of the data which must be obtained; (3) detailed design of the program including selection of the resolution of the monitoring network, instruments, quality control methods, navigation methods, logistics, and program duration; (4) implementation and execution of the program including modifications which become necessary during the life of the program; (5) data processing; and (6) data analysis.

Figure 3 summarizes these steps in the form of a flow chart. The first three fall within the planning stage and the latter three within the execution stage of the program.

The flow chart in Figure 3 implies a downward progression which is somewhat idealized. In fact there is likely to be a good deal of iteration during the first three steps as the designer faces the inevitable tradeoffs imposed by financial and technical constraints.

The discussion which follows will focus primarily on Steps 2 and 3. A fairly thorough discussion will be presented on parts 1 and 2 of Step 3, Program Design. The remaining parts of Step 3 are addressed only briefly primarily because of space limitations. Discussion of Step 1 is not included, but this should not be taken to imply that determination of the objectives of an O/M program is a trivial task. Rather, the usual processes of determining objectives is often influenced by political and financial considerations and is difficult to address in a general sense. It is simply assumed in the discussion which follows that the designers have (1) identified a set of reasonable objectives, (2) identified any financial constraints that may exist, and (3) defined the region or area to be monitored.

3. DATA IDENTIFICATION

There are two major questions which must be resolved at this stage. The first concerns identification of the data needed to satisfy the objectives of the program. The second is to determine what historical data is available for the region.

In programs primarily concerned with ecological impacts, the first question is a bit difficult to address in general terms. However, for programs whose results will be used primarily for design and operation

Figure 4: Time history of water level changes during a tropical storm.

Figure 5: Maximum surge profile along the coast during a tropical storm.

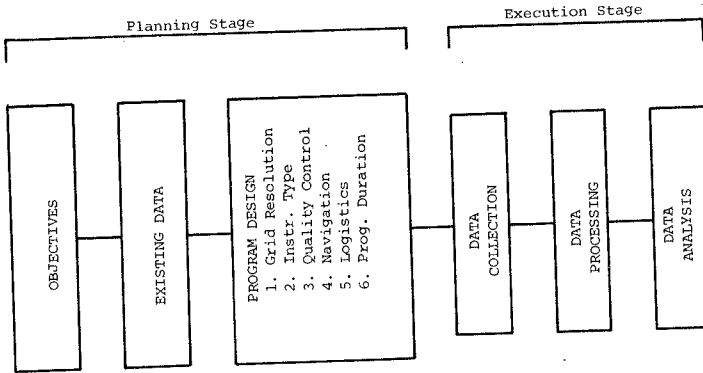

Figure 3: Steps in design & implementation of an O/M data collection Program.

of offshore structures, the questions are more easily addressed. The data of primary interest will include: (1) surface waves with 2 to 20 second period; (2) currents with periods of several minutes and longer; (3) winds, both gusts and sustained; and (4) tides, both astronomical and storm-induced. Some other parameters would probably be of secondary interest and these would include water conductivity, water temperature, air temperature and air pressure. The marginal cost of acquiring these secondary parameters for specific sites is relatively small.

The Data Identification stage should also include an assessment of historical data. This is important for several reasons. First, previous studies can give considerable insight into the nature of the processes which dominate in the region of interest. This information is particularly helpful in the selection of grid resolution, instrumentation, etc.. Second, existing data bases can sometimes be used to effectively extend the time span of a monitoring program. This is important since most data collection programs have a duration on the order of a year and calculation of extreme events with long recurrence intervals will be severely limited if other data sources are not available or are not used. Third, the historical data may satisfy some of the objectives of the program, thus making some data collection unnecessary.

4. DETAILED DESIGN

As indicated in Figure 3, Detailed Design involves six topics. An attempt has been made to place these topics in the order in which they should be addressed. However, all six are strongly interrelated, and initial choices limit options for later decisions. For instance, in specifying the resolution of the monitoring network, the designer must select the time increment between samples. If the designer chooses a relatively small interval between samples, this will often affect the instrument servicing interval, which in turn affects servicing vessel logistics, which in turn affect project costs, and project duration. This requires the designer to iterate many times in order to arrive at an optimal detailed design.

4.1 Resolution of the Monitoring Network

4.1.1 Characteristic Length and Time Scales. In designing the monitoring network, there are two main parameters which must be specified: T_I , the time increment between record samples of process I, and X_I , the distance between instruments which monitor process I. The term T_I refers to the time period between individual samples on the recording media. This, of course, implies a digital sampling method. For analog instruments such as the Datawell Waverider with a Wavrep receiver, the discussion of T_I which follows is not relevant, but comments regarding X_I remain valid.

One of the primary goals governing the choice of T_I and X_I is that both be small enough to adequately describe the process to be monitored. Determining the largest value of T_I and X_I which achieve sufficient

resolution is of considerable interest from the standpoint of minimizing program cost. Larger sampling intervals allow the use of fewer instruments which allow increased servicing intervals and reduced boat time. These optimizations can ultimately lead to substantial reductions in program costs.

As an illustration of how the maximum T_I can be estimated, consider the temporal variation of a process I . The process has a finite duration in which most of the energy associated with the process is concentrated. This duration will be referred to as t_I . To take the illustration a step further, assume the process to be the storm surge created by the passage of a hurricane or tropical storm. Figure 4 shows the time history of the normalized storm surge, H/H_{\max} , where H is the time history of the storm surge at the site of interest, and H_{\max} is the maximum observed surge at the site. Astronomical tides have been removed. The characteristic time scale (t_I) for a storm surge is on the order of 10 hours. Thus it follows that the sampling interval for a hurricane induced storm surge should be less than 10 hours, otherwise a definite risk exists that the event would go completely unrecorded.

In more general terms, the above example implies that the largest T_I which should be used for a monitoring network is slightly less than t_I . If such an interval is chosen, then some form of interpolation will be necessary in order to derive the extreme or peak at the site. On the other hand, if one wishes to eventually extrapolate the collected data to longer intervals, then many points must be taken within the storm period, t_I , so that the peak value (or near it) is recorded. For some processes it is possible to get these additional points with no substantial increase in program cost. Storm surges tend to be one of these processes. However, other processes, such as hurricane generated waves, can be costly to monitor frequently. If wave data is stored internally in a moored wave device, then storage space may become limiting long before the instrument might otherwise need servicing. This requires more frequent and costly retrieval and so the marginal cost of additional data points may be high. For such processes it is often more economical to apply mathematical models or statistical means to extrapolate and interpolate the data. In this mode, the data serves mainly to tune and verify the simulation method.

The determination of a maximum X_I can be approached in a manner similar to that used for determining the maximum T_I . Returning to the previous example of storm surge, it should be fairly evident that the largest X_I for storm surges should be less than the maximum distance x_I affected by the storm. Figure 5 indicates a typical spatial variation of the maximum surge associated with a tropical storm approaching a fairly straight coastline. In this figure, H is the maximum surge which occurred during the passage of the storm at locations along the coast and R is the radius to maximum winds. As indicated in the figure, the characteristic length scale of storm surges (x_I) is on the order of $8R$ and it follows that the largest X_I which could be used in a monitoring network is somewhat less than $8R$.

The characteristic length and time scales (i.e. x_L and t_L) can be identified for other processes besides surge and this is done in Figure 6. This figure is a modification of one appearing in Stolzenbach et al. (1977). Atmospheric disturbances are indicated by the lined regions and two current processes (tidal and geostrophic) are indicated in the clear regions. Other types of currents not shown are generated by local atmospheric disturbances and thus would occupy roughly the same region in the figure as the atmospheric disturbance which is responsible. For example, currents generated during a hurricane would tend to have the same characteristic length and time scales as the winds which create them. Similar observations can be made regarding surge and local wind-generated waves. Examples of processes contained in each region in the figure are: (1) weather system fluctuations - extratropical storms, tradewinds, and tropical storms; (2) mesoscale wind fluctuations - thermal and orographic types of air flow such as land-sea breezes and thunderstorms; (3) atmospheric boundary layer fluctuations - vortex shedding and natural convection near the sea surface; and (4) geostrophic currents - permanent currents such as the Gulf Stream and the gyres and eddies associated with them.

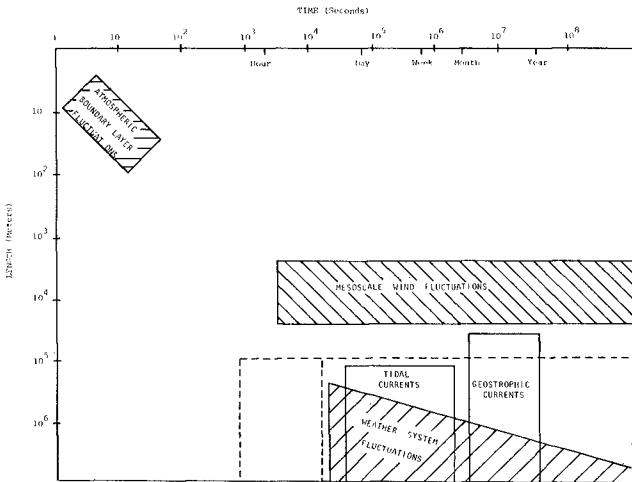

Figure 6: Typical length and time scales associated with winds (& the waves & currents associated with them) & currents in open areas.

It should be pointed out that the length scales shown in the figure apply primarily to open coastal regions. Complex coastlines or bathymetry tend to shorten the length scales of several of the processes such as currents and waves.

With the use of Figure 6, one can estimate the sampling intervals needed to describe various processes. In general, the maximum spatial distance (X_T) and time increment (T_T) needed to monitor a process will be given by the length and time scales associated with the upper left-hand corner of the appropriate region in Figure 6. For example, in order to monitor mesoscale wind fluctuations, the figure indicates that $X_T < 20$ km and $T_T < 1$ hour.

For most programs, one would not be interested in monitoring all the processes included in Figure 6 and this is indeed fortunate because doing so would be expensive, at least for programs covering any significant area. This is true because of the small sampling intervals which would be necessary to describe some of the processes shown in the figure, most notably atmospheric boundary layer fluctuations. Monitoring larger scale processes such as mesoscale wind fluctuations may be desirable from the standpoint of achieving certain objectives in the program. However, the cost of obtaining the data may be prohibitive if the region to be covered is large.

The comments on length scales made thus far have focused on horizontal spatial variations. A figure similar to Figure 6 can be constructed to show the vertical variations as well. This is of particular interest when deciding on the number of current meters to string in a given location.

4.1.2 Auxiliary Stations*. Losses of data and instruments are common and should be considered inevitable. It is interesting to examine data loss rates from a few O/M programs.

In the Orinoco Project, about 30% of potentially recoverable data was lost due to mooring failures, instrument malfunction or loss of instruments. The Integral Program has fared somewhat worse. Approximately 30, 65, 45, and 53% of the potentially recoverable data of waves, currents, tides and winds, respectively, has been lost, primarily due to outside interference.

One of the more extreme and recent cases of high data loss was the NEOCSPO program (EG&G, 1978), a study of the physical oceanography of New England outer continental shelf, including Georges Banks. In one region of the study, current meters were deployed for 8 months and of the 21 system-months of data potentially available, only 2 usable system-months were obtained. This translates to approximately a 10% recovery rate. A major factor in this poor showing was the use of unconventional instrumentation.

It should be evident from the above examples that significant data losses can be expected for O/M programs. If the monitoring network is

*The term "station" refers to a complete instrument package, e.g. current meter string, a meteorological buoy and mooring, etc.

designed such that $X_I \sim x_I$ and/or $T_I \sim t_I$ then loss of data may mean an inadequate description of the process. In the case of an O/M program oriented towards design of offshore structures, some loss of data during normal conditions would probably not meaningfully impair the overall success of the program. However, loss during significant storm events could be crucial.

There are several ways to minimize data losses. One way is to keep the instruments and moorings well maintained. Another is to use only instruments, moorings, and deployment techniques which are well proven in the ocean environment. Even with these precautions, some data losses are inevitable. Therefore, it may be wise to include some auxiliary stations to minimize the impact of those data losses.

A less expensive alternative to providing auxiliary stations would be the addition of more instruments at a station, e.g. the addition of an extra current meter on a string or the addition of extra anemometers to a meteorological buoy. In some situations, the marginal cost of the added instrumentation is relatively small and the method does improve the odds against loss due to instrument malfunction. Furthermore, the extra instrumentation can provide valuable data on the vertical variations of the process being monitored.

If it is decided to include auxiliary stations, the instrument capitalization costs can be minimal in some situations. For instance, if the storm patterns are highly seasonal, as they are on the coast of Venezuela (see Figure 7), then temporary stations can be established during the stormy seasons. In the case of Venezuela, temporary stations could be established during the months of August and September when about 85% of all major storm events occur. Since the temporary stations would only be deployed for 2 months per year, labor and capital expenses could be kept to a minimum. The additional instruments could be provided in a number of ways. Some of the spare instruments normally kept on hand in any large program could be temporarily utilized. Other instruments could be obtained by leasing. The typical rental rate for a two month lease would be about one-third of the retail price of the instrument. A further benefit of leasing is that it would not overburden servicing facilities since most leasing firms provide all servicing.

There are two primary schools of thought in positioning auxiliary stations. One may choose to place auxiliary instruments near primary stations. This was the method used for the BOMP and GAWWMP programs reported by McLeod (1979) in which the wave instruments were placed in clusters of three. This method has the advantage of minimizing retrieval-deployment time and giving a convenient means of calibration or inter-comparison. Clustering of instruments increases the visibility of the station and this is an advantage if the local outsiders are amicable towards the program, since they can more easily identify the station locations and avoid them. Needless to say the approach also offers considerable opportunity to outsiders with mischievous or larcenous intent.

The other school of thought is to place auxiliary stations at some distance between primary stations, possibly equidistant. The advantages include: (1) a decrease of the likelihood of multiple failures when such failures are caused by accidental interference by outsiders or by extreme

Figure 8: The paths of tropical storms in the southern Caribbean during the past 75 years of record.

Figure 7: Monthly histogram of storms for the Orinoco Delta (75 yrs of record).

Figure 9: Two mooring configurations (from Aanderaa Brochure).

local environmental conditions, and (2) if failures do not occur, horizontal spatial information can be gained which will lessen the need for interpolation during the data analysis step.

4.1.3 Other Siting Considerations. The two major considerations presented above should ideally be of foremost importance in design. But other factors will clearly influence the final positioning of stations. The more important of these are briefly discussed below.

Interference from people outside the program often claims more instruments than Mother Nature or mistakes by program personnel. Mcleod (1979) attributed roughly 50% of all mooring failures to outside interference. In the ocean, certain neighborhoods, as it were, should be avoided - shipping lanes constituting a prime example. Other areas are also undesirable, such as heavily fished regions, although avoiding these often large areas is not always possible.

A second consideration in siting stations is that deployment in deeper waters may require costly special equipment. This cost may not be justified, particularly if the location is near the continental break and a small shift in position would eliminate the problem.

The navigation method to be used should also be considered. In general, the further one gets from shore the more difficult and costly it is to navigate precisely.

A fourth consideration is the method of data retrieval. For instance, the distance between instrument and shore-based receiving stations for VHF telemetry must be less than 50 km for most standard instrument packages.

Boundary effects should be considered in the placement of stations as well. The method described in Section 4.1.1 applies to open coastal areas and does not include the complicating effects caused by coastlines, such as shear currents and land induced fetch limitations. If information within these areas is desired it may be necessary to decrease the spatial distance between instruments.

Finally, servicing logistics should be taken into account. The servicing interval may vary from a few weeks to many months depending on the instrument and measurement interval. The cost of a large servicing vessel dedicated solely to an O/M program can constitute a significant portion of the budget for a typical O/M program. In the Orinoco Program, roughly 50% of the total budget was spent on the servicing vessel and crew. Thus, significant cost savings can be achieved by establishing stations on or near a coastline, an island, a fixed platform, or a semi-permanent ship, hence minimizing the use of a large vessel. However, data from stations on or near land can be seriously distorted by the land forms to the extent that the data are not representative of the open ocean. Fixed offshore platforms are generally the most favorable sites since they offer: (1) minimum interference with O/M processes; (2) a fixed, relatively dry environment; (3) some protection from outside interference (e.g. fishing); and (4) improved reliability since damaged or missing instruments can often be spotted and replaced more quickly.

4.1.4 Illustration-Integral Program. Figure 2 indicates that the typical distance between stations in the Integral Program is on the order of 100 km. In the case of winds and tides there are also some additional stations maintained by the Venezuelan Government which can be used to augment the stations in the Integral Program.

The time sampling intervals used in the program are 10 minutes for currents and winds and 15 minutes for tides. For waves, 1 sample is recorded each second for 20 minutes. This is repeated every 4 hours. These space and time intervals are indicated on Figure 6 by the three dotted lines and it is apparent that the network should describe weather system fluctuations, tidal currents and most characteristics of geostrophic currents.

Note that no attempt was made to monitor mesoscale wind fluctuations primarily because the cost was prohibitive. But peak winds along the Venezuelan coast are dominated by convective storms (thunderstorms) which fall within the range of mesoscale wind fluctuations. Fortunately, even though thunderstorms control the maximum design winds, they do not govern design waves or currents, the two more important factors in most aspects of design. Furthermore, the wind data collected in the program can be supplemented by comparatively plentiful wind data recorded at government installations.

There are several other aspects of the Integral Network which should be of general interest. For instance currents, winds, tides and waves are all recorded at each station, this despite the fact that each process has a different X_I as discussed previously. Stations were centralized for two main reasons. First, Figure 6 implies that X_I is roughly equivalent for the three processes of primary interest (i.e. tidal currents, weather system fluctuations and geostrophic currents) justifying a constant X_I . Second, servicing logistics and retrieval-deployment are significantly simplified.

The space and time intervals used in the Integral Program are quite close to the X_I and t_I of the respective processes and, hence, there may be an insufficient number of data points to adequately resolve the process using data alone. In these cases, mathematical or statistical modeling will be necessary to extrapolate and interpolate the data. Examples of these processes include tropical storm induced waves, currents and winds. Mathematical modeling of these particular processes has been fairly successful. See, for example, Forristall et al. (1977) and Ross and Cardone (1977).

Essentially no auxiliary stations were included in the program. This was due to financial reasons, but it can also be argued that because of the unique storm patterns along the coast, the network already has some inherent redundancy. Figure 8 shows the paths of tropical storms which passed near the Venezuelan coast in the past 75 years of record. As one can see, the storms tend to parallel the coast. Returning to Figure 2, it can easily be seen that if a station does fail during a tropical storm, it is likely that the storm will pass another station further along the coast.

4.2 Instrument Selection

The data of primary interest in O/M data collection programs would generally include one or more of the following: currents, winds, waves and/or water level. The sections below will focus on the considerations involved in selecting instruments for collecting these four types of data.

Remote sensing via airplane, land based radar and satellites are not presented here. The first two have considerable problems, including accuracy. The last option also is somewhat limited by accuracy and in addition it is not a technique readily available to non-governmental groups. All three techniques, however, deserve considerable attention since they may ultimately become technically competitive and they already offer some significant cost advantages over in-situ monitoring.

4.2.1 Siting Requirements. Some instrument types have inherent deployment limitations. Three helpful publications by NOS (1977, 1978, & 1979) give information concerning these limitations as well as other valuable information.

Wind sensors can be deployed on a buoy, ship, fixed platform, or land. Land stations have the advantage of being easy to service and relatively inexpensive to construct. However, as Hsu (1978) and others note, the effects of land can seriously distort the wind field so that it is not representative of the open ocean. Additional analysis is usually necessary in order to at least partially correct for the influence of land. Buoys avoid this major disadvantage of land stations but usually at a significant cost in terms of increased initial capital expenditure, long term maintenance and increased likelihood of loss. A site on a semi-permanent ship or platform is perhaps the best location for wind measurements. Some of the advantages of these two sites were given in Section 4.1.3.

It is not uncommon to place the instrument recorder in a comparatively dry, fixed site such as a platform and to moor the instrument sensor. The sensor and recorder can be linked via cable or telemetry. Rose et al. (1979) and Howell (1980) report examples of this approach. The major advantages of separating the two are that the recorder can be placed in a location which can be conveniently accessed and the likelihood of total loss of the instrumentation is usually lessened. Servicing of the recording component can be performed regularly and the sensor need only be retrieved when it shows signs of deterioration.

It is interesting to note that in the field of wave measurement, the instrument types capable of measuring wave direction are limited primarily to wave staffs. It is likely that measurement of wave direction will become more important, particularly in light of some recent results reported by Forristall et al. (1978) which indicate that wave direction is an important consideration in wave force calculations. Several manufacturers including Datawell and ENDECO are planning to manufacture buoys which will monitor both wave direction and vertical displacement.

4.2.2 Data Storage Technique. Once the data is measured by the instrument sensor, some preprocessing is usually performed and the data is stored. Existing methods of data storage include: (1) internal recording

on magnetic tape or strip charts; (2) telemetry of data to the shore, a platform or a ship where data is received and recorded on magnetic tape or strip chart; and (3) transmitting of data to a land station via satellite.

There have been several successful applications of satellites in transmitting oceanographic data including one by the U.S. Bureau of Land Management (1978). The major limitation as of mid 1978 appeared to be data volume. For instance the American Electronic Lab transmitter in conjunction with the GOES satellite used by the Bureau allows hourly transmissions of 192 bits. Such a rate would not allow actual time series data to be transmitted for most parameters. Data transmission rates for the ARGOS satellite are somewhat higher for some locations on the globe. The status of satellite transmission will no doubt change, and given many of the advantages of telemetry the topic certainly deserves close attention in the future.

Telemetry of data from the instrument sensor to a conveniently located recorder has many advantages. First the method minimizes the costly boat time required to retrieve and deploy internal recording instruments. Second, the recording station can usually be checked frequently at minimal cost and malfunctioning or lost equipment can be quickly identified. Third, once the sensor is in place it is often not necessary to remove it for extended periods of time unless the signal shows deterioration. This is a significant advantage since the deployment-retrieval process is costly and often damages instruments.

There are, however, several problems with existing, non-satellite, methods of telemetry. Most off-the-shelf O/M equipment with telemetry uses very high frequency (VHF) signals and the range is restricted to line of sight, or about 50 km under ideal conditions. Interference from sources such as citizens band radio can also be a problem.

The most popular recording media are magnetic tape (usually cassettes) and paper strip charts. The latter medium is a left-over from older technology and should be avoided for larger programs. Though the initial cost of the magnetic tape unit is somewhat higher than for a strip chart recorder, the labor saved during data processing usually more than justifies the additional expense in most data collection programs involving more than a few stations. Tapes can be processed quickly and accurately with computers and most manufacturers offer some form of data processing to the user who prefers not to purchase a reader and set up his own break-out facility.

Several recent developments in digital electronics will soon have some significant effects on recording techniques. For instance, it appears likely that solid state recording media such as bubble memory will soon become economically competitive with magnetic tape. This development should significantly enhance instrument reliability, increase storage capacity and lessen overall instrument size and weight.

The other area of significant progress is in the field of microprocessors. Several O/M instruments such as the EG&G current meter, already include internal microprocessors. Microprocessors have not yet

been incorporated extensively into other types of instruments. It is likely that this will change in the next few years, particularly for wave measurement devices where microprocessors appear to offer many advantages.

4.2.3 Servicing Frequency. Instruments must be routinely retrieved and serviced for one or more of the following reasons: (1) replacement of the instrument recording media; (2) replacement of the instrument batteries; (3) cleaning of sensors made necessary by fouling; (4) maintenance of mooring systems; and (5) replacement of deteriorated components. Not all of these reasons would apply to all types of instruments.

For instruments which record internally, retrieval is usually the only way of determining if the instrument was lost or functioned improperly. Thus there is a strong incentive to service these types of instruments frequently in order to minimize data gaps. This is particularly true if relatively few auxiliary stations have been incorporated into the program, making data gaps more difficult to fill. If an instrument is lost while on station, frequent servicing will probably increase the likelihood of recovery.

The cost of retrieving and deploying moored instruments can be high, since a large, well equipped servicing vessel is often needed. The cost of routine servicing is significantly less for instruments which have the recording unit on land or on a platform or ship. In these cases, servicing of the recording portion of the instrument should probably be done fairly frequently (i.e. on the order of a week) since the cost is small and benefits are substantial. The choice of a servicing interval for moored instruments with internal recorders is not nearly so simple. One must ultimately trade off the cost of servicing against the increased possibility of lost instruments and data.

4.2.4 Maintenance. The cost of maintaining instruments can vary substantially from one model to the next and thus should be considered when choosing instrumentation. Maintenance costs will clearly be affected by: (1) the technical sophistication of the instrumentation, (2) the quality of the components and the design, (3) calibration requirements and (4) availability and cost of replacement parts. Unfortunately, the NOS documents cited earlier give little information regarding these aspects, no doubt due to their subjective nature. Information on maintenance is best gathered from past experience, detailed instrument evaluations by independent sources (see NOS documents) or discussions with frequent users of the instruments being considered.

4.2.5 Reliability. The term is probably best defined as "an instrument's resistance to failure during conditions in which it will normally be used in the program". Some instrument models will experience more failure for a given usage than others. This may occur because of: (1) design, (2) quality of materials and workmanship, or (3) routine servicing which is not up to the manufacturer's specifications. Unfortunately it seems that little independent work has been done in evaluating the dependability of various instruments under similar conditions. Like the situation with maintenance, information on reliability is probably best gained from past experience, detailed instrument evaluations or discussions with others who have extensively used the instrument models being considered.

4.2.6 Cost. Equipment purchases normally constitute a significant portion of the overall program costs: roughly 25% in the case of the Integral and Orinoco Programs. Thus, significant cost savings could conceivably be made by careful shopping. Prices of instruments vary by an order of magnitude within each of the four groups (i.e. waves, currents, etc.). However, in many cases it is unfair to compare the price of one instrument model to another. For instance two instruments may have different capabilities, despite the fact that they both fall within the same group. When comparing purchase prices one should also keep in mind other long term costs associated with the instruments such as servicing. One model may initially cost somewhat more than another but the servicing costs of the less expensive instrument may outweigh the initial advantage.

Another complication to consider is that the life of O/M instruments is often quite short. In the Venezuelan Integral Program twenty instruments from a total of thirty-eight deployments were lost within 6 months. Losses were attributed to outside interference, particularly from fishermen. Since the life expectancy of O/M instruments is usually low, there is a definite incentive to use the least expensive equipment so as to minimize the financial loss of missing equipment.

4.2.7 Accuracy. The error incorporated into the instrument reading can be conveniently conceptualized into two categories: the error registered by the instrument when used under ideal conditions and the error registered under the actual conditions which will prevail in the field. Instrument manufacturers only list the first type of error and these are given in the NOS publications. For most O/M studies the first source of error is negligible when compared to the error from the second source. The Aanderaa RCM4 current meter is a classic example. The manufacturer lists the indicated speed to be accurate to $\pm 2\%$. However, if the instrument is used in the field in the presence of large wave-induced velocities then the error of the speed measurements is more on the order of 50% (Halpern and Pillsbury, 1976)¹.

Most O/M instruments available on the market are limited and the accuracy listed by the manufacturer will hardly ever be obtainable in the field. When considering an instrument model, the designer should examine all independent evaluations of the model in order to determine the instrument limitations and whether those limitations will be a problem in the study.

4.2.8 Instrument Standardization. A large portion of O/M programs monitor more than one parameter (e.g. waves, currents, etc.). In this case it can be advantageous to have instruments from the same manufacturer. This is no doubt one of the reasons Aanderaa Instruments have been popular. The manufacturer offers current meters, tide gauges, and meteorology stations, all using the same data logger (recorder). The advantages of the standardizing are: servicing personnel can be highly specialized, which probably results in more timely, high quality service; spare parts inventories can be minimized; only one reader for data processing of magnetic tape equipped instruments is needed; and data processing software is

¹ Aanderaa Instruments now recommends the RCM4 not be used in the wave zone.

simplified. Though the benefits seem significant it is somewhat difficult in practice to standardize instrumentation for several reasons. To begin with, there are only a few manufacturers which produce a line of instruments which measure more than one parameter. In addition, it is not likely that standardization can be achieved without some sacrifice in terms of the other important factors to be considered when selecting instruments (e.g. accuracy, reliability, purchase price, etc.).

4.2.9 Mooring Configuration. If it is not possible to provide a fixed platform at the station site then it will be necessary to moor the instruments. The term mooring is loosely defined here to include anchor, mooring line, connectors, acoustic release (if used) and buoyancy units (if used). Though deceptively simple in concept, moorings allow a multitude of problems. In many studies including the Venezuelan Orinoco Study and GAWWMP Study reported by Mcleod, mooring failures were the primary cause of instrument loss.

In designing a mooring one must consider the following points: (1) deployment and retrieval techniques; (2) environmental loads at the site; (3) deployment and retrieval loads; (4) strength requirements of the connectors and mooring line; (5) buoyancy and anchoring requirements; (6) long term maintenance including considerations of fatigue, corrosion and deterioration due to marine life.

Many instrument manufacturers can suggest mooring configurations which have been used successfully in the past. An example is shown in Figure 9. The I-anchoring system shown in the figure incorporates an acoustic release device and this configuration seems to be the most popular. Its popularity arises from the fact that the system is invisible from the surface and hence less susceptible to outside interference. The system is, however, obviously dependent upon the ability of the ship to get within range of the release in order to activate it. Also if the release should fail it may be difficult and time consuming to recover not only the release but the other instrument on the line. Finally, the cost of the release is often significant, varying from \$3,000 to \$10,000. Add to this the cost of the surface activation unit which is on the order of \$10,000.

4.3 Quality Control

The larger the O/M program the more quality control of the data will be a problem. The volume of data which must be processed from a large program can become staggering. Consider the Orinoco program as an example. During that program, approximately 2×10^7 words of data were collected and most were eventually processed. The likelihood for error even with the aid of extensive computerization should be obvious.

Errors can be incorporated into the data in a variety of ways. Calibration errors or instrument malfunctions are of major concern and a routine calibration schedule should be established and rigorously followed. An instrument log should be established and records kept of servicing and calibration for each instrument. Each instrument and station location should have unique numbers assigned to them.

Errors also occur in handling and processing the data. Each tape (or chart) must be properly labeled with essential information such as: instru-

ment type (i.e. currents, waves, etc.), instrument number, station number, time of start-up, time of deployment, time of retrieval and time of shut down. In the case where magnetic tapes are used as the instrument recording medium, the tapes should be quickly processed by computer into a form which expedites rapid scanning by program personnel. The quick break-out of data will assist in identifying problems and rectifying them quickly. This latter point is particularly advantageous if the error originates from an instrument malfunction which might otherwise go undetected.

4.4 Navigation

Whenever moored instruments are used, some form of navigation, however rudimentary, will be necessary. If the stations are within a few kilometers of the coastline then a compass or sextant will suffice. Locations further from the coast will require more sophisticated equipment. In the latter case, issues such as accuracy, cost, availability and reliability of the various alternatives should be thoroughly investigated.

4.5 Logistics

Issues involved here include: procurement of instrumentation and parts; scheduling of the servicing ship(s); and management of personnel.

It should be kept in mind that when procuring instruments, the manufacturer will often require several months delivery time. This means that in most cases spare instruments should be purchased in advance. Extra instruments should also be purchased if moored instruments are used in the program. This is necessary because most instruments can not be adequately serviced on the ship when they are retrieved but should usually be returned to a land-based servicing center. This of course means that replacement instruments must be on board the servicing ship so that at the time the old instruments are retrieved, the replacements can be deployed.

If servicing vessels are used then scheduling of the ships will be necessary. Suitable allowances should be made for contingencies such as poor weather or breakdown of the ship. A centralized servicing center should also be established and should be equipped with appropriate repair facilities and spare parts and staffed with competent personnel.

4.6 Program Duration

Most O/M programs last between 1 and 2 years, perhaps somewhat less in the case of environmental impact studies. In the case of design studies, this relatively short duration can present some problems when one attempts to derive design parameters for long recurrence intervals (i.e. on the order of 50 years). Resio (1975) suggests that the data itself should not be extrapolated in time for periods longer than 5 times the duration of the data. That would imply that data from a 2 year program should not be extrapolated past about 10 years.

The problem can be further aggravated if the recurrence interval of major storm events is large as is the case for Venezuela. Recall from Figure 8, the average recurrence interval for tropical storms along the

Venezuelan coast is about 8 years. Hence the probability of measuring a significant storm during a program of 2 year duration is small. As yet a significant tropical storm has not been recorded in either the Orinoco or Integral Programs.

Because data collection programs are costly it is usually not feasible to maintain the program for the time period needed to derive design information from data. Of course, the results from the program are usually needed long before a program of more desirable duration could be completed. Modeling, therefore, must play an important role in the derivation of design criteria. The data in effect serves primarily to calibrate and check the models, at least as the data pertains to deriving design criteria.

5. SUMMARY

The various steps involved in the planning and execution of an offshore data collection program have been outlined. The aspects that have been presented are most relevant to large programs involving the collection of oceanographic and meteorologic (O/M) data to be used ultimately in the design and operation of offshore oil production facilities. Many examples are taken from two large O/M programs off the coast of Venezuela in which the authors have been deeply involved. Although these are specific examples, the discussion is presented in fairly general terms and should be useful to planners and designers of other types of offshore data collection programs.

The discussion focuses on the steps in program design including selection of the resolution of the monitoring network, instruments, quality control methods, navigation methods, logistics, and program duration. Given the complexity of each topic and the space constraints, it is not feasible to discuss all the topics at a detailed level. A fairly detailed discussion of the monitoring network and instrument selection is given and a brief review of the major points involved in the other topics is presented.

AKNOWLEDGEMENTS

Thanks is expressed to Dr. Laurence Draper for several of his helpful comments. Mr. Bruce Fidler and Dr. Bryan Pearce are also acknowledged for their comments and assistance in preparing the final paper.

THE GERMAN "MORAN" PROJECT

by

Winfried Siefert^{*)} and
Volker Barthel^{**)}

Abstract

The project "MORAN" (Morphological Analyses of the North-Sea-Coast) is an extensive program in order to try and combine all knowledge of the morphologic behaviour of a transitional zone of 5 to 7 km width with weather, tide, current and wave data. The area to be considered is about 9000 km² size. The program started in 1979 and will probably continue until 1984.

*) Head, Coastal Engineering Research Group "Neuwerk", Cuxhaven, Fed. Rep. of Germany

***) Federal Waterways Administration, Wasser- und Schifffahrtsamt Bremerhaven, Fed. Rep. of Germany

Introduction

One of the supporters of the 16th ICCE was the "German Coastal Engineering Board" (KFKI). This committee is a board which is responsible for the administration of hydraulic engineering tasks on the North Sea coast and which has interested itself in encouraging practical applied research in the coastal area.

Though the German North Sea Coast is relatively short (370 km), its shape varies strongly with estuaries, extended tidal flats, partly protected by sandy islands with deep tidal gullies between them, sometimes with small unprotected islands etc. (fig. 1).

In order to gain more detailed informations and sufficient knowledge about variety and variations in this region, the KFKI (Kuratorium für Forschung im Küsteningenieurwesen) has initiated, supported and coordinated a number of extended projects. One of those was a synoptic survey program of the entire German North Sea Coast in 1974/75, covering an area of about 9.000 km². Moreover, the Board has inspired and promoted a lot of programs in order to sample data and learn about waves, currents, sediments etc. Now the amount of data and knowledge seems to be sufficient to start a demanding and extensive program, i.e. "MORAN".

"MORAN" means "Morphological Analyses of the North-Sea-Coast". The concern and the problems behind this project are manifold. A team of scientists and engineers coming from all German Coastal Engineering Authorities tries to find a way to the roots of morphological changes at the coast. Fundamentals for these investigations are:

- the first quasi-synoptical survey of coastal areas in 1974/75
- a second quasi-synoptical survey of this area in 1979/80
- charts of the changes between both states
- outline of tidal and wind-effected currents
- outline of wave climate
- outline of sediments and geology.

Of course this was already done, for small limited areas, in different parts of the world as case histories, but it will be the first time that this shall be done for an extended, complicated tidal area by synoptical data.

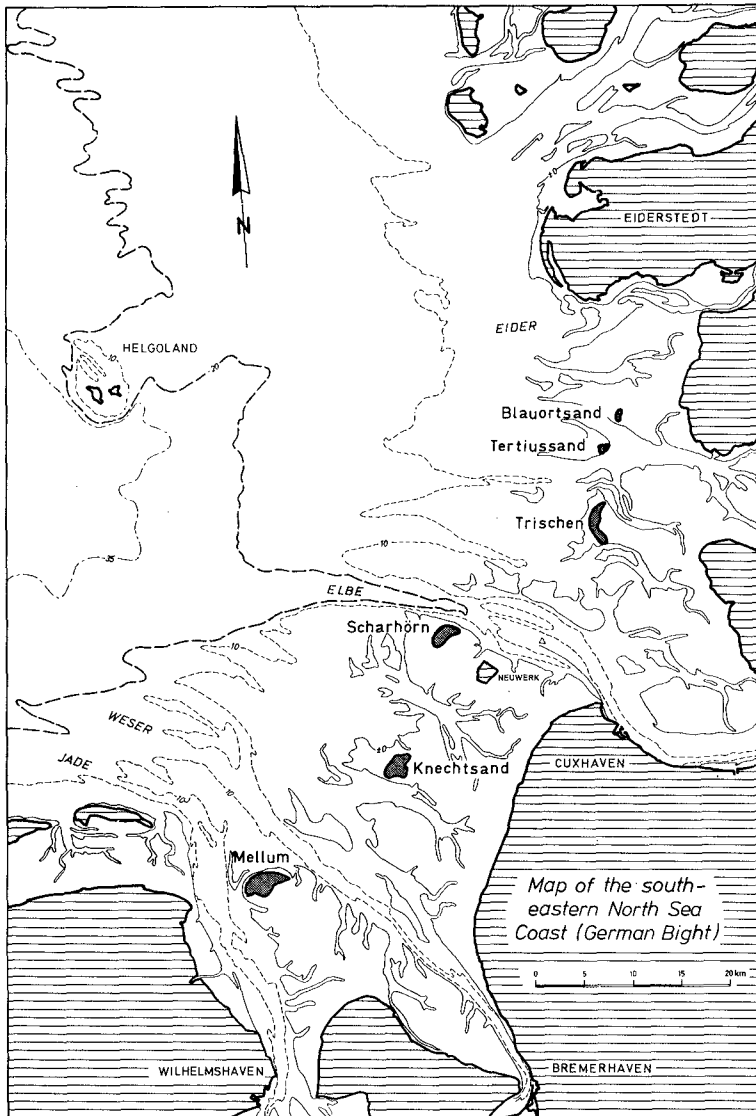

Fig. 1

General Review

The tidal flats and marshes form a transitional zone of an average width of 5 to 7 km in which various tidal flat facies interlock with lagoonal and limnic deposits and peat. These sediments lie on top of an old surface. In the high-lying Pleistocene areas, fluvial erosion and wind-born accretion have formed a rounded wavy relief cut through by separate channels. In the river valleys of the Ems, Weser and Elbe the base of the Holocene has a level surface gently dipping seawards. It corresponds there to the surface of the fluvial Weichselian low Terrace.

The Holocene marine transgression advanced first into these river valleys and channels. At these places there is sometimes a continuous from semi-terrestrial limnic facies to the brackish marine environment, and at other evidence of considerable processes of erosion, reworking and redeposition.

With further rises in sea level the marine influence spread laterally over the low lying regions. In the transitional zone of 5 to 7 km width fine sandy silty tidal flat sediments, mostly rich in lime, were deposited in the seaward part, or silty clayey brackish water deposits with varying lime content. To the landward follow clayey, mainly lime-free sediments with high organic components, and then muds and semi-terrestrial peats. The point of time when marine influenced sedimentation began varies from place to place, according both to its level and how exposed the deposition area was to the sea.

The tides are semidiurnal. The spring tide range lies around 2.6 m with a maximum of 4.1 m. Neap tide range is 1.8 m with a 3.1 m maximum. Mean tidal range in the inner German Bight is about 3 m with possible surges in winter of more than 3 m additional height.

The tidal currents over the flats reach velocities of 30 to 50 cm/s, with a maximum (at storm surges) of 150 cm/s. In smaller channels the current velocities are about 100 cm/s and in large channels sometimes up to 250 cm/s.

Wave movement is a very important factor. Waves procede from various directions and with changing strength. Nevertheless, the predominant movement is from the western sector. The wave movement over the tidal flats is the major factor influencing the distribution of sediments as well as erosion and sedimentation.

Tidal currents and wave movement combine to transport large quantities of suspended load over the tidal flats. Measurements in the Neuwerk flat gave concentrations of sus-

pension of 30 mg/l for a calm tide, and 300 mg/l was reached on a storm flood tide. If account is also taken of the shifting direction and volume with which the tide flows over the flats the transport of sediments during storm surges rises by two to three orders of magnitude.

The water temperature of the body of water which inundates the flats fluctuates greatly and is related to fluctuations in air temperature. In the same way the salt content in the large marine bays also varies, so that in dry summer weather the salt content can rise higher than that in the open sea. In winter the flats cool very much, so that the first ice forms here. When there are strong winds blowing in a landward direction there can be ice pressures which can endanger engineering structures.

Actual Situation

Prototype investigations were intensified during the last two decades. New survey programs have been carried out in the different areas, especially in the mouths of the large estuaries. In the early 1960s current and wave analyses started with concentrations in the areas round the island Norderney and in the Neuwerk/Scharhörn tidal flat complex. Later on a special KFKI project brought intense current investigations along the North Frisian coast, and wave climate measurements were carried out in front of the island Sylt and in the Jade-Weser estuary. Sedimentary and geologic knowledge was gained all over the coastal area with special stress on the region between Weser and Elbe mouths.

All investigations in Germany up to now were not synoptic, but most of them allow general conclusions and can improve our knowledge about the dynamic processes. But till now no attempt was made to include all these in a general survey for the 9.000 km² area in front of the coast.

Of course, we have a lot of examples from all over the world about what is now being done in this MORAN project. Here may be mentioned three of them, standing for others, also from the German coast, that will be incorporated in the actual program:

- One of the tidal channels - the Weser estuary - was presented by Barthel (1977). He investigated the migration of channels and sand banks in the outer Weser estuary from 1910 to 1973. The tendencies are tried to be explained by the predominant current situation.

- Göhren (1975) compared the movement of sand banks in the Elbe estuary (fig. 2), their grain size distributions and their cross sections with recorded currents during storm surges in these exposed tidal flats.
- Stability studies of natural tidal basin systems demand a regime-oriented analysis and a characteristic quantification of the morphological values. Hence Renger (1979) created relative form parameterization dependent on the location by means of a twodimensional system of natural coordinates (elevation and length). The relations derived may prove to be useful in the planning of future constructions and even in understanding and influencing the disadvantageous changes in running systems.

Performance of Project MORAN

Final results will not be available until the second survey will have been evaluated. Because of the vast amount of data this will probably last some years. To get first ideas of how to handle the data most efficiently and how to correlate morphology, topography, hydrology, meteorology and sedimentology, the managing KFKI group decided to select three test regions for a first-step evaluation under the following additional conditions:

- (1) earlier survey results available that can be used as a time series
- (2) no special dredging and depositing areas
- (3) current measurements, wave measurements, and surface sediment investigations during the last decade.

The 3 selected areas are (fig. 3):

- The gully system south of Norderney in a wadden sea area that is protected by an island;
- The unprotected tidal flat of Knechtsand with neighbouring gully systems;
- The wadden sea area west of Büsum, protected only by small islands and sands, in front of a new dike line.

In this first step the choice was influenced by the knowledge that the correlation of morphologic, hydrologic and sedimentologic data surely is simpler there than is in breaker areas or in deep estuaries.

Fig. 3
Southeastern North Sea coast with MORAN test areas

KNECHTSAND AREA

MORPHOLOGIC CHANGES 1974 TO 1979 IN DECIMETERS

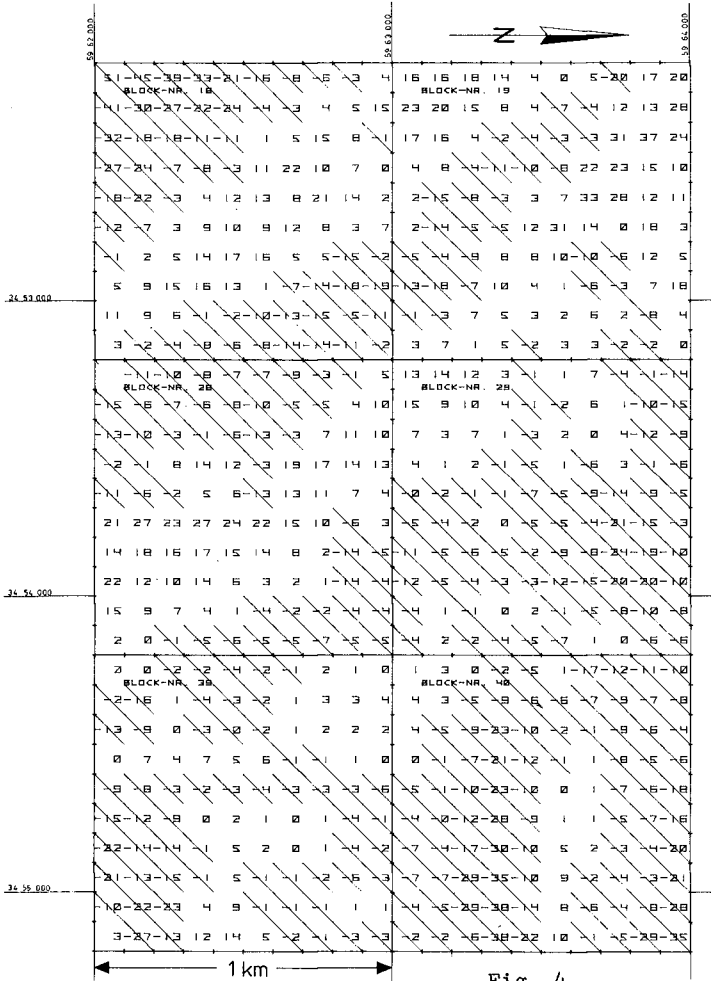

Fig. 4

The MORAN Project

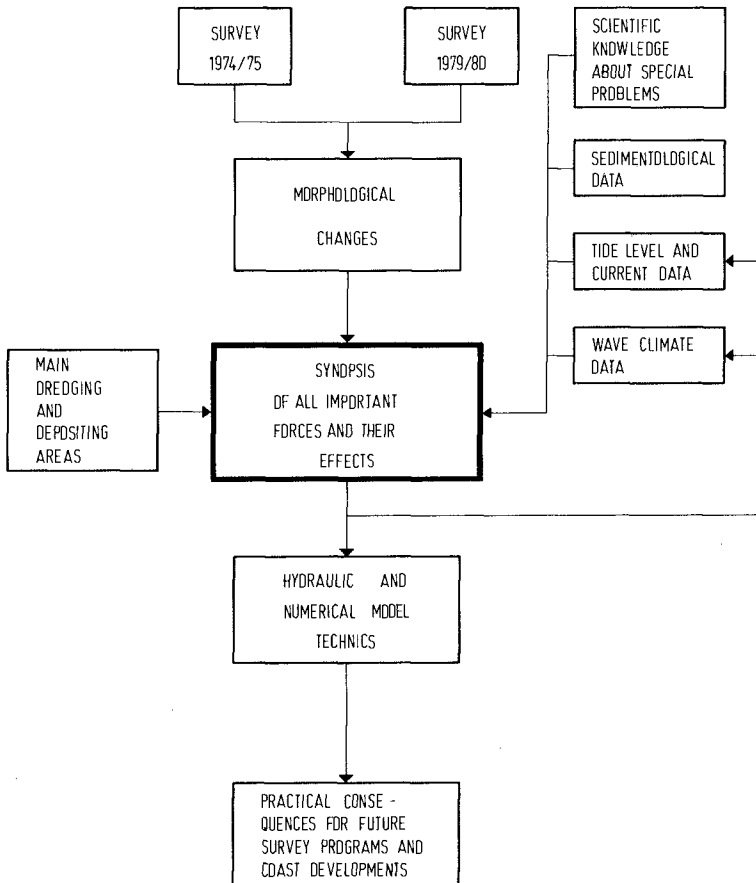

Fig. 5

Pilot Study

The test field is the Knechtsand area. About 1/3 of the survey data of 1974/75 are available in a digitized form. The rest of the data is now being transformed from conventional into digitized form, as is the data of 1979.

We had long discussions about how to evaluate the morphological changes. The result is that we now automatically evaluate mean heights of squares 100 x 100 m out of maps 1:10.000. The grid will be the same for all surveys. The net difference is then evaluated by a computer program and plotted afterwards. First results are shown fig. 4 with max. depth variations in the magnitude of 50 dm within 5 years.

Our Aim

Our aim is to demonstrate in these 3 test fields a synopsis of all available morphologic, hydrologic, sedimentologic and meteorologic informations (fig. 5) in order to find areas of similar morphologic behaviour and by that be able to predict morphological changes during the next decade.

ENVIRONMENTAL ASPECTS OF OIL AND GAS
PIPELINE LANDFALLS IN NORTHEAST SCOTLAND

William Ritchie

Professor of Physical Geography,
 University of Aberdeen, Scotland.

Abstract

Oil and gas pipelines from the North Sea have reached the northeast coast of Scotland from offshore production platforms. The pipelines date from 1973 to 1976. The environmental effects of these pipelines are compared as are the relationships between engineering work, environmental impact assessment and planning procedures. There is also a discussion of methods used to protect and restore these three landfall areas.

Introduction and Setting

Three oil and gas pipelines make their landfall on the northeast coast of Scotland (Figure 1.). The first pipeline, from the Forties Field, was pulled ashore at Cruden Bay in 1973. Later, pipelines bringing natural gas from the Frigg Field reached the coastline further north at St. Fergus in 1975, to be followed in 1976 by a pipeline (known as the Flags pipeline) from the Brent Field. All three pipelines have very long offshore sections, running up to several hundred kilometres from the production fields. On land, the Forties pipeline goes to a nearby pumping station from which the crude oil is pushed southwards to the refinery at Grangemouth.

In contrast, the gas pipelines at St. Fergus lead a short distance across an area of dunes and links to the St. Fergus Gas Terminal, operated by British Gas (Figure 2). This massive terminal consists of two elements; the larger operational British Gas/Total Oil Marine (U.K.) Ltd.

complex from which the gas is fed via land pipelines into the national gas grid, and a northern extension, which is not yet complete, being developed by Shell to receive and process gas from the Brent Field.

Although separated by 20 km, the landfalls at Cruden Bay and St. Fergus share the common characteristics of the North Sea coastal environment. In particular, the three elements that are

significant relate to tides, waves and near shore sediment movements. The tidal range is approximately 3.0 m but more significant, exceptional tides can elevate the water surface in excess of 4 or 5 metres. These elevations are related to North Sea surges and occur with various periodicities. The maximum increase in height might occur once every hundred or even thousand years but smaller surges of less than a metre have been detected within any given year (Stove, 1978).

Accordingly, the design of coastline structures must be related to these somewhat unpredictable factors.

Fig 2 Sketch Block Diagram Near Pipeline Landfalls

Photo 1. Pipeline Pulling of the Flags Gasline at St. Fergus.

Photo 2. A general view of the St. Fergus terminal and adjacent coastline at an early stage of site work.

Wave conditions tend to consist of relatively low, short period waves typical of the North Sea basin. Elevations greater than 2 metres are unusual, and the period is normally of the order of 6 to 7 seconds (Buchan 1976, Weatherill 1980). Again, exceptionally high waves can occur when fetch and storm directions coincide, especially from the northeast and easterly directions. Inspection of available meteorological statistics for and local experiences of the North Sea Coast indicate the need to consider the possibility of single highly destructive periods of wave attack. Nearshore sedimentary cover and movement is another variable which is difficult to predict. On the whole, most of the inshore ground is covered by sand or other loose deposits.

Fig 3

1976 SELECTED BEACH PROFILES

(upper and mid- beach)

CENTRE OF RATTRAY BAY

Cruden Bay, for example, being a bayhead structure, appears to have abundant nearshore sediment but offshore surveys show that bedrock is never far from the surface and, in places, outcrops as reefs and shoal areas. Boulder clay on top of rock is particularly common in the St. Fergus area where sand deposits have a patchy distribution and normally occupy the lower areas in the rock platform. The wide sandy beaches are thus somewhat deceptive and although there are migrating sand bars at

and just below low water mark, bedrock outcrops normally lie only a few scores of metres to seaward. The sand bars also appear to be rhythmic and rip cells are common. In fact, the approach of the St. Fergus pipelines to the coast uses an exceptional area of unconsolidated sediments that runs across the rock platform and provides a tract for pipeline burial. In so far as the prediction of sand movements is concerned it is probably correct to state that little is known about nearshore dynamics in both Cruden Bay and St. Fergus. Sediment movements have to be deduced from morphological evidence. Beach profiling revealed that the beach at St. Fergus varied considerably in thickness (Figure 3.). On the basis of these profiles the lowest profile was defined and used as the level below which the pipeline had to be buried under 2m of sand.

Engineering Techniques for Pipe-pulling

For the three landfall areas the engineering technique of pulling strings of large diameter (c. 1m.) coated pipes ashore was essentially the same. Broadly, a trench was cut through the dunes and adjacent surfaces, and maintained by sheet piling. A pulling wire, attached to a powerful winch to the landward, was fixed to the welded pipe strings which were pulled into the sea off a laybarge. (Photograph 1. shows the pipepulling operation for the Flags pipeline at St. Fergus.) This vessel was anchored a few hundred metres offshore and once the landfall was made, the barge gradually worked seawards, laying the pipeline, towards the production platform. After pipe testing and other related work, the onshore end of the sea pipeline was connected to a land pipeline going either a short distance into the Terminal at St. Fergus or for a further 190 kilometres southwards to Grangemouth from the Cruden Bay landfall. Although the same engineering technique was used in both areas the nature of the terrain caused several minor changes to be adopted. Firstly, at Cruden Bay the presence of a high former coastline about a hundred metres inland made the location of the pulling block a difficult one, in so far as the winch was placed on top of this 30m high boulder clay cliff. The actual landfall was made through a beach and dune environment. The dunes at Cruden Bay were only 3m high and relatively protected. The beach was not particularly dynamic and the coastal edge was rarely subjected to wave attack. In short, this was a relatively sheltered landfall and the low sand dune relief provided a relatively simple site for excavation and restoration (Ritchie, 1975). In contrast, the St. Fergus area was much more dynamic and exposed. The dune face was subjected to more frequent wave and tidal contact. The beach was demonstrably more variable in plan and profile (Figure 3). In addition, the dune ridge was up to 14 metres high and retreating in the form of an undercut sand cliff at an estimated rate of up to

half a metre a year. Equally important, there was a long, flat, low, easily flooded strip of land termed the Winter Loch in the lee of the maturely vegetated dune backslope (Photograph 2 and Figure 2). This surface lay beneath the level of high water mark and flooded to a depth of over 30 centimetres from October to April every year. In addition it was recorded as being environmentally sensitive. There is, for example an area of relatively rare vegetation to the north of the landfall and the entire Winter Loch is an important roosting and feeding area for migrant birds. Landwards of this low surface there is a low degraded cliffline cut into glacial deposits. This inner slope leads to a plateau upon which the Gas Terminal was built. For both landfalls at St. Fergus the engineering technique was again that of cutting of a trench down through the dunes and Winter Loch surface to enable wires to run from the lay-barge to the pulling winch on top of the landward plateau some 500m from the beach (Photograph 1). The cutting and sheet piling operations were much more massive than at Cruden Bay. There was also the problem of waterlogging, and the surfaces being crossed were very soft and liable to be damaged easily by the passage of even the lightest vehicle. Moreover, the trench levels at the coast were substantially lower than the beach and the seaward end of the trench required protection from the possibility of flooding and wave damage. As at Cruden Bay there was no question of digging the trench through the inter-tidal beach until a short time before the actual pipe pulling operation.

The first pipe pulling operation, for Total Oil Marine (U.K.) Ltd., required two pipes to be pulled and the trench had to be cut and sheet piled completely across the Winter Loch. Storing sand for back-filling was necessary as it was impossible to take sand from the beach for restoration of the dune ridge. A storage area was therefore required, so that sand excavated during trenching could be used later to replace and restore the dune and adjacent surfaces. The area damaged by the storing operation was equal to that affected by the actual cut. No attempt was made to preserve the turf layer as Marram grass (*Ammophila Arenaria*) tussocks cannot be handled in this way. Later, the Shell pipeline (the Flags Gasline) used a slightly different technique in that the cutting and sheet piling only extended to the limit of the backslope of the coastal dune (Photograph 1). Nevertheless this was also a massive excavation. After excavation however the sand from the cut through the dune was dumped to form an inclined ramp leading, at a gentle gradient, up to the landward plateau where the pulling winch was sited. This ramp provided an access ridge to the cut in the dune. This sand ramp was covered by a nylon sheet upon which was placed crushed rock to form a road bed. The nylon sheet and superimposed road bed were rolled-back after the pipe was pulled and the sand used to backfill the trench and dune breach. As will be demonstrated below, the

the evolution in techniques which were developed successively for the three pipelines was partly the result of experience gained from the earlier operation and partly modified by the nature of the terrain.

Planning Framework

The timing of the three landfalls, 1973, 1975 and 1976 offers an opportunity to compare the evolution of planning processes in relation to industrial developments and related engineering work. Planning approval is normally required for engineering and similar work everywhere in Scotland. Application for permission is made at the District level and major applications are normally also referred to the Regional Authority*. If there are sufficient objections, then the procedure of public inquiry can be instituted. The proposal to develop must satisfy various national and local government acts and statutes. It is not mandatory for an environmental impact statement to be submitted. Unlike current practice in U.S.A. there is no formal procedure for such a submission (for a fuller discussion of issues related to environmental assessment see Chapman, 1981). Nevertheless, over the last few years it has become exceptional for a major developer not to submit some form of environmental impact assessment and/or statement. One of the effects of this flexible situation is that it encourages considerable pre-application discussion. It promotes contact between the developer, the planning authority personnel and interested parties and may lead to a useful interchange of information. In relation to the pipeline landfalls it is probably correct to state that planning for the Cruden Bay landfall took place before the practice of submitting any form of environmental assessment was established. That was not to say that the developer or the contracting engineer did not consider environmental issues, in fact, B.P. Ltd. prepared a massive in-house environmental assessment. In addition, at an early stage, an established environmental scientist was approached to act as consultant with the responsibility for environmental management during site work and to produce proposals for restoration.

For the two developments at St. Fergus environmental

*In Scotland there are three tiers of government, Districts which combine to form a Region. There is also a national dimension in the form of the Secretary of State who is a Cabinet Minister and has the power to call-in any planning application if it is deemed to be in the national interest to do so. The three island regions, Western Isles, Orkneys and Shetland are single tier all-purpose authorities.

assessment procedures and documentation were followed. Nevertheless there was an appreciable difference in the level of assessment, in that the second proposal required fuller statements particularly with regard to ancillary developments. The three pipeline landfalls thus embrace a period of time when planning was evolving to a stage where environmental impact procedures were becoming more widely accepted. Coincidentally it was also the time of local government reform. There was also some changes in the operation of planning functions developed from the Local Government Act of 1972 and Local Government (Scotland) Act of 1973. By 1976 developers and local government agencies had gained experience in these new procedures and a guidance manual was available from the Department of the Environment (Clark, et al., 1976). Although the transitional period is over the stage of rigid statutory procedures has not been reached.

A crucial figure in the linkages between the developer and planning authorities is the environmental scientist. It is difficult to express succinctly how he operates but he is essentially involved in a series of discussions which begin with preliminary proposals that gradually harden into specifications for engineering work. At the same time operational conditions remain of great importance with the need for future restoration being kept continually in mind. It is also useful for the same individual to be involved in monitoring conditions after restoration. That is not to say that he would necessarily produce the full environmental impact statement but would confine himself to those issues that are essentially concerned with the physical environment calling, if need be, on the assistance of other scientists and specialists.

In Scotland, applications for development are submitted to the planning authority which circulates them to three groups; statutory, advisory and informal parties who are invited to comment on the proposal. Since these parties are known there is no objection to prior consultation taking place before the document is submitted. In the long run this saves time and, assuming a constructive approach is taken, leads to a much better environmental statement as well as better planning constraints and conditions. In general there has been little complaint at St. Fergus with the operation of the planning procedures in relation to the pipeline landfalls. In the opinion of the writer much of the success is due to the inherent flexibility of the present planning system.

Inevitably the discussion revolves around different issues for a specific site. At an early stage the construction of an environmental impact matrix allows both developer and planning authority to identify those issues that require further

analysis and information. For example, at Cruden Bay there was little scientific or wildlife interest and even the agricultural interest in the area was minimal. There was some informal beach recreation nearby but the main factor was the presence of a championship golf course only a few metres to the north of the site. At St. Fergus, in addition to the difficult geomorphological situation, particularly that relating to the interface between beach and dune, there was the sensitive and ecologically important environment of the Winter Loch area with important botanical and ornithological interests. At St. Fergus there was little recreational use and the area was not considered as being scenically attractive. This contrasts with Cruden Bay which is undoubtedly a scenic area. There was, therefore, greater interest shown by such bodies as the Scottish Wildlife Trust, The Royal Society for the Protection of Birds, the Nature Conservancy Council and other bodies and individuals in the St. Fergus area. Moreover the scale of development, particularly as the pipeline landfall was only part of the total terminal complex, inevitably produced more local and even national interest. It therefore followed that the exercise of assessing the environmental conditions and the consequence of the operations at St. Fergus became a much larger and more comprehensive exercise.

Nature of Environmental Assessments for Cruden Bay and St. Fergus

The Cruden Bay development did not require an environmental impact statement although as stated previously a comprehensive assessment was prepared internally by B.P. Ltd. During the course of site work written comments were prepared for the developer and the site engineer, relating site work to such environmental issues as prevention of erosion and sand deposition. Implicit in many of these guidance notes were arrangements that looked ahead to the stage of reinstatement. After the pipe was pulled and tested the ground was restored to specifications drawn up by the environmental consultant with the approval of the local planning authority.

At St. Fergus environmental impact assessments were prepared. Essentially the approach consisted of balancing three sets of information. Firstly, it was necessary to understand the construction and operational techniques that would be employed by the developer and his agents. Secondly, the attitude of the planning agencies had to be ascertained. Normally this consists of determining the types of questions that the planning authority and possible objectors would ask of the developer (see Clark et al, 1976). The third factor to be considered was the specific attributes of the landfall area. The environmental impact assessment took the form of a matrix which divided the different parts of the landscape into separate elements, as for

example, drainage, vegetation, surface stability and so on. The remainder of the table consisted of the three phases of work; that is, the construction phase (to cut the pipeline trench), the operational phase and the restoration phase. The matrix approach proved to be an acceptable method of presentation and analysis particularly as each impact was assessed on a simple scale of low, moderate, high, and in the case of a "high" assessment, the issue was discussed at length in a complementary text. The whole document was prefaced by a description of such general factors as weather conditions and physiographic setting.

Having completed this exercise for the three landfill sites it is possible to indicate some of the problems that arise in such work. On the one hand there is the need to collate existing information on the area. This may vary greatly in quality and quantity. There are gaps in basic environmental information. Accordingly, if time is available, it is necessary to obtain information by conducting surveys or commissioning particular studies. For some environmental variables this is not possible and it is necessary to make assessments that are based on theoretical knowledge and/or from indirect evidence. Experience also shows that should objections arise they often revolve around what can only be described as vague issues and terminology. One may contrast, for example, an environmental impact such as produced by sound or heat radiation, (these impacts are calculable and can be compared against statutory limits and regulations), with issues that derive from the opinion of an observer. The word environment itself is vague. Similarly, how does one assess a criticism that cites "disturbance to wildlife" or, how does one evaluate the effect on the scenic appearance of an area? There is no easy way to resolve these arguments other than by discussion with the parties involved so that some consensus of opinion can be obtained. In the end these issues have to be considered against relative rather than absolute standards. Another issue which is worth stressing is the need for all parties to recognise that there will always be gaps in the environmental knowledge for any given area, and that these gaps cannot be filled in the time available, if at all. For example at St. Fergus an important issue is the movement of sediment in the nearshore area. Anyone with a basic knowledge of coastal geomorphology will recognise that this fundamental question is incredibly difficult to answer and would require considerable instrumentation and time to establish a measure of the amount and direction of potential sediment movement. Environmental restoration is also a difficult problem. At St. Fergus, and to a lesser extent at Cruden Bay, it was also made clear from the outset that full environmental restoration was impossible. This was particularly true at St. Fergus where the eroding coastal dune and the maturity of the vegetation on the backslope and Winter Loch area created insurmountable difficulties for full and complete

restoration programmes. The argument was presented that restoration should aim to produce a surface that was compatible and similar to adjacent areas. It was thought that in the fullness of time natural forces would probably achieve an ecological situation that was increasingly similar to adjacent areas. It would be wrong for the writer of an environmental impact statement and the developer who contracts such a survey to claim that an exact replacement of a complex habitat and environment such as that pertaining to a changeable open beach and eroding, mature sand dunes would be attainable. Equally it is unreasonable for a planning authority to expect such replication. In dealing with an environmental impact statement for a natural landscape area such as a dynamic coastline a truly scientific and comprehensive evaluation of the physical and biological environment is not possible. One should look for a more general statement, backed up as far as possible by all available scientific evidence, to which one should add knowledge gained from comparative experience augmented by whatever site and local surveys are feasible. It is important that the developer and the planning authorities accept the limitations of such an approach. Nevertheless, the environmental assessment and statement are major advances in the functional relationship between planning and industrial development. They provide an invaluable common basis for worthwhile discussion which should lead to sound engineering practice and good environmental management. The experience of the North Sea pipelines would show that this approach is successful but one would not recommend that the environmental impact assessment process should become more structurally defined and rigid. The success of the projects at Cruden Bay and St. Fergus can, at least partially, be related to the use of environmental assessment statements and similar documents but just as important has been the flexibility and exchange of information that has been involved in producing, interpreting and discussing these documents.

Environmental Restoration - Case Studies

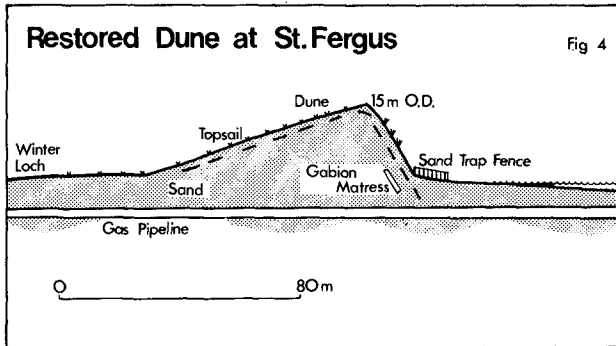

The Cruden Bay site was developed by B.P. Ltd. and they had selected what is arguably the best landfall site on the coast (Figure 1). It is a low energy, protected environment with little ecological or recreational interests. The only problem was the championship golf course nearby. The methods used to restore the surface were straightforward and largely adapted from the experience gained by workers in Holland on similar dune restoration problems. (For a useful summary see Brooks, 1979 or Quinn, 1977.) One of the important methods was the use of brushwood cuttings from local coniferous plantations. These branches were used to construct sand trapping fences and, later, they were used to clad the seaward face of the reconstructed dune. It should be stressed that the area involved in restoration was very small. The dune frontage was about 40 metres and the pipeline

trench and associated areas was of the order of 120 metres long. It is of interest that approximately the same area was affected by the need to store sand for back filling. The surface was restored in two stages since the landward end of the pipe had to remain open for several months for pipe testing procedures. Accordingly the access road was the last feature to be restored. Essentially the original profile was restored, but the dune face was set back and lowered slightly. The surface was then covered by a thin layer of top soil and seeded using a mixture determined by a local grassland expert. The alternative of leaving a bare surface and allowing natural recolonisation by plants was eschewed since sand might have blown onto the adjacent golf course. The crest was protected by a fence, designed to trap sand, but having an equally important function in preventing pedestrian access. The dune face was covered in brushwood and held down by netting. Dune grasses, Marram and Sea Lyme, were hand planted through this cover. Excess sand was deposited on the beach nearby. The remaining material that was used with great success was a water based bitumen compound called Crelawn, which not only held the surface stable but also promoted early and vigorous plant growth (Ritchie, 1975).

The success of this operation was obvious from the outset. Vegetation growth was rapid and the signs of engineering work disappeared within a year. At this stage it was possible to remove fences and other small structures. The beach surface was restored naturally by wave action within a few days. The situation now about seven years later is that the site is indistinguishable from adjacent areas. A botanical survey has shown that some of the early exotic species have been replaced by more local vegetation types. The dune face has built up, aided by the transfer of the excess sand from the beach. There is little sign of any brushwood or other devices used to promote restoration. Although one is tempted to suggest that this restoration was a product of good techniques, it is also important to stress that this was a particularly favourable location.

In contrast the sites at St. Fergus were recognised from the outset as being much more difficult. The scale of operation was larger and the coastline more open and changeable. Early discussions with the first developer, Total Oil Marine (U.K.) Ltd., emphasized that it would probably be impossible to provide complete restoration. The aim was to produce a surface that was similar to adjacent areas and to produce a series of landforms that effectively produced the same degree of stability and protection to the important Winter Loch zone to the landwards. At the St. Fergus site the same working procedures were involved as had been used at Cruden Bay but the area was much greater. There were also substantial delays in the timetable of sitework and pipe pulling,

related largely to the difficult progress of the offshore programme. Accordingly the period of storage of sand for backfilling was very long. There was also a protracted period of vehicle movements in all seasons across the various surfaces. The main access track required a surface bed of broken granite. The delay, a long storage period and considerable vehicle traffic across an artificial road bed combined to add to the problems of final restoration. The sequence of restoration consisted of replacing the sand in such a way as to restore the original profile. After considerable discussion it was agreed that a useful "insurance" should be pro-

vided by inserting a toe protection of gabions, buried at the base of the dune on the seaward face (Figure 4). The arguments of such emplacement concerned the need to protect the dune face in the interim period between restoration and the achievement of natural stability. The fear was that in this critical period the dune might be attacked by an exceptionally high water level with destructive waves. In the event, this did not happen and the gabion wall remains as a fail-safe device beneath about 1.5 metres of surface sand. The same device, for the same reasons, was used on the Shell pipeline landfall a hundred metres to the north. Once the profile was restored it was held in place by stretching old fishing nets from the toe of the dune over the crest and down the back-slope. A further 30 centimetres of sand was added, and the crest and back-slope were covered by a layer of topsoil. (Unfortunately in this particular area the topsoil proved to be of very low quality, with a high clay content, and this has led to some minor problems which had to be rectified at a later date.) The seaward face, crest and

backslope were then replanted. The backslope was planted by standard agricultural techniques using a carefully selected mixture of agricultural grasses. A small proportion of "wild" flower and grass species were also used; the species being selected from the list of plants that was compiled before site work commenced. A similar procedure was used for the Winter Loch surface. An open pattern of Marram grass was replanted by hand on the backslope although it was realised that it would have little chance of vigorous growth, as there was little sand accretion in the lee of the dune crest. The seaward face was hand planted exclusively with Marram grass.

Since the work was completed in 1976 it has been possible to assess the success of the various procedures. The best feature, and the feature that satisfies the prime need of protection, is that of the seaward face. There has been vigorous growth and ample sand accretion. This was certainly aided by constructing sand trapping fences at intervals along the toe of the dune. The backslope has been the least successful area for although growth was initially good this seems to have been aided more by the application of fertilizer than by any natural factors. It should be added that immediately after planting the weather for the next two years was exceptionally bad. There being periods of heavy rain followed by a summer of near-drought conditions. The situation was further exacerbated by the clay content of the top soil which is relatively impervious and caused surface runoff problems. The problem of compaction and the difficulty of removing all the crushed stone from the Winter Loch area also proved to be a problem and it is fortunate that the developer agreed to a second phase of restoration work so that this problem could be solved by a second period of surface clearing and reseeded. There were also minor drainage problems to the landward which were quite unforeseen and related to wider drainage changes brought about by the construction of the main terminal site. These highly localised problems were also solved but they emphasize the need for some form of monitoring programme for up to five years after site work is finished. Further north the same landform zones were breached by the trench for the Shell pipeline and with the experience of the B.P. Landfall at Cruden Bay and the Total Oil Marine (U.K.) Ltd. site a hundred metres or so to the south it was possible to anticipate some of the problems and refine environmental and restoration advice accordingly. It is possible to highlight these although one must stress that the techniques used were, in the main, the same as had proved successful on the two previous sites. One of the advantages was the greater lead-time which made it possible to complete a more thorough survey of the area before site work, this included a careful topographic survey. It was also possible to confine the working area by fencing before any vehicle reached the site area. Corridors

were established beyond which the areas were regarded as inaccessible. Since the storage of sand had proved to damage rather large areas, excavated sand was used to produce a ridge which descended at a low gradient to the dunes and became the bed for the access track and pulling wires (Photograph 1). This greatly reduced the area of surface damage. The sand ridge also had engineering advantages and these have already been described. After pipe pulling the sand ridge was used to fill the gap in the dunes, and the Winter Loch and adjacent surfaces were then carefully lowered to their previous elevation and slope. Exactly the same procedures were used for the dune face, the back-slope and Winter Loch surfaces as had been used previously with the significant difference that good quality top soil was imported to cover the backslope and Winter Loch surfaces. Another minor difference was that the seed mixture was cross-drilled rather than surface spread. This gave better establishment. In all other respects the methods and the progress has been similar to that of the other pipelines.

It is too early to judge the success of both St. Fergus operations but it is possible to state that the initial objectives have been satisfied in that environmental damage and disturbance was minimal and there were few if any side effects on adjacent areas and surfaces. The dune ridge is undoubtedly stable and providing a barrier which is equal if not superior to the original dune ridge. The hydrology of the Winter Loch surface has been restored and there are already signs that the vegetation is changing to that of its previous condition and the ecology, particularly the use of the area by birds, is little different from what it was before the onset of engineering work. It would be untrue to claim that the area is now indistinguishable from adjacent areas. Unlike Cruden Bay it was never felt that this was possible. The areas which give rise to least satisfaction are the backslope zones. It is doubtful if they will ever have their former Marram dominated, mature, tussocky appearance. Their pre-existing state was a sensitive combination of soil and micro-climatic conditions sustained by a precise input of blown sand escaping from the eroding front of the dune. By stabilizing the dune face and promoting vigorous vegetation growth the escape of sand to the backslope has been prevented. Since Marram grass requires an input of fresh sand for growth the situation is obviously one where a definite decision had to be taken. To achieve vigorous Marram growth one would have to have left large areas of dune face and back-slope bare of vegetation to enable sand to move freely across the dune crest. To do this would obviously have raised the possibility of severe sand erosion which could have disrupted the entire restoration programme; not only by creating blow-outs on the dune ridge but by transferring excessive amounts of sand to the fragile Winter Loch environment inland. Since priority was

given to physical stability it was obviously unacceptable to leave any areas bare of vegetation for any length of time.

Summary

Restoration and environmental work at Cruden Bay and St. Fergus has demonstrated the reciprocal advantages of environmental assessment and impact statements to the developer, the engineer and planner. It has also shown the value of early and informative discussions between the developer, site engineer, planning agencies and environmental consultants. It has also suggested the need for careful specific site selection in that some areas are manifestly easier to manage and restore than others. In this respect it is possible to recommend that an environmental consultant should be used before the precise site is chosen. No new techniques have been developed as a result of these three operational situations, although the policy of pre-determining access and working areas has been a useful innovation. Otherwise, the actual programme consisted of using techniques and methods developed elsewhere; they have simply been modified to suit particular local conditions. It has also been demonstrated that after restoration there is a need for a continuing monitoring programme to last at least 5 years. It has also shown that the developer needs to accept a commitment to review the progress of restoration work particularly in such dynamic and potentially fragile environments as the coastal zone. Management does not end when the pipelines come ashore. The input of capital and personnel for such monitoring is not great, amounting to little more than a few visits each year but this small provision will provide considerable benefits. It will also serve to improve or consolidate the relationships between the local community, the planning authority and the developing agent. At St. Fergus this has gone one stage further and the area including the restored ground has now assumed that status of Local Nature Reserve, with a Management Committee consisting of representatives of conservational interests and the pipeline and terminal operators.

Acknowledgements

The author wishes to record his gratitude to B.P. Ltd., Total Oil Marine (U.K.) Ltd. and Shell (Exploration and Production) Ltd. for financial assistance and permission to use the above information and data. Thanks are also expressed to Land and Marine Engineering Ltd. for technical advice and the use of Photograph 1. Dr. K. Chapman also provided valuable advice on matters relating to environmental impact assessment.

STATISTICAL PROPERTIES OF RANDOM WAVE GROUPS

AKIRA KIMURA^{*}

ABSTRACT

This study deals with the statistical properties of the group formation of random waves determined by the zero-up-cross method. Probability distributions about

- (1) the run of high waves
- (2) the total run
- (3) the run of resonant wave period

are derived theoretically providing that the time series of wave height and wave period form the Markov chain. Transition probabilities are given by the 2-dimensional Rayleigh distribution for the wave height train and the 2-dimensional Weibull distribution for the wave period train. And very good agreements between data and the theoretical distributions have been obtained. Then the paper discusses those parameters which affect the statistical properties of the runs and shows that the spectrum peakedness parameter for the run of wave height and the spectrum width parameter for the run of wave period are the most predominant.

INTRODUCTION

It is often observed in the field observations that a large wave makes a group with another large waves. This characteristic of sea waves makes significant effects on several coastal engineering problems such as slow drift oscillation of vessel, stability of rubble mound, drainage of overtopping discharge and some other problems.

Arranging order of random waves is usually analyzed with a concept of the run. There have been two kinds of theoretical studies on the run of random sea waves. One is done by Goda(1) and the other is done by Ewing(2) and Nolte-Hsu(3). Goda derived the probability distribution providing the randomness of waves. On the other hand Ewing, Nolte-Hsu derived the probability distributions providing the narrow band spectrum. As the result of this assumption, succeeding several waves correlate each other. However several authors pointed that consecutive wave heights correlate each other, but the correlation of alternative wave heights diminishes nearly zero.(4),(5),(6) Then random wave height train seems to have a intermediate characteristics between these two theoretical assumptions.

Sawhny(7) examined the time series of crest-to-trough wave height by means of the Markov chain and found that consecutive three half waves

* Assistant Professor of Department of Civil Engineering, Faculty of Engineering, Tottori University, Tottori, Japan

correlate each other. Recently the author(8) showed that time series of zero-up-crossing wave height and wave period have properties very close to those of the Markov chain and that their transition probabilities may well be approximated with the 2-dimensional Rayleigh distribution and the 2-dimensional Weibull distribution respectively.

RUN OF WAVE HEIGHT

Transition equation of the Markov chain is given as:

$$p_n = p_0 P^n \tag{1}$$

where p_0 is a initial distribution, p_n is a distribution after n time transitions and P is a transition probability matrix. If wave height train h_j ($j=1,2,3, \dots$) are classified into the following states with reference to the standard wave height h_* :

$$\left. \begin{aligned} \text{State 1 : } & 0 < h_j \leq h_* \\ \text{State 2 : } & h_* < h_j \leq 2h_* \\ \dots\dots\dots & \dots\dots\dots \\ \text{State i : } & (i-1)h_* < h_j \leq ih_* \\ \dots\dots\dots & \dots\dots\dots \end{aligned} \right\} \tag{2}$$

$\dots\dots\dots (j=1,2,3, \dots)$,

then transition probability matrix is given by the following equations.

$$P = \begin{pmatrix} P_{11} & P_{12} & P_{13} \dots \\ P_{21} & P_{22} & P_{23} \dots \\ P_{31} & P_{32} & P_{33} \dots \\ \dots\dots\dots \end{pmatrix} \tag{3}$$

where

$$P_{ij} = \int_{(j-1)h_*}^{jh_*} \int_{(i-1)h_*}^{ih_*} p(h_1, h_2) dh_1 dh_2 / \int_{(i-1)h_*}^{ih_*} Q(h_1) dh_1 \tag{4}$$

$(i,j=1,2,3, \dots)$,

in which:

$$p(h_1, h_2) = \frac{4h_1 h_2}{(1-4\rho^2)h_r^4} \exp\left[-\frac{1}{1-4\rho^2} \left(\frac{h_1^2 + h_2^2}{h_r^2}\right)\right] I_0\left[\frac{4h_1 h_2 \rho}{(1-4\rho^2)h_r^2}\right] \tag{5}$$

$$Q(h_1) = \frac{2h_1}{h_r^2} \exp\left[-\frac{h_1^2}{h_r^2}\right] \tag{6}$$

h_r is the rms wave height, ρ the correlation parameter, I_0 the modified Bessel function of the 0-th order. Eq.(5) is the 2-dimensional Rayleigh distribution and eq.(6) the Rayleigh distribution. Correlation coefficient of consecutive wave height h_1 and h_2 is:

$$\gamma_h = \frac{E(2\rho) - 1/2(1-4\rho^2)K(2\rho) - \pi/4}{1 - \pi/4} \tag{7}$$

in which K and E are the complete elliptic integrals of the first and second kind respectively. In fig.1 the curve(n=2) shows the relation between γ_h and ρ . It follows that p_{ij} in eq.(3) can be determined from the correlation coefficient of consecutive wave heights by using eqs.(4), (5),(6) and (7).

ESTIMATION OF THE SUCCEEDING WAVE HEIGHT

The problem to estimate the succeeding wave height h_2 from the present wave height h_1 is treated as follows:

If the present wave height h_1 falls in the State i, p_0 is given as:

$$p_0 = (0, 0, \dots, 1, \dots) \tag{8}$$

Substituting eq.(8) into eq.(1), distribution p_1 becomes

$$p_1 = (p_{i1}, p_{i2}, \dots) \tag{9}$$

Element p_{ij} (j=1,2, ...) is given by eq.(4). If h_* in eq.(4) is sufficiently small, expectation of h_2 is:

$$\begin{aligned} \bar{h}_2 &= \int_0^\infty h_2 p(h_2|h_1) dh_2 \\ &= \int_0^\infty \frac{2h_2^2}{(1-4\rho^2)h_r^2} \exp\left[-\frac{(h_1^2 + h_2^2)}{(1-4\rho^2)h_r^2} + \frac{h_1^2}{h_r^2}\right] I_0\left[\frac{4h_1h_2\rho}{(1-4\rho^2)h_r^2}\right] dh_2 \end{aligned} \tag{10}$$

where $p(h_2|h_1)$ is the conditional Rayleigh distribution. Fig.2 shows the relation of \bar{h}_2/h_r and h_1/h_r . It shows that according to the increase of γ_h , \bar{h}_2 approaches h_1 . But when γ_h equals 0, \bar{h}_2/h_r is always $\sqrt{2}/2$.

RUN OF HIGH WAVES

The run of high waves which exceed the standard wave height h_* is one of our greatest concern. In this problem, time series of wave height:

$$\dots, h_{i-1}, h_i, h_{i+1}, h_{i+2}, \dots \tag{a}$$

are classified into two states. One is $h < h_*$ and the other is $h \geq h_*$. If these states are distinguished with suffixes 1 and 2 respectively, eq.(3) is reduced to:

$$p = \begin{pmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{pmatrix} \tag{11}$$

where

$$p_{11} = \int_0^{h_*} \int_0^{h_*} p(h_1, h_2) dh_1 dh_2 / \int_0^{h_*} Q(h_1) dh_1$$

Fig.1 $\gamma_h \sim \rho/\phi$, $\gamma_t \sim \sigma/\phi$

Fig.2 $\bar{h}_2/h_r \sim h_1/h_r$

$$\begin{aligned}
 p_{12} &= \int_{h_*}^{\infty} \int_0^{h_*} p(h_1, h_2) dh_1 dh_2 / \int_0^{h_*} Q(h_1) dh_1 \\
 p_{21} &= \int_0^{h_*} \int_{h_*}^{\infty} p(h_1, h_2) dh_1 dh_2 / \int_{h_*}^{\infty} Q(h_1) dh_1 \\
 p_{22} &= \int_{h_*}^{\infty} \int_{h_*}^{\infty} p(h_1, h_2) dh_1 dh_2 / \int_{h_*}^{\infty} Q(h_1) dh_1 ,
 \end{aligned}
 \tag{12}$$

in which $p(h_1, h_2)$ and $Q(h_1)$ are given by eqs.(5) and (6).

The run of high waves starts when a wave height exceeds h_* initially. Suppose $h_{i-1} < h_*$ and $h_i \geq h_*$, in the wave height train (a). The run starts from h_i . The initial distribution p_0 is (0,1). Substitution of p_0 and eq.(11) into eq.(1) gives:

$$\begin{aligned}
 p_1 &= (p_{21}, p_{22}) \quad \dots (n=1) \\
 p_2 &= (p_{21}p_{11} + p_{22}p_{21}, p_{21}p_{12} + p_{22}^2) \quad \dots (n=2) \\
 &\dots \dots \dots
 \end{aligned}$$

p_{21} is the probability that $h_i \geq h_*$ and $h_{i+1} < h_*$. Then the first element of p_1 gives the probability that the length of run is 1. But the first element of p_2 does not give the probability that the length of run is 2. That is, since $p_{21}p_{11}$ is the probability that $h_i \geq h_*$, $h_{i+1} < h_*$ and $h_{i+2} < h_*$, only $p_{22}p_{21}$ gives the probability that the length of run is 2. The elements which give the transition probability from State 1 should be precluded since they have no relation to the run of high waves. Finally transition probability matrix becomes:

$$P = \begin{pmatrix} 0 & 0 \\ p_{21} & p_{22} \end{pmatrix} \tag{13}$$

By substituting initial distribution and eq.(13) into eq.(1),

$$\begin{aligned}
 p_1 &= (p_{21}, p_{22}) \\
 p_2 &= (p_{22}p_{21}, p_{22}^2) \\
 &\dots \dots \dots \\
 p_\ell &= (p_{22}^{(\ell-1)} p_{21}, p_{22}^\ell) \\
 &\dots \dots \dots
 \end{aligned}
 \tag{14}$$

By simple induction, probability distribution of the run of high waves is represented by:

$$p_1(\ell) = p_{22}^{(\ell-1)} p_{21} = p_{22}^{(\ell-1)} (1-p_{22}) , \tag{15}$$

where ℓ is the length of the run. Mean length of the run is defined as:

$$\bar{\ell} = 1/(1-p_{22}) \quad (16)$$

Fig.3 (a), (b) and (c) show the probability distribution of the run of high waves for (a) $h_* = h_{\text{mean}}$, (b) $h_* = h_{1/3}$ and (c) $h_* = h_{1/10}$ respectively. When γ_h equals 0 in each figure, the theoretical distribution corresponds to the Goda's theory.

By analogy, the probability distribution of the run of low waves which fall below h_* consecutively can be given as:

$$p_2(\ell) = p_{11}^{(\ell-1)} p_{12} = p_{11}^{(\ell-1)} (1-p_{11}), \quad (17)$$

where ℓ is the length of the run of low waves. p_{11} is given by eq.(12).

Fig.4 shows the mean length of the run of low waves for $h_* = h_{\text{mean}}$ (solid line), $h_* = h_{1/3}$ (dotted line) and $h_* = h_{1/10}$ (chain line). Mean duration in which high waves do not take place can be estimated from this figure.

TOTAL RUN (1)

From eqs.(15) and (17) the probability distribution of the total run can be introduced.

$$p_3(\ell_0) = \frac{(1-p_{11})(1-p_{22})}{p_{11} - p_{22}} (p_{11}^{\ell_0-1} - p_{22}^{\ell_0-1}), \quad (18)$$

where ℓ_0 is the length of the total run. Mean length of ℓ_0 is:

$$\bar{\ell}_0 = 1/(1-p_{11}) + 1/(1-p_{22}), \quad (19)$$

in which p_{11} and p_{22} are given by eq.(12). Fig.5(a) and (b) show the probability distribution of the total run for (a) $h_* = h_{\text{mean}}$ and (b) $h_* = h_{1/3}$.

Equations (15) to (19) are determined from γ_h or ρ with eqs(5), (6) and (12). Figs.6 and 7 show the theoretical relations of $p_{11} \sim \gamma_h$ and of $p_{22} \sim \gamma_h$ respectively, providing that $h_* = h_{\text{mean}}$ (real line), $h_* = h_{1/3}$ (broken line) and $h_* = h_{1/10}$ (chain line).

VERIFICATION OF THE THEORETICAL PROBABILITY DISTRIBUTIONS

It is very difficult to obtain random sea waves which are long enough and statistically stationary to examine the properties of run. Therefore some numerical simulation techniques (9) have been used to generate random wave trains. Fig.8 shows the target spectra of five cases used in the numerical simulations. Slope of the spectrum changes from minus 4th to 8th power of frequency in the high frequency region. 5000 waves have been generated in each case.

Figs.9 (a) ~ (e) show the comparison between data and the theoretic-

cal distribution of the run of high waves. The thick lines are the distributions from the theory developed here and the thin lines are those from the Goda's theory for $h_* = h_{\text{mean}}$ (solid line) and $h_* = h_{1/3}$ (dotted line). It can be seen that the plotted data agree very well with eq.(15). Figs.10 (a) ~ (e) show the comparison of data and the theoretical distribution of the total run providing $h_* = h_{\text{mean}}$. The solid curve shows eq.(18) and dotted curve is the theoretical distribution from Goda's theory. Good agreements between data and eq.(18) have been obtained. Tables 1 and 2 show the comparisons of the mean length of the run of high waves and the total run between data and theories. With the increase of the correlation coefficient γ_h , mean length of data becomes longer while the Goda's theory gives the constant value which is considerably small. And the theory by Nolte-Hsu gives also small values compared with data. Estimations with the theory presented here give reasonable values in each case.

RUN OF WAVE PERIOD

Time series of random wave period determined by the zero-up-cross method forms the Markov chain approximately(8). Then almost same analysis is available for the run of wave period with that of wave height. However in such a problem as a resonant oscillation of structure, it is more useful to analyze the run of wave periods which fall in the specified wave period band consecutively. For this purpose time series of wave period

$$\dots, t_{i-1}, t_i, t_{i+1}, t_{i+2}, \dots \tag{b}$$

may well be classified into these three states:

$$\begin{aligned} \text{State 1 :} & \quad t_j < t_{*1} \\ \text{State 2 :} & \quad t_{*1} \leq t_j \leq t_{*2} \\ \text{State 3 :} & \quad t_j < t_{*2} \end{aligned} \tag{20}$$

(j=1,2,3, ...),

in which t_{*1} and t_{*2} are the low and high limit of the resonant period band of the oscillation system. The transition probability matrix reduces to the matrix of order 3: (p_{ij}) (i,j=1,2,3). With the same discussion, the first and third row of the matrix, p_{1j}, p_{3j} (j=1,2,3) should be precluded to introduce the run of resonant wave period. Finally P becomes

$$P = \begin{pmatrix} 0 & 0 & 0 \\ p_{21} & p_{22} & p_{23} \\ 0 & 0 & 0 \end{pmatrix} \tag{21}$$

The run starts when a wave period falls in State 2 first; then initial distribution is (0,1,0) and the lth transition distribution is given as:

$$P_l = (p_{22}^{(l-1)} p_{21}^l, p_{22}^l, p_{22}^{(l-1)} p_{23}) \tag{22}$$

$p_{22}^{(l-1)} p_{21}^l$ and $p_{22}^{(l-1)} p_{23}$ are probability that consecutive l waves fall in State 2, but l+1th wave falls in State 1 or 3 respectively. Then the

5	0.38	5.36	5.32	"	10.71	11.57	"

probability that the length of the run becomes ℓ is given by the sum of these probabilities.

$$P_4(\ell) = p_{22}^{(\ell-1)} p_{21} + p_{22}^{(\ell-1)} p_{23} = p_{22}^{(\ell-1)} (1-p_{22}), \quad (23)$$

$$\bar{\ell} = 1/(1-p_{22}). \quad (24)$$

Transition probability of the time series of wave period may well be approximated with the 2-dimensional Weibull distribution (8),(10). Then p_{22} is given by:

$$p_{22} = \int_{t_{*1}}^{t_{*2}} \int_{t_{*1}}^{t_{*2}} f(t_1, t_2) dt_1 dt_2 / \int_{t_{*1}}^{t_{*2}} R(t_1) dt_1 \quad (25)$$

where

$$f(t_1, t_2) = \frac{n^2 (t_1 t_2)^{n-1}}{4A t_r^{2n}} \exp\left[-\frac{\phi}{2A} \frac{(t_1^n + t_2^n)}{t_r^n}\right] I_0\left[\frac{\sigma}{A} \frac{(t_1 t_2)^{n/2}}{t_r^n}\right], \quad (26)$$

$$R(t_1) = \frac{n}{2\phi} \frac{t_1^{n-1}}{t_r^n} \exp\left[-\frac{1}{2\phi} \frac{t_1^n}{t_r^n}\right], \quad (27)$$

$$A = \phi^2 - \sigma^2, \quad \phi = \frac{1}{2} [\Gamma(\frac{n+2}{n})]^{-n/2},$$

in which $f(t_1, t_2)$ is the 2-dimensional Weibull distribution and $R(t_1)$ the Weibull distribution, σ the correlation parameter, n the shape parameter, t_r the rms wave period, Γ the Gamma function. Correlation coefficient of consecutive wave period t_1 and t_2 is:

$$\gamma_t = \frac{[\Gamma(\frac{n+1}{n})]^2 \{F[-\frac{1}{n}, -\frac{1}{n}; 1; (\frac{\sigma}{\phi})^2] - 1\}}{\Gamma(\frac{n+2}{n}) - [\Gamma(\frac{n+1}{n})]^2}, \quad (28)$$

in which F is the hypergeometric function. It follows that p_{22} can be determined from the correlation coefficient of consecutive wave period and the shape parameter with equations (25) to (28). But both parameters are closely correlated with each other as shown in Fig.11. Plotted data are obtained from the numerical simulations. Then p_{22} can be determined by either of these parameters using the average relation between them. Fig.12 shows the relation between p_{22} and γ_t for $t_{*1} = 0.4t_{\text{mean}}$, $t_{*2} = 0.6t_{\text{mean}}$ (solid line), $t_{*1} = 0.9t_{\text{mean}}$, $t_{*2} = 1.1t_{\text{mean}}$ (dotted line) and $t_{*1} = 1.4t_{\text{mean}}$, $t_{*2} = 1.6t_{\text{mean}}$ (chain line) for example.

Fig.13 shows the theoretical distribution of the resonant wave period providing $t_{*1} = 0.7t_{\text{mean}}$ and $t_{*2} = 1.2t_{\text{mean}}$. This is the period band in which dynamic response of a spring is greater than twice the static loading providing that the resonant period of the spring equals t_{mean} . Figs.14 (a) ~ (e) show the comparison of data and the theoretical distribution. The agreement of data and the distribution is very well.

ESTIMATION OF PARAMETERS

Statistical properties of the run of wave height can be determined from the correlation coefficient of consecutive wave height γ_h . But γ_h changes with the width of the power spectrum. Fig.15 shows the relation between γ_h and wave peakedness parameter Q_p proposed by Goda(1). Plotted data are obtained from the numerical simulations. It is known from this figure that since γ_h can be approximated from Q_p , statistical properties of the run of wave height can be estimated from Q_p .

On the other hand in determining the run of wave period, n and γ_t are needed. But since both parameters are mutually correlated, statistical properties of the run can be determined by knowing either of them. Fig.16 shows the relation between γ_t and the spectrum width parameter ϵ . γ_t has close correlation with ϵ .

From Figs.15,16 it can be concluded that if the power spectrum of random waves is known, statistical properties of the run of wave height and wave period can be estimated.

On the Synthesis of Realistic Sea States

by

E.R. Funke* and E.P.D. Mansard**

1.0 INTRODUCTION

Recent investigations by some researchers (Johnson et al, 1978; Burchart, 1979; Gravesen and Sorensen, 1977) have indicated that it is no longer sufficient to match the variance spectral density of a simulated sea state to that of the prototype. When testing models of various fixed and floating structures, it appears to be most important to simulate the wave grouping phenomenon as well. Some researchers also believe that the wave steepness, the particular sequencing of high and low waves (Burchart, 1979) and the ratio of the maximum to the significant wave height within a wave train are also of significance.

Methods for the generation of 'random' waves throughout the world vary greatly. One may, however, categorize these in terms of two substantially different approaches. These may be referred to as "probabilistic" on the one hand and "deterministic" on the other.

In the former, a random or pseudo-random noise source is used which will never repeat or which has a very long repetition period. The assumption is then made that, in the course of the long testing period, all possible outcomes of wave heights, wave periods and wave groups will occur. The only constraint, which is usually placed on the synthesis, is the shape of the variance spectral density and its zeroth moment. The "deterministic" approach, on the other hand, attempts to create very specific and typically extreme conditions. Subsequent analysis of structural response to these conditions must, of course, be related to the likelihood of these conditions occurring in the prevailing climate. The old standby method of testing with monochromatic waves is a typical example of this category. However, other techniques such as Funke and Mansard (1979a) and the reproduction of prototype wave trains as favoured by several laboratories (Gravesen and Sorensen, 1977) may also be described as deterministic.

* Senior Research Officer and **Assistant Research Officer, Hydraulics Laboratory, National Research Council of Canada, Ottawa, Canada.

This paper describes a method which can synthesize a wave train with a well defined grouping characteristic. Although, in principle, the wave train could be made arbitrarily long, for practical reasons it will normally be limited to a recycling period of 5 or 10 minutes in the laboratory. The method, which may also be identified as "deterministic", can synthesize a wave train with well defined grouping characteristics and, at the same time, with a good approximation to a specified continuous variance spectral density. Although these two features may not be sufficient for a completely realistic simulation of a natural sea state, the method is believed to be a step in the right direction.

The method produces a time series which describes the wave train as it is to be monitored at a prespecified location in a wave flume or basin and in the absence of reflections. It is therefore assumed that there exists a real time signal generator, such as an on-line digital computer (Funke, Crookshank and Wingham, 1980) which is capable of converting a number sequence (after suitable amplitude and phase compensation) into a smooth driving signal to a servo-controlled wavemaking machine. The method described here addresses itself only to the synthetic creation of the time series. Its conversion into a train of water waves at a specified location in the flume is the subject of other publications (Funke and Mansard, 1979a; Funke and Mansard, 1980).

As an input to the procedure, it is necessary to specify:

- a) the variance spectral density $S(f)$ of the desired water surface displacement (this includes, by implication, the characteristic wave height),
- b) the groupiness factor, GF ,
- c) the SIWEH spectral density, $\epsilon(f)$, and
- d) the desired repetition (or recycling) period of the wave train, T_n .

Both the SIWEH and the groupiness factor are concepts which had to be developed as descriptors for the sea state in order to realize a systematic procedure for synthesis. Whereas this paper addresses itself to the subject of how wave group activity may be defined and how this definition can be used to synthesize a wave train, it remains to be determined how important these parameters are in describing a wave climate and in causing severe and damaging structural response.

2.0 THE SIWEH

SIWEH is an abbreviation for Smoothed Intermediate Wave Energy History (Funke and Mansard, 1979b). It is a function of time which describes the distribution of energy along the time axis. This somewhat awkward name is proposed (with apologies) in order to distinguish this energy function of time from the more commonly used energy function of frequency and it is believed that the word history does suggest a time function.

The SIWEH is proposed as an alternative to 'envelope functions' for the purpose of describing group activity within a wave train. Fig. 1 illustrates a typical wave train and two envelope functions. The 'half-wave rectified' envelope has been constructed by joining all peaks of the wave record whereas the 'full-wave rectified' envelope requires first a folding of all negative values about the mean before the peaks are joined. The former does not properly account for wave troughs and the latter is always affected by the presence of non-linear waves which have sharp peaks and flat troughs. Therefore, the concept of computing the average wave energy over the period of the dominant wave appeals intuitively. If $\eta(t)$ is the water surface displacement with zero mean value, then the smoothed instantaneous wave energy history may be defined initially as:

$$E^*(t) = \frac{1}{T_p} \int_{\tau=-T_p/2}^{T_p/2} \eta^2(t+\tau) \cdot d\tau \quad (1.1)$$

This function provides a uniform, running average of the squared water surface displacement over the interval $T_p = 1/f_p$, where f_p is the frequency at which the variance spectral density of $\eta(t)$ is a maximum. The operation defined by equation 1.1 may be considered convolution of a rectangular data window, Q_0 , with the function $\eta^2(t)$, i.e.

$$E^*(t) = \frac{1}{T_p} \int_{-\infty}^{\infty} \eta^2(t+\tau) \cdot Q_0(\tau) \cdot d\tau \quad (1.2)$$

Another window function is the Bartlett window, Q_1 , which has a triangular shape with a base of $2 \cdot T_p$. The result of this smoothing operation is also included in Fig. 1.

From Fig. 1 it may be observed that the SIWEH provides superior identification of groups and that the Bartlett window achieves better smoothing without an apparent loss of contrast.

IDENTIFICATION

3.0 SPECTRAL CONSIDERATION TO SMOOTHING OF THE SIWEH

Convolution between two functions in the time domain is equivalent to multiplication between their respective Fourier transforms in the frequency domain. For this reason it is instructive to consider the Fourier transform of the smoothing windows, which were used for Fig. 1. Fig. 2 shows these frequency functions as a function of nor-

FIG. 2 FREQUENCY CHARACTERISTICS OF SMOOTHING FUNCTIONS

malized frequency f/f_p where f_p is the frequency at which the variance spectral density is a maximum. For comparison purposes the square root of a JONSWAP spectrum is also included. It should be noted that the rectangular window has a frequency response which is quite oscillatory. The consequence of using this function as a digital filter is leakage of energy from outside its nominal pass band. The Bartlett window, on the other hand, has smaller side-band leakage but suffers from reduced contrast in the pass band.

As the filters are applied to the square of the water surface displacement, it is essential to assess them in terms of the spectrum of $\eta^2(t)$. Fig. 3 illustrates first the function $\eta(t)$ and then its square after removal of the mean value $\bar{\eta}^2$. The SIWEH function, which was smoothed using the Bartlett window, is also shown with its mean value removed.

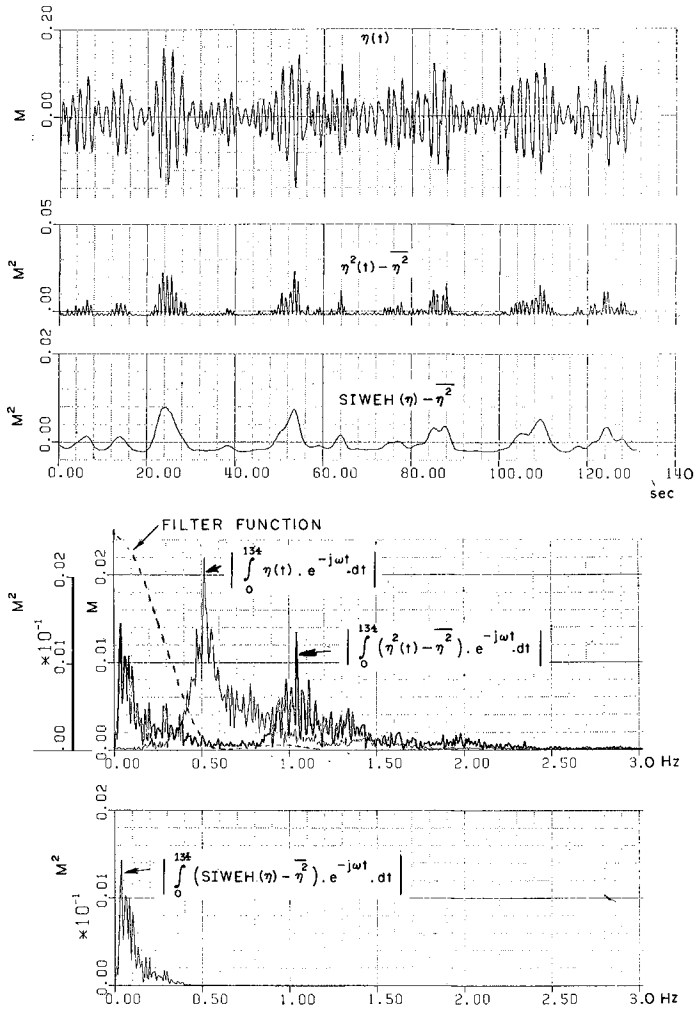

FIG. 3 SPECTRUM OF SQUARED WATER SURFACE ELEVATION

The fourth function in Fig. 3 gives the absolute values of the Fourier transforms of both $\eta(t)$ and $(\eta^2(t) - \bar{\eta}^2)$. The frequency response of the Bartlett filter function is also shown. The most surprising observation is the redistribution of energy in the frequency domain as a result of squaring in the time domain. It appears that energy is moved both above as well as below the band that was previously occupied by the variance spectral density of $\eta(t)$ with a notable absence of energy remaining in this latter band. The Bartlett smoothing filter which was selected intuitively does appear to be quite effective in separating the low-frequency from the high frequency part of the spectrum, although as can be seen, with some attenuation in accordance with its filter characteristics.

These frequency considerations suggest that convolution with a Bartlett window is superior to rectangular smoothing. Therefore, the following formulation for the computation of the SIWEH is proposed,

$$E'(t) = \frac{1}{T_p} \int_{\tau=-T_p}^{T_p} \eta^2(t+\tau) \cdot Q_1(\tau) \cdot d\tau \quad \text{for } T_p \leq t \leq T_n - T_p \quad (3.1)$$

and for the beginning and the tail end of the record:

$$E'(t) = \frac{2}{T_p+t} \int_{\tau=-t}^{T_p} \eta^2(t+\tau) \cdot Q_1(\tau) \cdot d\tau \quad \text{for } 0 \leq t \leq T_p \quad (3.2)$$

$$E'(t) = \frac{2}{T_p+T_n-t} \int_{\tau=-T_p}^{T_n-t} \eta^2(t+\tau) \cdot Q_1(\tau) \cdot d\tau \quad \text{for } T_n - T_p \leq t \leq T_n \quad (3.3)$$

where

$$Q_1(\tau) = 1 - |\tau|/T_p \quad \text{for } -T_p \leq \tau \leq T_p \\ = 0 \quad \text{everywhere else.}$$

4.0 AN ALTERNATE WAY OF DEFINING AND COMPUTING THE SIWEH

If the wave record of length T_n is given as a Fourier series expansion, i.e.

$$\eta(t) = \sum_{i=1}^N c_i \cdot \cos(\omega_i \cdot t + \phi_i) \quad (4.1)$$

with $\omega = 2\pi \cdot i \cdot t/T$ and

c_i being the Fourier coefficients, then $\eta^2(t)$ may be shown to contain four distinctly different groups of terms (Naes, 1978) namely:

- a) a group involving c_i^2 ,

- b) a group including the frequencies $2\omega_i$,
- c) another group with frequencies $\omega_j + \omega_i$, and
- d) finally, the fourth group with frequencies $\omega_j - \omega_i$.

The first and fourth group together make up the SIWEH of $\eta(t)$ which may thus be defined for the interval $0 \leq t \leq T$, SIWEH($\eta(t)$) = $E(t)$ =

$$\frac{1}{2} \sum_{i=1}^N c_i + \sum_{i,j} c_i \cdot c_j \cdot \cos[(\omega_j - \omega_i) + (\omega_j - \omega_i)] \quad 1 \leq i \leq j \leq N \quad (4.2)$$

The first term of this expansion is evidently the mean square value of $\eta(t)$ and must therefore be equal to the area under the variance spectral density of $\eta(t)$. In other words:

$$\overline{E(t)} = \mu_0$$

Although the authors are not, at the time of writing, applying equation 4.2 for the computation of the SIWEH, it is believed that it will prove superior to equations 3.1 to 3.3 as it is not dependent on smoothing windows in the time domain or the treatment of start-up and end transitions in the associated convolution operation.

5.0 THE SIWEH SPECTRUM

The unsmoothed SIWEH variance spectral density may also be computed in two possible ways. By application of the Fourier transform to the SIWEH one obtains:

$$e^*(f) = \frac{1}{2\Delta f} \left| \frac{2}{T_n} \int_0^{T_n} (E(t) - \bar{E}) \cdot e^{-j\omega t} \cdot dt \right|^2 \quad (5.1)$$

$$= \frac{2}{T_n} \left| \int_0^{T_n} (E(t) - \bar{E}) \cdot e^{-j\omega t} \cdot dt \right|^2 \quad (5.2)$$

where $\Delta f = 1/T_n$.

The second method may be derived from equation 4.2 by re-ordering the difference frequencies so that all terms with the same difference frequency are grouped together. Therefore, letting $j=i+k$ with $k=1,2,\dots,N-1$, equation 4.2 may

be written thus,

$$E(t) = \frac{1}{2} \sum_{i=1}^N c_i^2 + \sum_{k=1}^{N-1} \sum_{i=1}^{N-k} c_i \cdot c_{i+k} \cdot \cos(k \cdot \Delta\omega \cdot t + \theta_{i,k}) \quad (5.3)$$

where $\Delta\omega = \omega_{i+1} - \omega_i = 2\pi/T_n$

and $\theta_{i,k} = \phi_{i+k} - \phi_i$

Equation 5.3 may be abbreviated as:

$$E(t) = \frac{1}{2} \sum_{i=1}^N c_i^2 + \sum_{k=1}^{N-1} A_k \cdot \cos(k \cdot \Delta\omega \cdot t + \gamma_k) \quad (5.4)$$

where

$$A_k = \sqrt{\left(\sum_{i=1}^{N-k} (c_{i+k} \cdot c_i \cdot \cos \theta_{i,k}) \right)^2 + \left(\sum_{i=1}^{N-k} (c_{i+k} \cdot c_i \cdot \sin \theta_{i,k}) \right)^2} \quad (5.5)$$

and

$$\gamma_k = \text{atan} \left(\frac{\sum_{i=1}^{N-k} c_{i+k} \cdot c_i \cdot \sin \theta_{i,k}}{\sum_{i=1}^{N-k} c_{i+k} \cdot c_i \cdot \cos \theta_{i,k}} \right) \quad (5.6)$$

The unsmoothed SIWEH variance spectral density may then be obtained from equation 5.5 as follows:

$$\epsilon(f) = [A(k \cdot \Delta f)]^2 / (2 \cdot \Delta f) \quad (5.7)$$

It is of particular interest to note that the SIWEH spectral density is completely defined in terms of the Fourier coefficients and Fourier phases of the water surface displacement $\eta(t)$. The term

$$\sum_{i=1}^{N-k} c_{i+k} \cdot c_i \quad (5.8)$$

in equation 5.5 is reminiscent of the auto-covariance of the spectrum defined by c_i . It has been suggested by Nolte and Hsu (1972) that the spectrum of the envelope function is related to:

$$H(f) = \int_0^{\infty} S(x) \cdot S(x+f) \cdot dx / \int_0^{\infty} S^2(x) \cdot dx \quad (5.9)$$

where $S(f)$ is the variance spectral density of $\eta(t)$. This proposition is, however, challenged on the grounds that according to equation 5.9

$$H(0) > H(f)$$

It is known from observations that this does not describe reality because highly periodic wave group phenomena lead to a peak in the SIWEH spectral density at non-zero frequencies and this cannot be reproduced with equation 5.9.

On the other hand, equation 5.5 indicates that the SIWEH spectral density is also affected by the phase differences between adjacent frequency components. This suggests for the first time how the phase spectrum of wave trains may be related to the grouping phenomenon.

Smoothing of SIWEH variance spectral densities may be implemented by the usual statistical techniques.

6.0 THE GROUPINESS FACTOR

The SIWEH or its spectral density may be used to describe the degree of group activity. The groupiness factor is defined as

$$GF = \left(\sqrt{\int_0^T \eta (E(t) - \bar{E})^2 \cdot dt} \right) / \bar{E} \quad (6.1)$$

which gives the standard deviation of the SIWEH about its mean value \bar{E} .

Since the variance of $E(t)$ about its mean must equal the area under the variance spectral density, the groupiness factor may also be given as

$$GF = \sqrt{m_{c_0} / m_0} \quad (6.2)$$

where m_{c_0} is the zeroth moment of the SIWEH spectral density.

Groupiness factors for prototype wave data so far observed at one location over a period of six months (Sea of Japan, N38 44'33", E139 39'48") fall in the range $0.46 \leq GF \leq 0.94$.

7.0 A POSSIBLE MODEL FOR THE SIWEH SPECTRUM

It is expected that analysis of prototype wave data will reveal that SIWEH spectral densities will, occasionally exhibit a more or less pronounced peak indicating a periodicity of groups. However, the majority of SIWEH spectral densities, particularly for low wave heights, will decay almost exponentially with increasing frequencies. The

broadness of the SIWEH spectral densities are expected to be inversely related to the width of the average wave groups.

A model which may provide enough control over the spectral shape has been borrowed from linear system analysis and is given by

$$\epsilon(\lambda) = \frac{1}{\sqrt{(1-\lambda^2)^2 + 4 \cdot \zeta^2 \cdot \lambda^2}} \cdot \frac{\lambda}{\sqrt{1 + \lambda^2}}$$

This function is shown in Fig. 4 for $\lambda = 0.1$, $\zeta = 0.1, 0.3$ and 1 and the area under the function has been adjusted so that the groupiness factor according to the definition of equation 6.2 is 0.95.

8.0 SYNTHESIS OF A SIWEH FROM ITS SPECTRAL DENSITY

As it is expected that, in future, a sea state may be specified both in terms of its variance spectral density as well as its SIWEH spectral density, it must be determined if one can synthesize a SIWEH from the SIWEH spectral density. It is evident from inspection of a SIWEH that this function is highly non-Gaussian. This fact imposes a severe problem on the ability to synthesize such a function through inverse Fourier transformation as may be seen from the following argument.

When applying the inverse Fourier transform to an amplitude spectrum, some arbitrary phase spectrum must first be assumed. It is common practice to create such a phase spectrum by selecting phases for each of the constituent frequencies from a random number generator which has a uniform distribution of random numbers over the interval $-\pi$ to π . As a consequence of such a phase spectrum, the function resulting from inverse Fourier transformation can be shown to have a Gaussian amplitude probability density and non-Gaussian functions cannot be generated in this way.

The technique which has been used here to overcome this difficulty is an iterative procedure (see Funke and Mansard, 1979b). After the first inverse Fourier transform following a random phase selection, the resulting time function is then clipped below $-\alpha \cdot m_0$ so that the resultant time signal now looks highly distorted with all troughs being flat at $-\alpha \cdot m_0$. A subsequent forward Fourier transform of this clipped function will produce a new amplitude and phase spectrum. Evidently the new amplitude spectrum is wrong but the new phase spectrum is a better approximation of the unknown phase spectrum than the first guess. One therefore pairs up this new phase spectrum with the original amplitude spectrum and repeats the inverse Fourier transform. The resultant time function will now be non-Gaussian, however, there will still be exceedances below the $-\alpha \cdot m_0$ level. It

FIG. 4 THE SYNTHESIS OF A SIWEH

is therefore necessary to repeat this operation of clipping and transforming until these exceedances no longer occur.

Different values of α have been tried which appear to work equally well. For $\alpha = 0.6$ it was found that 20 iterations were required.

Fig. 4 gives three different SIWEHs which were synthesized from the three spectral densities also given in this figure. The SIWEH for $\zeta = 0.1$ is the one which has the most pronounced periodicity of groups.

9.0 THE SYNTHESIS OF A GROUPED WAVE

Fig. 5 illustrates the procedure which is now followed in order to create a wave train which not only has a given variance spectral density, but also has wave grouping as specified by a SIWEH, which may have been synthesized by the method described in section 8.0.

With reference to Fig. 5 one will recognize the desired variance spectral density and the desired SIWEH. From the latter a phase modulating function is created which is also shown in Fig. 5. It may be noticed that this phase modulator has large values when the SIWEH is small and vice versa. It is being used to phase modulate a constant amplitude sinusoid with a dominant frequency of 0.5 Hz, which is the peak frequency of the desired variance spectral density. Closer observation will reveal that the dominant frequency has been preserved in those intervals where the SIWEH has large values while everywhere else the frequency is increased. The reasoning behind this is that each wave group should have a dominance of energy in the peak frequency band if one wishes to match the desired variance spectral density by this initial approximation.

After this, the phase modulated carrier is also amplitude modulated by using the square root of the SIWEH as the modulating function. The result of these manipulations is a rough approximation of the synthesized wave train. Fourier transformation, as shown in Fig. 5, does in fact show that the amplitude spectrum approximates quite well the desired amplitude spectrum (which has been obtained by square-rooting the spectral density). The phase spectrum, which has been obtained from the Fourier transform of the rough approximator, is now paired with the desired amplitude spectrum. Subsequent inverse Fourier transformation will then produce the desired wave train or at least something which comes very close to the ideal.

By computing the SIWEH for this wave train, $E_2(t)$ and comparing it to the originally specified SIWEH, $E_1(t)$, a correcting function $C(t)$ may be computed which is

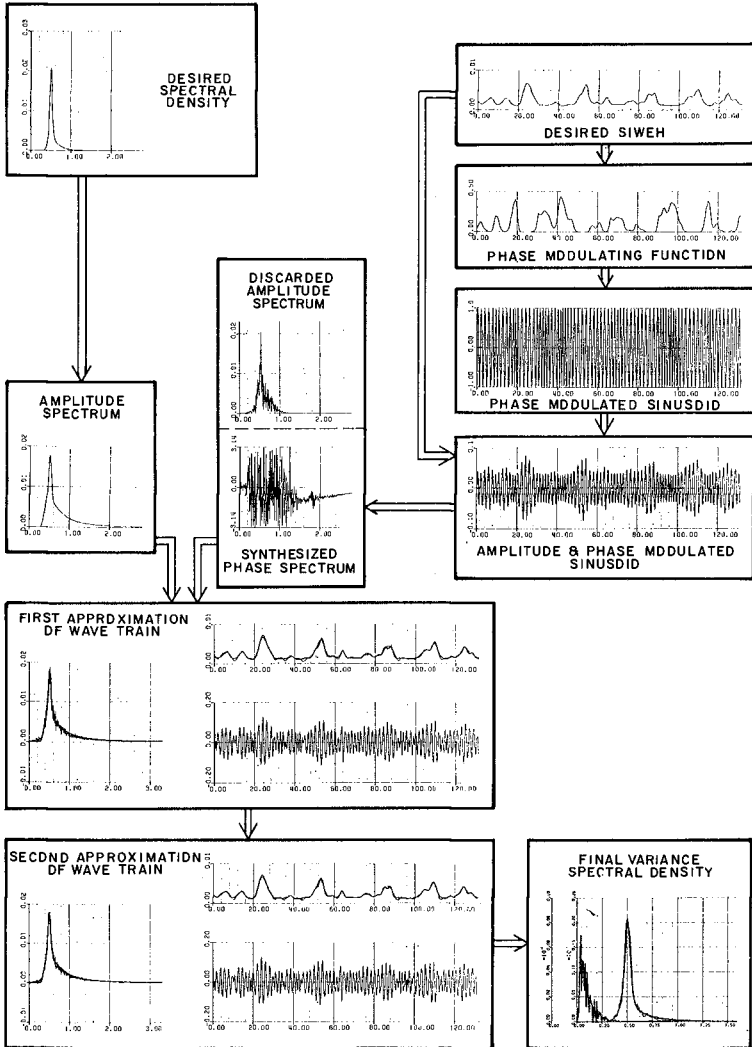

FIG. 5 THE SYNTHESIS OF A GROUPED WAVE

$$C(t) = \sqrt{E_1(t)/E_2(t)}$$

The first wave train is now multiplied by $C(t)$ and the product is also Fourier transformed. Again one obtains an amplitude and a phase spectrum. The new phase spectrum is then paired with the original amplitude spectrum and an inverse Fourier transform will then provide the second approximation of the desired wave train. This may be repeated a few times which occasionally leads to further improvements. Fig. 6 shows some other synthesized wave trains. Attention is drawn to the difference between the actual and the desired variance spectral density. It may be noticed that there are some differences, particularly in the higher frequency tail of the spectrum.

Beside this, Fig. 6 illustrates how one may generate any number of grouped wave trains from the same input specifications. In all three cases the same SIWEH spectral density and the same variance spectral densities were used. However, for the purpose of synthesizing the SIWEHs, three different random number sequences were generated.

10.0 SPECTRAL BROADNESS FACTOR AND GROUPINESS

With the availability of the synthesis tool described here, one may address oneself to the question of how the spectral broadness factor is related to wave groupiness. It has been generally accepted that waves with a narrow variance spectral density also have a more pronounced groupiness than broad-banded waves. It may, in fact be true that there is a strong correlation between these two which is a characteristic of natural gravity waves. This could be explained if strong grouping occurs after waves have travelled over long distances and, as is well known, waves due to swell do have narrow band spectra.

However, it should be noted that there is no necessary relationship between a spectral width parameter and groupiness. Fig. 7 illustrates three synthesized wave trains. Each of these were synthesized from the same SIWEH spectral density with the only difference that the area under the SIWEH spectral densities was rescaled according to equation 6.2 so that the groupiness factor could be varied from $GF = 0.95$ to 0.2 . In all three cases the variance spectral densities are more or less the same. Whereas the wave train for $GF = 0.95$ shows very pronounced grouping, the wave train for $GF = 0.2$ is almost of constant amplitude.

It may, perhaps, appear unbelievable that this latter wave record can have the variance spectral density which is shown. It must, however, be remembered that the record shown is not a pure sinusoid and that there is an appreciable amount of phase modulation which causes the

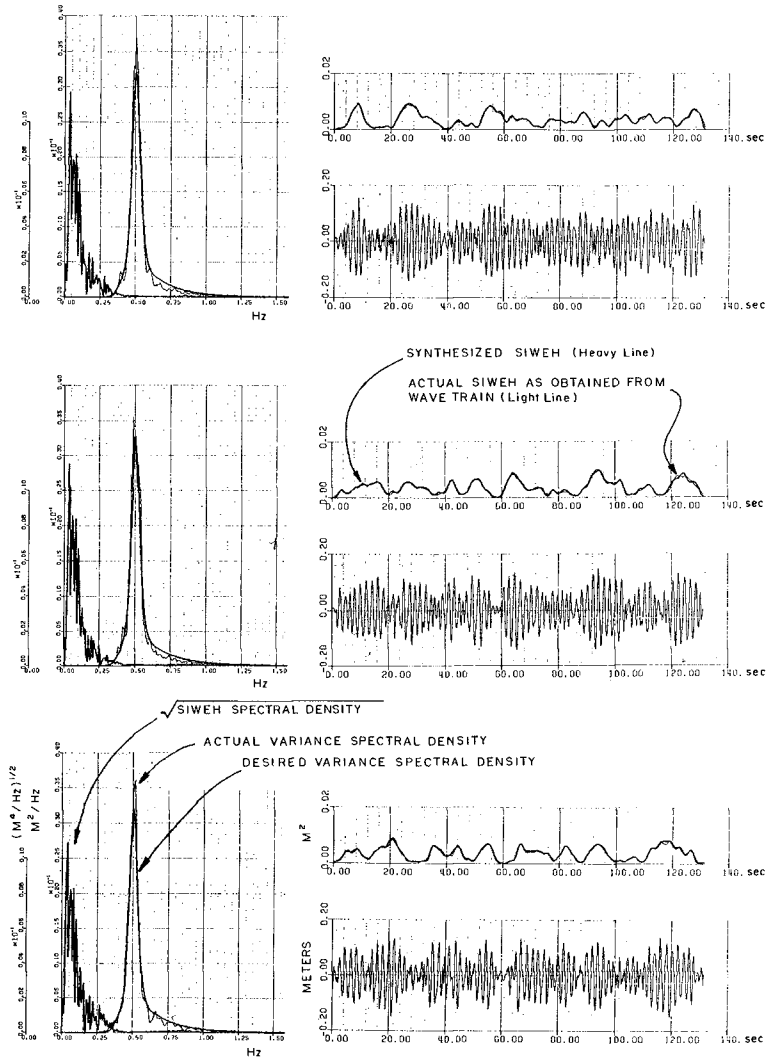

FIG. 6 THE SYNTHESIS OF GROUPED WAVES FROM COMMON SIWEH SPECTRAL DENSITIES

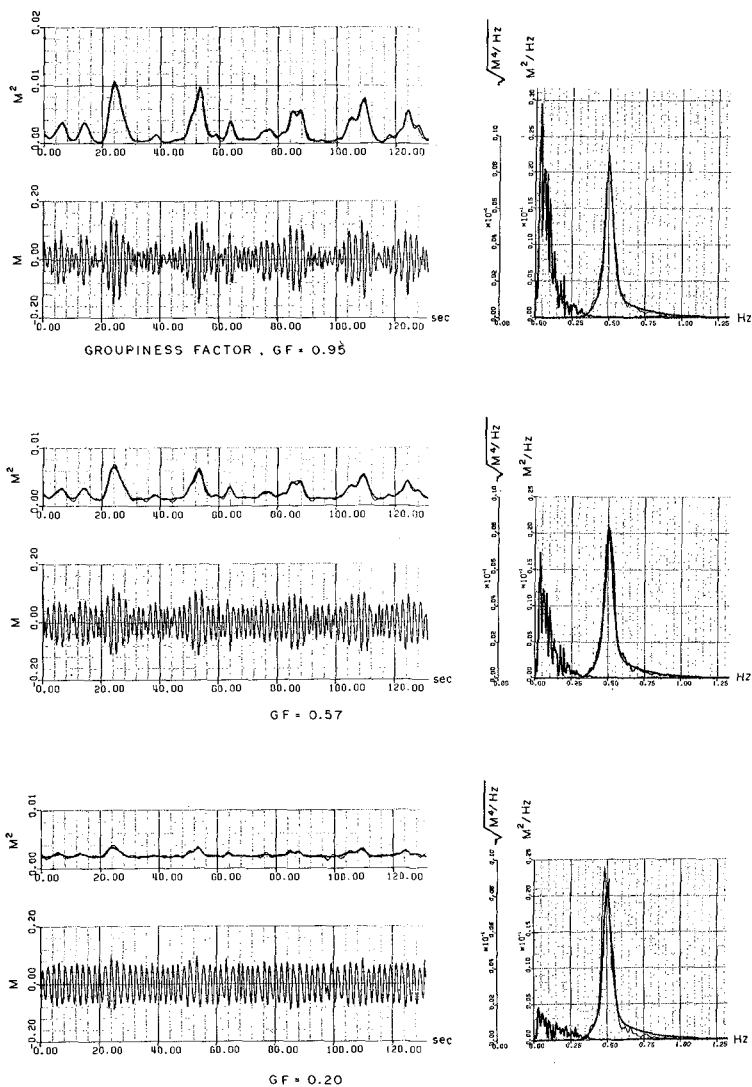

FIG. 7 SYNTHESIS OF GROUPED WAVE TRAINS FROM THE SAME SIWEH BUT WITH DIFFERENT GROUPINESS FACTORS

spectrum to be non-monochromatic. The authors have not attempted to reproduce this latter wave train in a wave flume, and it is therefore not known if this particular wave train is physically realizable.

A COMPARISON OF NATURE WAVES AND MODEL WAVES
WITH SPECIAL REFERENCE TO WAVE GROUPING

by

Hans F. Burcharth**

1. ABSTRACT

This paper represents a comparative analysis of the occurrence of wave grouping in field storm waves and laboratory waves with similar power spectra and wave height distribution.

Two wave patterns - runs of waves and jumps in wave heights - which have significant influence on the impact on coastal structures were included in the analysis of storm wave records off the coasts of Cornwall, U.K. and Jutland, Denmark. Two different laboratory wave generator systems, based on random phase distribution of component waves, were used. Within the limitations given by the relatively small number of analysed records it is shown that wave group statistics can be satisfactorily reproduced by random phase generators that are not based on a limited number of component waves, but for example based on filtering of white noise. It is also shown that the statistics of large waves and wave groups containing large waves depend on whether the waves are defined from zero-upcrossings or zero-downcrossings. Although very similar seas were chosen for the analysis it was found that significant differences in the wave group statistics from the two locations existed. Also a considerable scatter in the wave group statistics throughout the storms was found.

** Prof. of Marine Civil Engineering, Aalborg University, Denmark.

2. INTRODUCTION

Very few quantitative data are available on the differences in stochastic nature of wave groups in model and prototype wave records. This in spite of the fact that it has been shown by authors like Johnson et al (1978) and Burcharth (1977), that certain sequences of waves - or wave groups - are important to the impact of waves on structures. For example, the stability of rubble mound breakwaters and also run-up are affected by wave grouping. It is therefore important that the statistics of wave grouping in model waves are the same as those in nature.

It may be argued that a safe method in model testing is a direct reproduction of recorded natural wave trains, but accepting this statement we are left with the problem of selecting the typical or say critical records, especially when the number of available records is limited. This is so because very often there is a considerable scatter in the wave group statistics throughout storms on a given location. Also, it is not possible to make a statistical analysis of any impact from waves if the model waves are reproduced - and maybe repeated - from a time limited wave record. This problem can, however, be overcome if the phase spectrum can be found and the model waves reproduced accordingly, for example as done by Funke et al. (1980). But to get it right, we need a good deal of knowledge and understanding of the variation of the phase spectrum - which we normally do not have. If, however, we are so lucky that a further analysis shows that the phase spectra do not vary too much during storms on a given location the method may be useful.

Another problem is that very few laboratories have facilities for a direct reproduction of natural wave trains or a reproduction based on a given phase spectrum. Most laboratories use wave generators which can reproduce waves in accordance with the shape of any power spectrum, but with phases of component waves more or less equally distributed.

The question is, therefore, can these random phase wave generators be used without introducing too big errors in the many cases where wave grouping has a significant influence on the impact from waves?

In order to answer this question a comparative study of wave groups in field waves and laboratory waves was performed.

3. METHOD

3.1 Wave Patterns

A relevant comparison between wave patterns in field waves and laboratory waves must be related to large waves if we are thinking in terms of wave impact on fixed structures and if we are not dealing with fatigue problems. Runs of large waves were included in the study because it has been demonstrated by Johnson et al. (1978) that such wave groups are dangerous to armour layer block stability. The definition of a run, which is shown in Fig. 1, is the same as previously used by Goda (1970) and Rye (1974). Only runs of waves bigger than or equal to the significant wave height were considered.

Fig. 1. Definition of runs.

Besides runs of large waves, another dangerous wave pattern in form of big jumps in wave height between successive waves was investigated. The definition of the jump is shown in Fig. 2. It consists of a small wave with the height a constant C times the mean wave height, followed by a large wave with a height bigger than or equal to the significant wave height. Only sizes of jumps corresponding to values of C of 0.5, 0.75 and 1 were considered.

Fig. 2. Definition of jumps.

The jump pattern was included in the analysis because Burcharth (1977) found, from a series of experiments, that of the three wave patterns shown in Fig. 3 (regular waves, runs of waves, and jumps - all containing the same max. waveheight) the jump was the most dangerous to rubble mound breakwater stability and caused the highest run-up on slopes.

Fig. 3. Wave patterns.

Besides the physical relevance of the two described wave patterns it is important to mention that by including two different patterns in the comparative analysis a very strong proof of identity of the statistics of wave patterns in general is obtained.

3.2. Field Waves

The basic principle of the study was to analyse the statistics of runs and jumps in real sea and in laboratory waves, both with the same power spectra. The field data were collected from Waverider buoys at two rather exposed locations, see Fig. 4.

Fig. 4. Location of wave recording sites.

The one is Perran Bay on the north west coast of Cornwall in U.K., which is exposed to Atlantic waves. The other is Hanstholm, the north west corner of Denmark, which is exposed to North Sea waves. The Water depth at the Perran Bay buoy is approximately 22 m and at the Hanstholm buoy 20 m.

Two storms from Perran Bay and one from Hanstholm were analysed. Situations, where no or very little swell was present, were deliberately chosen in order to avoid the complicated

mixture of swell and storm waves. A total of 20 records was analysed. In both places waves were recorded during 20 minutes every 3 or 4 hours. The number of waves in each record varied from 115 to 300.

The variation in significant wave height during the storms is shown in Fig. 5. It is not extreme storm situations, but rather rough sea situations, which set in a couple of times every year.

Fig. 5. Histories of analysed storms.

Fig. 6 shows some typical power spectra from two of the storms. It is seen that the spectra vary from fairly wide-band spectra to fairly narrow-band spectra.

Fig. 6. Typical power spectra from analysed storms.

The wave height distribution in the field records was found to be fairly close to the Rayleigh distribution although the distributions showed a dependence on the applied wave height definition, see chapter 4.1. The waves on the most energy containing frequencies correspond to waves in the transition between deep-water waves and shallow-water waves.

3.3 Laboratory Waves

Modelwaves with the same power spectra as for the real sea records were generated in two laboratories.

The Perran Bay waves were generated at the Hydraulics Research Station, Wallingford, in a waveflume at a length scale of 1 in 25. The paddle was a hydraulic operated piston type controlled by a synthesizer, which operated on the basis of equally distributed phase angles. The synthesizer which is described in detail in a paper by Fryer et al. (1973) works on the principle of filtering white noise by means of a digital method.

The Hanstholm waves were generated at the Hydraulics Laboratory, Aalborg University, Denmark, in a small wave basin at a length scale of 1 in 70. Also this paddle was a hydraulic operated piston type, which could be controlled in different ways, but for this study the most simple way of generating irregular sea, namely that of adding sinewaves of different frequencies and amplitudes, was deliberately chosen. In order to make it as rough as possible, only 10 different frequencies were used. The phases of the component waves were random and different in each test.

For each field wave record batches of 4 or 5 records were generated in the laboratories. Each laboratory record contained approximately the same number of waves as the corresponding field record. It was found that the wave heights in the lab. waves were Rayleigh distributed and it was checked that the lab. wave spectra corresponded to the field wave spectra.

4. ANALYSIS AND RESULTS

4.1 Influence of Wave Height Definition

In the analysis two different definitions of waves were used, the zero-upcrossing definition and the zero-downcrossing definition, both of which are shown in Fig.7. The zero-downcrossing analysis uses the wave trough and the proceeding wave crest in the definition of a single wave and defines the wave height as the difference between these water levels.

The conventional zero-upcrossing analysis defines the wave height from a wave crest and the following wave trough. Generally it is difficult to say which of the two definitions gives the best representation of the physical conditions, but in cases where - for example - impact from breaking or almost breaking waves is important, the zero-downcrossing definition must be the most relevant.

Fig. 7. Definitions of wave height.

The first interesting result that appeared from the analysis was that in the field wave records a zero-upcrossing definition gave significantly more high waves than a zero-downcrossing definition. In the Perran Bay records the upcrossing definition gave on an average 13% more waves bigger than significant wave height, and in the Hanstholm records it was 12%. Fig. 8 shows as an example the wave height distributions in some of the Perran Bay records.

In the lab. wave records no such difference was found. Eight Perran Bay records of typical swell situations were also analysed, and here again there was no difference. So it was only in the field storm wave records that the phenomenon was found, which then might be explained by the asymmetry of the waves caused by the wind. Fig. 9 shows the sort of asymmetry that would lead to differences in wave heights.

Fig. 8. Example of the influence of wave height definition on the wave height distribution in natural waves.

Fig. 9. Influence of zero-crossing definition on wave heights.

Field wave records from other near-shore areas than the two included in this project should be analysed in order to see if the wave definition influences the number of big waves. If it be so, a standard definition must be agreed.

4.2. Wave Grouping Analysis

The results from the comparative analysis of the occurrence of wave grouping in field waves and laboratory waves are shown in Fig. 10 and Fig. 11.

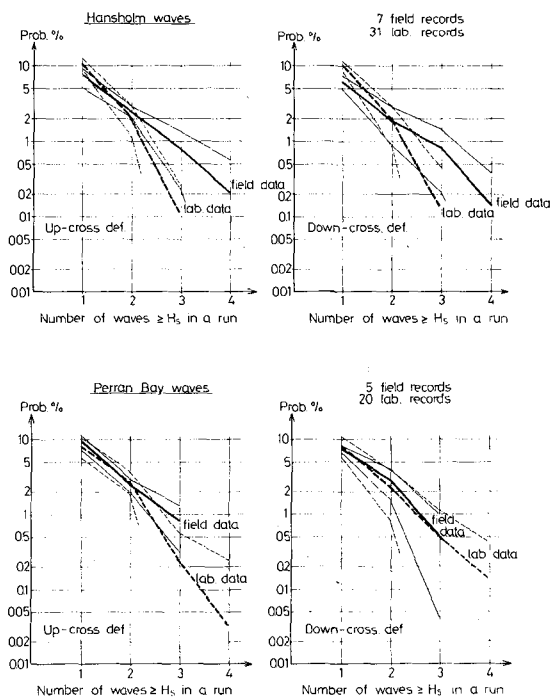

Fig. 10. Probability of runs in field storm wave records and laboratory records with the same power spectra. Graphs are mean values \pm standard deviation.

The vertical axes are the absolute probability of the wave patterns, which means that the events are related to the total number of analysed waves in the record. The graphs represent the mean values plus minus the standard deviation.

Fig. 10 shows the probabilities of the formation of runs of different lengths. Hanstholm data and Perran Bay data based on both zero-upcrossing and zero-downcrossing wave definition are represented. It is seen that in the case of the Perran Bay waves there is a good agreement between the field wave graphs and the lab. wave graphs if the zero-downcrossing definition is applied.

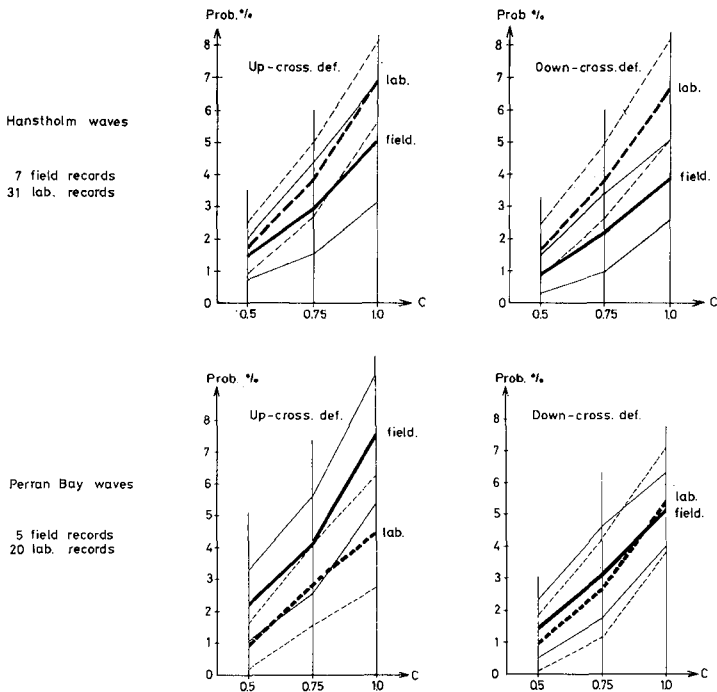

Fig.11. Probability of jumps in field storm wave records and laboratory records with the same power spectra. Graphs are mean values \pm standard deviation.

For the Hanstholm waves there is considerable discrepancy between field waves and lab. waves. The number of long runs in the lab. waves is much too small.

Fig. 11 shows the probabilities of the formation of jumps defined by the jump parameter C , see Fig. 2. Small values of C correspond to big jumps in successive wave heights. For the Hanstholm waves there is actually no acceptable agreement between the lab. and the field data results. For the Perran Bay waves, however, it is seen that the agreement is very good if, again, the downcrossing definition is used.

From Fig. 10 and Fig. 11 it is seen that in the Hanstholm case the lab. simulations of both runs and jumps are so bad that it can be concluded - as also expected - that the very simple wave generator used in this case is far from satisfactory, whereas the much more sophisticated generator or synthesizer, used for the Perran Bay waves, seems to be good if the downcrossing definition is applied. The last part of this conclusion must be regarded as a preliminary conclusion since the wave group statistics for the Perran Bay waves and the Hanstholm waves are different (see chapter 4.3) and a reproduction of the Hanstholm waves by means of the more complicated generator has not been tried.

4.3 Variations in The Wave Group Statistics

From the field data graphs in Figures 10 and 11 it is seen that the Perran Bay records contain considerable more jumps and fewer long runs than the Hanstholm records. So the wave-group statistics are different for the two sets of records.

If the group statistics for a single field wave record are compared with the group statistics for the corresponding batch of lab. wave records the agreement is generally not very good. Only approximately half of the field wave results will be well inside mean plus minus standard deviation for lab. wave results.

This is understandable since the group statistics for the field records vary considerably, and since each of the records contains a very limited number of waves. Because of this scatter in the field wave group statistics one has to be very careful if a model test procedure based on a direct reproduction of natural waves is applied. The selection of the wave records is difficult and can only be done properly if based on the analysis of many field records.

4.4 Comparison with Random Theory

From the field wave records it was found, as also reported by Wilson et al. (1972) and Rye (1974), that the formation of runs of big waves is more pronounced than would be expected from a random distribution of the wave height successions. Corresponding to this, fewer jumps than given by random theory were recorded. This is illustrated in Fig. 12 where graphs representing the theoretical distribution for jumps and runs are shown. The graphs are based on the assumption of independence between successive waves and Rayleigh distributed wave heights.

The theoretical expression for the graph representing runs is,

$$P(n) = (1 - P [H > H_s]) P [H > H_s]^{n-1}, \quad (1)$$

where $P(n)$ is the relative probability of the occurrence of a run of n waves that are bigger than H_s , and $P [H > H_s]$ is the probability of occurrence of a wave bigger than H_s , which, in the case of a Rayleigh distribution, is $\exp(-2)$.

The expression for the graph representing jumps is,

$$P = P [H > H_s] P [H < \bar{C}H], \quad (2)$$

where P is the absolute probability of the occurrence of a jump from a wave height smaller than or equal to C times the mean wave height to a wave height bigger than H_s .

Fig. 12. Comparison of wave group formation with random theory.

Fig. 12 confirms that a correlation between successive wave heights exists. The lab. waves are not shown in the figure, but this conclusion also holds for the Perran Bay model waves.

4.5 Comparison with other Field Wave Records

The statistics of runs in the field waves have been compared with the results presented by Rye (1974). Rye's results are based on 60 storm wave records from a Waverider buoy outside Utsira on the west coast of Norway, where the water depth is approximately 100 m. In Fig. 13 the two sets of results, which both represent the average from many records, are compared. It is seen that the agreement between these averaged data is good.

Rye and other authors found that the formation of runs of large waves tends to be more pronounced for a growing sea than for a decaying sea and that growing seas have more sharply peaked spectra than decaying seas.

Fig. 13. The average probability of occurrence of runs of waves for field data from Utsira and from Hansthholm and Perran Bay

However in the Perran Bay and the Hansthholm data no significant correlation was found between the sea state and the occurrences of runs and jumps. But as to the spectral peakedness it was found - but only for the Hansthholm records - that there was a correlation between spectral width and sea state, as Rye also did. Many more records are needed, especially from near-shore areas, before a conclusion about the correlation between sea state and groupiness can be made.

5. CONCLUSIONS AND RECOMMENDATIONS

The main conclusion of this study is that if only pure storm waves in near-shore areas are considered, it seems possible to generate laboratory waves with a fairly good reproduction of nature wave trains by using random phase wave generators, but the very simple type of generators based on a limited number of pre-set sine components can not be used. It is important to stress that since the number of analysed records is little, much more work has to be done before a general

conclusion on the generation of wave patterns by means of random phase generators can be made.

It was found that the wave group statistics in the field records from the two locations are different. Further analysis from other near-shore areas could clarify if a general correlation between wave grouping and location exists.

The analysis of field wave records from a given location shows a considerable scatter in the wave group statistics. A model test procedure based on a direct reproduction of natural wave records might therefore imply unsafe results if not based on knowledge about the variations in the wave grouping.

The statistics of high waves in the field records were found to be influenced by the wave height definition. A zero-up-crossing definition gave significantly more high waves than a zero-downcrossing definition. If this holds for other near-shore areas a standard definition must be agreed. But in any case, the zero-downcrossing definition seems to be the most relevant if impacts on structures are considered.

In this study only wave grouping with respect to wave heights has been considered. However, since the dynamics of the waves are very important the wave period or the wave steepness should also be included in the wave grouping analysis. Work in this field has already been done by Cavanie et al. (1976), Ezraty et al. (1977) and Arhan et al. (1978) but more work has to be done before an applicable method is obtained.

6. ACKNOWLEDGEMENTS

Most of the work on which this paper is based was done during the author's stay at the Hydraulics Research Station, Wallingford in 1977 - 78. I would like to thank the Director and his staff for their kind assistance.

WATER MOVEMENT STUDIES REQUIRED FOR PORT PLANNING

by

Graeme C. Dandy¹

Desmond A. Mills²

and Jon B. Hinwood³

1 INTRODUCTION

Some of the factors involved in the design of a programme of measurement and analysis of current, temperature and salinity data, required for the environmental assessment of an estuarine port, are considered in the context of a study carried out in the Port of Melbourne, Australia. The study was undertaken as part of the Port of Melbourne Environmental Study, 6 Webb Dock Marine Study which was aimed at assessing the present regime and the effects on the marine and coastal environments resulting from the construction of Berth 6, Webb Dock in Hobsons Bay (Figure 1). To this end, integrated investigations of water movement, water quality, coastal processes and marine ecology were conducted.

Although the results presented in this paper are specific to Hobsons Bay, the approach taken is of general applicability to the environmental assessment of proposed physical changes in complex estuaries and embayments. In such cases, the prediction of changed patterns of currents and density structure is a key element in assessing likely changes in other environmental factors such as water quality and the biota.

In general, an environmental study of water movement in an estuary will involve some measurements of the existing conditions of current, temperature and salinity, followed by appropriate analyses of these data to enable the likely changes to be predicted.

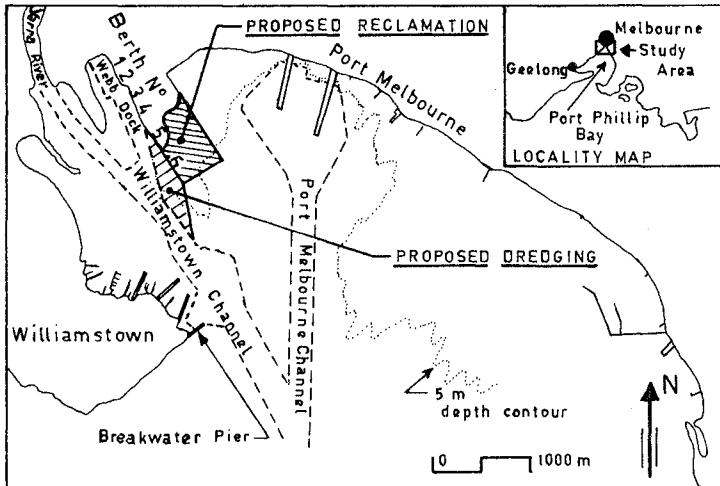

Figure 1. Hobsons Bay

The principal factors which must be considered in undertaking a study of water movement in a complex estuary are:

- (i) The major forcing functions and their relative influence on currents (i.e. tide, wind, freshwater inflow, etc.)
- (ii) The variability which exists in the processes under study, including time scales, range of variation and spatial scale.
- (iii) The choice of instrumentation and methods of data analysis which could be used in the study.
- (iv) The accuracy required in the predicted changes in flow regime.
- (v) The methods which could be used to predict likely changes in the estuary as a result of proposed development works (e.g. are mathematical or physical models appropriate?)

The consideration of these factors in relation to the Port of Melbourne Study is described in this paper.

2 DESCRIPTION OF STUDY AREA

Hobsons Bay, at the northern end of Port Phillip Bay, is a tidal embayment containing the delta and outer estuary of the Yarra River (see Figure 1). It is bounded to the west by the Williamstown promontory, and to the east by the north-east Port Phillip Bay coastline. The bay is of varying depth, being typically 6 m deep but with shipping channels dredged to approximately 12 m.

The bay is subject to a tide with a dominant M_2 constituent of 0.46 m range and spring tides of over 1 m range. Freshwater inflow from the Yarra River is received throughout the year. The minimum mean monthly flow occurs during March ($6.35 \text{ m}^3/\text{s}$) and the maximum occurs in October ($47.8 \text{ m}^3/\text{s}$). This water reaches the bay via an estuarine section of the river system. The dilution of the sea water creates a density stratified system of varying character.

The bay is subject to direct meteorological influence, principally from the action of wind and barometric pressure. Winds are predominantly from the north in winter, whereas southerly winds tend to predominate in summer.

Hobsons Bay is a complex embayment, both because of its irregular geometry and because of the fact that the currents are quite weak and may be influenced at various times by tide, wind and/or fresh water inflow from the Yarra River. The significant influence of meteorological factors, principally wind, means that the current regime is highly variable in time, in depth and in location in the bay.

3 FIELD PROGRAMME

Because of the complex flow regime known to exist in Hobsons Bay and time limitations on the study, the possible use of physical or mathematical models was not considered to be practicable. Instead, considerable effort was concentrated on the collection of a comprehensive set of field data which would form the basis for predicted changes in the physical regime.

The major forcing functions could not be identified *a priori* so the measurement programme had to embrace time scales appropriate to meteorological, hydrological and tidal phenomena. This was achieved by combining several intensive field exercises of short duration with continuous monitoring at a few locations over a 12 month period in order to cover as wide a range of conditions as possible.

The intensive field exercises provided detailed spatial resolution for relatively short periods, thus enabling overall flow patterns to be identified. The continuous monitoring, on the other hand, provided detailed time series information of currents at particular locations and thereby enabled statistical correlations of currents with external forcing factors to be carried out.

Current speeds were expected to be small, in general, hence current meters with a low threshold were required. The variability of the currents meant that net circulation had to be obtained by integrating over long periods of time. This variability also imposed severe demands on the accuracy of measurement.

The current meters selected had threshold speeds of 2.0 to 2.5 cm/s and were chosen on grounds of anticipated reliability, immediate availability and cost. To improve the measurement of net circulation, continuous recording current meters were used as described below. No special problems relating to salinity and temperature measurement were anticipated, however frequent calibration was necessary due to fouling of electrodes.

In essence, the field programme comprised the following activities:

- (i) Four intensive field exercises, each of three days duration conducted over the whole of Hobsons Bay
- (ii) Additional one day field exercises concentrated in areas of particular interest, namely Webb Dock and the Lower Yarra Estuary
- (iii) Long term continuous recording of currents, temperature, salinity and water levels at selected locations.

The four intensive field exercises were held in June, August and December 1977 and in February 1978 in order to obtain a range of external influences and flow conditions in the bay. During each exercise, monitoring was carried out over a full tidal cycle on each of three consecutive days. Direct profile measurements of current speed and direction, temperature and salinity were made from five boats each anchored at a fixed location in the bay or alternating between two stations. In general, readings were taken at 0.5 m intervals to 2 m depth and then at 1 m intervals to the bottom. Complete profiles were repeated at approximately half hour intervals.

In conjunction with the profiling, direct Lagrangian measurements of the current field were conducted on six of the monitored tidal cycles. Methods used included tracing the movements of free drogues and of dye releases. The drogues were suspended at selected depths and were connected to surface buoys and targets. Up to 20 drogues were tracked at any one time from a field radar station. On selected

days, dye was introduced into the near-surface waters and the movement and rate of spread of dye patches were monitored using radar fixes and aerial photography.

The one day field exercises conducted in Webb-Dock and the Lower Yarra Estuary were conducted in a similar manner to the bay-wide exercises but had a finer spatial focus. Two exercises were conducted in each of these locations.

To supplement the limited range of conditions which were covered in the intensive exercises, four automatic current recording instruments were deployed at selected locations in the bay. The meters used were Alexseev instruments which record current speed and direction at pre-set time intervals on paper tape. Each meter was deployed for a period ranging from one to six months at a particular location using a 15 minute recording interval. To record near-bottom currents, the meters were suspended from tripods which rested on the bay floor. Near-surface currents were recorded by suspending the meters from several floats which were free to move vertically with the rise and fall of the water level. In total, about 1166 days of useful data were recorded in this way.

Data from continuous temperature recorders at 8 locations in the bay were collected during the period of the field investigations. These had been installed by the State Electricity Commission of Victoria and provided records of three-hourly temperature readings dating back several years.

To provide information on the penetration of river water into the existing Webb Dock area, a continuous temperature/salinity recorder was installed in the dock for a period of two months.

The above field programme was complemented by the acquisition of suitable data by other agencies. These data included:

- (i) Meteorological measurements such as wind speed and direction, barometric pressure, rainfall and air temperature
- (ii) Freshwater inflow from the Yarra River System.
- (iii) Water level data at Breakwater Pier, Williamstown.

4 DATA ANALYSIS AND RESULTS

4.1 Velocity and Salinity Data

The field data were edited and adjusted for calibration errors before being entered on to computer files. These, together with data obtained from other agencies, formed a comprehensive data base for analysis. A variety of analyses were carried out using computer programs written specifically for the purpose.

The data from intensive field exercises were processed to produce

line printer plots of depth profiles at all stations. Density layers were defined by the occurrence of steep vertical density gradients in the profile. It was found that the bay was density stratified in most conditions. Vertical temperature gradients in the bay were found to be rather small, with most of the density variation being due to salinity differences between the fresher river water and the deeper bay water.

Usually two and sometimes three distinct density layers could be identified in water deeper than 4 metres, although the depth of the upper layer varied significantly in time and space. On occasions more complex layering occurred. Kinematic layers were identified by noting the change in the directional component of profiled current data.

The continuous current records were analysed to determine the relative importance of the various factors which influence currents in the bay. The current records were analysed using a tidal harmonic analysis to identify the tidal component. It was found that the M_2 tidal constituent accounted for about 25% of the variance in currents at each location. The non-tidal components of current were correlated with riverflow, wind speed, barometric pressure and rainfall in order to determine the relevant influence of these factors. It was found that wind, and principally its north-south component, had a major influence on currents in the bay. Riverflow had a significant effect on the currents at some locations and other parameters were of lesser importance. These results were substantiated by detailed examination of the results from the intensive field investigations.

4.2 Time Scales in Response to Wind Stress

There appear to be two time scales involved in the hydrodynamic response of Hobsons Bay to a change in the wind stress field. The first depends upon the rate of downward transport of the momentum imparted by the wind stress. The second relates to the time for establishment of flows driven by horizontal pressure gradients which arise due to the wind-induced set up (down) of water level near coastlines.

Neglecting the influence of lateral boundaries and in the absence of stratification, it is possible to make a rough estimate of the first time scale. It is assumed that, from an initial state of rest, a wind stress is imposed uniformly over the surface of the water. Empirical relationships allow an estimate of the surface shear stress, τ_w , and the surface wind drift speed, u_d (Spillane, Robinson and Hess, 1978). Application of the boundary layer momentum integral equation leads to an expression for the momentum thickness, θ , as a function of τ_w , u_d , ρ , the density of water, and t , the time elapsed:

$$\theta = \frac{\tau_w}{\rho u_d} t \dots\dots\dots (1)$$

Assuming a wind speed of 5 m/s, we obtain $u_d \approx 0.03$ $u_w = .15$ m/s and $\tau_w = \rho k u_w^2 = .03$ N/m². For $\theta = 1$ m, $t = 1.5$ hours; for $\theta = 2.5$ m, $t = 3.8$ hours.

Assuming a wind speed of 10 m/s, we obtain, for $\theta = 1$ m, $t = 0.6$ hours; for $\theta = 2.5$ m, $t = 1.6$ hours.

Drogues located from 0.5 - 2.5 m below the water surface were used to track upper layer water movement. It was possible to examine the response of drogue trajectories to sudden changes in wind direction. The response times varied between 45 minutes to approximately 3 hours. For example, on 23 February 1978, between 1200 and 1400 hours, drogue velocity vectors rotated about 45° in an anticlockwise direction. This appears to have been in response to the wind field which swung from west to south between 1000 and 1100 hours, while maintaining a low speed of 2 m/s, and then, maintaining direction, intensified to a speed of about 5 m/s during the period 1200-1400. A response time of about 3 hours seems in reasonable agreement with the above calculations.

Flows driven by pressure gradients become established as the pressure gradients become established. The latter require times in the order of L/\sqrt{gy} , where L is the fetch and y the depth. For $L = 4$ km and $y = 10$ m, the time is in the order of 7 minutes. If we say 5 to 30 minutes allowing for the approximate nature of the analysis, this is still less than the first time scale which then becomes the effective one.

5 TYPICAL FLOW PATTERNS

Information on the kinematic and density stratification of the bay was used to choose the most appropriate way of classifying and presenting the current field. In most cases, the movements of near-surface (0 - 2.5 m), mid (3 - 5 m) and deep (6 - 8 m) waters provided a useful division. Within each of these divisions, current vectors representative of each two hour period from all data sources were plotted on a single map; the two hour period being approximately equal to the response time of the bay to wind stress. The data sources included current profiles, drogue trajectories, dye patch trajectories, and recording current meters. Bay-wide plots of near-surface salinities were obtained for the same two hour periods. Temperature differences across the bay were small and had little influence on the flow patterns.

Typical current and salinity fields are shown in Figures 2 and 3. A detailed examination of these quasi-steady velocity and salinity fields indicated that certain flow patterns could be identified on the basis of wind speed and direction and river flow, with tidal influence being of minor importance.

Figure 2 shows the surface current and salinity fields on February 23, 1978, at 0800 to 1000 hours. During this time, the wind was from the north-west at 2 m/s, the river flow was 4.5 m³/s (low) and the tide was falling.

Figure 2. Surface Current and Salinity Fields on Feb. 23, 1978;
at 0800-1000 hours

Figure 3. Surface Current and Salinity Fields on Feb. 23, 1978,
at 1800-2000 hours

It can be seen from Figure 2 that the near-surface water adjacent to the Yarra mouth exhibits a generally south-easterly movement with speeds in the range of 0.1 to 0.2 m/s. Once beyond the line of the proposed Webb Dock 6 extension, the surface water spread to the north-east and then re-aligned itself with the south-east trending coastline.

Water movement at mid-depth was quite sluggish, particularly in locations of large total water depth. Its direction of movement tended not to differ significantly from that of near-surface water except where it was deflected by the direct effect of the bay's bathymetry. Deeper water appeared to flow northward in the vicinity of both shipping channels with maximum speeds of about 0.1 m/s. Much of this deep water flux must have been induced in order to compensate for the net efflux of near-surface waters southward out of Hobsons Bay.

The surface salinities recorded at this time are in the range 30-34 g/l (Figure 2). They indicate the existence of a plume of river water moving towards the south-east in response to the currents in that direction. The depth of the maximum salinity gradient was about 0.7 m for locations near the central axis of the plume and about 2 m for the more marginal stations.

A different set of conditions are illustrated in Figure 3 which shows the near-surface current field and surface salinity distribution observed on February 23, 1978, at 1800 to 2000 hours. During this period, the wind speed averaged 7 m/s from the south-south-east, the river flow as 4.5 m³/s (low) and the tide was falling.

At this time, the near-surface currents throughout most of Hobsons Bay (except near the mouth of the Yarra River) exhibited a significant northward velocity component. Near-surface water on the east side of the Port Melbourne Channel moved to the north-west in conformity both with the direction of the wind and the coastal alignment. Water to the west of the channel moved north-north-east to north-east. There was a noticeable convergence of surface waters in the vicinity of the swinging basin located at the head of the Port Melbourne Channel.

The pattern of mid to deeper water movement was not well defined, with mid-depth water being essentially stagnant. The most unmistakable feature was a deeper-water movement to the south in the vicinity of the Port Melbourne Channel. Mass balance calculations indicated that this deep water flux to the south essentially balanced the near-surface flux to the north and the mass deficit due to the falling water level.

The near-surface salinity field (Figure 3) indicated a weak plume of less saline water extending into Hobsons Bay in an easterly direction from the Yarra mouth.

6 CLASSIFICATION OF FLOW PATTERNS

The detailed analysis of flow patterns in Hobsons Bay enabled the classification of these patterns into a limited number of representa-

tive conditions. Seven representative patterns were identified, each resulting from a different combination of high or low river flow and wind direction as shown in Table 1. It was found that tide made little difference to the basic flow patterns. The choice of $50 \text{ m}^3/\text{s}$ as a dividing point between high and low river flow was based on the measurements taken in the Lower Yarra Estuary which indicated the formation of a salt wedge for discharges greater than this figure. Below $50 \text{ m}^3/\text{s}$ the estuary was partially mixed.

The near-surface flow fields for two of the flow patterns are shown in Figures 4 and 5. Pattern A (Figure 4) corresponds to north to north-west winds and low river flow, while Pattern C (Figure 5) corresponds to south to south-east winds and low river flow. The tendency for the near-surface waters to converge in the vicinity of Station and Princes Piers under conditions of south to south-east winds should be noted.

The frequency of occurrence of each flow pattern was determined by analysing historical records of wind and river flow and determining the relative frequency of occurrence of each combination of these. These relative frequencies are included in Table 1 expressed in the form of the average number of days per year for which a particular pattern is expected to occur.

7. USE OF OBJECTIVE CLASSIFICATION SCHEMES

Attempts were made to put this descriptive classification into dynamic terms. Dynamic classification schemes relate the external forces or fluxes of energy which determine the water movement. The most complete of these schemes, that of Hansen and Rattray (1966), was applied successfully to the Lower Yarra estuary. However in the case of Hobsons Bay gross parameters used by Hansen and Rattray could not be measured with sufficient accuracy while the theoretical parameters contained products and ratios of diffusion parameters, which could only be inferred indirectly and then only for certain of the flow conditions.

Of the various energy ratio schemes, that of Ippen and Harleman (1961) is typical and has been well correlated with flow patterns through their model studies. Their scheme is based on the ratio of two parameters, one representing the rate of tidal energy dissipation per unit mass of water and the other the rate of gain of potential energy per unit mass of water. This scheme may be extended by considering also the energy input by the wind acting on the water surface and the inflow of kinetic energy to the bay from the river. A difficulty with all of these parameters is that the detailed information necessary to obtain exact numerical values is not available, so gross physical variables are used instead. Hence the quantities calculated are likely to suffer from errors ranging from perhaps 25% in the case of tidal and wind energy to perhaps 50% for the other two quantities (the potential energy term used is that of Ippen and Harleman (1961) and is not an actual energy change but it is a quantity indicative of the relative magnitude of the potential energy change as the river flow passes through an estuary).

TABLE 1. Flow Patterns in Hobsons Bay

Pattern	Occurrence (days/year)	River Flow (m ³ /s)	Wind Direction at Breakwater Pier	Flow Pattern
A	95.8	Low (< 50)	NW & N	Surface: SSE; mid and deep water: N and up channel at 0.1 m/s
B	54.9	Low	NE & E	Surface: S, SE; mid-depth: weak but similar; deep: up channel
C	96.5	Low	SE & S	Surface: generally NE, Yarra outflow swings E, inflow to N along Williamstown shore, convergence near Station Pier; mid: similar; deep: S in Pt. Melbourne Channel
D	83.0	Low	SW & W	Surface: generally NE, Yarra outflow swings E to NE, inflow to N along Williamstown shore; mid: similar to weak; deep: weak
E	5.2	High (> 50)	W	Surface: ESE with strong river plume extending into bay, N near Breakwater Pier; mid and deep: N to NW
F	13.8	High	NW to E	Surface: strong river plume following Williamstown Channel; deep: up channel
G	14.0	High	SE to SW	Surface: Strong river plume flowing S to Breakwater Pier then ESE; deep: up channel

Figure 4. Flow Pattern A

Figure 5. Flow Pattern C

The energy terms, calculated for an area of 8 km² of the bay for typical and high winds, for typical and high tidal currents and for typical and flood river flows, are given in Table 2. The most obvious feature of these results is the high energy input by the wind, and the small input by the tides. From this it may be inferred that mixing is primarily caused by the wind and hence in the absence of winds the bay is likely to be stratified, while wind is likely to be less important under high flow conditions. Both these features have been observed.

Under flood conditions, for the wind to impart sufficient power to negate the potential energy input of the river plume would require a very strong wind or a large area of bay surface. Thus the plume should persist as an identifiable feature for some distance. Using data from the flood of February 1973, a river plume with a well defined boundary covered an area of 3.6 km² on 7 February. The wind was relatively steady with a speed of 9 m/s and the river flow over the preceding 24 hours averaged 120 m³/s. For these conditions, the power input to the plume from the wind was 197 kw and that from the river was 240 kw. This agreement, which is surprisingly close in view of the usually low efficiency of the mixing process, can possibly be accounted for by the fact that mixing is only partially complete just outside the plume, and weakly stratified water extends over tens of square kilometres.

TABLE 2. Rates of Energy Dissipation in Hobsons Bay.

Wind Speed (m/s)	5		10	
Power Input by wind over 8 km ² (kw)	75		600	
Tidal Velocity (m/s)	0.02	0.02	0.05	0.05
Depth (m)	10	6	10	6
Tidal Power dissipated over 8 km ² (kw)	0.15	0.18	2.33	2.77
River Flow (m ³ /s)	5		150	
Rate of Potential Energy Change (kw)	1.50		300	

8 USE OF LONG-TERM CHANGES FOR ENVIRONMENTAL PREDICTION

Predictions of changes in the long term average currents, salinities and water quality variables (nutrients and dissolved oxygen)

TABLE 3. Projected Changes in Salinity and Current Speed Following Construction of Berth No. 6.

Pattern	Maximum Changes following Construction of Berth No. 6 1				
	Existing Dock	Berth No. 6	Within 300m E of No.6	Williamstown	Other
A	Nil	V+	Nil	Nil	(Bottom V+)
B	Nil	Nil	Nil	Nil	S - 0.2 at Parsons
C	Top layer 0.3m thicker	Plume impinge on No. 6	V-, S+1	S+0.4 to 1 maximum V-	Flotsam South of No. 6
D	S - 0.5	Plume impinge on No. 6	V-, S+0.5	Nil	Flotsam South of No. 6
E	S - 5	Nil	S+2,V+	Nil	Nil
F	Nil	Nil	Nil	Nil	Nil
G	Top S - 2.5, V+ Mid S ± 2	Top S - 2.5, V+ Mid S ± 2	Top S - 2.5 Mid S ± 1	Nil	River Entrance: Mid S ± 1

1. Changes given are maxima in all cases and unless specified apply only to the top 1.5 m; + indicates an increase, - a fall. Changes of less than 0.05 g/l in salinity and 3 cm/s in current speed have not been given a numerical estimate. Changes in salinity (S) are in g/l and in current speed (V) are in cm/s.

TABLE 4. Estimated Changes in Long-Term Average Velocities and Salinities

Location	Maximum change in average current speed (m/s)	Standard deviation of measured current speed (m/s)	Maximum change in average salinity of upper 1.5 m (g/l)	Standard deviation of measured salinity (g/l)
Existing Dock	Negligible	Not applicable	-0.3	4.0
Berth 6 Webb Dock	+ .01	.027	-0.1	3.9
Within 300m to the east of Berth 6	Negligible	Not applicable	+0.4 OR -0.1	4.0
Williamstown Foreshore	- .01	.04	+0.3	6.0
Other Locations	Less than .01	.03 to .04	Less than 0.05	3.0 to 6.0

resulting from dock construction were required in order to assess the likely effects on the biota in the bay. Predictions of changes in the physical variables to an accuracy of one significant figure was deemed adequate for the subsequent biological assessment. It was decided therefore to use relatively simple methods for predicting these physical changes.

The expected change in each flow pattern was determined by a close examination of the streamlines and by applying judgement to assess the way in which these would change following dock construction. The equations of continuity and conservation of salt were then applied to determine the expected changes in the velocities and salinities resulting from the displacement of the streamlines. The predicted changes are given in Table 3. The expected changes are, in general, relatively small except for infrequent combinations of external factors, e.g. high river flow and westerly wind which is expected to occur only about 5 days per year on average.

The long term average changes in velocities and salinities were computed by combining the changes expected in each flow pattern with the relative frequency of occurrence of that pattern. These are shown in Table 4 together with estimated standard deviations of the parameters due to natural variability. In general, it was found that the expected long term average changes in currents and salinity were much less than the natural variability which occurs in these parameters.

9 CONCLUSIONS

- (i) The investigation of water movement was central in assessing the environmental effects of port development works by enabling prediction of future water movements and environmental parameters. It was found that the proposed berth would not have a major effect on currents or salinity (or on other parameters) in Hobsons Bay.
- (ii) Current patterns in Hobsons Bay are influenced by salinity stratification at all times and are determined principally by river flow and wind, with tide having a minor influence. Currents take up to two to three hours to respond to changes in the wind.
- (iii) Published estuary classification schemes were not useful, but consideration of gross energy inputs by the different forcing processes provides a basis for understanding flow patterns.

CHAPTER 182

INTEGRATION AND COMPUTATION IN AN ENVIRONMENTAL STUDY

by

J.B. Hinwood¹, J.E. Watson² and D.M. Burrage³

ABSTRACT

A high level of integration of disciplines and use of a centralised computer data base and programming system were seen to offer advantages in a study of the marine and coastal environment of the Port Melbourne Authority. These goals were only partially attained but the effort was well worthwhile.

1. INTRODUCTION

For an environmental study to achieve an overview of the wide range of variables, processes and interactions in a given region, the results of work in many disciplines must be integrated. The integration of the different disciplines depends critically upon flows of information. These in turn depend upon the use of the computer to store, process and display information.

This paper describes the integration of disciplines and the centralised computer data base and programming system used in the Port of Melbourne Environmental Study. The purpose and results of the study are outlined first to provide the context.

2. THE PORT OF MELBOURNE ENVIRONMENTAL STUDY

2.1 Purpose

The Port of Melbourne Environmental Study was divided into firstly a study of the sociological implications of the possible expansion of Webb Dock with some emphasis on land transport serving the dock and secondly the Marine Study of 6 Webb Dock. The Marine Study was aimed at assessing the effects on the marine and coastal environment of reclamation and dredging activities associated with the construction of Berth 6 Webb Dock. The site of the proposed construction is in Hobsons Bay, close to the mouth of the Yarra River. The study involved investigations of water movement, water quality, coastal processes and the ecology of the Bay.

¹ Department of Mechanical Engineering, Monash University and Centre for Environmental Studies, University of Melbourne.

² Marine Science and Ecology, Melbourne.

³ Centre for Environmental Studies, University of Melbourne.

The Port of Melbourne has been developed over the last 150 years along the lower Yarra River and around its mouth, in an indentation of Port Phillip Bay known as Hobsons Bay. The Webb Dock container terminal is in Hobsons Bay immediately to the east of the mouth of the Yarra River (Fig. 1). Hobsons Bay forms the southern boundary to Melbourne, and hence is of importance to the city as a recreational area for boating, fishing, for swimming, and for the aesthetic enjoyment of water and its shoreline. The value of Hobsons Bay would be lowered if the water quality were to be reduced, if the ecosystem of the bay were to be disturbed or if the beaches were severely eroded. Severe changes in the regime of the bay could adversely affect commercial fishing within Port Phillip or could conceivably interfere with port operations. Proper management can avoid these problems, but management requires reliable baseline information on the present state of the bay, an understanding of the processes which are important and, based upon both of these, strategies for predicting changes to the ecosystem of the bay following construction or other activities. The study provided the baseline data on water circulation, water quality, beaches and sediments and marine ecology, an understanding of the important processes and specific predictions for the changes which would result following construction of Berth 6 Webb Dock.

2.2 Method

The Port of Melbourne Authority commissioned the Centre for Environmental Studies, University of Melbourne, to carry out a study to provide baseline information and to assess the consequences of construction of a new berth — No.6 — in Webb Dock. This study was commenced in 1977 and the final report was presented in August 1979. Following a three months planning period, twelve months of measurement were carried out within Hobsons Bay and the lower Yarra River. In addition to the data obtained specifically by the study, historical data and data collected on a continuing basis by government authorities were used.

Water movement was determined by direct current metering, continuous current metering, drogue tracking and from temperature and salinity data (Mills et al 1978, Dandy et al 1980). Wave records, tidal data, long-term meteorological data for the Melbourne Regional Station and wind data for periods of interest at Breakwater Pier were obtained from government departments. Water quality parameters measured were temperature, salinity, dissolved oxygen, light transmission, turbidity, nitrogen, phosphorus, *E. coli* and *Salmonella* bacteria and inflows from minor drains.

For the study of the beaches and sediments, beach profiling and lead-lining were carried out, sediment samples were collected and analysed, a sand tracer test was conducted and waves, winds and currents were measured. Other data used were air photos, records of construction, dredging and shipping movements.

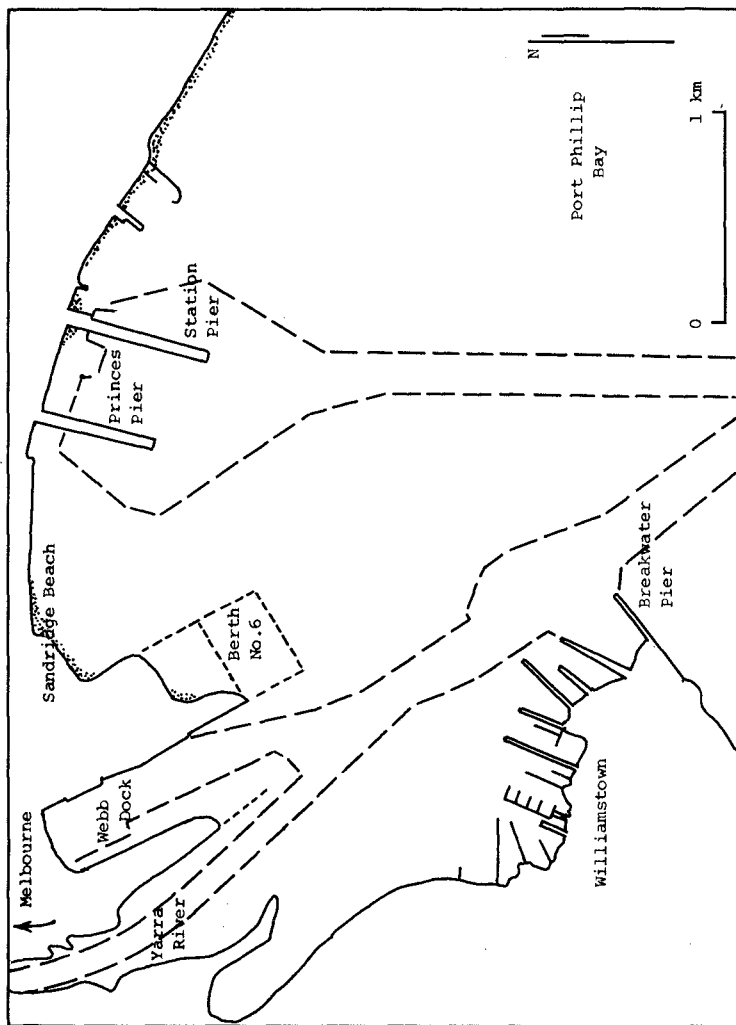

Fig. 1 Hobsons Bay, Melbourne

The ecological studies concentrated on sampling the intertidal and subtidal epibiota (algae and fauna) on port structures, and the benthic infauna of the bed and intertidal margins of the bay. Fish populations were sampled by seining in shallow water. A survey of recreational fishing in Hobsons Bay was conducted.

2.3 Results

The principal findings were:

- The water circulation in Hobsons Bay is primarily wind driven, but the effects of Yarra River flow and stratification must be taken into account and tides may be important in some circumstances.
- Except in the surface plume of water from the Yarra River, the water of Hobsons Bay is predominantly derived from Port Phillip Bay. Within the Yarra River and river plume, bacterial and nutrient levels are high and dissolved oxygen concentrations are below desirable levels. Elsewhere the water quality meets EPA objectives.
- Sand is found on and just offshore of the beaches. Sediment movement on Sandridge Beach, to the east of Webb Dock, is highly variable but is predominantly to the west. The silt bed of Hobsons Bay may be resuspended by wave action but is not undergoing significant net movement.
- Both the hard and soft substrates of Hobsons Bay and Webb Dock support a diverse and productive biota, and there are significant populations of fish. Productivity is lower in Webb Dock than in Hobsons Bay, but it is still high by general standards. The biological communities are well adapted to the existing environmental conditions and can withstand the disturbances imposed by shipping and the natural stresses of variable temperature and salinity.

All variables were related to water movement and water quality, hence predicted changes in flow patterns enabled the changes following construction of Berth 6 to be predicted.

3. COMPUTATION

3.1 Purpose

The extensive use of a computer data base and centralised programming system was anticipated to provide economical and fast data reduction and presentation and ready access to all data by all participants in the study. The advantages of centralisation are that by examining the needs of all groups together, uniformity of recording is obtained where possible, the number of data handling programs and the computational effort are reduced and ease of access and ease of inter-comparison of different types of variables are increased.

3.2 Method

The e.d.p. work was placed under the control of one staff member possessing both a broad knowledge of disciplines involved in environmental studies plus expert knowledge of computing, assisted by junior programmers and data entry personnel. The use of a purely computer oriented specialist was not seen to provide the proper liaison which this position required, but we recognise that we were very fortunate in obtaining the services of a man expert in both areas.

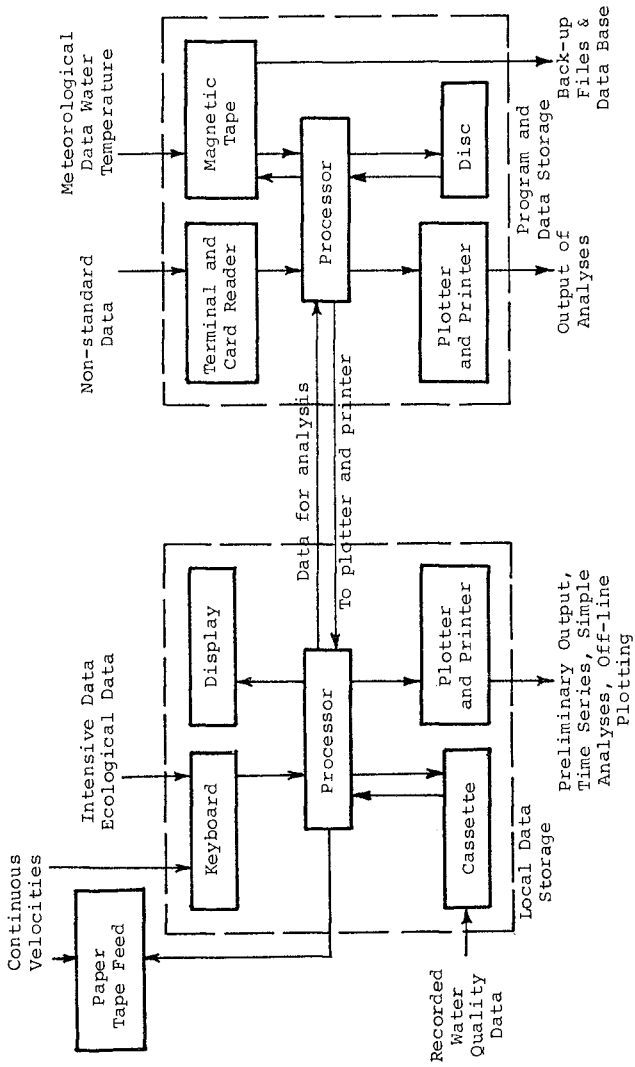

The e.d.p. specialist developed a general strategy for data entry and error checking, data file structure, frequently used data manipulation and reduction programs, and frequently used tabular and graphical presentations of data. He collaborated with other senior staff in development of these and specialised analysis programs required, supervised junior staff in preparing programs and using them, and trained all staff in the use of the system as it was developed.

Available funds permitted minor improvements to be made to the existing computer hardware. The existing system, shown schematically in Fig. 2, consisted of a Hewlett Packard model 9830 programmable calculator, with 8-K words memory, programmable in BASIC, with extended string and matrix handling capabilities. An internal cassette drive permitted storage of data with the capacity of 32-K words per cassette. The calculator was usable as stand-alone machine or as an intelligent terminal for data transmission to and from the University's Central Computer — a CDC Cyber. A small plotter was connected to the 9830 and other plotters were available at the University Computer Centre. This system serviced the Centre for Environmental Studies, and could not be wholly dedicated to this study, hence the decision was taken to provide an additional direct line to the University Computer and to provide an auxiliary cassette drive for the 9830.

The software required may be divided into four groups. Data entry and error checking routines were specially prepared for the study. Data manipulation, reformatting and editing routines were also specially written, to enable correction of data files, combination of files for use in calculations and to enable stranger tapes written in other computer installations to be read by the Cyber. Data preparation routines, including those used in smoothing raw data, for changing time base intervals, resolving vectors and so on, were again specially written although they utilised well known algorithms. Finally, the more substantial programs for tasks such as time series analysis or statistical analysis were obtained from other installations wherever possible. Because of its great convenience the SPSS package was utilised for all basic statistics operations, despite its inefficiency for some types of calculations.

3.3 Results

Approximately 300,000 data values were entered to form the main

CYBER

HP9830

Fig. 2 Computer configuration used for data entry archiving and processing

data base, while tapes obtained from government agencies contributed a further 200,000 data values, primarily meteorological data. The centralised programming facility provided approximately 80 programs, most of them in the area of data manipulation, reformatting and editing. Approximately 80 additional programs or variations of programs were prepared outside the central system, mostly in the areas of data analysis and presentation. Averaged over the course of the study, the computer specialist devoted between one and two days of each week to the job. Junior programmers contributed approximately one man year of work and data entry personnel approximately three man years. Other project staff contributed approximately half a man year to the programming and about the same to the data entry.

The forms of data input, principal computer files created and the source of the principal computer programs used are shown in Table 1 for the water quality and water movement data; the first six columns represent over 98% of the data. The table shows that a wide variety of input forms were used, most data were put onto local cassette for limited local computations and onto the central data base, and processed on the central computer programs. The similar tables for the sediment data again showed the same features with nearly all computation done centrally. The tables for the ecological and human activity data showed that most data were keyed in and entered into local cassette files and the central data base, but most computation was done locally or on programmable calculators.

The use of this system resulted in an excellent data base, achieved economically.

The anticipated benefits of rapidly available data and rapid presentation of simple analyses were not realised for three reasons. Firstly, at the conclusion of the year of data collection a bottleneck developed because of the excessive amount of data entry simultaneously with development and utilisation of the analysis programs. Computer specialists and hardware were both overloaded for several months and remained under pressure for a considerable time. Secondly, some members of the team possessed programming skills and chose to exercise them rather than await the development of programs by the hard-pressed computer specialist. This practical but necessary decision resulted in some duplication of efforts and reduced the future utility of the sets of programs developed, through use of different formats and less complete documentation.

Finally, the proper development of the analysis programs had to await the development of an understanding of the Hobsons Bay systems. For example, the spatial and temporal variability of currents in Hobsons Bay was greater than anticipated, so that the drogue movements — with their built in averaging — provided a better picture of water movements than did the current metering. The unexpectedly large populations of subtidal epibiota also lead to changes in methods of analysis.

The appendix contains a description of one of the data entry programs and illustrates the passage of data from input to analysis.

4. INTEGRATION OF DISCIPLINES

4.1 Purposes of Integration of Disciplines

Direct collaboration between specialists in different disciplines is required for two principal reasons: firstly because of the need to utilise information obtained by one discipline to explain and extend the results obtained within another. For example, biomass and populations of the biota were found to depend upon the physical and chemical variables of temperature, salinity, turbidity, water velocity and location with respect to the river plume. Analysis and interpretation of these data required collaboration of sedimentologists, marine chemists, engineers and biologists.

Secondly, unless all factors are favourable, the making of a recommendation on proposed works requires that unlike quantities be compared or unlike measures be combined — for example a loss of water suitable for swimming might be offset by an increase in waters available for fish nursery areas.

4.2 Methods of Integration of Disciplines

Integration of the different disciplines required that the individuals perceive the benefits of close cooperation and that the facility for this cooperation be provided. As has been pointed out by many others, it is necessary to put effort into such collaborative work for it to succeed. Even the gaining of working knowledge of the jargon of the other disciplines requires effort, but is an essential pre-requisite to collaboration.

In the planning of this environmental study, as with most others, the tasks were distributed according to the specialised backgrounds of the different workers, so that one of the team was responsible for the ecological studies, another for the sediment studies, and so on. Such a division of labour seems to be unavoidable if high technical standards within each area of the study are to be achieved. The initial division then had to be overcome by conscious effort, by planning for the different parts of the study to interlock and by arranging for the offices of the different specialists to be in close proximity and for them to work together as much as possible.

Total integration was clearly not essential or even desirable. Determination of the hydrodynamic patterns required hour by hour measurements while determination of the typical populations of barnacles at a site required seasonal measurements and even the actual days of measurement did not have to coincide for the one series to provide support to the other. By not striving for needless synchronisation,

better use was made of boats, instruments and support personnel.

The flows of information are illustrated in Figs. 3, 4 and 5. Each figure shows the flows from left to right of raw data, reduced data and basic statistics, combined and correlated results of several types of data, culminating in the predicted change in a selected variable following construction. The flows of all levels of data to the data base have not been shown for clarity. Similar figures could be presented for other variables such as turbidity, epibiota, bacteria, algae, etc.

Both the correlated results, which describe the present regime of the bay, and the predictions are useful outputs from the study as are the raw data and basic statistics which provide a baseline against which future states may be compared.

4.3 Results of Integration of Disciplines

Despite an appreciation of the need for integration, the different specialist tasks diverged very early and some of the field measurements were carried out with inadequate regard to integration of the disciplines.

However, at the stage of analysis and reporting of results, a high degree of integration was achieved, in large measure by the channelling of all data through the e.d.p. specialist and by one of the senior staff making some contribution to the writing of all of the component parts of the report. The pressures of meeting deadlines within the specific tasks discouraged the other members of the team to become involved outside their own speciality except upon direct request. This is a very common experience with inter-group cooperation, where the willingness of the various individuals is not a sufficient stimulus in the face of the more clearly perceived pressures within their own specialist task, and since the collaboration between groups frequently depends on one or two individuals it may break down completely under such stress.

5. CONCLUSIONS

The interdependence of all parts of the study, at the level of interpretation and prediction has been shown. The water movement investigation and the water quality investigation proved so interdependent that they were completely merged early in the study. All parts of the study depended on the results of the water quality and water movement investigations with the latter playing the major role in the prediction of changes following construction. In this study, the predicted changes in all variables were very small and so application of multi-objective planning techniques was not necessary.

Integration was encouraged by joint planning, by working in close proximity, and by joint writing of each major section of the report.

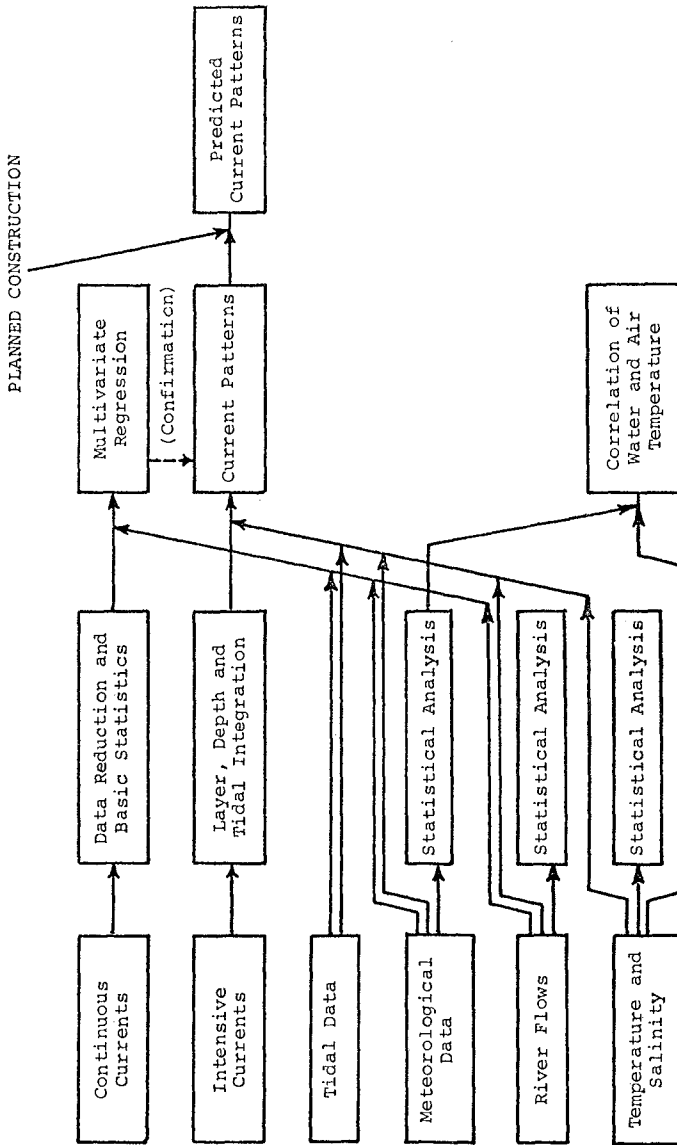

Fig. 3 Flows of information used to analyse currents and water temperatures

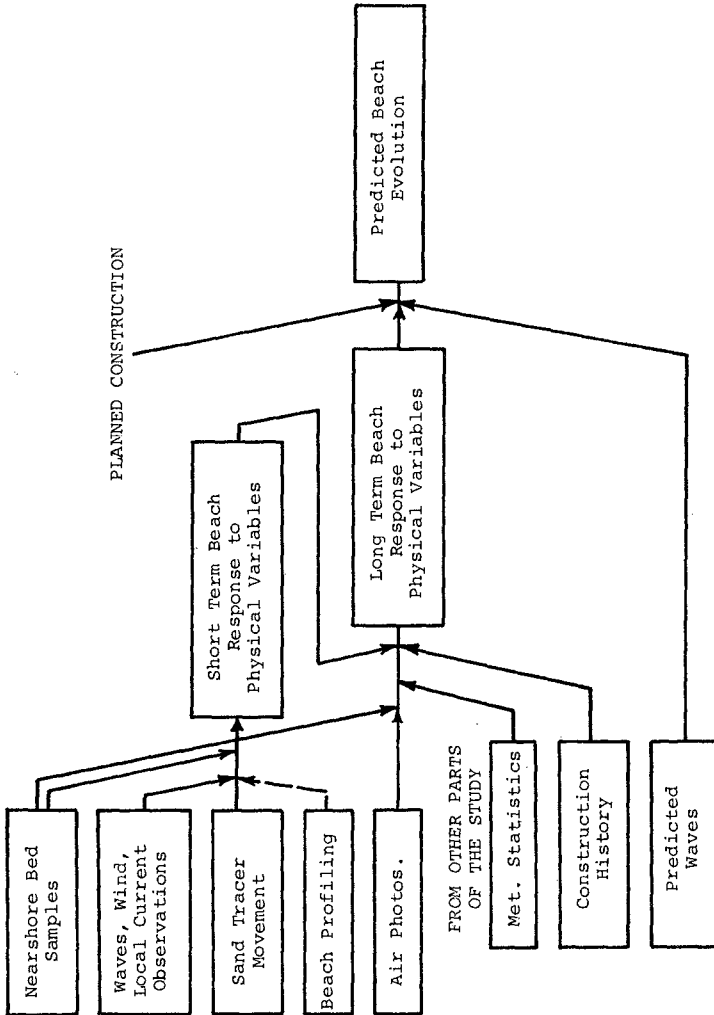

Fig. 4 Flows of information used to analyse beach dynamics

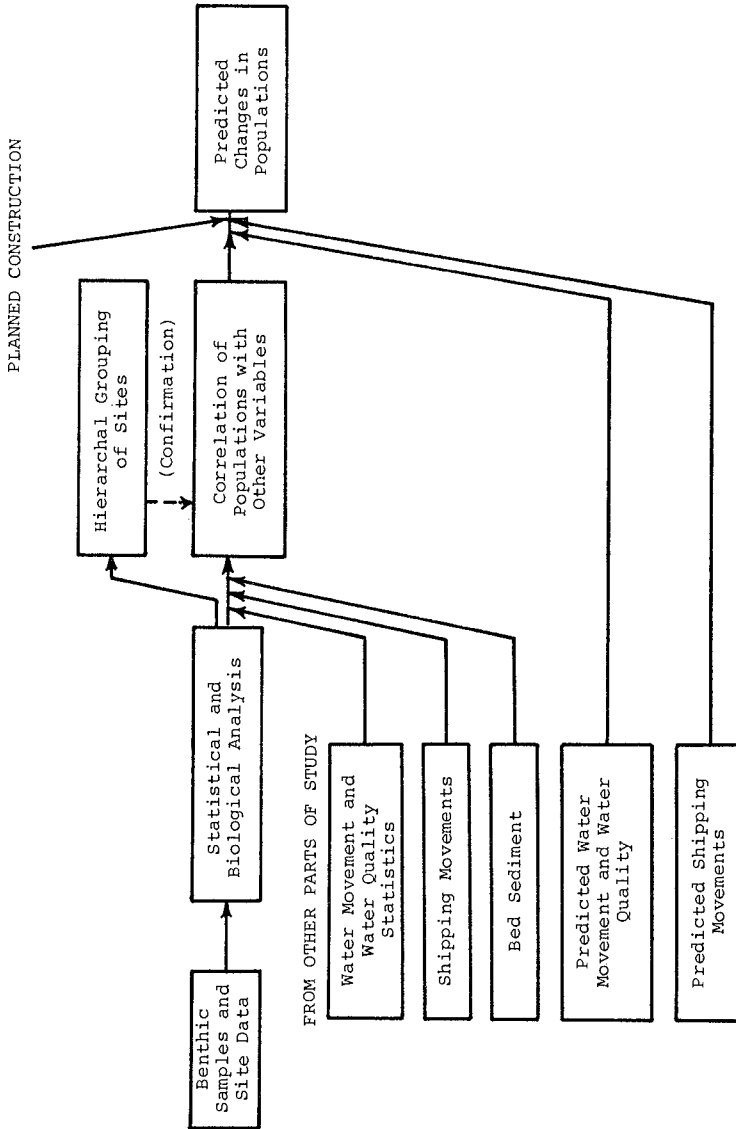

Fig. 5 Flows of information used to analyse benthic biota

However, full integration was not obtained because of the need to meet deadlines and the need to utilise specialists in each area to ensure high technical standards

The objective of a centralised computing service for the study was not wholly successful but was worthwhile by making available documented programs and data files, with common formats. The success achieved was largely due to having a person skilled in both computing and the disciplines involved in the study. Periods of high demand lead to delays, and to individually written programs which met the study objectives but are not of general use.

6. ACKNOWLEDGEMENT

The study was funded by the Port of Melbourne Authority, whose staff were of great assistance.

7. APPENDIX: DATA ENTRY, EDITING AND STORAGE

A suite of programs for use on the Hewlett Packard Model 9830 calculator was developed to facilitate data entry, error checking and transfer for the purposes of the study. Data collected during the intensive field exercise were recorded on special field sheets. These were hand edited in the office to correct for calibration and instrument errors prior to entry on the computer. Data were entered from the edited field sheets, or from printed paper tapes produced by the current meters, by specially trained operators, through the keyboard of the 9830, were stored on cassettes and were later transferred to the Cyber computer. Once stored in the Cyber, the data files could be corrected, data could be transformed, files could be joined or merged and listings or plots of data prepared.

As an example the sequence of steps for the continuously recording current meters will be described. These instruments printed the speed and direction on a paper tape at pre-determined intervals, normally five or fifteen minutes. For data entry the tapes were mounted in a specially constructed transport, mounted on the 9830. The operator, after mounting the tape and cassette, generated a header file on the cassette, specifying the maximum record length, number of data fields per record and the number of characters in each field. He then entered specifications of the parameters, comprising parameter name, measuring unit, alphanumeric or numeric, scalar or vector, precision, maximum and minimum expected values, time or position sequence of data, coordinate location of data point and time index.

The operator then commenced the actual entry of data entering a number for current speed and one for current direction. The following tests were automatically performed and if any succeeded, an error condition was signalled:

- Incorrect field length (number of characters).
- Illegal alpha characters.
- Number of decimal places does not correspond to specified precision.
- Decimal place omission.
- Presence of more than one decimal point.
- Presence of decimal point in integer field.
- Data out of range specified.

These errors had to be corrected by the operators before the data were stored on cassette. They could arise due to discrepancy between the raw data and the value entered or as a result of an anomalous value appearing in the data field resulting from instrumental or recording errors. Other errors were usually detected using basic statistical and time series functions, following data entry. The simplest check was to prepare a time series plot of the velocity magnitude and direction, or of the orthogonal components and to examine this plot for anomalous values. Basic statistics were obtained at the same time and gave an indication if the nature of the record differed from previous records.

The cassette prepared on the 9830 was then batched with various others to the Cyber as a raw data file. Errors detected through the time series plot and other means were then corrected using the file editing capability of the Cyber. Missing data were indicated by an asterisk or a sequence of 9s, but were not replaced. The raw data files then prepared form part of the data base.

Before the continuously recorded velocities could be used for analysis, files of 30 days of data had to be prepared. First the data were manipulated, to obtain values at constant time intervals throughout the files to be combined. This step was necessary as the starting time of one file might not be at an integral number of time steps after the end of the previous file, the time steps might not be equal in the two files, or the time step might be shorter than that needed for the analysis so that alternate data only might be required in the combined file. The two files were then combined, with the gap between them treated as any other missing data. If the sequences of missing data were short, they were filled by interpolation but if long they were filled manually utilising the best estimates after considering all of the available data. The resultant 30 day files were then stored as part of the data base and were utilised in data analysis.

Analyses performed using the 30 day files of current data included the preparation of velocity scattergrams, analysis of tidal harmonics, correlation of velocity data with wind and with atmospheric pressure, and correlation with velocity data obtained at other sites. From these analyses the physical factors responsible for the currents were ascertained, the likely velocities under particular sets of physical circumstances were predicted for periods of interest, and annual averages were estimated. In addition to time series plots and scattergrams, hodographs, cumulative vector plots and other pictorial representations were used to display the information on the velocity field. This work is presented by Dandy, Mills and Hinwood (1980). Tapes from

the instruments which were recorded in a computer compatible form were handled in the same fashion as 9830 raw data cassettes.

SOME RECENT RESULTS FOR WAVE INDUCED MOTIONS
OF A SHIP IN SHALLOW WATER

P. Å. Madsen* I. A. Svendsen* C. Michaelsen*

ABSTRACT

The paper describes an analytical approach to the problem of wave induced oscillations of a long ship in water with a depth which is only slightly larger than the draught of the ship. The problem is linearized (i.e. small amplitude motions and waves) and the water flow induced by the incident waves, and by the motion of the ship is determined. This also yields results for the forces in the equations of motion for the ship. These equations can be solved analytically, but the paper concentrates on giving numerical results for the solutions. Results are also given for the hydrodynamic masses and movements of inertia, and for the damping due to radiation of wave energy.

1. INTRODUCTION

The problem of ship motions in water of limited depth has been approached by several authors previously. The difficulty is the presence of the sea bed. Wilson (1958) represented this by empirically increasing the hydrodynamic mass and the damping of the ship, and Wendel (1950) determined the hydrodynamic mass of a hull section theoretically by conformal mapping. More successful is the integral equation method which consists in transforming the boundary value problem of the flow equations into an integral equation assuming the waves to be small amplitude sinusoidal (see e.g. Bai and Yeung (1974) and van Oortmerssen (1976)). Whereas this method works well for deep water conditions, the numerical computations require an increasingly large number of integration points as the depth decreases towards the draught of the ship. Yet van Oortmerssen is able to present results for hydrodynamic masses at a draught to depth ratio as large as 0.95.

Recently Andersen (1979) used a finite element technique to solve the problem numerically, but in principle had the same difficulties in describing the flow close to and underneath the ship when the draught of the ship is close to the depth of water. The largest value of the draught to depth ratio for which results are given is 0.67. Both van Oortmerssen and Andersen, however, can treat the full three-dimensional problem. The same does in principle Tuck (1970) who uses a slender body approach for which he gives results for added mass and damping coefficients.

*Inst. of Hydrodyn. and Hydraulic Engrg. (ISVA), Tech. Univ. Denmark, Build. 115, DK-2800 Lyngby. — Mail should be sent to: I. A. Svendsen.

The method presented in this paper is based on an approximation which makes it well suited to treat exactly the cases of very small underkeel clearance. In fact, the smaller the underkeel clearance, the better is the approximation. It is, however, essentially based on the assumptions of two-dimensional motion and hence restricted to application to a long ship and the heave, roll and sway motion of such a ship. Actually we will see that as the sway motion for a ship in very shallow water is strongly influenced by three-dimensional effects (the water can flow around the ends of the ship as well as beneath it) the results for sway are the least accurate. This is further discussed in § 5. The paper formulates the problem which originates from the above mentioned idea (§ 2). The equations are linearized, and the solution for the water flow is then determined by dividing the problem into subproblems which are described briefly, and examples of the solutions are given (§ 3). In § 4 we discuss the wave induced heave motion and in § 5 the roll and sway motions. Finally, the results for hydrodynamic masses and moments of inertia are given in § 6 and results for the wave generation (i.e. the damping coefficients) are presented in § 7.

2. BASIC ASSUMPTIONS AND EQUATIONS FOR THE WATER MOTION

The motion of the ship is caused by the pressure forces generated by the water motion. To determine this we consider the two-dimensional situation of a ship in beam seas. The hull is approximated by a rectangular shape (Fig. 1, which also shows the notation) and the basic assumptions are then

- (i) In the clearance $R \ll h$ the flow velocity is entirely horizontal (i.e. $w \ll u$) and uniform over R . This is assumed to apply at sections 1-1 and 2-2, and it implies static pressure variation under the ship.
- (ii) The motion under the ship is considered separately and matched directly to the flow outside the gap by requiring continuity in pressure (averaged over R) at 1-1 and 2-2.

Fig. 1 Definition sketch.

a. The water motion beneath the hull

With reference to (i) the continuity equation for the flow beneath the hull is written

$$\frac{\partial Q}{\partial x} = - \frac{\partial R}{\partial t} \quad \text{with} \quad Q \equiv \int_0^R u dz = uR \quad (1)$$

Since

$$R = R_0 + z_0(t) + \theta(t) x \quad (2)$$

where R_0 represents the equilibrium position, z_0 and θ the heave and roll motions, respectively, we get

$$\frac{\partial R}{\partial t} = z_{0t} + \theta_t x \equiv W(t) + \Omega(t) x \quad (3)$$

where $W(t)$ and $\Omega(t)$ represent the velocity of the heave motion and the angular velocity of the roll, respectively, of the ship. Substituting (3) into (1) and integrating yields Q and hence U as a function of W and Ω

$$U(x,t) = -\frac{1}{R} \left\{ Wx + \Omega \frac{x^2}{2} + A(t) \right\} \quad (4)$$

where the arbitrary function $A(t)$ represents the net flux through the gap caused by different (wave) pressures at the two sides of the hull.

The horizontal component of the equation of momentum becomes

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} = -\frac{1}{\rho} \frac{\partial p}{\partial x} \quad (5)$$

The pressure $p^+(x,z,t)$ generated by the wave and ship motion is extracted from p by the definition

$$p(x,z,t) = p^+(x,t) + \rho g(h-z) \quad (6)$$

where p^+ according to (i) is independent of z .

Substitution of (4) and (6) into (5) then yields (after integration) the following relation between the pressure p^+ in the gap beneath the hull and the roll and heave motion described by Ω and W

$$\begin{aligned} -\frac{1}{\rho} p^+(x,t) = & \frac{1}{R^2} \left\{ \frac{\Omega^2}{8} x^4 + \frac{1}{2} W \Omega x^3 + \frac{1}{2} (W^2 + \Omega A) x^2 + W A x + \frac{1}{2} A^2 \right\} \\ & + \frac{1}{2} \Omega^2 \int x^3/R^2 dx + \frac{3}{2} W \Omega \int x^2/R^2 dx + (W^2 + \Omega A) \int x/R^2 dx \\ & + W A \int R^{-2} dx - W_t \int x/R dx - \frac{1}{2} \Omega_t \int x^2/R dx - A_t \int R^{-1} dx \\ & - p_0^+(t)/\rho \quad \quad \quad -\frac{B}{2} \leq x \leq \frac{B}{2} \quad (7) \end{aligned}$$

where the arbitrary function $p_0(t)$ represents the pressure $x=0$, and the integrals may be evaluated by substituting (2) for R .

Eq. (7) is the general result for the pressure beneath the hull, expressed in terms of the heave and roll motions of the ship, and $A(t)$ and p_0^+ . We can find $A(t)$ and p_0^+ and determine the water pressures on the side of the hull and then substitute this into the equations of motion for the hull we get three simultaneous, ordinary (but non-linear) second order differential equations for the heave, roll and sway motions. These equations can in principle be solved by straightforward numerical procedures.

To obtain analytical solutions, however, we will here assume that the vertical component of the ship motion causes only small changes in R (which will be true for most situations in practice anyway). Then

(7) in the first approximation can be shown to reduce to the far simpler

$$\frac{1}{\rho} p^+(x,t) = \omega_t \frac{x^2}{2R} + \Omega_t \frac{x^3}{6R} - \frac{A_t}{R} x + p_0^+(t)/\rho \tag{8}$$

The only real problem left is then to determine the pressure p_0^+ , the function A and the pressures on the side of the hull. All these quantities are closely related to the water motion at the side of the hull (i.e. $|x| \geq B/2$).

b. The water motion at the side of the hull

This water motion is caused by a combination of the incoming waves, their reflection from the hull and transmission through the gap beneath the ship hull to the other side, and by the waves generated by the heave, roll and sway motion of the ship.

The following additional assumptions are used:

- (iii) We neglect all energy dissipation and boundary layer effects and assume potential flow everywhere.
- (iv) Both incoming and generated waves are assumed of small amplitude.

Thus the problem of wave motion at the side of the ship is linear too and we may consider the different components separately. Introducing the velocity potential ϕ (with $\vec{v} = (u,w) = -\nabla\phi$) the problem is to solve the Laplace equation

$$\nabla^2 \phi = 0 \tag{9}$$

at each side of the ship satisfying the following boundary conditions (here formulated for the right hand side of the ship)

$$\phi_{tt} + g \phi_z = 0 \quad \text{at } z = h \quad 0 < x_1 < \infty \tag{10}$$

(with $x_1 = x - B/2$, see Fig. 1)

$$\phi_z = 0 \quad \text{at } z = 0 \quad 0 < x_1 < \infty \tag{11}$$

$$\phi_x = \begin{cases} -U_2 \\ \Omega(t)(z-m) - V \end{cases} \quad \left. \begin{matrix} 0 < z < R \\ R < z < h \end{matrix} \right\} x_1 = 0 \tag{12}$$

where $U_2 = U(x=B/2,t)$ in (4), and V is the velocity of the sway motion of the ship. m is the height of the point of rotation above the sea bed.

Finally at $x_1 \rightarrow \infty$ a radiation condition applies. This boundary value problem for the flow at $|x| > B/2$ is illustrated in Fig. 2.

Fig. 2
Boundary value problem for flow at the side of the hull.

The total motion in the linear problem then consists of the following components:

1. The standing wave composed of the incoming plus a (formally) fully reflected wave. This motion occurs only at one side of the hull (assumed to be the left side in Fig. 1). (ϕ_W, H_W, p_W^+ etc.)
2. The motion generated under a fixed ship by the above mentioned standing wave. On the right hand side this represents the waves transmitted through the opening beneath the hull. On the left hand side it represents the reduction in reflection due to the transmission. (ϕ_G, H_G, p_G^+ etc.)
3. The waves generated by the sway motion of the ship. (ϕ_S, H_S, p_S^+ etc.)
4. The waves generated by the heave motion of the ship. (ϕ_H, H_H, p_H^+ etc.)
5. The waves generated by the roll motion of the ship. (ϕ_R, H_R, p_R^+ etc.) where we have

$$\phi = \phi_W + \phi_G + \phi_S + \phi_H + \phi_R; \text{ etc.} \quad (13)$$

It should be mentioned that it is not strictly necessary for a solution to split the problem into the components described above. The solution may, of course, well be obtained by solving the complete boundary value problem described by (9) - (12). The splitting is convenient, however, since the results are rather complicated and since the effect of the individual components of the total motion has to be separated anyway later on in the equations of motion for ship.

3. DESCRIPTION OF FLOW COMPONENTS AND RESULTS

In the following we give some results for the pressures induced on the ship in each of the flow situations mentioned above. As the calculations are rather tedious it will be impossible at the space available to bring details of the derivations.

A more detailed description of the solution for the heave generated flow was given by Svendsen (1968) (who in fact considered the case of large amplitudes). For roll (point 5 in the list above) the flow problem was analysed by Svendsen et al. (1977 a), and the reflection-transmission problem (points 1 and 2) was discussed in Svendsen et al. (1977 c).

The method of solution is to write the velocity potential at $|x| \geq B/2$ for each of the flow components

$$\phi_i = e^{i(\omega t + \psi_i)} \sum_n X_{in}(x) Z_{in}(z) \quad (14)$$

and assume that in (4) and (12) U_2, W, Ω and V vary as $e^{i(\omega t + \gamma_i)}$.

a. The reflection-transmission problem

The water flow around a fixed ship in waves is sketched in Fig. 3. The wave pattern consists of the standing wave which yields the pressure

$$p_W^+ = \rho g H_i \frac{\cosh kz}{\cosh kh} \cos \omega t \quad \text{at} \quad x = -B/2 \quad (15)$$

Fig. 3 Description of wave induced flow around a fixed ship.

and the waves generated by the water flow under the hull. This flow is induced by a combination of the standing wave pressure given by (15) and the pressure from the waves generated by the flow itself. Therefore the solution to the problem involves determination of the velocity U_G beneath the hull, and since the body of water has a certain inertia (finite width of the ship) U_G is not in phase with p_W^+ and neither are the waves generated.

To illustrate the nature of the results we find for U_G

$$U_G = \frac{H_i \omega}{a^2 + b^2} e^{(b \cos \omega t + a \sin \omega t)} \quad (16)$$

where

$$e = \frac{g}{\omega^2 B} \frac{\sinh kR}{kR \cosh kh} \quad (17)$$

$$a = 1 + 8h B_W/B; \quad b = 8h A_W/B \quad (18)$$

and

$$A_W = \frac{\sinh^2 kR}{(kR)^2 (\sinh 2kh + 2kh)} \frac{R}{h} \quad (19)$$

$$B_W = \sum_n \frac{\sin^2 \sqrt{\lambda_n} R}{(\sqrt{\lambda_n} R)^2 (\sin 2\sqrt{\lambda_n} h + 2\sqrt{\lambda_n} h)} \frac{R}{h} \quad (20)$$

The parameter k is the wave number which in general satisfies the dispersion relation

$$\omega^2 - gk \tanh kh = 0 \quad (21)$$

where ω is the frequency of the incident and the generated waves, and $\sqrt{\lambda_n}$ similarly satisfies the equation

$$\omega^2 + g\sqrt{\lambda_n} \tan \sqrt{\lambda_n} h = 0 \quad (22)$$

Eq. (21) has one root whereas (22) has infinitely many roots.

The total pressures p_{WG} under the hull corresponding to the combination of the standing wave and the generated waves may then be written

$$p_{WG}^+(x, t) = 8\rho\omega h \left\{ A_W U + B_W U_G/\omega \right\} \frac{x}{B} + \rho g H_i \frac{\sinh kR}{kR \cosh kh} \cos \omega t \left(\frac{1}{2} - \frac{x}{B} \right) \quad -\frac{B}{2} \leq x \leq \frac{B}{2} \quad (23)$$

and along the sides of the hull ($x = \pm B/2$) we get (in addition to p_W in (15))

$$\begin{aligned}
 p_G^+(\frac{B}{2}, z, t) &= - p_G^+(-\frac{B}{2}, z, t) \\
 &= 4 \rho \omega h \left\{ A U \cosh kz + \sum b_n \frac{U_t}{\omega} \cos \sqrt{\lambda_n} z \right\}
 \end{aligned}
 \tag{24}$$

where

$$A = \frac{\sinh kR}{kR(\sinh 2kh + 2kh)}
 \tag{25}$$

$$b_n = \frac{\sin \sqrt{\lambda_n} R}{\sqrt{\lambda_n} R (\sin 2 \sqrt{\lambda_n} h + 2 \sqrt{\lambda_n} h)}
 \tag{26}$$

Notice that in this case where U is independent of x we find (in accordance with (the linearized version of) (5)) that p^+ varies linearly with x in the gap underneath the ship ($- B/2 < x < B/2$). It should also be mentioned that since the pressure due to (24) varies with z , which p^+ under the ship by assumption does not (see (6)), the continuity in pressures at 1-1 and 2-2 (Fig. 1), has been imposed on the mean values over R .

Figs. 4 and 5 show the variation of the pressures given by (23) (at $x = B/2$) and (24), respectively. We see that for most situations the assumption of p^+ constant over k , which led to averaging p^+ over R for the flow outside the gap, is actually quite reasonable, in particular for long waves.

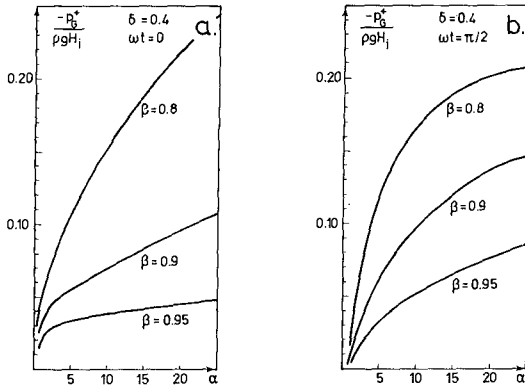

Fig. 4 Pressure variation at 2-2 versus $\alpha = g/\omega^2 h$ and $\beta = d/h$ for a fixed ship

Fig. 5 Pressure variation along the side of a fixed ship.

b. Flow and pressures induced by sway

The instantaneous flow pattern generated by a forced sway motion is shown in Fig. 6. Qualitatively this flow resembles the motion generated by the standing wave system described above, but quantitatively the problem is closer related to the flow around a piston type wave generator with a large leak at the bottom. The difference is that in our problem the width of the ship is significant which (as mentioned above) makes the inertia of the water volume beneath the hull an important factor. It causes both a change in amplitude of the waves generated, and a phase shift relative to the motion of the ship.

Fig. 6 Description of flow induced by a sway motion.

In the end the pressures on the hull corresponding to the flow will be integrated to forces which enter the equations of motion, and in principle we may envisage both horizontal and vertical forces, and moments about the center of gravity to originate from each component of motion considered. Since each of these forces or movements represents

the reaction on the ship from the surrounding water due to the motion in question and hence depends on that motion (e.g. the sway), it is crucial for the solution of the equations for the motion of the ship to express the magnitude of the above mentioned forces and moments in terms of the velocity and acceleration associated with the component of motion in question. Thus for sway the solution for the pressures on the hull is written

$$P_S^+ = f_1 \left(g/\omega^2 h, \frac{d}{h}, \frac{d}{B}, x \right) V + f_2 \left(g/\omega^2 h, \frac{d}{h}, \frac{d}{B}, x \right) V_t/\omega \quad -\frac{B}{2} \leq x \leq \frac{B}{2} \quad (27)$$

where V and V_t are instantaneous velocities and accelerations, respectively, in the sway motion.

Both Ω and W are zero for pure sway, so we see from (8) that for sway the pressure under the ship must vary linearly with x . The variation at $x = B/2$ (sect. 2-2) is shown in Fig. 7. The pressures are shown at two different times, namely at the time when $V_t = 0$ (Fig. 7 a) and at the time when $V = 0$ (Fig. 7 b). Thus the two figures give the coefficients of each of the two terms in (27). Along the side the pressure variation is a cosh kz superimposed by the classical $\cos \sqrt{\lambda_n} z$ terms also present in (24), and the same averaging of the pressures over R has again been applied in the matching procedure.

Fig. 7 Pressure variation at 2-2 versus $\alpha = g/\omega^2 h$ and $\beta = d/h$ for sway induced flow.

c. Flow and pressures induced by heave

The results for this case can be derived directly from Svendsen (1968) by linearizing with respect to W , the velocity in the heave motion. The flow is described in Fig. 8.

Fig. 8 Description of flow induced by a heave motion.

As can also be inferred from (8) the pressure under the ship varies as x^2 , because for symmetry reasons we must have $A(t) = 0$. Here we show figures with the pressure variation with x under the ship (Fig. 9) and the variation at sect. 2-2 (Fig. 10), in both cases at two different times, namely when $\dot{W}_t = 0$ (Fig. 10 a) and when $W = 0$ (Fig. 10 b). Writing again the pressures as

$$p_H^+ = g_1 W + g_2 \dot{W}_t / \omega \tag{28}$$

this means that Fig. 10 shows the two coefficients in (28) at sect. 2-2.

Fig. 9 Pressure variation under the ship induced by a heave motion.

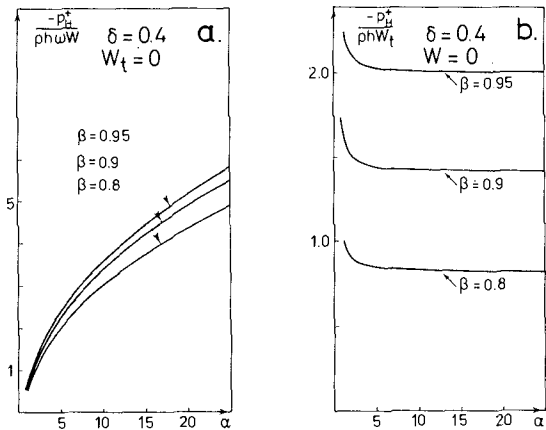

Fig. 10 Variation of pressure at 2-2 for heave induced flow.

d. Flow and pressures induced by roll

This represents by far the most complicated flow conditions. The situation is shown in Fig. 11. Whereas the flow outside the gap is more or less the same as in the previous cases we see that under the ship the direction of the flow changes at two points. The flow is illustrated quantitatively in Fig. 12 where the discharge Q is shown versus x for different phases. Two cases are shown: a typical deep water situation (Fig. 12 a) and a long wave situation (Fig. 12 b). Since $Q = UR$ we see from (4) that Q varies as x^2 . The situation is somewhat more complicated, however, because the waves generated are in antiphase which causes $A(t)$ to be non-zero which again means there is a phase difference between U and the angular velocity Ω of the roll motion (as for sway). This is particularly clear in Fig. 12 b where $U \neq 0$ when $\Omega = 0$ and the points of zero velocity are changing with time.

Fig. 11 Description of flow induced by a roll motion.

Fig. 12 Discharge Q under the ship induced by a roll motion.

Fig. 13 Pressure variation under the ship induced by a roll motion.

Fig. 13 shows the corresponding pressures which according to (8) vary as x^3 with an x component due to $A(t)$.

As in the previous cases the result for the pressure along the side of the ship contains one term varying as $\cosh kz$ and an infinite number of terms varying as $\cos \sqrt{\lambda_n} z$ (where $\sqrt{\lambda_n}$ are the solutions to (22)) which are necessary to satisfy the boundary conditions for the flow at $|x| = B/2$. All the results for roll are rather complicated and we shall omit them here.

4. WAVE INDUCED HEAVE MOTION

The equations of motion for the ship are the three components of Newton's second law corresponding to horizontal and vertical projection, and moment about an axis perpendicular to the x - z -plane through the center of gravity G .

It turns out that neither roll nor sway produce total pressure forces on the ship which has vertical components. Similarly heave does not produce net horizontal forces or forces that have a moment about G . Consequently the equation for heave (vertical projection) does not contain terms proportional to V , V_t , Ω or Ω_t and the other two equations have no terms with W or W_t . This means that heave is not coupled to

the other two degrees of freedom, and the equation for wave induced heave may be solved independently of the equations for roll and sway. This problem of wave induced heave was described in some detail by Svendsen et al. (1977 b).

When the forces are integrated as mentioned previously we find for the heave motion $z_0(t)$ the equation

$$M_H \frac{d^2 z_0}{dt^2} + S_H \frac{dz_0}{dt} + g z_0/d = g \frac{H_i}{2d} \frac{\sinh kR}{kR \cosh kh} \cos \omega t \quad (29)$$

where

$$M_H = 1 + \frac{2B}{d} B_w + \frac{B^2}{12Rd} \quad (30)$$

$$S_H = \frac{2B}{d} A_w \omega \quad (31)$$

In (30) the first term (1) represents the mass of the ship. The other two terms in (30) originate from the components of the water pressures which are proportional to W_t . Hence these two terms represent the hydrodynamical mass for the heave motion.

The coefficient S_H represents the damping of the oscillation which is linear, i.e. proportional to W . The energy dissipation described by this W -term is physically caused by the generated waves which carry energy away from the ship.

Even though the problem has been linearized it still contains the leading or dominating effect of the presence of the bottom. From (29) we can deduce that this effect emerges as a quite significant change in the resonance frequency, relative to the value we would have in deep water. The reason is that the hydrodynamic mass increases rapidly when the underkeel clearance decreases (as we shall see later).

In Fig. 14 is shown the resonance or natural frequency ω_e (undamped) nondimensionalized as $g/(\omega_e^2 h \beta)$. The deep water value for ω_e shown in the figure has been determined using the results for the hydrodynamic mass in deep water given by Andersen (1978).

The equation (29) may be solved analytically, and the result becomes

$$\left. \begin{aligned} \frac{z_0(t)}{H_i} &= \frac{\alpha(\alpha - \beta M_H)}{2(\beta^2 S_H^2 + (\alpha - \beta M_H)^2)} \frac{\sinh kR}{kR \cosh kh} \frac{\cos(\omega t + \phi)}{\cos \phi} \\ \text{where} \quad \phi &= \arctan \left(\frac{-\beta S_H}{\alpha - \beta M_H} \right) \\ \text{and} \quad \alpha &\equiv g/\omega^2 h \quad \beta = d/h \end{aligned} \right\} (32)$$

Numerical results for the amplitude of (32) are shown in Fig. 15 for three different values of β . We notice that somewhat unexpected perhaps the amplitudes generally increase as the underkeel clearance decreases.

Fig. 14 The resonance frequency ω_e for heave versus $\beta = d/h$

Fig. 15 The amplitudes of wave generated heave motion versus $\alpha = g/\omega^2 h$

5. WAVE INDUCED ROLL AND SWAY MOTION

In contrast to heave the presence of a sway motion will automatically generate a roll motion and vice versa. These two motions are even in this simple model coupled, and the corresponding two equations of motion consequently contain terms with both independent variables (simultaneous differential equations). This naturally complicates matters a great deal, but since the equations for a given incident wave are ordinary second order differential equations with constant coefficients an analytical solution is in principle straightforward. The algebra and the results are just rather complicated, so we only present the equations and numerical results for the solution. The equations may be written

$$a_1 \frac{d^2 \xi}{dt^2} + a_2 \frac{d\xi}{dt} + a_3 \xi = a_4 \frac{d^2 \theta}{dt^2} + a_5 \frac{d\theta}{dt} + a_6 \theta + a_7 \cos \omega t + a_8 \sin \omega t \quad (33)$$

$$b_1 \frac{d^2 \theta}{dt^2} + b_2 \frac{d\theta}{dt} + b_3 \theta = b_4 \frac{d^2 \xi}{dt^2} + b_5 \frac{d\xi}{dt} + b_6 \xi + b_7 \cos \omega t + b_8 \sin \omega t \quad (34)$$

where $\xi(t)$ represents the sway motion and $\theta(t)$ the roll.

The coefficients (a_i, b_i) are here functions of the parameters of the problem. Of those we have already mentioned $\delta = d/B$, $\beta = d/h$ and $\alpha = g/\omega^2 h$.

However, other parameters enter the problem too. Firstly, the coefficient a_3 which represents the restoring force in the sway motion can

only be nonzero if we introduce e.g. mooring lines. This brings two new parameters into the problem: $k_F/\rho gh$, the nondimensional stiffness of the moorings (pr. m length of the ship), and l/h the nondimensional height of the mooring point above the center of gravity (see Fig. 16). These parameters actually occur in a_3, b_3, a_6 and b_6 .

Fig. 16 The geometry of moorings and ship's stability.

Secondly, the roll motion of course depends on the stability of the ship, i.e. on the height n of the center of gravity above the bottom of the ship (Fig. 16). In the presentation of the numerical results n is nondimensionalized as $v = n/d$.

Quite obviously it is not possible numerically to map the variation of the results with all these parameters. We have therefore chosen to show the variation with what we consider the most interesting two, namely α and β , and in doing so we keep the other parameters fixed at chosen values.

Thus from stability considerations (ships usually have a metacentric height of a few metres) we have chosen $\gamma = 0.8$. For $k_F/\rho gh$ it may be shown that even a set of the stiffest steel wires cannot bring $k_F/\rho gh$ above about 0.1, and we will see that the stiffest moorings are the most interesting for our conclusions. So we show results for $k_F/\rho gh = 0.1$ only. Further we use (a little unrealistically) $l = 0$, but it may be inferred from the results that this is not so important. Finally we choose $\delta = 0.4$ which is a realistic value particularly for bulky ships as tankers or bulk carriers.

Fig. 17 then shows results for the resonance periods at different β . Since there are two degrees of freedom there are also two resonance frequencies. Each of these represents a free oscillation in which both roll and sway occur but locked together phasewise and with a fixed ratio between their amplitudes.

We notice that one of the resonance frequencies is much smaller than the other. The associated mode of resonant oscillation consists predominantly of sway. This shows that even for the stiffest moorings we can think of ($k_F/\rho gh = 0.1$) the resonance period for the sway-type mode of oscillations corresponding to very long period waves. In storm waves such waves merely occur as subharmonics. The phenomenon is quite well-known, as in harbours or model experiments with harbours particularly sway (and surge) motions often occur at a subharmonic frequency.

Fig. 17 Resonance frequencies for coupled roll and sway.

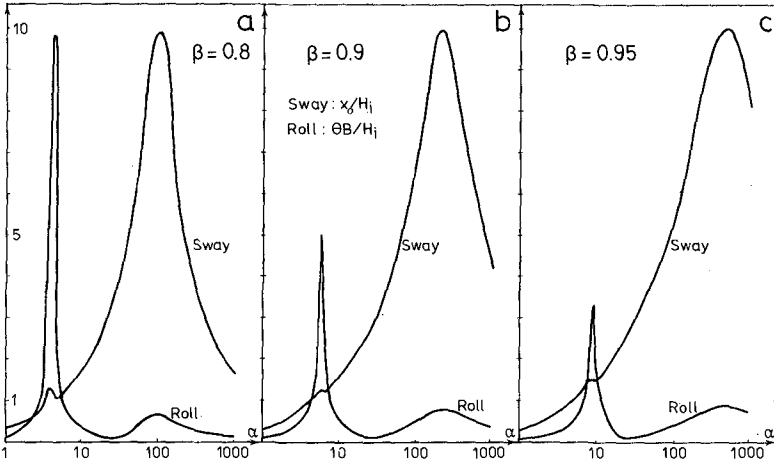

Fig. 18 The amplitudes of wave generated roll and sway.

It should be added, however, that in particular for sway the three-dimensional effects may be quite important. In a three-dimensional model the water can escape both beneath the ship and around the ends. The latter possibility is not included in our two-dimensional model, and in particular for a small underkeel clearance this will yield too large values of the hydrodynamical mass and consequently too large values of the resonance period.

Results for the wave induced amplitudes are given in Fig. 18 versus α for three different values of β .

6. HYDRODYNAMIC MASSES AND MOMENTS OF INERTIA

As was already indicated in the description of wave induced heave, one of the by-products of the solution for the water flow is the hydrodynamic masses for heave and sway and the hydrodynamic moment of inertia for roll.

These quantities represent that part of the pressure forces which is proportional to the acceleration in the motion considered. Numerical results are given in Fig. 19. The values given are relative to the ships mass or moment of inertia.

Fig. 19 Hydrodynamic masses for heave and sway, and moment of inertia for roll.

We see that in particular the hydrodynamic mass of heave (Fig. 19 a) is many times the ship's own mass and depends strongly on β , the relative draught of the ship.

The hydrodynamic moment of inertia found for roll is small — of the same order of magnitude as the ships own moment of inertia. Yet the result depends very much on β .

Both for heave and roll the results are virtually independent of α , the nondimensional wave period. This indicates that the major contribution in these cases comes from the flow underneath the ship which is consistent with the fact that when these two motions occur water is necessarily squeezed in and out of the gap.

This is not the case with sway (Fig. 19 c) where the water motion in the gap is driven entirely by the pressure from the waves generated which means that the hydrodynamic mass results from a combination of the e^{-x} -terms in the wave solution and the phase shift in that solution caused by the flow under the ship.

7. RESULTS FOR THE WAVE GENERATION

The oscillating ship acts as a wave generator, and the radiation of energy due to the waves represents the damping in the oscillations. It is therefore of interest to look at the height of the waves generated.

Fig. 20 shows numerical results for these waves for each of the three motions in question. In each of the translatory cases the wave height has been related to the amplitude of the motion, for roll to twice the amplitude $\theta_0 B$ at $x = B/2$.

Fig. 20 Height of the generated waves.

We see that in particular at a sway motion the ship is a very efficient wave generator. We also notice that the difference in wave height at sway for different values of $\beta = d/h$ indicates the influence of the flow beneath the ship (i.e. the 'leakage' in the wave generator problem).

In contrast to the less frequency dependent damping at sway, both heave and roll show a maximum damping at intermediate frequencies. The reason is that in these two cases the waves are generated almost entirely by the water flow in and out of the gap. In the case of deep water waves (small α) this is a very inefficient way of generating waves, hence the small heights. For very long waves (large α) the height of the waves will decrease to the limit given by a purely 'hydraulic' model which e.g. for heave yields

$$\frac{H}{z_0} = \alpha^{-1/2} \frac{B}{h} \quad (35)$$

This result is also shown in Fig. 20 for $\beta = 0.95$.

It should be added that of course energy is conserved also in the case of a fixed ship even though it seems as if a standing wave (to the left in Fig. 1) — which yields no net energy flux towards the ship — causes generation of progressive waves which on both sides of the ship represents an energy flux away from the ship. The reason for this paradox is that the sum of the standing wave and the wave propagating towards the left at $x < -B/2$ actually has an energy flux towards the right which is exactly the energy transmitted through the gap and away from the ship through the wave at $x > B/2$.

8. CONCLUDING REMARKS

As mentioned in § 2 the method presented in this paper is based on a number of assumptions. The validity of some of these were already discussed by Svendsen (1968) who showed by comparison with experiments for heave that the pressure underneath the hull is quite accurately described by the present model. He also found that for a certain phase interval of each wave period the pressure close to 1-1 and 2-2 may (for β close to one) be influenced by the separation of the outgoing flow from the hull of the ship (jet-like flow). However, this deviation from the assumption (iii) will only have a minor effect on the total forces. Finally the results in Fig. 5 show that the patching of the average of the pressures at 1-1 and 2-2 will be a very good approximation except perhaps for quite short wave periods.

Thus in general we must expect that the model will yield rather accurate results for the two-dimensional situations it covers.

ABSTRACT

Possible contributing factors to the 1978 failure of the massive main breakwater at Sines, Portugal are presented in a selective summary of the report of the Port Sines Investigating Panel. A failure scenario involving the impact breakage of unreinforced concrete armor units is developed.

INTRODUCTION

The final report of the Port Sines Investigating Panel is summarized in this paper. The objective of the Panel, which was funded in part by the U.S. National Science Foundation, was to collect data concerning and to evaluate possible causes of the failure on February 26, 1978, of the massive rubble mound breakwater at Port Sines, on the Atlantic coast of Portugal.

⁵Senior Project Engineer, Woodward-Clyde Consultants, San Francisco, California, U.S.A.

The breakwater at Port Sines is among the largest in the world. Further, it is situated in a previously untried combination of unusually deep water (about 50 meters at the seaward terminus) and a high-energy marine setting (the 100-year return period significant wave height was estimated to be 11 meters). Construction was nearly complete when critical damage was sustained in storm waves thought by most to be below the 11 meter significant wave height for which the structure was designed. The damage consisted of the loss of about two-thirds of the armor layer of 42 metric tons dolos units. At a few locations, the concrete superstructure was severely damaged as a result of undermining and of wave impact on the front face where loss of the dolos has occurred. Figures 1 and 2 illustrate some of the damage to the breakwater.

The structure has sustained further damage since the February 1978 storm. In December 1978 and in February 1979, storm action removed all armor protection, including some temporary remedial works placed in the fall of 1978, from the seaward 1.5 km of the breakwater. Much of the concrete superstructure has been lost.

The scope of the Panel's study, as delineated in the proposal to the National Science Foundation for the Sines investigation, covered four simplified failure possibilities: (1) that design criteria were exceeded by the February 1978 storm; (2) that the breakwater construction was faulty; (3) that the materials used for breakwater construction were sub-standard; (4) that the procedures followed during the design of the breakwater were incomplete or incorrect for this specific set of environmental conditions.

The investigation undertaken by the Panel was based on two site visits and on discussions with responsible Portuguese authorities, the design engineers, the engineers of the Portuguese hydraulic laboratory (LNEC), and the officials of the construction company. The objective of the investigation was to report on possible problems, omissions, and errors that could have contributed to the failure of the Sines breakwater. It is the hope of the Panel that engineers will be able to benefit from the experience at Sines in the design of future breakwaters.

PROJECT DESCRIPTION

The Sines breakwater is the most critical single component of a vast industrial complex planned by the Portuguese government. The Atlantic deepwater port and extensive landside facilities depend on the efficient, safe operation of the port, which in turn depends on the breakwater. Port Sines, about 100 km south of Lishon on the Atlantic coast, lies along the present international routes for crude oil and iron ore carriers. The site has the steep ocean falloff needed for a supertanker port; required depths for an oil terminal occur within 0.5 to 1.5 km of the shore.

Development of a major port at Sines involved the construction of the main breakwater in depths of up to 50 meters. A layout of the port

Figure 1 Damage to the seawall and dolos, taken immediately after the February 1978 storm (photo from GAS)

Figure 2 Dolos removed from the front of the seawall and broken dolos and superstructure
(photo from GAS)

facility is given in Figure 3. Design was begun in 1972 by a consortium (BCL) of Bertlin and Partners of the United Kingdom and Consulmar and Lusotechna, both of Lisbon; the contractor chosen was Societa Italiana per Condotte d'Acqua of Italy. Construction began in mid-1973.

The breakwater is a dual-purpose structure, supporting oil pipelines as well as providing shelter from the Atlantic for the port. A quarry fill core is armored with heavier-cut stone, and on the seaward side that "selected" stone is blanketed with 42 metric concrete dolos. A concrete superstructure includes a wave wall, an inner (portside) roadway, and support for the oil pipelines. The latter are intended to serve the three harbor-side berths, built on caissons and connected to the breakwater. The three berths, beginning with the closest to shore, are intended to accommodate 100,000, 350,000 and 500,000 DWT tankers, respectively. A cross-section of the final breakwater design is shown on Figure 4.

About 160 square miles of inland facilities also depend on the port. These included an oil refinery, a steel mill, a pyrite plant, a petrochemical complex, and other industry, both heavy and light. Yet another aspect of the master plan is a "new town", for which a population of about 100,000 has been projected. Over 5,000 dwellings are complete, and the construction of schools, recreation centers, shopping facilities and related infrastructure are all underway.

The Gabinete da Area de Sines (GAS) has been the responsible Government agency for the entire Sines development since the project inception over a decade ago. At the time of the failure in February 1978, the Portuguese government is reported to have spent \$176,000,000 on the breakwater alone.

PANEL REPORT

The report prepared by the Panel includes discussions of the project, the physical setting and environment, the design and construction of the breakwater, the storm of February 1978, the status of the breakwater after the storm, studies performed after the failure, and considerations in evaluation of the failure. The report also includes appendices containing official replies to investigative inquiries, photographs of the damaged sections, records of dolos placement, summaries of wave climate during construction, and the like. The report is currently in final review by the Coastal Engineering Research Council of the American Society of Civil Engineers and should be available to practicing engineers and other interested parties in the near future.

No attempt has been made in this paper to completely summarize the report. Rather, the following sections present factors which may have contributed to the failure of the breakwater and a failure scenario which appears to fit the available evidence. It is recommended that the report and other published information be studied carefully by coastal engineers charged with the design and construction of future major shore protection structures.

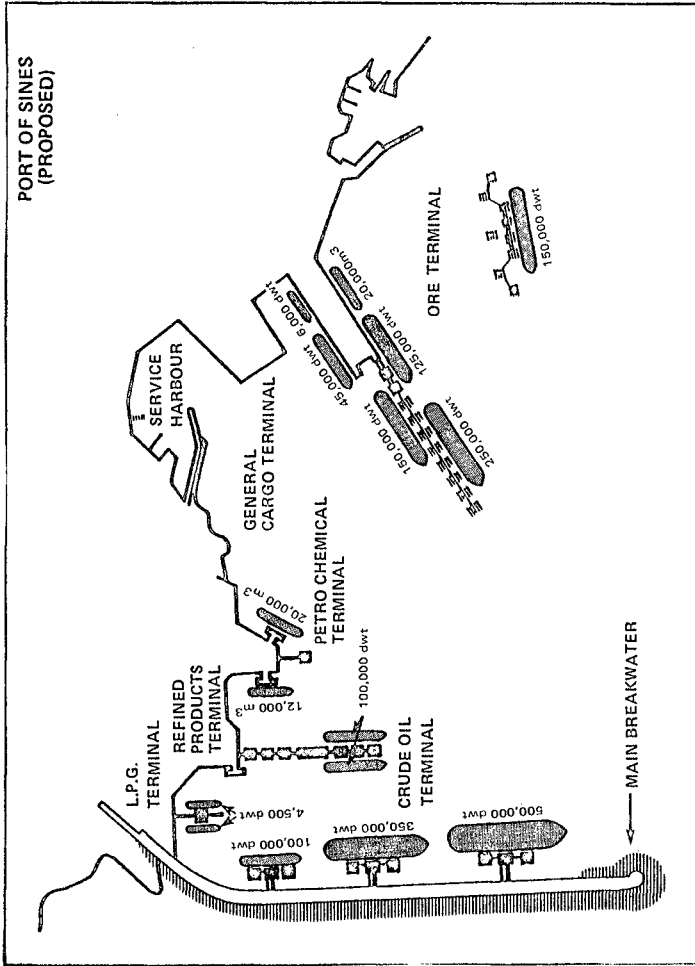

FIGURE 3 Proposed layout of the Port of Sines

Figure 4 Cross-section of the final design

POSSIBLE FACTORS CONTRIBUTING TO FAILURE

In a project this complex, there are many possibilities for uncertainties in design and construction. What follows is a compilation of possible contributing factors mentioned to or observed by the Panel. Some appear to be difficulties inherent in any large construction project; others are more specifically related to the Sines project. They are all a legitimate part of the Sines data and should be taken into account when additional study of the Sines failure is in order and when future projects of this sort are considered. It is stressed that the list of factors should not be interpreted as identifying the cause(s) of failure.

Owner-Designer-Contractor Relationships

The designer (BCL) felt the primary area of concern was that they had no control over the execution of their plans during construction. In many cases, the designer is retained for inspection purposes or is the technical agent dealing with the contractor for the client. In the case of Sines, the Gabinete da Area de Sines (GAS) retained all inspection and technical supervision of the project. It may also be important to note that all official communication was in Portuguese. This may have contributed to difficulties in communication among the English design firm, the Italian contractor, and the Portuguese authorities.

Selection of Design Waves

Wave data available for the initial design of the Sines breakwater were sparse. Even by the end of the design process only a minimal amount of wave data were available. Thus it was difficult to estimate the design wave conditions with a high level of statistical reliability. The 100-year storm design wave belongs to a different statistical population than the non-storm design wave commonly measured along the Atlantic coast of Portugal. Moreover, it is commonly accepted that the extrapolation of extreme value events should not extend more than two or three times the total length of record. Nevertheless, project demands do at times dictate that insufficient data be used. Under these conditions, the designer's recourse is to perform a detailed error or confidence analysis of the data.

The effects of refraction and wave groupings were not considered in the selection of the design wave. Zwamborn (1979) says that:

"it appears that no tests were done on the final design,... using irregular waves of sufficient duration (say 6 to 12 hours prototype) with a significant wave height equal to or exceeding the design wave height of 11 m."

Furthermore, Zwamborn cites studies done by the French hydraulic laboratory (LCHF) after the failure:

"recent tests carried out by the LCHF showed that for wave periods between 16 to 18 s and wave heights in excess of 11 m, the vertical

upward water velocity near the still water line could be the same order of magnitude as the terminal settling velocity of 42-t dolosse in still water. As a result, groups of dolosse could be lifted from the slope by these long and high waves, a phenomenon frequently observed in model tests."

Three particular items that escaped consideration in the design wave selection were: (1) climatic analysis, an overall review that would show protection of the Portuguese coast by the Azores high and show the dependency of the results of a climatic analysis on the phenomenon; (2) error analysis, identification of the accuracy of the design wave; and (3) shallow water effects on the available recorded wave data and on the waves approaching the Sines area.

Storm of February 26, 1978

As indicated in the Panel's report, it is extremely difficult to identify the size of the waves that occurred on February 26 and those that preceded that day. The data measured at Cabo da Roca indicate waves with a significant height of 8 to 9 m. Refraction analyses by LCHF indicate significantly larger waves may have occurred at the structure. Because the wave recorder was not working, an indisputable definition of the wave field will never be available.

Breakwater Design

Although the breakwater was designed using available methods, the design still may not have been sufficient to resist the forces exerted by the February 1978 storm; this is not a criticism of the design but of the available references for design. The design for this very deep site which is exposed to deep ocean waves was predicated on an extension of the procedures which were well-understood for small breakwaters in shallow water conditions. Another aspect of the design that causes some concern is the complexity of the breakwater cross-section; the section would be difficult to inspect, as well as to construct, in these extreme water depths.

Dolos Placement

One item of concern is the ability of the floating cranes to adequately place the dolos above and below the water in characteristically rough conditions. The dolos were not placed by location but by density (instead of a coordinate for a particular dolos, a certain number were to be placed in a given area). Underwater inspection of dolos placement was infrequent because of the heavy seas during most of the year. Zwamborn (1979) reports that between 3.5 and 16.8 percent of the dolos in a sampled section were broken by August 1977 as a result of placement, settlement of the structure, and/or previous storms. Arrangement of the dolos was generally random (not with 60 percent having the vertical leg seaward as specified in the design, although the significance of this criteria has been discounted).

Dolos Reinforcement

The dolos were not reinforced. Subsequent to the February 1978 storm, some reinforced units were used as a test for the outer layer of dolos, to prepare the breakwater for the coming winter; both reinforced and unreinforced units sustained extreme damage in the 1978-1979 winter. This application of reinforced armor units (of both types) should not be considered a true test of the response of the original structure to storm waves.

Model Studies

The official model studies were done by Laboratorio Nacional de Engenharia Civil (LNEC) for CAS and not for the designer. Therefore, indirect communication resulted. The results of the irregular wave tests were not available to the designer before the design was complete. The model tests did not account for the effect of wave grouping that occurs in the wave data recorded at Sines. Refraction was also not analyzed or considered in the model studies. The model tests were not designed to simulate structural properties of the dolos armor units.

Permeability of the Core

The permeability of the quarry run (TOT) material in the core may have been significantly less in some sectors than that used in the model tests and specified in the contract. This difference may have resulted in added wave run-up on the face of the breakwater; and this, in turn, may have had an adverse effect on the stability of the armor layer. It is important to recognize that the stability of the armor layer might be jeopardized by the increased wave run-up that would result from a lack of permeability of the core. The volume of both wave uprush and the return flow down the face of the breakwater would impose a greater force on the individual breakwater armor units and could cause their dislodgment from the protective layer.

OFFICIAL STATEMENTS OF CAUSE

Several investigations have been conducted, at various levels of effort, to understand and identify the causes of failure. One of the first assessments was made by a team of Dutch engineers. They concluded that a likely cause of failure was the removal of the 16 to 20 t stone from the toe by the larger waves; subsequent to the removal of these stones the dolos layer shifted and was damaged.

The National Research Institute for Oceanography, South Africa, noted the cause of failure as follows:

"...the main causes of the damage and part failure of the Sines main breakwater during the February 1978 storm are the particularly damaging effect of the large waves in the spectrum which, because of the great water depth in front of the breakwater, could reach the structure without being reduced by prior breaking.

With a probable incident significant wave height during the peak of the storm of 9.5 to 10 m, maximum incident wave heights of at least 14 to 17 m must have occurred which, although infrequent, caused excessive movements of dolosse, probably resulting in breakages, particularly at and just below the still water level, thereby weakening the armor. In addition, the wave heights of the longer waves (peak periods at the height of the storm were 18 to 20 s) were locally increased due to wave refraction causing both the significant and the maximum wave heights in the failure areas to increase by, on average, 20 percent, that is to about 12 m and 17 to 20 m, respectively. These waves resulted in the removal and further breakage of the dolosse causing the collapse of the superstructure in the failure areas." (Zwamborn, 1979).

The official comments from the design team (BCL) have been included in the Panel's report. In these comments the problem is focused on project management, supervision, and construction. Mr. Peter Mornement of Bertlin & Partners, in an interview with the New Civil Engineer, said "we are sure inaccurate placing of the dolos and the supporting toe were the main causes of failure."

The official Portuguese investigation team filed their report with the Government in April 1979. Some of their conclusions are presented below:

- o Structural fragility of the dolos was the primary cause of failure.
- o There were serious shortcomings in the design wave selection.
- o The design of the breakwater was "theoretical" and difficult to build.
- o Consideration was not given to refraction of wave energy.
- o The LNEC was not exhaustive enough in its testing program.
- o The reliability of the dolos should have been questioned.
- o Gabinete da Area de Sines did not have the capability to plan and execute a marine project of such magnitude.
- o There were shortcomings in the management and supervision of the project by CAS.
- o LNEC should have had a more active role in the design phase.

A FAILURE SCENARIO

The causes of failure and the sequence of events leading to the failed armor layer during the storm of February 26, 1978 will never be

completely defined. This is because of the scarcity of information concerning the exact state of the structure prior to the storm, the wave conditions at the breakwater during the storm, and the condition of the breakwater during the storm. Many explanations of the cause of failure have been proposed, and the state of the breakwater following the storm was such that any number of events might have caused or contributed to the failure.

A description of the probable pattern of events leading to the destruction of the armor layer is proposed by the authors. The critical observations leading to the failure scenario are those on the extensive breakage of the dolos, the profile of the damaged breakwater, the model tests with irregular waves which showed rocking of dolos, the model tests with the artificially weakened dolos, and personal experiences with other breakwaters. It is the Panel's opinion that this description is plausible in that it fits with the available evidence. It is recognized that other failure scenarios can be proposed from the available data.

In the early stages of the storm, when the significant wave height reached 6 m, some dolos units began to move in the vicinity of the mean water level. These units were the ones which had been placed in a relatively unstable position and had little support from the adjacent units. (It is practically impossible to place dolos so that every unit is in a stable position.) The initial movements occurred when a larger wave ran up through the armor layer.

As the wave height and period increased, the movements became more severe and the units were accelerated to the velocity of the uprushing wave. The following impact with adjacent units produced stresses in the units that exceeded the strength of concrete. This resulted in breakage, and frequently the pieces were carried away by the uprushing or downrushing wave. During this process, the pieces themselves collided with other units, in some cases causing additional breakage.

At the peak of the storm, when the significant wave height exceeded 8 m, a large number of units located just below the water level broke. As the pieces were carried away, adjacent units were free to move and a rapid disintegration of the armor layer occurred. Initially the greatest damage occurred immediately below the mean water level. The broken pieces were moved by water motion and gravity from the armor layer to the lower part of the mound. The slope of the seaward side of the breakwater below the water level then became flatter.

During the final stages of the storm the armor layer was completely removed at some locations. The broken dolos pieces were displaced to the base of the armor layer and the underlying stone layers were exposed. Wave action then moved these exposed stones over the broken dolos pieces. Continuing wave action eroded the core material and began to undermine the superstructure.

As the concrete superstructure was undermined it tilted forward. In some instances, the structure broke in the base (where the pipelines carrying petroleum from the berths to shore would be located) and at some of these locations the wave wall at the top of the structure was snapped off and thrown back as a result of wave impact.

The reasoning leading to the above scenario of the failure of the Sines breakwater suggests the following:

- o The dolos units rocked, broke and moved in the armor layer under the wave conditions that existed during the storm of February 26, 1978.
- o The dolos units were of sufficient strength to withstand the forces of wave action except when they moved. In movement, however, they were unable to resist the impact stresses produced.

Support for the argument that the damage occurred as a result of breakage of dolos units is provided by model studies, prototype testing of dolos strength, and observation of damage to the Sines and other breakwaters.

CONCLUSIONS

In recent years, coastal and nearshore rubble mound structures (both proposed and constructed) have become much more massive and have been sited in deeper water than ever before. Examples of this sort of structure include breakwaters for petroleum terminals and offshore power plants and artificial islands for petroleum exploration and production facilities.

For critical facilities such as these, many traditional assumptions of rubble mound design and construction are being reexamined in response to environmental and safety concerns and the harsh economic consequences which accompany disruptions in energy supplies. One example of the design profession's recognition of these concerns is the recent emphasis on the evaluation of extreme wave conditions and their potential effect on the integrity of the structure, especially in cases where concrete armor units are utilized; another is the renewed interest in the management of design, construction, and inspection services.

The case history of the failure of the main breakwater at Port Sines is believed to be an important addition to coastal engineering knowledge. The members of the Panel hope that engineers will be able to benefit from the Sines experience in the design and construction of future breakwaters.

ACKNOWLEDGEMENTS

The efforts of the Port Sines Investigating Panel were made possible by the U.S. National Science Foundation under NSF Grant No. OP A78-18769;

special appreciation is given to those NSF staff members who expedited the normal review procedures. The Coastal Engineering Research Council of the American Society of Civil Engineers, represented by chairman M.P. O'Brien and vice-chairman R.L. Wiegel, recognized the need for the study and identified sources of support for the Panel. The efforts of Virginia Fairweather of ASCE also deserve special mention.

The cooperation of the following firms and organizations in sharing information and the results of special studies is gratefully acknowledged: Department of Public Works, Canada; National Research Council, Canada; Bertlin & Partners, U.K.; Institute of Oceanographic Sciences, U.K.; Gabinete da Area de Sines, Lisbon; Portuguese Investigating Commission, Lisbon; Societa Italiana per Condotte d'Acqua, Rome; Laboratorio Nacional de Engenharia Civil, Lisbon; Laboratoire Central d'Hydraulique de France; Consulmar, Lisbon; and the United States Nuclear Regulatory Commission.

Significant support in terms of staff time and other services was provided by: the American Society of Civil Engineers, New York; Woodward-Clyde Consultants, San Francisco; Clemson University, Clemson, South Carolina; Dames & Moore, Washington, D.C. and the U.S. Army Corps of Engineers, San Francisco.

DISCRETE-TIME MODELLING OF DISPERSION IN ESTUARIES

T. WOOD

Senior Lecturer, Department of Chemical Engineering,
The University of Sydney, N.S.W. 2006 Australia.

1 INTRODUCTION

This paper aims to put forward a case in favour of a simple discrete-time model describing mixing in an estuary. The model derives from the remarkably simple concepts developed by Ketchum (1951 a,b) which describe mixing in terms of tidal prism exchanges between segments. The author's view is that Ketchum's ideas were abandoned before they were fully explored. A major factor was the advent of the high-speed computer which opened up the possibility of using an approach based on the space-time formulation of the problem in terms of the partial differential equations of transport theory.

Intrinsically this approach, based on a continuum description, is more attractive than a gross description based on relatively large segments: one obvious reason is the possibility of providing a comprehensive space-time prediction of the spread of a pollutant. In practice, though, significant problems arise in its use: in particular, the following can be mentioned -

- a) substantial computing costs relating to computer program development and machine time
- b) specification of transport parameters inherent in the partial differential equations of transport: for example, dispersion coefficients
- c) model validation and state/parameter estimation.

The last of these is the primary concern of this paper. It is probably true to say that, to date, too little attention has been given to these topics, in the context of estuarine modelling. The point to be made is that there is small justification in using a sophisticated description of a system if the resulting predictions of the model cannot be effectively validated.

The ideas used in this paper stem from those put forward by Beck and Young (1975) in studies on non-tidal river pollution. The subsequent discussion suggests an extension to estuarine systems.

2 BASIS OF THE PROPOSED MODEL

A complete description of the proposed model can be found in the published paper by Wood (1979). Only the essentials relevant to the subsequent discussion in this paper are presented here, namely, the segmentation procedure and the exchanges between segments.

2.1 Segmentation

The estuary is segmented sequentially from the fresh water end. Segment (1) is always fresh; thereafter a progressive increase in salinity takes place through segments (2), (3), ..., (n). The high tide volumes H_i , and the low-tide volumes L_i , are determined from the fresh water input R per tidal cycle (assumed known) and the hydrography of the estuary, as follows -

$$L_i = R \quad (1a)$$

$$L_i = H_{i-1} \quad (1b)$$

Thus, except for segment (1), the low-tide volume of any segment is equal to the high-tide volume of its upstream neighbour.

2.2 Exchanges Between Segments

As a consequence of the chosen segmentation procedure, water is exchanged over a tidal cycle between a segment and its nearest neighbours. Thus the high-tide volume, H_i , of segment (i) is distributed over a tidal cycle, as follows -

$v_{i-1,i}$: the volume transferred to segment (i-1) from segment (i)

$v_{i,i}$: the volume returned to segment (i)

$v_{i+1,i}$: the volume transferred to segment (i+1) from segment (i)

Each volume of water carries with it the salinity, s_i , of its origin. Therefore, from one high-tide to the next, the discrete-time model describing salinity distribution changes is as follows -

$$H_i s_i(k) = v_{i,i-1} s_{i-1}(k-1) + v_{i,i} s_i(k-1) + v_{i,i+1} s_{i+1}(k-1) \quad (2)$$

where $i = 2$ to $n - 1$

and k is a time index based on a tidal cycle.

3 STATE/PARAMETER ESTIMATION

The principal point to be made in this paper is that the discrete-time model proposed in the previous section is directly amenable to the techniques of state and parameter estimation formulated by Kalman (1960). The mathematical background is too extensive to be discussed here and, indeed, the main purpose is to demonstrate what can be achieved by using these techniques, rather than to put forward an exposition of the mathematics per se. Excellent accounts are available in texts by Eykhoff (1974) and Jazwinski (1970).

3.1 The Defining Equations

The following equations describe the change in the state vector of salinity, \underline{s} , at discrete-time intervals and the relationship between the vector of salinity measurements, \underline{z} , and the salinity vector -

$$\text{Model Equation: } \underline{s}(k+1) = T.\underline{s}(k) + \underline{n}(k) \quad (3a)$$

$$\text{Measurement Equation: } \underline{z}(k) = M.\underline{s}(k) + \underline{e}(k) \quad (3b)$$

\underline{s} : (nx1) vector describing salinity distribution
 T : (nxn) matrix describing exchanges between segments
 \underline{n} : (nx1) vector of model error (Gaussian)
 \underline{z} : (mx1) vector of measured salinities
 M : (mxn) matrix relating measurement to salinity
 \underline{e} : (mx1) vector of measurement error (Gaussian)
 k : an index of discrete-time

3.2 The Kalman Filter: State Estimation

The Kalman Filter provides an estimate of the salinity vector at each time interval, based upon the measurements received up to that time. The procedure is recursive in that an updated estimate can readily be made each time new measurement information is received, based on the previous estimate and the new information. This scheme of sequential updating of estimates is particularly well suited to a system which is monitored in a regular way.

Kalman's solution to the problem of recursive state estimation assumes that the statistical properties of the vectors $\underline{n}(k)$ and $\underline{e}(k)$, representing system and measurement noise respectively, are known and described by -

$$\begin{aligned} E[\underline{n}(k)] &= E[\underline{e}(k)] = 0 \\ E[\underline{n}(k) \underline{n}(j)] &= Q \delta_{kj} \\ E[\underline{e}(k) \underline{e}(j)] &= R \delta_{kj} \\ E[\underline{n}(k) \underline{e}(j)] &= 0 \text{ for all } k, j \end{aligned} \quad (3c)$$

The following two-stage filter estimation algorithm can now be deduced -

Stage 1 - Prediction

$$\begin{aligned} \hat{\underline{s}}(k, k-1) &= T \hat{\underline{s}}(k) \\ P(k, k-1) &= T P(k-1) T + Q \end{aligned}$$

Stage 2 - Correction

$$\begin{aligned} \hat{\underline{s}}(k) &= \hat{\underline{s}}(k, k-1) + P(k, k-1) \begin{matrix} 1 \\ M \end{matrix} [M P(k, k-1) \begin{matrix} 1 \\ M + R \end{matrix}]^{-1} [\underline{z}(k) - M \hat{\underline{s}}(k, k-1)] \\ P(k) &= P(k, k-1) - P(k, k-1) \begin{matrix} 1 \\ M \end{matrix} [M P(k, k-1) \begin{matrix} 1 \\ M + R \end{matrix}]^{-1} M P(k, k-1) \end{aligned} \quad (3c)$$

where $\hat{\underline{s}}(k, k-1)$ is the first-stage estimate of the salinity distribution, previous estimate $\hat{\underline{s}}(k-1)$

$P(k, k-1)$ is the covariance matrix of the estimation error with $\hat{\underline{s}}(k, k-1)$

$\hat{\underline{s}}(k)$ is the second-stage estimate, based on the first-stage estimate $\hat{\underline{s}}(k, k-1)$ and the latest measurement information $\underline{z}(k)$

$P(k)$ is the covariance matrix of the estimation error associated with $\hat{\underline{s}}(k)$

The second-stage estimates $\hat{\underline{s}}(k)$, $P(k)$ for the k th time instant are therefore based on the complete data set collected between instants 1 and k .

3.3 The Extended Kalman Filter: State-Parameter Estimation

In many practical problems, the matrix appearing in the model equation cannot be specified because some of its elements are unknown. In the context of the dispersion model, the T matrix describing the exchanges between segments contains unknowns which have to be estimated from salinity measurements. The estimation problem then extends to the unknown parameters of the T matrix as well as the state vector of salinities mentioned in the previous section. The approach adopted essentially involves reformulating the defining equations (3a) and (3b) in terms of an augmented vector which contains as its elements the salinity vector elements and the unknown parameters. A simple example in the next section demonstrates the principle but for a comprehensive account of the technique the reader should consult the references previously mentioned, Eykhoff (1974) and Jazwinski (1970).

4 SIMPLE EXAMPLE OF THE APPLICATION OF STATE/PARAMETER ESTIMATION

A simple 4-segment example is used to demonstrate the use of the proposed discrete-time model and the application of the Kalman filter. Segment (1) is completely fresh at all times and segment (4) is completely saline at all times ($s_1 = 0$, $s_4 = 1$ all values of k). The transition matrix, T , in equation (3a) is -

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ t_{21} & t_{22} & t_{23} & 0 \\ 0 & t_{32} & t_{33} & t_{34} \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

where $t_{ij} = v_{ij}/H_i$

Various categories of problem can be analysed, as described below.

4.1 State Estimation Only (all elements of T known).

4.1.1 Segments (2) and (3) monitored.

The Kalman filter provides estimates $\hat{s}_2(k)$, $\hat{s}_3(k)$ of the salinities in segments (2) and (3) from a sequence of monitored salinities $z_2(p)$, $z_3(p)$, for $p = 1$ to k . The measurement matrix, M, is

$$\begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

4.1.2 Either segment (2) or segment (3) monitored.

The Kalman filter provides estimates $\hat{s}_2(k)$, $\hat{s}_3(k)$ from a sequence of monitored salinities: either $z_2(p)$ or $z_3(p)$, for $p = 1$ to k . The measurement matrix, M, is -

$$\text{either } \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \quad \text{or} \quad \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

Segment (2) monitored

Segment (3) monitored

4.1.3 A numerical example of state estimation

Consider a system with a T matrix specified as -

$$T = \begin{vmatrix} 1 & 0 & 0 & 0 \\ 0.5 & 0.3 & 0.2 & 0 \\ 0 & 0.35 & 0.45 & 0.2 \\ 0 & 0 & 0 & 1 \end{vmatrix}$$

Let the covariance matrices Q, R representing the system noise and the measurement noise, respectively, be -

$$Q = R = \begin{vmatrix} 0 & 0 & 0 & 0 \\ 0 & 4 \times 10^{-4} & 0 & 0 \\ 0 & 0 & 4 \times 10^{-4} & 0 \\ 0 & 0 & 0 & 0 \end{vmatrix}$$

Then, given a set of monitored salinities at successive sampling instants $k = 1, 2, \dots, 10$, for segments (2) and (3), the recursive estimates for the true salinities s_2, s_3 can be obtained using the Kalman Filter algorithm. Table 1 summarizes the results.

TABLE 1

k	z_2	\hat{s}_2	$P_{22} \times 10^3$	z_3	\hat{s}_3	$P_{33} \times 10^3$
1	0.526	0.499	3.94	1.02	1.02	0.398
2	0.358	0.326	0.626	0.753	0.775	0.289
3	0.254	0.252	0.470	0.660	0.661	0.237
4	0.197	0.209	0.451	0.594	0.590	0.226

10	0.130	0.134	0.447	0.476	0.470	0.224

k is the discrete sampling time index, based on an interval of a tidal cycle

z_2, z_3 are the monitored salinities in segments (2), (3) (relative to sea water as unity).

\hat{s}_2, \hat{s}_3 are the filtered estimates of the relative salinities in segments (2), (3).

P_{22}, P_{33} are the variances associated with the filtered estimates.

4.2 State/Parameter Estimation (some elements of T unknown)

4.2.1 Dimension of the problem

Although it would appear that there are six nonzero elements to be specified in the T matrix, only two need, in fact, to be estimated. The element t_{21} is fixed by the fresh water flow from segment (1) to segment (2). Also the following relationship for the exchanges between neighbouring segments leaves only two elements unknown -

$$H_i = v_{i,i-1} + v_{i,i} + v_{i,i+1} = v_{i-1,i} + v_{i,i} + v_{i+1,i} \quad (4)$$

where $i = 2$ to $n - 1$

Therefore in the 4-segment example there are two states and two parameters to be estimated: $\hat{s}_2, \hat{s}_3, \hat{t}_{22}, \hat{t}_{33}$.

4.2.2 The augmented state vector

The state vector $(0 \ s_1 \ s_2 \ 1)^T$ is augmented with the two unknown parameters t_{22}, t_{33} to yield $(0 \ s_1 \ s_2 \ 1 \ t_{22} \ t_{33})^T$. Let the augmented vector be designated \underline{x} . The defining equations can then be reformulated as follows -

$$\text{Model Equation:} \quad \underline{x}(k+1) = T\underline{x}(k) + \underline{n}'(k) \quad (5a)$$

$$\text{Measurement Equation:} \quad \underline{z}(k) = C\underline{x}(k) + \underline{e}'(k) \quad (5b)$$

The problem now becomes non-linear because some of the elements of T' contain elements of the augmented vector \underline{x} . After each estimate of the augmented vector $\hat{\underline{x}}$ the matrix T' is accordingly updated. Apart from this the Extended Kalman Filter follows the same algorithms as before, so that monitored salinities in segment (2) and/or segment (3) can provide recursive estimates of $\hat{s}_2, \hat{s}_3, \hat{t}_{22}$ and \hat{t}_{33} .

4.2.3 A numerical example of state/parameter estimation

As explained above, the T matrix contains effectively two unknown elements, and these are to be estimated in addition to the salinity values in segments (2),(3). The T matrix itself must therefore be updated at the beginning of each cycle of the Kalman Filtering process, using the best available estimates for $\hat{t}_{22}, \hat{t}_{33}$. At the beginning of the calculation, the initial values for the elements of the augmented vector \underline{x} and its associated error covariance matrix P must be guessed.

Consider a system with noise covariance matrices Q, R (for the model and measurements respectively), as follows -

$$Q \text{ Matrix (diagonal terms): } 0 \quad 9 \times 10^{-4} \quad 9 \times 10^{-4} \quad 0 \quad 0 \quad 0$$

$$R \text{ Matrix (diagonal terms): } 0 \quad 4 \times 10^{-4} \quad 4 \times 10^{-4} \quad 0 \quad 0 \quad 0$$

(all off-diagonal terms are zero).

Let the initial guesses for the augmented vector \underline{x} and its associated error covariance matrix P , be as follows -

$$\begin{array}{l} \underline{x}(0): \quad 0 \quad 0.5 \quad 0.5 \quad 1 \quad 0.5 \quad 0.5 \\ P(0): \quad 0 \quad 10 \quad 10 \quad 0 \quad 10 \quad 10 \end{array}$$

(diagonal terms only; off-diagonal terms zero)

Table 2 summarizes the filtered estimates from a sequence of monitored salinity values z_2, z_3 in segments (2), (3).

5 DISCUSSION

The potential advantage to be gained from using a discrete-time modelling approach to dispersion studies in estuaries would appear to lie in the area of model validation, and in particular in state/parameter estimation. The principal disadvantage is the trade-off of model accuracy, whereby the less rigorous, spatially segmented, discrete-time description is adopted in place of a continuum model in continuous time, in favour of a well-proven approach to system identification in the form of Kalman filtering. Clearly, the issue is far from proven either way, and only a series of thorough assessments based on actual case studies will indicate which is the more fruitful approach.

The principal merits of the discrete-time model are related to the principal features of the Kalman Filter, as follows -

- a) The procedure is recursive whereby the latest estimates are obtained from the most recent estimates and the latest available measurement information.

- b) The Kalman Filter algorithms incorporate measures of the uncertainties inherent in the model equations and the measured data.
- c) The method can be applied to a partially monitored system which is an important factor when resources of manpower and money are limited.
- d) The method provides a continuous updating of estimates and the errors associated with the estimates.
- e) The method offers a consistent approach to parameter estimation which is undoubtedly the key problem in modelling studies.

MEASUREMENTS OF OSCILLATORY DRAG ON SAND RIPPLES

Karl E. B. Lofquist
National Bureau of Standards
Washington, D.C.

ABSTRACT

Measurements have been made of drag on naturally rippled sand beds in an oscillatory-flow water tunnel. A partition splits the tunnel into two parallel channels with equal cross sections and volume rates of flow, one with a smooth flat rigid bottom and the other containing the sand bed. Roughly, the difference in the two bottom drags, the one known, is equal to the difference in the net pressure forces on the water in the two channels, which is obtained from measurements of pressure differences across the partition at each end of the sand bed. Each experiment provides the drag, or average bottom stress, on the rippled sand bed as a function of the phase, θ , of the sinusoidal flow. From a first set of thirteen experiments with a medium sand, a stress coefficient, $f(\theta)$, is presented in three families of curves which explore the additional effects of flow velocity, ripple length, and deviations of the ripple profile from normal equilibrium. Average rates of energy dissipation are calculated. Results show f to be a complicated function of θ and other parameters. In particular, the instantaneous stress is not simply related to the instantaneous velocity. Some salient features of $f(\theta)$ are described, qualitatively, by a simple model.

I. INTRODUCTION

1. General

Water waves on the sea surface and sand ripples on the sea bed interact by processes of drag. Surface waves provide an oscillatory flow above the bed which produces and maintains bed forms by local movements of sand. The sand is scoured from the bed by tangential stresses under flows which include separation and vortex formation and which largely are shaped by the pressure field around the bed form. This field produces a distribution of normal stress over the surface of the bed. The horizontal force of these tangential and normal stresses on a large area of the bed, divided by that area, defines the average bottom stress. This is a function of time which becomes periodic as the bed forms become stable. When the bed form is two dimensional and periodic in space, the bottom stress is obtained by an average over a single ripple length. The reverse effect of the ripples on the surface waves is less direct and relatively minor, but is significant. The bottom stress combines with the oscillatory flow above the bed to dissipate energy. Ultimately, this energy is supplied by the surface waves which decay in the process. Also, the bottom stress is a factor in the refraction of surface waves. This paper describes laboratory measurements of bottom stress on naturally rippled sand beds as function of time.

2. Definition of Terms

Terms introduced in the preceding paragraph with others to be used in this study are defined by a few equations. Above the bed and beyond its effects the velocity of flow is

$$u_{\infty} = \left(\frac{2\pi a}{T} \right) \sin \left(\frac{2\pi t}{T} \right) = U \sin \theta \quad (1)$$

where t is the time, T is the period and $2a$ is the orbital diameter of the water motion. Equation (1) defines the maximum velocity, U , and the phase, θ . The bed surface profile, assumed two dimensional and periodic with length λ , has elevation $h(x, \theta)$, where x is the horizontal coordinate. The average bottom stress is then defined by

$$\bar{\tau}(\theta) = \frac{1}{\lambda} \int_0^{\lambda} \left[\tau_h + (p_h - p_{\infty}) \frac{\partial h}{\partial x} \right] dx \quad (2)$$

where τ_h is the local tangential stress on the bed, and $(p_h - p_{\infty})$ is the difference between pressures at the bed surface and at any fixed elevation beyond the influence of the bed. Separate integrals for the two terms in the integrand would resolve $\bar{\tau}(\theta)$ into components expressing the effects of tangential and normal stresses, the latter being a form drag. However, such a separation is generally impossible. A stress coefficient,

$$f(\theta) = \frac{2 \bar{\tau}(\theta)}{\rho U^2} \quad (3)$$

where ρ is the density of the water, has been made dimensionless by dividing by ρU^2 , rather than by $\rho u_{\infty}^2(\theta)$, in order to keep $f(\theta)$ proportional to $\bar{\tau}(\theta)$ throughout the cycle. The maximum of $f(\theta)$ is denoted f_m . The energy dissipated per unit area of bed per period, or twice that per half period, is given by

$$\Delta E = 2 \int_0^{T/2} \bar{\tau} u_{\infty} dt \quad (4)$$

Then, inserting equations (1) and (3) into equation (4) and defining the average coefficient,

$$\bar{f}_1 = \frac{1}{\pi} \int_0^{\pi} f(\theta) \sin \theta d\theta \quad (5)$$

produces,

$$\frac{\Delta E}{T} = \rho \frac{U^3}{2} \bar{f}_1 \quad (6)$$

Thus, the rate of energy dissipation is proportional to \bar{f}_1 .

3. Past Work

In the past, $f(\theta)$, f_m and \bar{f}_1 have been measured or estimated by various methods. These methods are here divided into two groups according to whether the surface of the bed was (1) artificially rigid or (2) naturally rippled.

(1) With rigid surfaces: Bagnold (1946) calculated \bar{f}_1 by the work needed to oscillate a metal cusp-shaped profile in still water. Kalkanis (1964) oscillated roughened plates in still water and observed flows which could be analyzed to provide $f(\theta)$. Using oscillatory-flow water tunnels, Jonsson and Carlsen (1976), in two experiments, measured velocity profiles over a flat roughened bed to obtain $f(\theta)$, while Kamphuis (1975) obtained f_m on a roughened shear plate in terms of relative grain roughness and a Reynolds number.

(2) With naturally rippled beds, \bar{f}_1 only has been obtained. By observation of the decay of surface waves, \bar{f}_1 has been calculated, in wave tanks, by Savage (1953) and by Inman and Bowen (1962) and, in field studies, by Bretschneider (1954) and by Iwagaki and Kakinuma (1967). Values of \bar{f}_1 from these field studies are summarized by Vitale (1979) and vary widely. Carstens, Neilson and Altinbilek (1969) measured the energy input required to maintain flows over sand beds in an oscillatory-flow tunnel restricted to a single period of 3.56 seconds and, within this limitation, presented \bar{f}_1 as function of grain size, D , and of a/D . Vitale (1979) has further analyzed and interpreted their results.

In sum, except with rigid flat roughened beds, measurements of bottom drag remain fragmentary. In particular, no previous measurements of $f(\theta)$ with naturally rippled beds have been reported.

4. Scope of the Present Study

To help fill this gap, the present study measures $f(\theta)$ in laboratory experiments with naturally rippled sand beds. Experiments are still in progress, but results from thirteen of them are presented, and preliminary conclusions are drawn. Values of \bar{f}_1 are calculated, and some features of $f(\theta)$ are discussed in terms of a simple model.

II. EQUIPMENT AND PROCEDURES

1. The Tunnel and its Modifications

The experiments are carried out in an oscillatory-flow water tunnel described by Lofquist (1977). Briefly, it is of U-tube design, and two tight fitting pistons in cylinders, side by side at one end, moving sinusoidally in unison, drive water back and forth through a horizontal test section and into and out of two reservoirs open to the air at the other end. The test section is 255 cm long, 21 cm wide, and has a mean depth of flow of 30 cm. The orbital diameter, $2a$, and the period, T , can be selected arbitrarily below 250 cm and above, approximately, 1.5 seconds. Ranges in the present experiments are: $34.8 \text{ cm} < 2a < 76.6 \text{ cm}$, and $2.70 \text{ s} < T < 5.93 \text{ s}$.

Figure 1. Schematic drawings of the tunnel and test section, (a) side view, (b) top view, (c) details of the two ends.

The tunnel has been modified for the present study as shown in the three schematic drawings of Figure 1(a),(b),(c). Of these, only (c) is drawn to scale. The channel has been split into two channels, each 10.1 cm wide, by a vertical partition (Fig.1,b). This partition separates each side from the other all the way from the pistons, at the right, to a point beyond the left end of the test section where the partition ends at a screen and there is a bypass over the channel top (Fig.1,c). (A screened bypass enlargement was cut in the partition just before the last three experiments.) One channel has a flat smooth metal bottom, while the other contains the rippled sand bed (Fig.1,b). In both channels, beyond the test section at either end, pressure taps have been mounted in the channel walls. These are indicated in all the drawings. A pitot tube has also been mounted which can be raised and lowered and which, with oppositely directed openings at its tip serving alternately as static and dynamic holes, can measure continuously the velocity of the reversing flow. The pressure taps in the walls and the pitot tube openings are connected to two differential pressure transducers which are located as indicated in Figure 1,(a). The connecting conduits are not shown. The purpose of these modifications will appear in the derivation of the stress measurement in section II,3 below.

2. End Conditions, Natural and Strained Profiles

The analysis in section II,3 requires that the areas of the four cross sections at the pressure taps be equal, so that migrations of the sand profiles into the conduits must be prevented. Therefore, rigid crest-shaped objects have been mounted at each end of the sand bed and, also, just before the first screens in order to stabilize the profiles and to keep the floor below the taps free of sand. These objects are shown in Figure 1,(c). The rigid crests at the ends of the bed are either of two sizes, selected best to match the sand crests between them. These rigid end crests condition the profiles since the number of sand ripple crests between them is some integer, M , and the fixed distance between them must equal $\lambda(M+1)$. Studies have shown (Lofquist, 1978, Fig. 22 and, more fully, Brebner, elsewhere in these proceedings) that an unconstrained two-dimensional profile adjusts λ/a to a natural value $(\lambda/a)_n$ which is a function of the degree of sand agitation and grain size but for low and moderate agitation is approximately equal to 1.33. Thus, in the tunnel, with λ and a selected such that $\lambda/a = (\lambda/a)_n$, the rigid end crests create minimum distortion of the sand profile between them.

With λ fixed by a selected number of sand ripple crests between the fixed end crests, it is possible, by varying a , deliberately to force λ/a away from $(\lambda/a)_n$ and so to produce a "strained" profile. Such profiles are described by Lofquist (1978), V,5. Briefly, as λ/a is reduced below 1.33, crests steepen and the profile appears "compressed" until at around $\lambda/a = 1.1$ somewhere a crest shrinks and disappears, and λ abruptly increases. As λ/a is increased above 1.33, crests flatten and the profile appears "extended", with low humps forming in the troughs, until at around $\lambda/a = 1.6$ one of these humps rises to become a new crest, and λ abruptly decreases. The deliberate variation of λ/a permits an investigation of the effect of profile strain on $f(\theta)$ and whether a natural profile gives $f(\theta)$ any special character.

3. Derivation of the Measurement of Stress

A simple analysis provides the average stress on the sand bed in terms of the pressures at the four taps and the velocity profiles measured by the pitot tube. Symbols used in the analysis are identified as applying either to the channel with the sand bed or with the smooth bottom by a subscript "s" or "o" respectively. These symbols are: L, H and b, the length, depth and width of the channels (the same for each); p(0) and p(L), the pressures at the taps at x = 0 and L; $\bar{\tau}$ and $\bar{\tau}_p$, the average stresses on the bottom and on the smooth perimeter of the walls and top; Q, the volume rate of flow; \bar{u}^2 , the average of u^2 over a cross section, where u is the local velocity.

Then, by momentum balance in each of the channels,

$$bH [p(0)-p(L)]_s - bL \bar{\tau}_s - L(2H+b) \bar{\tau}_{ps} = \rho L \dot{Q}_s + \rho bH [\bar{u}^2(L) - \bar{u}^2(0)]_s \quad (7)$$

and

$$bH [p(0)-p(L)]_o - bL \bar{\tau}_o - L(2H+b) \bar{\tau}_{po} = \rho L \dot{Q}_o + \rho bH [\bar{u}^2(L) - \bar{u}^2(0)]_o \quad (8)$$

where a dot denotes a derivative with respect to time. Since \dot{Q}_s is known and $\bar{\tau}_{ps}$ can be estimated, $\bar{\tau}_s$ can, in principle, be determined by equation (7). This approach was attempted before the channel was divided. But each side of equation (7) is dominated by its first term, and $L\bar{\tau}_s$ is easily obscured by noise and scatter in measurements of $H[p(0)-p(L)]_s$. Instead, equation (7) is subtracted from equation (8). In doing so, $\dot{Q}_o - \dot{Q}_s$ vanishes, since Q_o and Q_s are made equal by construction of the tunnel with two pistons of equal area. Also, $\bar{\tau}_{ps} - \bar{\tau}_{po}$ can be discarded, since the terms are of nearly equal magnitude and each, as estimated by laminar theory, is small compared with $\bar{\tau}_s$ as eventually determined. Finally, since the development of the velocity profile over the smooth bottom is relatively small, the last term in equation (8) can be discarded. The subtraction then provides,

$$\bar{\tau}_s - \bar{\tau}_o = \frac{H}{L} [(p_o - p_s)_L - (p_o - p_s)_0] - \frac{\rho H}{L} [\bar{u}_s^2(L) - \bar{u}_s^2(0)] \quad (9)$$

where the pressure differences are between pairs of taps at x = L, 0.

With $\bar{\tau}_o$ calculated by laminar theory, results of the experiments eventually show that $\bar{\tau}_s$ dominates the left side of equation (9) and that the right side is dominated by the first pressure difference, with the second kept relatively small by the action of the by-pass. The last term, which, like $\bar{\tau}_o$, proves to be small compared with $\bar{\tau}_s$, is provided by the single pitot tube at x=L with the assumption that, with z the vertical coordinate, $u_s(x, z, \theta)$ satisfies the condition of symmetry,

$$u_s(0, z, \theta) = -u_s(L, z, \theta + \pi) \quad (10)$$

4. Pressure Measurement

A differential pressure transducer mounted over the test section near the taps at $x = L$ (Fig.1,a) is alternately connected with the two pairs of taps at $x = 0, L$ by suitable conduits and valves (not shown in the drawings). Next to it is mounted a second pressure transducer connected with the pitot tube. Signals from the transducers are recorded on paper tape as functions of time. Pen deflections, in mm, are translated into pressure units by a calibration in which, immediately following an experiment, a simple device provides selected hydrostatic pressure differences to a transducer while the recorder runs with the same amplification as before.

Filters are required to reduce noise in the transducer output signals. These filters consist of six sand-filled glass loops one of which is included in each of the conduits between the transducers and the four pressure taps and the two pitot tube openings. This filtering reduces the amplitude and slows the response of the output signal. These distortions must be removed by calibration of another type. With the pressure at one tap, or pitot opening, fixed by draining the water in the tank to the level of an open hatch, the other is connected by a flexible tube to a vessel which is filled with water to this same level. The vessel is then oscillated vertically in simple harmonic motion with selected amplitude, h_c , and period, T_c , to supply a known (non hydrostatic) sinusoidal pressure difference to the transducer. Denoting, for given h_c , the ratio of the amplitude of the output signal as $T_c \rightarrow \infty$ to that at T_c by F_1 , and the phase lag by ϕ , calibrations are obtained in the form,

$$T_c^2 (\phi^2 - 1) = F_1(T_c) \quad (11)$$

and

$$T_c \tan \phi = F_2(T_c) \quad (12)$$

where F_1 and F_2 are independent of h_c and are slowly varying functions of T_c or constant. Although subject to T_c adjustments and slight drift over long periods of time, representative constant average values for both pairs of taps are, $F_1 \approx 4.3 \text{ sec}^2$, $F_2 \approx 2.5 \text{ sec}$, and for the pitot tube, $F_1 \approx 9.7 \text{ sec}^2$, $F_2 \approx 4.3 \text{ sec}$.

5. Processing the Data

As the first term on the right side of equation (9) has been found to dominate the last term, the processing of records from the pressure taps has differed from that of records from the pitot tube and will be considered first. The primary records from the pairs of taps at $x = 0, L$ are the pen deflections, in mm, which are denoted $P(0, \theta)$ and $P(L, \theta)$ respectively. Figure 2 shows $P(L, \theta)$ and $P(0, \theta)$ for a typical experiment (no. 2 in Table 1 below). In each case residual noise has been averaged out to produce a smoother curve. The deflections of $P(0, \theta)$ are kept relatively small by the action of the by-pass. The phase is marked for $\theta = 0, \pi, 2\pi$. A digitizing pad, or table, reads the analog tape records at each

Figure 2. A typical record of transducer output from the two pairs of pressure taps.

10 degrees of phase and stores the data in a microcomputer. The computer then processes the data in the following steps:

(1) As required in equation (9), the difference in the records is taken to form

$$D(\theta) = P(L, \theta) - P(0, \theta) \quad (13)$$

(2) Ideally, the stress at any time should be the negative of that a half cycle earlier or later in the opposite direction, so that $D(\theta)$ should equal $-D(\theta + \pi)$. This condition is only approximately realized. Therefore, $D(\theta)$ is averaged with $-D(\theta + \pi)$ to produce the function

$$\bar{D}(\theta) = \frac{1}{2} [D(\theta) - D(\theta + \pi)] \quad (14)$$

which changes only in sign when advanced a half cycle. In Figure 3 below, for each of the thirteen experiments, points giving $\bar{D}(\theta)$ and $-D(\theta + \pi)$ are plotted at each 10 degrees of phase, and $\bar{D}(\theta)$ is shown.

(3) $\bar{D}(\theta)$ is resolved into a sum of sinusoidal components by Fourier analysis. Both sine and cosine terms are present with arguments $n\theta$, where n , an integer, is the number of the harmonic, but since $\bar{D}(\theta) = -\bar{D}(\theta + \pi)$, even harmonics are absent, and n is odd.

(4) Successively taking $T_c = T/n$, the calibration corrections for the filter distortions given by equations (11), (12) are applied to each component, and

(5) The series is reassembled to provide a corrected $\bar{D}(\theta)$. This reassembly has included terms as far as the 7th harmonic while checking that the increment from the 9th harmonic is insignificant.

(6) By use of the hydrostatic pressure calibrations, $\bar{D}(\theta)$ is expressed in pressure units to provide the first term on the right side of equation (9).

The records from the pitot tube, also contained on the paper tapes, have been processed manually, without computer or Fourier analysis. The last term in equation (9) has been approximated using overall filter corrections, those provided by equations (11) and (12) for $n = 1$. Errors associated with this approximation cannot be serious, since this term has been found to be small, its range less than 8%, and typically less than 5%, of the main term.

The remaining unknown term in equation (9), $\bar{\tau}_o$, is calculated by the theory for laminar oscillatory flow over a plane surface. Its range has proven to be less than 3% of that of $\bar{\tau}_s$.

IV. RESULTS

1. Summary of Experiments

The major results of this paper are curves of f as function of θ and of the parameters U , λ , λ/a from the thirteen experiments analyzed so far. In Table 1 these experiments are identified by number, in chronological sequence, and by values of their parameters M , λ , a , U , and including the redundant $T = 2\pi a/U$. The trough to crest ripple height, η , has also been added (except where the record remains on undeveloped film). M is the number of sand crests between the fixed end crests and determines λ , as described in section II,2. Experiments for which λ/a differs from $(\lambda/a)_p$, that is, those with strained profiles (sec. II,2), are denoted by asterisks. Experiment "C" is a composite of nos. 2 and 26 as described in section IV,2. All thirteen experiments have used quartz sand with $D_{50} = 0.55$ mm.

Table 1. Parameters for the Thirteen Experiments

$$D_{50} = 0.55 \text{ mm}$$

Exp. no.	M	λ , cm	a, cm	U, cm/s	T, s	η , cm
1	7	31.8	23.9	27.0	5.57	7.3
2	7	31.8	23.9	40.6	3.71	6.9
3	7	31.8	23.9	33.1	4.55	7.8
4*	7	31.8	25.5	33.3	4.83	7.2
5*	7	31.8	21.9	33.1	4.16	6.7
6*	7	31.8	20.6	33.15	3.90	5.7
7*	7	31.8	27.7	33.2	5.25	7.6
13	10	23.1	17.4	40.5	2.70	4.8
18	5	43.5	31.9	40.6	4.94	9.3
24	4	52.5	38.3	40.6	5.93	11.9
26	7	31.8	23.9	40.5	3.72	-
27	7	31.8	25.9	52.1	3.13	-
28	7	31.8	28.9	63.6	2.86	-
C	7	31.8	23.9	40.5	3.71	-

*With strained profiles, $\lambda/a \neq (\lambda/a)_n$

2. Reliability

Interpretation of the results to follow requires some assessment of their reliability. The most convenient measure of reliability is the extent to which the stress, and related measurements, change only in sign as θ is increased by π , that is, the agreement between $D(\theta)$ and $-D(\theta + \pi)$ defined in sec.II,5 and by equation (13). In Figure 3, $D(\theta)$, $-D(\theta + \pi)$ and their average $D(\theta)$ (eq. 14) are shown for each experiment, identified by its number in Table 1. The scales of $D(\theta)$ and $-D(\theta + \pi)$, are in tape units before calibration and are of no interest beyond the indicated zero marks. Discrepancies between $D(\theta)$ and $-D(\theta + \pi)$ remain within 10% for the most part but are occasionally considerably larger. Their cause is unknown. They are most plausibly associated with pressure buildups behind the screens and resulting

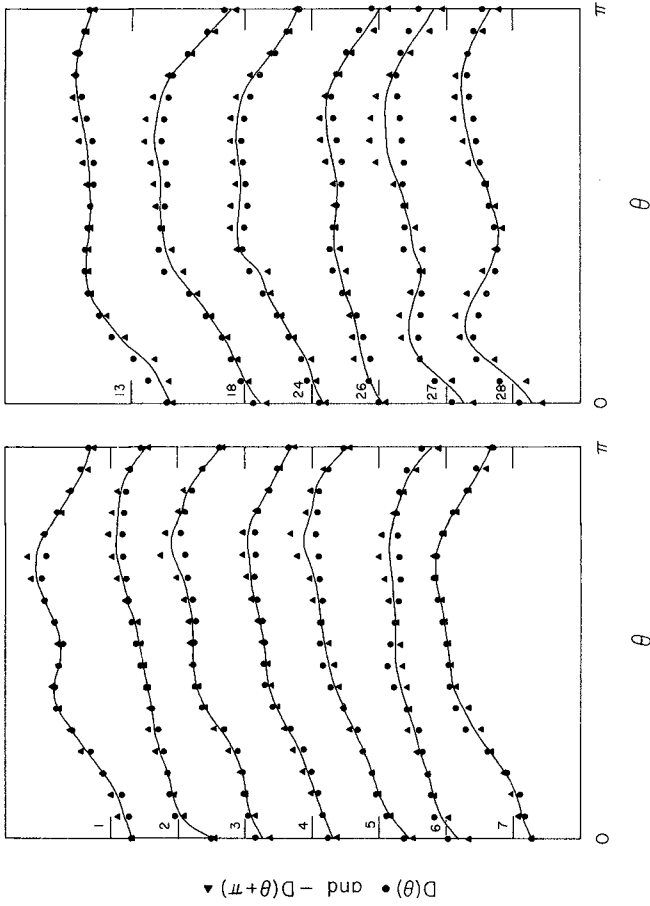

Figure 3. Applying the condition of symmetry between flows left to right, $D(\theta)$, and right to left, $-D(\theta+\pi)$. Experiments are numbered as in Table I.

flows through the by-pass. Pressure buildups are caused especially by sand in suspension being carried to and accumulating against a screen during a part of the cycle and become large enough to require limitations on U in order to forestall damage to the screens. The discrepancies may, in part, also derive from slight asymmetries in the sand profiles from one end of the bed to the other, particularly near the fixed end crests. Whatever their cause, such discrepancies reduce confidence in an experiment and if too large may cause it to be discarded.

Three of the experiments, nos. 26, 27, 28, were performed (after the oral presentation) following an enlargement of the by-pass to reduce the pressure difference $(p_o - p_s)_0$ (eq. 9) especially at higher values of U . Except for this enlargement, expts. 2 and 26 are ostensibly the same, and have been combined into a composite experiment numbered "C". Figure 4 shows $f(\theta)$ for expts. 2, 26, and "C". These curves agree reasonably well over most of the range but diverge substantially near times of flow reversal. Exps. 27 and 28 replace two experiments, included in the oral presentation, which had the same values of U , but had $\lambda/a = 1.33$, rather than $(\lambda/a)_n$ as in exps. 27 and 28. At these high values of U , $(\lambda/a)_n$ is significantly less than 1.33. In these two earlier experiments, ranges of $P(0, \theta)$ exceeded one half those of $P(L, \theta)$ and discrepancies between $D(\theta)$ and $-D(\theta + \pi)$ were substantially larger than in exps. 27 and 28, and, perhaps in consequence, their curves of $f(\theta)$ were quite different.

Figure 4. $f(\theta)$ for experiments 2 and 26 and their composite "C".

3. The Curves of $f(\theta)$

The curves of $f(\theta)$ from the twelve experiments (after combining nos. 2 and 26), for selected parameters, are shown in Figures 5,6,7. In Figures 5 and 6 the profiles are natural, with $\lambda/a = (\lambda/a)_n$, and in Figure 7 they are strained. $(\lambda/a)_n = 1.33$ in all experiments except nos. 27 and 28, in Figure 5, where it is reduced by the large values of U. In each figure, or family, the curves are identified at their left by their numbers in Table 1 and are arranged in order of monotonic increase or decrease in the defining parameter. In Figures 5 and 6 this parameter is U and λ , respectively, and in Figure 7 it is λ/a . The numerical value of the varying parameter is given at the right of each curve, and conditions and values of parameters held constant are shown above each family or figure. Although $f(\theta)$ is determined by its behavior over the restricted range $0 < \theta < \pi$, since $f(\theta + \pi) = -f(\theta)$, it is here presented over the entire cycle $-\pi/2 < \theta < 3\pi/2$ so that features of $f(\theta)$, such as maxima and minima, can more easily be followed from one curve to the next as the parameter is varied.

4. Values of \bar{f}_1 and f_m

With equation (5), values of \bar{f}_1 , the measure of energy dissipation, have been calculated from the twelve curves of $f(\theta)$ already presented. Table 2 lists these values in the same order as the curves in Figures 5, 6,7. For comparison, maximum values of $f(\theta)$, f_m , have been included.

Table 2. Values of \bar{f}_1 , proportional to the rate of energy dissipation, and f_m for the curves in Figures 5,6,7.

Natural profiles						Strained profiles		
$\lambda = 31.8 \text{ cm}$			$U \approx 40.6 \text{ cm/s}$			$\lambda = 31.8 \text{ cm}$ $U \approx 33.2 \text{ cm/s}$		
U, cm/s	\bar{f}_1	f_m	λ, cm	\bar{f}_1	f_m	λ/a	\bar{f}_1	f_m
27.0	.122	.299	52.2	.129	.282	1.15	.113	.253
33.1	.102	.236	43.5	.115	.259	1.25	.105	.228
40.5	.083	.180	31.8	.083	.180	1.33	.102	.236
52.1	.075	.218	23.1	.115	.452	1.45	.107	.228
63.6	.072	.348				1.54	.086	.227

The combination $U = 40.6 \text{ cm/s}$ and $a = 23.0 \text{ cm}$ occurs in the observations of Carstens, Neilson and Altinbilek (1969) where $T = 3.56\text{s}$. At this value of a and with $D = 0.585 \text{ mm}$, curves in their Figures 11 and 23 give $\lambda \approx 27.0 \text{ cm}$ and $\bar{f}_1 \approx .111$ (with their \bar{f} replaced by $3\pi\bar{f}_1$).

Figure 5. Stress coefficient f as function of phase θ and velocity U , for natural profiles.

Figure 6. Stress coefficient f as function of phase θ and ripple length λ , for natural profiles.

Figure 7. Stress coefficient f as function of phase θ and λ/a , for strained profiles.

IV. DISCUSSION

1. Conclusions Regarding $f(\theta)$ and \bar{f}_1 .

Defined by the magnitude, shape and phase of their peaks and valleys, the character of the curves in Figures 5,6,7 is found to progress continuously from one to the next as, within each family, U , λ and λ/a take on successive values. This continuity supports the reliability of the curves at hand, some of which will be repeated for further confirmation. Although restricted in the ranges of their parameters, the curves obtained permit some preliminary conclusions to be drawn. It is to be remembered that $u_{\infty}(\theta) = U \sin \theta$, as in equation (1).

The shapes of the functions $f(\theta)$ in Figures 5,6,7 differ markedly for different values of the parameters. Therefore, there can exist no "universal" function $f(\theta)$ to which all curves can be reduced by a selection of scale. In particular, in no case has $f(\theta)$ been found to be proportional to $\sin^2 \theta$. Thus, the instantaneous stress is not, in general, proportional to the square of the instantaneous velocity.

The values of \bar{f}_1 listed in Table 2 are found to vary smoothly with their parameters and, so far, to be fairly constant. In contrast, f_m , which is also listed, varies more abruptly and does not remain proportional to \bar{f}_1 . Thus, f_m does not provide a reliable measure of the rate of energy dissipation.^m

2. No Effect of Strain

It might be supposed that as a developing profile approaches equilibrium, or as a strained profile approaches an unstrained "natural" condition, the stress would take on some special stationary character, expressing, in some form, the principle of least action. However, the curves of $f(\theta)$ in Figure 7 and the values of \bar{f}_1 in Table 2 vary continuously with λ/a , with no discernible special character or extremum at $\lambda/a = 1.33$ where the profile is unstrained or natural. The ripple profiles of Figure 7, though strained, are stable, and these experiments have not examined the stress on unstable profiles during times of growth or change.

3. A Simple Model

Certain features common to all the curves of $f(\theta)$ in Figures 5,6,7 suggest a general, though limited, interpretation in terms of a simplified physical model. These features are three: (1) a positive stress at $\theta = 0$, (2) one or two peaks in $f(\theta)$ in the range $0 \leq \theta < \pi/2$, and (3) a single peak in $f(\theta)$ in the range $\pi/2 < \theta < \pi$. It is first recalled that the stress on a rigid flat bed precedes $u_{\infty}(\theta)$ by a shift in phase which is a maximum, $\pi/4$, for a smooth bed with laminar flow and stress and decreases as the bed becomes more rough and the stress more turbulent. Thus, with $u_{\infty}(\theta) = U \sin \theta$ such a stress would have a maximum in the range $\pi/4 < \theta < \pi/2$. The model simply combines such a "flat-bed stress" on the upstream face of the ripple crest with the stresses of vortex action, which is essential to ripple equilibrium.

The process of vortex formation and action adopted by the model is familiar. Following flow reversal, tangential stress on the upstream ripple face generates a boundary-vorticity layer and sets sand into motion, skewing the crest to end abruptly in a steep lee slope and sliding and spilling into the trough. The sharp curvature of the crest enhances separation of flow, and, as it is carried past, the boundary layer, with its vorticity, detaches and rolls into a vortex, still spilling sand into the trough. The center of the vortex is slowed and then held over the trough by reduced pressure on the lee slope of the crest, creating a form drag. Around the time of the succeeding flow reversal, the spinning vortex sweeps sand out of the trough and back up or over the crest, thus maintaining the profile.

Returning to $\theta = 0$, the spin of the vortex formed during the preceding half cycle and centered over the trough contributes a positive stress, while pressures needed to hold the vortex in position vanish at about this time. Thus, $f(0) > 0$. Following flow reversal, the vortex, decaying but still spinning, is carried up the ripple face where its spin hastens and increases the stress. Spin decay and the rapid drop off in spin stress as the vortex passes the ripple crest can account for an early maximum of the spin stress, slightly before or after $\theta = 0$, and preceding the maximum of the flat-bed stress. Thus, depending upon the relative strengths of these two maxima and their separation in time, $f(\theta)$ can display one or two peaks in the range $0 < \theta < \pi/2$. The deceleration of the forming vortex (or, more accurately, of several small vortices which later amalgamate) by reduced pressure on the lee slope begins with flow separation soon after flow reversal, but the associated form drag reaches a single peak as the vortex approaches full development sometime in the range $\pi/2 < \theta < \pi$, when the flat-bed stress is in decline. A negative back-flow stress on the lee ripple slope and under the vortex accompanies this form drag, and develops to make $f(\pi) < 0$ as the form drag vanishes.

The value of \bar{f}_1 from Carstens, Neilson and Altinbilek (1969), noted in section III, 4 above, fits well with values listed in Table 2. However, in Figures 5,6,7 the peaks in $f(\theta)$ preceding and nearest $\theta = \pi/2$, which the model associates with the flat-bed stress, are an order of magnitude larger than values of f_m obtained by Kamphuis (1975) at the same values of a/D and aU/ν . At least to some extent, this large increase may be a result of the movement of sand grains on the ripple face (cf. Lofquist in discussion of Vitale, 1979). Similarly, the peaks in $f(\theta)$ following $\theta = \pi/2$, which the model associates with form drag and vortex formation, suggest a form drag contribution to \bar{f}_1 of, roughly, one third. This is several times the seven percent which Tunstall and Inman (1975) have estimated for the ratio of vortex energy to the total energy dissipated in a half cycle. Their estimate was based upon a study of vortex formation behind rounded rigid (lithified) ripple crests. Possibly, the relative sharpness of a naturally skewing crest substantially enhances flow separation and vortex formation, or, the vortex energy is only a part of the form drag contribution to \bar{f}_1 .

4. Limitations and a Correction

Whatever its merits, the model is severely limited. Processes which interact cannot simply be added as flat-bed and vortex stresses. Concentration of all the vorticity generated on the upstream face of a crest into a single vortex formed in its lee is not a universal mechanism. In particular, at higher rates of flow, and scour, the ripple crests become lower and closer and unable to form and hold vortices large enough to contain all the detached boundary layer, and flow patterns modify. Such appeared to be the case with exp. 28.

When large quantities of sand are set in motion, $f(\theta)$ as calculated by equation (9) itself loses precision and requires the addition of a correction, $\Delta f(\theta)$. If, at any θ , the sand in motion lowers the mean surface by Δh (a positive quantity) and has a momentum \dot{m}_s per unit area of the bed, and with $Q_s = bHu \sin \theta$, a rederivation of $f(\theta)$ produces the correction term

$$\Delta f(\theta) = \frac{2\Delta h}{a} \cos \theta - \frac{2}{\rho U^2} \dot{m}_s \quad (15)$$

In experiment 28, Figure 5 shows $f(\theta)$, surprisingly, to be negative in the neighborhood of $\theta = \pi/3$. Here, $\Delta h \cos \theta$ is positive while \dot{m}_s is presumably negative, as sand scoured from the bed during the preceding peak in $f(\theta)$ falls back to impact the bed and lose its momentum. Thus, $\Delta f(\theta)$ is presumably positive and, while its magnitude can only be guessed at, it could suffice to keep the corrected $f(\theta)$ positive.

5. Future Work

The experiments described here are part of a larger program interrupted by the timing of the conference. As noted above, future experiments will investigate the repeatability of present results, and will extend the ranges and the number of combinations of the parameters. One or two finer sands will be included. Future more complete analyses will more consistently combine parameters into dimensionless ratios. A completed study is scheduled for publication in 1981 by the Coastal Engineering Research Center, Ft. Belvoir, Virginia.

ACKNOWLEDGEMENT

The results presented in this paper are based on research conducted at the National Bureau of Standards. This research is wholly supported by the Coastal Engineering Research Center under the Beach Behavior and Restoration Research Program of the U.S. Army Corps of Engineers. The findings reported here are not to be construed as an official Department of the Army position unless so designated by other authorized documents. Permission to publish this information is appreciated.

Contribution to the Discussion During Session C,
Coastal Processes, Friday, March 28, 2:00 p.m.

by

M. S. Longuet-Higgins
Institute of Oceanographic Sciences
Wormley, Surrey, England

Professor Brebner suggested that the profile of sand ripples should be approximated by a conformal transformation into a hexagon, as has been done for steep surface waves (Longuet-Higgins, 1973). In fact the ripple profile is often steeper than this, the angle at the crest being closer to 108° (the interior angle of a pentagon) than to 120° . See, for example, the experimental data summarized by Nielsen (1979), Figures 5.7 to 5.11. For the pentagon approximation, the ratio of ripple height to ripple wavelength would be

$$\frac{H}{L} = \frac{1n \sec \pi/5}{2\pi/5} = 0.169 .$$

In fact polygons with any number P of sides may be used, and we may extend the analysis to all rational values $P = N/M$ by considering polygons enclosing their centre M times.

The great advantage of the polygon approximation is that the flow outside the polygon (i.e., above the ripple) may be quite simply mapped onto the interior of a circle. Irrotational flow over the ripple is represented by a simple vortex at the center of the circle. Any other vorticity shed by boundary layers at the crests can be represented by point-vortices and their images in the circle.

Calculations using these ideas are at present in hand (Longuet-Higgins, 1980 a,b). It has already been shown that they yield drag coefficients in excellent agreement with those measured by Bagnold (1946) and by Carstens, et al. (1969).

Inshore-Nearshore Morphodynamics - A Predictive Model, John Chappell, 963
- Bays (topographic features); Beach erosion; Beaches; Littoral drift; Shore protection; Wave action**
Zeta Bays, Pocket Beaches and Headland Control, R. Silvester, Y. Tsuchiya and Y. Shibano, 1305
- Bays (topographic features); Coastal engineering; Currents (water); Estuaries; Maine; Models; Three-dimensional; Water pollution control; Water quality**
A 3-D Model for Penobscot Bay, Maine, Bryan R. Pearce, Bruce R. Fidler and Adrian C. Humphreys, 2395
- Bays (topographic features); Inlets (waterways); Tidal effects; Tide gages; Tides**
Tidal Prism-Inlet Area Relations for Small Tidal Inlets, R. J. Byrne, R. A. Gammisch and G. R. Thomas, 2515
- Bays (topographic features); Japan; Numerical calculations; Tsunamis; Wave equations; Wave runup**
Run-Up of Tsunamis by Linear and Nonlinear Theories, Chiaki Goto and Nobuo Shuto, 695
- Beach erosion; Beaches; Beach nourishment; Coastal engineering; Dunes; Sand pumps; Australia**
Noosa Beach Restoration Scheme, R. J. Lloyd, 1618
- Beach erosion; Beaches; Beach nourishment; Coastal engineering; Dunes; Shore protection; Australia**
The Beach Improvement Programme, New South Wales, Neale A. Philip and Philip H. Waite, 1666
- Beach erosion; Beaches; Beach nourishment; Morphology; Sand; Sediment transport; Wave energy; Wave height; Waves**
Beach Response to Variations in Breaker Height, A. D. Short, 1016
- Beach erosion; Beaches; California; Sediment transport; Topographic features; Wave action; Wave period**
Beach Cusps at Point Reyes and Drakes Bay Beaches, California, R. G. Dean and E. M. Maurmeyer, 863
- Beach erosion; Beaches; Coastal engineering; Shore protection; Australia**
Capricorn Coast Beaches, D. C. Patterson and L. R. Ford, 1648

- Beach erosion; Beaches; Field tests; Stability; Surf; Topography; Wave action; Australia**
Beach Cut in Relation to Surf Zone Morphodynamics, L. D. Wright, 978
- Beach erosion; Beaches; Littoral drift; Shore protection; Wave action; Bays (topographic features)**
Zeta Bays, Pocket Beaches and Headland Control, R. Silvester, Y. Tsuchiya and Y. Shibano, 1305
- Beach erosion; Beach sands; Deltas; Flood protection; Rivers; Sediment transport; Alluvial deposits; Australia**
Barron River Delta Investigation, D. A. Robinson, D. J. Cook and J. G. Barff, 885
- Beach erosion; Breakwaters; Coastal engineering; Dredging; Field investigations; Islands; Shore protection; South Carolina; Wave action**
Soft Designs for Coastal Protection at Seabrook Island, S.C., Miles O. Hayes, Timothy W. Kana and John H. Barwis, 897
- Beach erosion; Breakwaters; Design practices; Lakes; Lake shores; Lake waves; Ohio; Shore protection; Storms**
A Detached Breakwater System for Beach Protection, James R. Walker, Denton Clark and Joan Pope, 1969
- Beach erosion; Coastal engineering; Field investigations; Flood control; Inlets (waterways); Research projects; Tidal waters; U.S. Corps of Engineers**
The Corps of Engineer's General Investigation of Tidal Inlets, Robert M. Sorensen, 2563
- Beach erosion; Coastal engineering; Field work; Wave action; Accretion (geomorphology); Australia**
Beach Erosion-Accretion at Two Time Scales, B. G. Thom and G. M. Bowman, 934
- Beach erosion; Coastal Processes; Louisiana; Sedimentation; Shore protection; Wave energy**
Fluid Mud Dynamics and Shoreline Stabilization: Louisiana Chenier Plain, John T. Wells and Harry H. Roberts, 1381
- Beach erosion; Dunes; Dune sands; Revegetation; Sand control; Shore protection; Australia**
Research in Southern Queensland into the Management of Coastal Sand Dunes, James B. McKenzie and David A. Barr, 1547
- Beach erosion; Laboratory tests; Models; Sand; Sediment transport; Shallow water; Wave action**
A Laboratory Study of Offshore Transport of Sediment and a Model for Eroding Beaches, Tsuguo Sunamura, 1051
- Beaches; Beach nourishment; Coastal engineering; Coasts; Morphology; Prisms; Wave action; Australia**
The Dynamic Swept Prism, David M. Chapman and A. W. Smith, 1036
- Beaches; Beach nourishment; Coastal engineering; Dunes; Sand pumps; Australia; Beach erosion**
Noosa Beach Restoration Scheme, R. J. Lloyd, 1618
- Beaches; Beach nourishment; Coastal engineering; Dunes; Shore protection; Australia; Beach erosion**
The Beach Improvement Programme: New South Wales, Neale A. Philip and Philip H. White, 1668
- Beaches; Beach nourishment; Coastal engineering; Management methods; Sand; Topography; Australia**
Beach Nourishment as a Management Technique, David M. Chapman, 1635
- Beaches; Beach nourishment; Morphology; Sand; Sediment transport; Wave energy; Wave height; Waves; Beach erosion**
Beach Response to Variations in Breaker Height, A. D. Short, 1016
- Beaches; Beach sands; Coastal Processes; Hydraulics; Laboratory tests; Permeability (soils); Profiles; Surf; Waves**
Beaches: Profiles, Processes and Permeability, Michael R. Gourlay, 1319
- Beaches; Breaking energy; Phase shift; Wave action; Wave height; Waves; Wave velocity**
Breaker Type and Phase Shifts on Natural Beaches, Peter J. Cowell, 997
- Beaches; Breakwaters; Coastal engineering; Groins (structures); Japan; Shore protection**
Artificial Resort Beach Protected by Offshore Breakwaters and Groins, Shoji Sato and Norio Tanaka, 2004
- Beaches; California; Sediment transport; Topographic features; Wave action; Wave period; Beach erosion**
Beach Cusps at Point Reyes and Drakes Bay Beaches, California, R. G. Dean and E. M. Maurmeyer, 863
- Beaches; Coastal engineering; Currents (water); Flow; Waveguides; Waves**
Longshore Current Flows in a Wave Basin, P. J. Visser, 462
- Beaches; Coastal engineering; Currents (water); Japan; Littoral current; Power plant location; Wave action; Wave energy**
Nearshore Currents on a Partially Rocky Shore, T. O. Sasaki, H. Igarashi and S. Harikai, 1071
- Beaches; Coastal engineering; Experimental data; Wave action; Wave energy; Waves; Wave velocity**
Experimental Investigations of Periodic Wave Near Breaking, J. Buir Hansen, 260
- Beaches; Coastal engineering; Fluid mechanics; Similarities; Surf; Wave energy; Waves**
A Similarity Model in the Surf Zone, Hsiang Wang and Wei-Chong Yang, 529
- Beaches; Coastal engineering; Heuristic methods; Surf; Wave energy; Wave height; Waves**
An Heuristic Model of Wave Height Distribution in Surf Zone, Masaru Mizuguchi, 278
- Beaches; Coastal engineering; Littoral deposits; Littoral drift; Sediment transport; Shear stress; Wave action**
Beach Profiles and On-Offshore Sediment Transport, Akira Watanabe, Yoshihiko Riho and Kiyoshi Horikawa, 1106
- Beaches; Coastal engineering; Shore protection; Australia; Beach erosion**
Capricorn Coast Beaches, D. C. Patterson and L. R. Ford, 1648
- Beaches; Coastal Processes; Littoral drift; Sandbars; Shores; Topography; Wave action**
Migration of Longshore Bars, Hans H. Dette, 1475

- Beaches; Coasts; Littoral materials; Mathematical models; Water circulation; Water pollution; Water waves; Wave action**
Numerical Modelling of Nearshore Circulation, Bruce A. Ebersole and Robert A. Dalrymple, 2708
- Beaches; Computer applications; Construction; Docks; Dredging; Environmental surveys; Ports; Water flow; Water quality; Australia**
Integration and Computation in an Environmental Study, J. B. Hinwood, J. E. Watson and D. M. Burrage, 3024
- Beaches; Currents (water); Groundwater elevation; Slopes; Surf; Wave action; Wave energy**
Wave Forcing of Beach Groundwater, Evans Waddell, 1435
- Beaches; Currents (water); Littoral current; Surf; Topography; Wave energy; Wave height; Wave runup**
Topographic Control of Run-Up Variability, Mark P. Bradshaw, 1091
- Beaches; Deep water; Sediment transport; Stability analysis; Wave energy; Waves**
Criterion for Stability of Shoreline Platform, John D. Wang and Bernard Le Mehaute, 1994
- Beaches; Deformation; Littoral deposits; Littoral drift; Models; Sediment transport; Surf**
On-Offshore Sediment Transport Rate in the Surf Zone, Toru Sawaragi and Ichiro Deguchi, 1194
- Beaches; Disturbances; Experimentation; Flumes; Predictions; Wave equations; Waves**
Long Period Disturbances Due to Wave Groups, E. C. Bowers, 610
- Beaches; Field investigations; Japan; Littoral drift; Littoral materials; Ports; Sand**
Littoral Drift on Sand Near Port of Oarai, Kazumasa Mizumura, 2157
- Beaches; Field tests; Stability; Surf; Topography; Wave action; Australia; Beach erosion**
Beach Cut in Relation to Surf Zone Morphodynamics, L. D. Wright, 978
- Beaches; Hydraulics; Littoral drift; Sand; Sediment transport; Wave energy**
Secondary Sand Transport Mechanisms, A. W. Smith and A. D. Gordon, 1122
- Beaches; Littoral deposits; Littoral drift; Models; Sand; Sediment transport; Surf; Waves**
Onshore-Offshore Transport and Beach Profile Change, Masataro Hattori and Ryoichi Kawamata, 1178
- Beaches; Littoral drift; Shore protection; Wave action; Bays (topographic features); Beach erosion**
Zeta Bays, Pocket Beaches and Headland Control, R. Silverster, Y. Tsuchiya and Y. Shibano, 1305
- Beach nourishment; Bed forms; Dredging; Estuaries; Rivers; Sand; Sediment transport; Tidal hydraulics; Australia**
Estuarine Response to Dredging in the Tweed River, Australia, Bruce M. Druery, 1598
- Beach nourishment; Coastal engineering; Coasts; Morphology; Prisms; Wave action; Australia; Beaches**
The Dynamic Swept Prism, David M. Chapman and A. W. Smith, 1036
- Beach nourishment; Coastal engineering; Dunes; Sand pumps; Australia; Beach erosion; Beaches**
Noosa Beach Restoration Scheme, R. J. Lloyd, 1618
- Beach nourishment; Coastal engineering; Dunes; Shore protection; Australia; Beach erosion; Beaches**
The Beach Improvement Programme: New South Wales, Neale A. Philip and Philip H. Whaite, 1668
- Beach nourishment; Coastal engineering; Management methods; Sand; Topography; Australia; Beaches**
Beach Nourishment as a Management Technique, David M. Chapman, 1635
- Beach nourishment; Morphology; Sand; Sediment transport; Wave energy; Wave height; Waves; Beach erosion; Beaches**
Beach Response to Variations in Breaker Height, A. D. Short, 1016
- Beach sands; Coastal Processes; Hydraulics; Laboratory tests; Permeability (soils); Profiles; Surf; Waves; Beaches**
Beaches: Profiles, Processes and Permeability, Michael R. Gourlay, 1319

Soft Designs for Coastal Protection at Seabrook Island, S.C., Miles O. Hayes, Timothy W. Kana and John H. Barwis, 897
- Coastal engineering; Dredging; Ocean waves; Ports; Real time operations; Wave action; Wave height; Analysis; Australia**
Realtime Wave Analysis, Newcastle, Australia, N. V. Lawson and P. H. Youll, 412
- Coastal engineering; Dunes; Sand pumps; Australia; Beach erosion; Beaches; Beach nourishment**
Noosa Beach Restoration Scheme, R. J. Lloyd, 1618
- Coastal engineering; Dunes; Shore protection; Australia; Beach erosion; Beaches; Beach nourishment**
The Beach Improvement Programme: New South Wales, Neale A. Philip and Philip H. White, 1668
- Coastal engineering; Dynamic characteristics; Shores; Surf; Wave action; Waves**
Dynamic Characteristics in the Nearshore Area, Kiyoshi Horikawa and Masahiko Isobe, 480
- Coastal engineering; Engineering evaluation; Nuclear power plants; Oceanography; Philippines; Tsunamis; Coastal engineering**
Tsunamis Along West Coast of Luzon, Philippines, R. L. Wiegell, 652
- Coastal engineering; Environmental effects; Estuaries; Estuarine environment; Models; Salinity**
Separation of Climatic Fluctuations and Impacts of Engineering Activities in Estuaries, G. Krause, 2323
- Coastal engineering; Environmental impact statements; Estuaries; Planning; Ports; Water flow; Australia**
Water Movement Studies Required for Port Planning, Graeme C. Dandy, Desmond A. Mills and John B. Hinwood, 3007
- Coastal engineering; Environmental impact statements; Gas pipelines; Petroleum pipelines; Scotland; Shore protection; Submarine pipelines**
Environmental Aspects of Oil and Gas Pipeline Landfalls in Northeast Scotland, William Ritchie, 2935
- Coastal engineering; Estuaries; Harbors; Research; Sediment transport; Shore protection; China**
Some Aspects of Coastal Engineering Research Works in China, Yen Kai, 1734

- Coastal engineering; Estuaries; Hydraulic tests; Netherlands; Storm surges; Barriers**
Hydraulic Research in the Oosterschelde Estuary.
A. W. Walther, 2358
- Coastal engineering; Estuaries; Mathematical models; Models; Rivers; Tidal waters; Tides; Waves; West Germany; Calibration**
Automatic Calibration of Numerical Tidal Models, K.-P. Holz and U. Januszewski, 2448
- Coastal engineering; Estuaries; Models; Physical tests; Storm surges; Tides**
Artificial Roughness in Physical Models of Estuaries for Storm Surge Investigations, D. Berndt, E. Giese, H. Schwarze and H.-J. Vollmers, 2493
- Coastal engineering; Experimental data; Wave action; Wave energy; Waves; Wave velocity; Beaches**
Experimental Investigations of Periodic Wave Near Breaking, J. Buhr Hansen, 260
- Coastal engineering; Field Investigations; Flood control; Inlets (waterways); Research projects; Tidal waters; U.S. Corps of Engineers; Beach erosion**
The Corps of Engineer's General Investigation of Tidal Inlets, Robert M. Sorensen, 2563
- Coastal engineering; Field tests; Harbors; Sand traps; Sediment transport; Wave measurement; Breakwaters; California**
Longshore Transport Evaluations at a Detached Breakwater, R. O. Bruno, R. G. Dean and C. G. Gable, 1452
- Coastal engineering; Field tests; Numerical calculations; Wave height; Waves; Breakwaters**
Wave Height Distribution Around Permeable Breakwaters, Shintaro Hotta, 221
- Coastal engineering; Field work; Wave action; Accretion (geomorphology); Australia; Beach erosion**
Beach Erosion-Accretion at Two Time Scales, B. G. Thom and G. M. Bowman, 934
- Coastal engineering; Finite difference method; Islands; Shallow water; Tsunamis; Wave equations**
Transient Finite-Difference Tsunami Calculations, Ove Skovgaard and Ivar G. Jonsson, 823
- Coastal engineering; Flowmeters; Laboratory tests; Velocity measurement; Velocity meters; Waves; Wave velocity**
Orbital Velocities in Irregular Waves, F. C. Vis, 173
- Coastal engineering; Fluid mechanics; Similarities; Surf; Wave energy; Waves; Beaches**
A Similarity Model in the Surf Zone, Hsiang Wang and Wei-Chong Yang, 529
- Coastal engineering; Flumes; Sand; Sediment transport; Wave action; Waves; Bottom sediments**
Sand Transport by Waves, Jan van de Graaff and Wiel M.K. Tilmans, 1140
- Coastal engineering; Froude number; Mixing; Outflows; Rivers; Saline water-freshwater interfaces; Water flow**
On a Role of the Interfacial Froude Number, Masakazu Kashiwamura, 2778
- Coastal engineering; Gages; Littoral zone; Visual surveillance; Wave height; Wave measurement; Waves; California**
Visually Observed Wave Data at PT. Mugu, Calif., Christine Schneider and J. Richard Weggel, 381
- Coastal engineering; Gravity waves; Ocean engineering; Oceanography; Water waves; Wave period; Wave reflection; Wave refraction; Waves**
Ray Curvature and Refraction of Wave Packets, J. Ernest Breeding, Jr., 82
- Coastal engineering; Gravity waves; Predictions; Shoaling; Two-dimensional; Wave height; Calculations**
Wave Shoaling Calculated From Cokerlet's Theory, T. Sakai and J. A. Battjes, 121
- Coastal engineering; Groins (structures); Japan; Shore protection; Beaches; Breakwaters**
Artificial Resort Beach Protected by Offshore Breakwaters and Groins, Shoji Sato and Norio Tanaka, 2004
- Coastal engineering; Harbors; Hydraulic design; Marinas; Water circulation; Water quality**
Hydraulic Circulation Performance of a Curvilinear Marina, Jeffrey A. Layton, 2743
- Coastal engineering; Harbors; Marinas; Model studies; Water waves; Wave action; Wave energy; Waves**
Non-Resonant Wave Agitation in Small Craft Harbours, J. W. Kamphuis and D. A.Y. Smith, 241
- Coastal engineering; Heuristic methods; Surf; Wave energy; Wave height; Waves; Beaches**
An Heuristic Model of Wave Height Distribution in Surf Zone, Masaru Mizuguchi, 278
- Coastal engineering; Hydraulic test tunnels; Sediment transport; Wave action; Waves; Wave velocity**
A Closely Responding, Versatile Wave Tunnel, C. H. Hulsbergen and J. J. Bosman, 310
- Coastal engineering; Littoral deposits; Littoral drift; Sediment transport; Shear stress; Wave action; Beaches**
Beach Profiles and On-Offshore Sediment Transport, Akira Watanabe, Yoshihiko Riho and Kiyoshi Horikawa, 1106
- Coastal engineering; Management methods; Sand; Topography; Australia; Beaches; Beach nourishment**
Beach Nourishment as a Management Technique, David M. Chapman, 1635
- Coastal engineering; Marinas; Porous materials; Wave action; Wave propagation; Waves; Wind; Breakwaters**
Wind Waves Transmission Through Porous Breakwater, Stanislaw R. Massel and Piotr Butowski, 333
- Coastal engineering; Mass transfer; Shallow water; Velocity; Water waves; Wave propagation; Waves; Wave tanks**
Mass Transport in Progressive Waves of Permanent Type, Yoshito Tsuchiya, Takashi Yasuda and Takao Yamashita, 70

- Coastal engineering; Measurement; Oceanography; Wind; Wind profiles; Wind speed**
On the Correction of Land-Based Wind Measurements for Oceanographic Applications, S. A. Hsu, 708
- Coastal engineering; Modets; Wave energy; Wave height; Wave refraction; Waves; Wind**
Verification of a Wave Refraction Model Utilizing Recorded and Observed Wave Data, G. Henderson and N. B. Webber, 101
- Coastal engineering; Oceanographic data; Wave measurement; Waves; Catalogs**
Sources of Measured Wave Data, Laurence Draper, 372
- Coastal engineering; Resonance; Sea level changes; Subsonic flow; Waves; Australia**
Resonances of Coastal Waters Between Perth and Geraldton, H. Allison, A. Grassia and R. Litchfield, 290
- Coastal engineering; Rubble-mound breakwaters; Sand; Shore protection; Bitumens; Breakwaters**
Breakwater with a Sand Bitumen Core, E. Loewy, K. G. Witthaus, R. J. Maddrell and J. P. Wood, 2192
- Coastal engineering; Sedimentation; Sediment transport; Suspended load; Trenches; Wave action; Channels (waterways)**
Sedimentation in Channels and Trenches, E. W. Bijker, 1707
- Coastal engineering; Shore protection; Australia; Beach erosion; Beaches**
Capricorn Coast Beaches, D. C. Patterson and L. R. Ford, 1648
- Coastal engineering; Spilling; Surf; Water waves; Wave measurement; Wave pressure; Waves; Wave velocity**
Velocity and Pressure Field of Spilling Breakers, M. J.F. Stive, 547
- Coastal Processes; Coasts; Geologic control; Marine geology; Sediment transport; Wave action; Wave energy; Australia; Coastal engineering**
Geological Controls on Process-Response, SE Australia, P. S. Roy and A. W. Stephens, 913
- Coastal Processes; Coasts; Model studies; Reclamation; Singapore; Coastal engineering**
Major Reclamation Scheme for Marina City, Singapore, S. Y. Chew and J. Wei, 2243
- Coastal Processes; Currents (water); Models; Predictions; Sediment transport; Waves; California; Coastal engineering**
Nearshore Sediment Transport Study Experiments, R. J. Seymour and C. G. Gable, 1401
- Coastal Processes; Dredging; Harbors; Shoaling; California; Channel improvements**
A Phased-Dredging Program for Santa Cruz Harbor, James R. Walker and Peter J. Williams, 1492
- Coastal Processes; Erosion; Sea-ice; Sediment transport; Tundra; Wave energy; Alaska; Cliffs**
Sediment Transport Processes and Coastal Variability on the Alaskan North Slope, E. H. Owens, J. R. Harper and D. Nummndal, 1343
- Coastal Processes; Estuaries; Floods; Inlets (waterways); Lakes; Littoral drift; Stability criteria; Tidal effects; Tidal waters; Australia**
Tidal Inlet Behavioural Analysis, A. F. Nielsen and A. D. Gordon, 2459
- Coastal Processes; Fluid mechanics; Sand; Sand waves; Calculations**
Contribution to the Discussion During Session C, Coastal Processes, Friday, March 28, 2:00 P.M., M. S. Longuet-Higgins, 3107
- Coastal Processes; Hydraulics; Laboratory tests; Permeability (soils); Profiles; Surf; Waves; Beaches; Beach sands**
Beaches: Profiles, Processes and Permeability, Michael R. Gourlay, 1319
- Coastal Processes; Littoral drift; Sandbars; Shores; Topography; Wave action; Beaches**
Migration of Longshore Bars, Hans H. Dette, 1475
- Coastal Processes; Louisiana; Sedimentation; Shore protection; Wave energy; Beach erosion**
Fluid Mud Dynamics and Shoreline Stabilization: Louisiana Chenier Plain, John T. Wells and Harry H. Roberts, 1381
- Coastal Processes; Model tests; Sediments; Australia; Budgeting; Coastal engineering**
An Approach to Understanding Coastal Processes, A. D. Gordon and D. B. Lord, 1234
- Coastal structures; Concrete construction; Model tests; Outfall sewers; Storm water; Coastal engineering**
Construction and Model Investigation of Stormwater Outfall, K. A. Heathcote and G. W. Britton, 1850
- Coastal structures; Concrete structures; Damage; Ports; Rubble-mound breakwaters; Breakwaters**
Dolosse Past, Present, Future?, J. A. Zwamborn, D. E. Bosman and J. Moes, 1949
- Coastal structures; Concrete structures failure; Damages; Portugal; Rubble-mound breakwaters; Breakwaters; Coastal engineering**
Report on the Damages to the Sines Breakwater, Portugal, William F. Baird, Joseph M. Caldwell, Billy L. Edge and Orville T. Magoon, 3060
- Coastal structures; Design; Harbors; Shore protection; Storms; Storm surges; Wind forces; Australia; Breakwaters**
The Design Concept of Dual Breakwaters and its Application to Townsville, Australia, W. Bremner, D. N. Foster, C. A. Miller and B. C. Wallace, 1899
- Coastal structures; Design; Hawaii; Mathematical models; Reefs; Wave attenuation; Coastal engineering**
Wave Attenuation and Wave Set-Up on a Coastal Reef, Francisus Gerritsen, 444
- Coastal structures; Design; Offshore structures; Predictions; Sea states; Statistical data; Wave height**
Prediction of the Severest Significant Wave Height, Michel K. Ochi and Joseph E. Whalen, 587

- Coastal structures; Model studies; Statistics; Storms; Wave generation; Wave height; Waves**
A Comparison of Nature Waves and Model Waves with Special Reference to Wave Grouping, Hans F. Burcharth, 2989
- Coastal structures; Rubble-mound breakwaters; Sea walls; Water waves; Wave reflection; Wave spectra; Coastal engineering**
Method of Analysis of Random Wave Experiments with Reflecting Coastal Structures, Pierre Gaillard, Michael Gauthier and Forrest Holly, 204
- Coasts; Currents (water); Shore protection; Union of Soviet Socialist Republics; Wave action; Coastal engineering**
Coast Protection Against the Action of Waves and Currents, Leren P. Mikhailov and Sergei M. Uspenskiĭ, 2120
- Coasts; Design; Outfall sewers; San Francisco; Sediment deposits; Shallow water; Wastewater (pollution); Water pollution; Wave energy; Antifouling materials; California**
Design of an Intermittently Operated Outfall, Roger W. Lindquist and George J. Murphy, 2834
- Coasts; Dredging; Field tests; Morphology; Projects; Sedimentology; Tides; West Germany; Coastal engineering**
The German "Moran" Project, Winfried Siefert and Volker Barthel, 2924
- Coasts; Estuaries; Inlets (waterways); Tidal effects; Australia; Coastal engineering**
A Coastal Inlet with Fixed Bed and Mobile Sides, R. C. Nelson and A. J. Keats, 2532
- Coasts; Field investigations; Sand; Sand control; Sediment transport; West Germany; Wind action geology; Wind speed**
Sand Transport Under the Action of Wind, Ulrich Zanke, 1575
- Coasts; Floods; Inlets (waterways); Sand; Sandy soils; Storms; Tidal effects; Tidal hydraulics; Wave action**
Comments on Tidal Entrances on Sandy Coasts, Morrrough P. O'Brien, 2502
- Coasts; Geologic control; Marine geology; Sediment transport; Wave action; Wave energy; Australia; Coastal engineering; Coastal Processes**
Geological Controls on Process-Response, SE Australia, P. S. Roy and A. W. Stephens, 913
- Coasts; Inlets (waterways); Landsat; Littoral drift; Remote sensing; Sandbars; Satellite Mapping; Bathymetry**
Satellite Applications on a Coastal Inlet Stability Study, Yu-Hwa Wang, 2579
- Coasts; Littoral drift; Taiwan; Wave energy; Wave measurement; Breaking energy; Coastal engineering**
Relationship Between Alongshore Wave Energy and Littoral Drift in the Mid West Coast at Taiwan, Ho-Shong Hou, Chung-Pan Lee and Lung-Hui Lin, 1254
- Coasts; Littoral materials; Mathematical models; Water circulation; Water pollution; Water waves; Wave action; Beaches**
Numerical Modelling of Nearshore Circulation, Bruce A. Ebersole and Robert A. Dalrymple, 2708
- Coasts; Model studies; Reclamation; Singapore; Coastal engineering; Coastal Processes**
Major Reclamation Scheme for Marina City, Singapore, S. Y. Chew and J. Wei, 2243
- Coasts; Morphology; Prisms; Wave action; Australia; Beaches; Beach nourishment; Coastal engineering**
The Dynamic Swept Prism, David M. Chapman and A. W. Smith, 1036
- Composite structures; Design; Impact loads; Laboratory tests; Wave action; Breakwaters; Caissons**
Wave Impact Pressures on Composite Breakwaters, G. R. Mogridge and W. W. Jamieson, 1830
- Computer applications; Construction; Docks; Dredging; Environmental surveys; Ports; Water flow; Water quality; Australia; Beaches**
Integration and Computation in an Environmental Study, J. B. Hinwood, J. E. Watson and D. M. Burrage, 3024
- Computer applications; Design; France; Harbors; Hydraulic tests; Models; Sedimentology; Wave diffraction; Wave refraction**
Harbour Design Including Sedimentological Problems Using Mainly Numerical Technics, B. Latteux, 2211
- Computer applications; Flumes; Hydraulic models; Wave generation; Waves; Wave tanks; Coastal engineering**
A Survey of "Random" Wave Generation Techniques, J. Ploeg and E. R. Funke, 135
- Computerized simulation; Fourier transformation; Ocean waves; Wave velocity; Coastal engineering**
Conditional Simulations of Ocean Wave Properties, Leon R. Borgman, 318
- Concrete construction; Deep water; Design; Japan; Overtopping; Sea walls; Waves; Caissons**
Seawalls in Deep Seas, Shoshichiro Nagai and Shohachi Kakuno, 2024
- Concrete construction; Design; Islands; Shore protection; Terminals; Breakwaters; Caissons**
The Effects of Construction Techniques & Bulk Terminal Operational Requirements on the Design Criteria for Island Breakwaters, A. G.F. Eddie, J. D. Lawson, H. R. Graze and B. K. Dean, 2061
- Concrete construction; Design; Model tests; Rubble-mound breakwaters; Breakwaters; Coastal engineering**
Can We Develop New Breakwater Formulae, John Dorrington Mettam, 2302
- Concrete construction; Design; Mooring; Petroleum transportation; Piers (docks); Ports; Tanker ships; Berths; Caissons; China**
The Design and Construction of the New Oil Port in Dalian, CPR, Zhu-zhuang Xin and Yu-cheng Li, 2081
- Concrete construction; Model tests; Outfall sewers; Storm water; Coastal engineering; Coastal structures**
Construction and Model Investigation of Stormwater Outfall, K. A. Heathcote and G. W. Britton, 1850

- Concrete structures; Damage; Ports; Rubble-mound breakwaters; Breakwaters; Coastal structures**
Dolosse Past, Present, Future?, J. A Zwamborn, D. E. Bosman and J. Moes, 1949
- Concrete structures; Destructive tests; Dynamic loads; Hydraulic tests; Model tests; Reinforced concrete; Rubble-mound breakwaters**
Full Scale Trails of Dolosse to Destruction, Hans F. Burcharth, 1929
- Concrete structures failure; Damages; Portugal; Rubble-mound breakwaters; Breakwaters; Coastal engineering; Coastal structures**
Report on the Damages to the Sines Breakwater, Portugal, William F. Baird, Joseph M. Caldwell, Billy L. Edge and Orville T. Magoon, 3060

Non-Resonant Wave Agitation in Small Craft Harbours, J. W. Kamphuis and D. A. Y. Smith, 241
- Harbors; Mathematical models; Sedimentation; Sedimentation tanks; Suspended sediments; Tidal effects; Coastal engineering; Cost estimates; Flooding**
Design of Enclosed Harbors to Reduce Sedimentation, Craig H. Everts, 1511

- Harbors; Models; Numerical calculations; Shallow water; Storms; Storm water; Waves**
A Numerical Model of Storm Waves in Shallow Water, A. Hauguel, 746
- Harbors; Nigeria; Sedimentation; Sediment transport; Channels (waterways); Dredging; Field work**
Sedimentation in Dredged Navigation Channels, Lars Mikkelsen, Preben Mortensen and Torben Sorensen, 1718
- Harbors; Research; Sediment transport; Shore protection; China; Coastal engineering; Estuaries**
Some Aspects of Coastal Engineering Research Works in China, Yen Kai, 1734
- Harbors; Sand traps; Sediment transport; Wave measurement; Breakwaters; California; Coastal engineering; Field tests**
Longshore Transport Evaluations at a Detached Breakwater, R. O. Bruno, R. G. Dean and C. G. Gable, 1452
- Harbors; Shoaling; California; Channel improvements; Coastal Processes; Dredging**
A Phased-Dredging Program for Santa Cruz Harbor, James R. Walker and Peter J. Williams, 1492
- Harbors; Shore protection; Storms; Storm surges; Wind forces; Australia; Breakwaters; Coastal structures; Design**
The Design Concept of Dual Breakwaters and its Application to Townsville, Australia, W. Bremner, D. N. Foster, C. A. Miller and B. C. Wallace, 1899
- Harbors; Truncation errors; West Germany; Breakwaters; Case reports; Deep water; Design criteria; Energy transfer**
Energy Transmission Over Break Water - A Design Criterion?, P. Bade and H. Kaldenhoff, 1886
- Hawaii; Mathematical models; Reefs; Wave attenuation; Coastal engineering; Coastal structures; Design**
Wave Attenuation and Wave Set-Up on a Coastal Reef, Francisus Gerritsen, 444
- Hawaii; Tsunamis; Turbulent flow; Wind profiles; Wind velocity; Anemometers; Friction factor**
Tsunami Prone Friction Factors From Wind Measurements, Charles L. Bretschneider, 672
- Heat balance; Powerplants; Rivers; Thermal pollution; Wastewater (pollution); Water surface; Earth atmosphere; Experimentation**
Experimental Evaluation of Heat Exchange Between Water Surface and Atmosphere, Gunther Barg, Horst Schwarze and Gerhard Visscher, 2848
- Heated water; Industrial plants; Liquefied natural gas; Refractometers; Temperature rise; Water pollution control; Cooling water; Discharge (water)**
Dispersion of Cooling Water from a Coastal LNG Plant, P. Ackers, J. D. Pitt, G. Thompson and K. G. Rippin, 2794
- Heuristic methods; Surf; Wave energy; Wave height; Waves; Beaches; Coastal engineering**
An Heuristic Model of Wave Height Distribution in Surf Zone, Masaru Mizuguchi, 278
- High frequency; Meteorological data; Oceanographic data; Ocean waves; Radar mapping; Wave measurement; Wave spectra; Wind**
HF Radar Mapping of Extensive Ocean Windfields, P. E. Dexter and R. C. Casey, 363
- Hurricanes; Hydrodynamics; Models; Numerical calculations; Storms; Storm surges; Tropical cyclones**
Numerical Modelling of Tropical Cyclone Storm Surge, Rodney J. Sobey, Bruce A. Harper and George M. Mitchell, 725
- Hurricanes; Kinematics; Wave action; Wave measurement; Wave spectra; Wave velocity**
Directional Wave Spectra and Wave Kinematics in Hurricanes Carmen and Eloise, G. Z. Forristall, E. G. Ward and V. J. Cardone, 567
- Hurricanes; Predictions; Wave energy; Wave generation; Wave height; Waves; Wind direction**
Prediction of Dominant Wave Properties Ahead of Hurricanes, Omar H. Shemdin, 600
- Hydraulic design; Marinas; Water circulation; Water quality; Coastal engineering; Harbors**
Hydraulic Circulation Performance of a Curvilinear Marina, Jeffrey A. Layton, 2743
- Hydraulic models; Identification; Mathematical models; Parameters; Salinity; Estuaries; Estuarine environment**
Parameter Identification in Estuarine Modeling, Wen-Sen Chu and William W.-G. Yeh, 2431
- Hydraulic models; Japan; Landsat; Remote sensing; Saline water-freshwater interfaces; Sea water intrusion; Straits; Tidal currents; Vortices**
Study on Vortex Current in Strait with Remote-Sensing, Sotoaki Omishi and Tsukasa Nishimura, 2653
- Hydraulic models; Simulation; Wave generation; Wave pressure; Waves; Wave velocity**
Investigations on Irregular Waves in Hydraulic Models, Karl-Friedrich Daemrich, Wolf-Dietrich Eggert and Soren Kohlhasse, 186
- Hydraulic models; Wave generation; Waves; Wave tanks; Coastal engineering; Computer applications; Flumes**
A Survey of "Random" Wave Generation Techniques, J. Ploeg and E. R. Funke, 135
- Hydraulics; Laboratory tests; Permeability (soils); Profiles; Surf; Waves; Beaches; Beach sands; Coastal Processes**
Beaches: Profiles, Processes and Permeability, Michael R. Gourlay, 1319
- Hydraulics; Littoral drift; Sand; Sediment transport; Wave energy; Beaches**
Secondary Sand Transport Mechanisms, A. W. Smith and A. D. Gordon, 1122
- Hydraulic tests; Models; Sedimentology; Wave diffraction; Wave refraction; Computer applications; Design; France; Harbors**
Harbour Design Including Sedimentological Problems Using Mainly Numerical Technics, B. Latteux, 2211
- Hydraulic tests; Model tests; Reinforced concretes; Rubble-mound breakwaters; Concrete structures; Destructive tests; Dynamic loads**
Full Scale Trails of Dolosse to Destruction, Hans F. Burcharth, 1929

- Hydraulic tests; Netherlands; Storm surges; Barriers; Coastal engineering; Estuaries**
Hydraulic Research in the Oosterschelde Estuary, A. W. Walther, 2358
- Hydraulic test tunnels; Sediment transport; Wave action; Waves; Wave velocity; Coastal engineering**
A Closely Responding, Versatile Wave Tunnel, C. H. Hulsbergen and J. J. Bosman, 310
- Hydrodynamics; Models; Numerical calculations; Storms; Storm surges; Tropical cyclones; Hurricanes**
Numerical Modelling of Tropical Cyclone Storm Surge, Rodney J. Sobey, Bruce A. Harper and George M. Mitchell, 725
- Hydrodynamics; Ocean bottom; Ocean engineering; Petroleum pipelines; Submarine pipelines; Wave action; Gas pipelines**
Waves Forces on Offshore Pipelines, N. Jothishankar and V. Sundar, 1820
- Hydrofoils; Turbulent flow; Wakes; Waves; Wave velocity; Boundary layer flow**
Velocity Field in a Steady Breaker, J. A. Battjes and T. Sakai, 499
- Identification; Mathematical models; Parameters; Salinity; Estuaries; Estuarine environment; Hydraulic models**
Parameter Identification in Estuarine Modeling, Wen-Sen Chu and William W.-G. Yeh, 2431
- Impact loads; Laboratory tests; Wave action; Breakwaters; Caissons; Composite structures; Design**
Wave Impact Pressures on Composite Breakwaters, G. R. Mogridge and W. W. Jamieson, 1830
- Industrial plants; Liquefied natural gas; Refractometers; Temperature rise; Water pollution control; Cooling water; Discharge (water); Heated water**
Dispersion of Cooling Water from a Coastal LNG Plant, P. Ackers, J. D. Pitt, G. Thompson and K. G. Rippin, 2794
- Inlets (waterways); Lakes; Littoral drift; Stability criteria; Tidal effects; Tidal waters; Australia; Coastal Processes; Estuaries; Floods**
Tidal Inlet Behavioural Analysis, A. F. Nielsen and A. D. Gordon, 2459
- Inlets (waterways); Land reclamation; Littoral drift; Tidal effects; Tides; Airport construction; Australia; Estuaries**
Inlets/Estuaries Discharging into Sheltered Waters, H. P. Riedel and M. R. Gourlay, 2548
- Inlets (waterways); Landsat; Littoral drift; Remote sensing; Sandbars; Satellite Mapping; Bathymetry; Coasts**
Satellite Applications on a Coastal Inlet Stability Study, Yu-Hwa Wang, 2579
- Inlets (waterways); Littoral deposits; Littoral materials; Migration; North Carolina; Shoals; Tidal effects; Case reports**
Barden Inlet, NC a Case Study of Inlet Migration, Limberios Vallianos, 2638
- Inlets (waterways); North Carolina; Tidal waters; Water flow; Boundary conditions; Downstream Boundary Conditions for Analysis of Flow in Tidal Inlets, T. C. Gopalakrishnan and J. L. Machemehl, 2593**
- Inlets (waterways); Research projects; Tidal waters; U.S. Corps of Engineers; Beach erosion; Coastal engineering; Field investigations; Flood control**
The Corps of Engineer's General Investigation of Tidal Inlets, Robert M. Sorensen, 2563
- Inlets (waterways); Sand; Sandy soils; Storms; Tidal effects; Tidal hydraulics; Wave action; Coasts; Floods**
Comments on Tidal Entrances on Sandy Coasts, Morrough P. O'Brien, 2502
- Inlets (waterways); Sedimentation; Tidal currents; West Germany; Barriers; Basins; Channels (waterways); Dams; Estuaries**
Sedimentation Processes in Tidal Channels and Tidal Basins Caused by Artificial Constructions, E. Renger and H. W. Partensky, 2479
- Inlets (waterways); Tidal effects; Australia; Coastal engineering; Coasts; Estuaries**
A Coastal Inlet with Fixed Bed and Mobile Sides, R. C. Nelson and A. J. Keats, 2532
- Inlets (waterways); Tidal effects; Tide gages; Tides; Bays (topographic features)**
Tidal Prism-Inlet Area Relations for Small Tidal Inlets, R. J. Byrne, R. A. Gammisch and G. R. Thomas, 2515
- Islands; Piers (docks); Site investigation; Site selection; Coastal engineering; Design criteria; Docks**
Siting and Design Criteria of Dock Structures in the Marshall Islands, R. M. Noble, K. C. Leslie and D. O'Day, 2106
- Islands; Shallow water; Tsunamis; Wave equations; Coastal engineering; Finite difference method**
Transient Finite-Difference Tsunami Calculations, Ove Skovgaard and Ivar G. Jonsson, 823
- Islands; Shore protection; South Carolina; Wave action; Beach erosion; Breakwaters; Coastal engineering; Dredging; Field investigations**
Soft Designs for Coastal Protection at Seabrook Island, S.C., Miles O. Hayes, Timothy W. Kana and John H. Barwis, 897
- Islands; Shore protection; Terminals; Breakwaters; Caissons; Concrete construction; Design**
The Effects of Construction Techniques & Bulk Terminal Operational Requirements on the Design Criteria for Island Breakwaters, A. G.F. Eddie, J. D. Lawson, H. R. Graze and B. K. Dean, 2061
- Islands; Wave energy; Wave measurement; Waves; Wave spectra; California**
An Investigation of Wave Sheltering by Islands, S. V. Hsiao, J. F. Vesecky and O. H. Shemdin, 840
- Japan; Landsat; Remote sensing; Saline water-freshwater interfaces; Sea water intrusion; Straits; Tidal currents; Vortices; Hydraulic models**
Study on Vortex Current in Strait with Remote-Sensing, Sotoaki Onishi and Tsukasa Nishimura, 2653
- Japan; Littoral current; Power plant location; Wave action; Wave energy; Beaches; Coastal engineering; Currents (water)**
Nearshore Currents on a Partially Rocky Shore, T. O. Sasaki, H. Igarashi and S. Harikai, 1071

- Japan; Littoral drift; Littoral materials; Ports; Sand; Beaches; Field investigations**
Littoral Drift on Sand Near Port of Oarai, Kazumasa Mizumura, 2157
- Japan; Numerical calculations; Tsunamis; Wave equations; Wave runup; Bays (topographic features)**
Run-Up of Tsunamis by Linear and Nonlinear Theories, Chiaki Goto and Nobuo Shuto, 695
- Japan; Overtopping; Sea walls; Waves; Calssons; Concrete construction; Deep water; Design**
Seawalls in Deep Seas, Shoshichiro Nagai and Shohachi Kakuno, 2024
- Japan; Shore protection; Beaches; Breakwaters; Coastal engineering; Groins (structures)**
Artificial Resort Beach Protected by Offshore Breakwaters and Groins, Shoji Sato and Norio Tanaka, 2004
- Jets; Powerplants; Thermal pollution; Coastal engineering; Cooling water; Currents (water); Discharge (water); Experimentation**
Experimental Study of the Buoyant Surface Jet with the Presence of Bottom Boundary and Cross Current, B. Safaie, 2814
- Jetties; Littoral drift; Shoaling; Taiwan; Dredging; Fishing; Harbors**
New Jetties for Tung-Kang Fishing Harbor, Taiwan, Chi-Fu Su, 2228
- Jetties; Mathematical models; Mooring; Ships; Wind forces; Bulk cargo; Currents (water)**
Mooring Forces Induced by Passing Ships Measurements in Prototype, K. Haffke, 2689
- Jetties; Models; Morphology; Rivers; Rubble mounds; Sediment transport; Australia**
Mechanisms Operating at a Jettied River Entrance, Bruce M. Drury and Alexander F. Nielsen, 2605
- Kinematics; Ocean waves; Offshore platforms; Statistics; Wave measurement; Wave velocity; Wind**
Field Measurements of Wind Wave Kinematics, J. A. Battjes and J. van Heteren, 347
- Kinematics; Ocean waves; Structural members; Tidal currents; Tubes; Wave action; Wave velocity; Cylindrical bodies**
Full Scale Near Surface Water Particle Velocities and Pressure Acting on an Inclined Tubular Member, Fritz Busching and Eckehard Martini, 1870
- Kinematics; Wave action; Wave measurement; Wave spectra; Wave velocity; Hurricanes**
Directional Wave Spectra and Wave Kinematics in Hurricanes Carmen and Eloise, G. Z. Forristall, E. G. Ward and V. J. Cardone, 567
