Despite the possible sources of error listed above, the present data offer unique evidence that there is a great increase in suspended sediment transport during storm conditions. Measured point source concentrations ranging up to just 5 times higher during the storm, but extending significantly seaward and higher in the water column, produced an effective sediment load over 10 times higher. Estimated longshore current velocities 5 times higher during the storm resulted in a predicted transport rate over 60 times higher on the 13th than on the 15th. The close agreement on 13 September between suspended sediment transport and transport predicted from P_{1S} is probably fortuitous, but it is not unreasonable to believe these rates are of the right order.

The Importance of Suspended Sediment on Total Transport

An interesting result of these data is that during the storm, transport predicted from wave energy flux is totally accounted for by sediment 5 cm or higher in the water column. During post-storm swell conditions, however, suspended sediment flux only accounted for 30% of the transport predicted from P_{1S} . This may indicate that transport by sediment suspension is more important during storms, but may be secondary to bedload transport during post-storm swell conditions.

The data contained herein by no means resolve the controversy over the relative importance of suspended vs. bedload transport on beaches (Komar, 1978). However, they add an interesting twist. These results indicate that suspensions extend higher in the water column and farther offshore during storms. And, as Leonard and Brenninkmeyer (1978) reported, the frequency of suspensions may also be higher.

On the other hand, surf zone suspensions of sand during post-storm swell conditions appear to be lower in concentration, of lesser extent through the water column, and, perhaps, of lower frequency. This is analogous to the case for plunging vs. spilling waves reported by Kana (1979), where plunging waves suspend much greater quantities of sand. The present data, therefore, suggest that the suspension mode of transport is much more important during storms than during post-storm average conditions.

CONCLUSIONS

The present study at Duck, North Carolina provides some unique information on the relative quantities of sediment in suspension during storm and post-storm conditions. The following conclusions are offered:

1. Suspended sediment load in the surf zone is significantly higher during storms than post-storm swell conditions due to greater vertical and horizontal extent of the suspensions.
2. Sediment suspensions are relatively more important during storms in terms of their role in sediment transport.
3. Intermittent suspensions of sand from the bed are a less important component of longshore transport during post-storm recovery periods dominated by a swell wave environment.

ACKNOWLEDGMENTS

Support for the present study was provided by the U.S. Army under CERC Contract No. DACW72-78-M-0865. The authors wish to thank the staff from CERC who provided support, including David Lichy (DUCK-X coordinator), Curt Mason (Chief, Coastal Processes Branch), Phil Vitale (CERC technical monitor) and Charley Judge (CERC FRF manager). Data from radar and wave gauges were reduced by CERC before transmitting to University of South Carolina. Field assistance was provided by members of the Coastal Research Division at the University of South Carolina, including Aileen Duc, Kenneth Finkelstein, John Hodge, Tom Moslow, Pete Reinhart and Craig Shipp. Special thanks to Dag Nummedal and Shea Penland, Department of Geology, Louisiana State University who provided much technical assistance during the field work. The bulk of the data reduction was completed by Helen Johnson at the University of South Carolina. The manuscript and graphics were ably prepared by Pris Ridgell, Tom Vose, and Burk Scheper.

ABSTRACT

In this paper a model is presented to describe onshore-offshore sand transport in the surf zone. The model is based on the physical consideration that when the net transport attains a state of equilibrium, the power expended through gravitational force in suspending sand grains is balanced by that due to the uplifting force arising from the turbulence generated by breaking waves.

Two important parameters controlling sand transport are the dimensionless fall-time parameter and bottom slope. Using these parameters, the direction of onshore-offshore transport and the beach profile in the surf zone are expressed as

$$\begin{array}{l} (H_0/L_0) \tan \beta / \frac{w}{gT} < \quad \text{(onshore transport; accretive profile)} \\ \phantom{(H_0/L_0) \tan \beta / \frac{w}{gT}} = 0.5 \quad \text{(neutral; equilibrium profile)} \\ \phantom{(H_0/L_0) \tan \beta / \frac{w}{gT}} > \quad \text{(offshore transport; erosive profile)} \end{array}$$

INTRODUCTION

The aim of this study is obtain a better understandings of the mechanism governing onshore-offshore sediment transport and the transformation of beach profiles resulting from sediment transport across the surf zone. In treating coastal processes, sediment transport is usually divided into longshore and onshore-offshore components. It is generally believed that the longshore component controls relatively long-term systematic profile changes, whereas the onshore-offshore component has a marked connection with short-term profile changes, observed during either storm or post-storm wave climates.

The onshore-offshore shift of sand in the surf zone plays a very important role in shoreline migration as well as in the transformation of beach profiles. In other words, the beach profile has great bearing on coastal phenomena related to littoral sediment transport.

Since 1949, after Johnson proposed a criteria for beach profile classification in terms of the wave steepness in deep water, much effort has been devoted to clarify the mechanism of the profile change for two-dimensional beaches. Rector(1954), Iwagaki and Noda(1962), Nayak(1971), Watts(1954), Dean(1973); and Sunamura and Horikawa(1974) proposed certain parameters related to beach transformation and the direction of net sediment transport. The authors(1979) also obtained criteria for classifying the beach profile in terms of the "delay distance" (Kemp, 1960) and "surf similarity parameter" (Battjes, 1974). However, onshore-offshore processes, especially in the surf zone, have not yet been fully understood even under constant wave conditions.

Since the mechanics of sediment transport in the surf zone is more complex than in the offshore zone, all the relevant parameters can not be taken into account in a model description. In this paper, a model is developed on the basis of the concept of the balance of power expended on sand grains suspended by breaking waves.

DESCRIPTION OF MODEL

The turbulence generated by breaking waves acts as a stirring agent for suspending sediment particles. Using available field data of kinematic energy and momentum fluxes in the surf zone, Thornton(1978) presented a relationship between the ratio of the turbulent velocity intensity to the wave-induced velocity intensity and a parameter corresponding to the wave steepness.

Fig. 1 Ratio of turbulent to wave-induced velocity intensity (Thornton, 1978)

ponding to the offshore parameter $\xi_0 = \tan\beta/\sqrt{H_0/L_0}$ (Battjes, 1974). His result is given in Fig. 1, in which σ_u and $\sigma_{\hat{u}}$ are the standard deviations of the turbulent and wave-induced velocities, σ_{η} is the standard deviation of the free surface calculated from the spectrum of the waves, ω is the angular frequency, and $\tan\beta$ is the bottom slope. Figure 1 indicates that the velocity ratio is almost constant regardless of the breaking type, which is represented by the value of the abscissa (Galvin, 1972).

Based on Thornton's result, the stirring power, P_s , for suspending sand grains due to turbulence as the stirring agent is written as Eq.(1),

$$P_s = a'W \hat{u} \tan\beta, \tag{1}$$

in which W is the submerged weight of sand grains, \hat{u} is the maximum wave-induced velocity, $\tan\beta (= h_b/X_b)$ is the bottom slope in the surf zone, h_b is the water depth at the breaking position, X_b is the width of the surf zone, and a' is a constant. Notations used are shown in Fig. 2.

Fig. 2 Definition sketch.

Using the linear long wave theory, we have Eq.(2) as an expression for the maximum wave-induced velocity,

$$\hat{u} = 2\pi (H_b/L_b) gT, \tag{2}$$

where H_b and L_b are the wave height and length at the breaking position, T is the wave period, and g is the gravitational acceleration. Substituting Eq.(2) into Eq.(1), we have Eq.(3) for the expression of P_s ,

$$P_s = a'' W (H_b/L_b) g T \tan\beta, \tag{3}$$

where a'' is a constant.

Since it is considered that the resisting power against lifting sand grains from the bottom is due to the gravitational force, the resistive power expended on sand grains is written as Eq.(4),

$$P_r = a'' w_s(d), \quad (4)$$

in which $w_s(d)$ is the fall velocity of a sand grain of diameter d , and a'' is a constant.

If the stirring power, P_s , is greater than the resisting power, P_r , sand grains tend to keep in suspension due to breaking waves. Then, suspended sand grains would be transported seaward in the form of a sand cloud by wave-induced currents (Sunamura, 1980). If, on the other hand, the resisting power is greater than the stirring one, sand grains tend to roll and jump on the bottom surface. Then, sand grains are shifted shoreward as bed load.

It is, therefore concluded that the predominant or net direction of onshore-offshore sand transport, which has a close connection with beach profile change, can be described with the ratio of the above two powers, P_s and P_r . Combining Eqs.(3) and (4), the ratio P_s/P_r is written as

$$\begin{aligned} \frac{(H_b/L_b) \tan\beta}{w_s(d)/(gT)} &< && \text{(onshore transport)} \\ &= && C' \quad \text{(neutral)} \\ &> && \text{(offshore transport)} \end{aligned}, \quad (5)$$

in which C' is a constant.

As is well known, there are many difficulties in measuring wave and sediment processes within the surf zone, both in the laboratory and in the field. Most of the available data are usually represented by the wave characteristics in deep water and the median diameter of the sediment particles.

Wave steepness at the breaking position depends on the beach slope and incident wave steepness in deep water may be calculated within the limits of linear wave theory. Accordingly the wave steepness in Eq.(5) can be replaced with that in deep water. In addition, we write $w_s(d_{50})$ in place of $w_s(d)$ in Eq.(5), where $w_s(d_{50})$ is the fall velocity of sand grains determined from the median diameter of the sediment particles. Then Eq.(5) is rewritten as follows,

$$\begin{aligned} \frac{(H_0/L_0) \tan\beta}{w_s(d_{50})/(gT)} &< && \text{(onshore transport)} \\ &= && C \quad \text{(neutral)} \\ &> && \text{(offshore transport)} \end{aligned}, \quad (6)$$

in which C is a constant to be determined from laboratory and field data. It is noticed that Eq.(6), the final expression of the present model, is quite similar to the criterion proposed by Dean(1973), in which the effect of beach slope was not included.

By using the relation $L_0 = (g/2\pi)T^2$, Eq.(6) can be written as

$$\frac{H_0}{w_s (d_{50}) T} \tan\beta \begin{matrix} < \\ > \end{matrix} \frac{1}{2\pi} C. \quad (7)$$

Equation (7) indicates that two important parameters control onshore-offshore sand transport in the surf zone; the dimensionless fall-time parameter, $H_0/w_s T$, (SPM, 1977), and the relative width of the surf zone, $\tan\beta$. Dean (1973) also pointed out the importance of the quantity $H_0/(w_s T)$ for the prediction of accreted or eroded profiles.

COMPATIBILITY OF THE PRESENT MODEL

The present model emphasizes the importance of the beach slope for onshore-offshore sediment transport. Before discussing the validity of the model, it must be shown to be compatible with general observation both in laboratory experiments and in nature.

The beach slope in the surf zone may depend on the size of the beach material, the energy level of waves incident on the beach, the steepness of incident waves, the rate of percolation and the degree of sediment sorting of the beach, and the change in water level (Komar, 1976). Among these factors, the dependence of grain size on the beach slope has been investigated by geologists (Bascom, 1951; King, 1972; SPM, 1977).

The following has been deduced from previous studies:

(1) The beach slope of the foreshore depends mainly on grain size, and tends to increase with the median grain diameter. In addition, laboratory experiments with movable beds reveal that the specific gravity of beach material is an important parameter controlling the beach slope (Nayak, 1970). These facts imply that beach slope depends predominantly on the fall velocity, which is a function of the size, shape and specific gravity of the sediment particles.

$$(\tan\beta \sim w_s (d))$$

(2) For a given grain size, low-energy beaches have larger slopes than high-energy beaches.

(3) The effect of wave period (or, in effect, wave length) on the beach slope has been examined with both laboratory experiments and field investigations. The results indicate that the beach slope tends to increase with decreasing wave period.

$$(\tan\beta \sim 1/T \text{ or } \tan\beta \sim 1/L)$$

(4) The relationship between beach slope and steepness of incident waves is that the beach slope becomes flatter with increasing wave steepness (Rector, 1954; King, 1972).

$$(\tan\beta \sim 1/(H/L))$$

Combining the above results, we obtain the following relationship for the beach slope,

$$\tan\beta \sim \frac{w_s(d)/T}{(H/L)}, \quad (8)$$

which is essentially equivalent to Eq.(6).

TEST EQUIPMENT

In order to verify the present model and to determine the constant appearing in Eq.(6), laboratory experiments were performed in a two-dimensional wave tank, 0.4 m wide, 0.7 m deep, and 16 m long, with a glass wall on one side of the entire length. Figure 3 shows the general arrangement of the test equipment.

Fig. 3 General arrangement of test equipment.

The experiments were performed using monochromatic waves generated by a flap-type wave maker installed at one end of the tank. The incident wave height was measured by a capacitance type wave gage placed just offshore from the toe of the model beach. The breaker height was measured with a small capacitance type wave gage mounted on a carriage capable of moving with constant speed along the centerline of the tank. The horizontal distance from a base line on the model beach to the breaking position was measured with a ruler.

Beaches for the experiments were molded to an initial slope of 1 on 20 by using natural sand or Amberlite, a kind of plastic grain. The fall velocity of the bed materials was measured by means of a settling tube. Physical properties of the bed materials are given in Table 1.

Table 1 Physical properties of bed materials.

Bed Material	Amberlite	Natural Sand
Median Diameter (mm)	0.55	0.22
Specific gravity in Air	1.33	2.70
Fall Velocity (cm/sec)	3.20	2.60

Each experiment was performed in a series of runs. Beach profiles were surveyed along the centerline of the tank after each run using a specially designed bottom-touch type (Hattori and Kawamata, 1979). Immediately after starting a run, measurements of the incident wave height, and breaking characteristics were taken. Wave characteristics in the uniform depth of 0.35 m were determined from the threshold condition of sediment movement proposed by Horikawa and Watanabe (1967).

EXPERIMENTAL RESULTS AND DISCUSSIONS

As Sunamura and Horikawa (1974) have pointed out, from previous results obtained both in the laboratory and in the field, there exists some difficulty in grouping beach profiles into bar and step types according to the conventional criteria, because of the complexity of the beach configuration and of the tendency for shoreline migration. Figures 4 and 5, examples of the experimental results, show time changes of beach profiles of the accretive type. Arrows pointing toward the still water level represent the breaking position. As seen in Fig. 4, a break-point bar (King, 1972) moved shoreward gradually. It was noticed from the experiments that the breaking position also moved with the bar. When the migrating bar reached the beach face, the shoreline advanced considerably and the beach profile transformed to a step or reflective type profile (Hattori and Kawamata, 1979). On the other hand, sand outside the surf zone was shifted offshore. Due to this sand transport, the water depth around the breaking position deepened progressively, and the beach slope in the surf zone became steeper.

Fig. 4 Profile changes of accretive beach (Amberlite).

Fig. 5 Profile changes of accretive beach (sand).

Figures 6 and 7 illustrate profile changes of receding beaches. As the coastal berm eroded, sand shifted from the beach face was transported seaward and deposited in the offshore zone. Although an offshore bar sometimes formed at the breaking position, this bar tended to migrate offshore. With retreat of the shoreline, the beach slope within the nearshore zone became flatter and the width of the surf zone broadened in the course of time. It was also observed in the experiments that the breaker wave type changed from plunging to spilling.

Fig. 6 Profile changes of erosive beach (Amberlite).

Fig. 7 Profile changes of erosive beach (sand).

When the cumulative time, t' , was greater than four hours, waves broke twice: by first spilling and then by plunging at the toe of the foreshore. Under these circumstances, as seen in Fig. 7, a step was formed at the foreshore face and the shoreline migrated seaward. In this figure, broken arrows pointing toward the still water level indicate the breaking position of reformed waves.

CLASSIFICATION OF BEACH PROFILE

On the basis of the experimental results, the authors classified beach profiles into the following three groups as determined by the direction of net sand transport inside and outside the surf zone as shown in Fig. 8.

TYPE I is the accretive beach profile with a step on the foreshore. For this profile a landward sand shift is dominant in the surf zone, and the shoreline advances.

TYPE III is the erosive or storm beach profile without bars. Intense offshore sand transport occurs in the nearshore zone.

On a beach of TYPE II, a bar is formed at the breaking position. This bar sometimes migrates either landward or seaward. Under certain conditions, which depend mainly on the wave characteristics in the nearshore zone, the TYPE II profile transforms to the TYPE I or to the TYPE III profile.

Fig. 8 Classification of beach profiles (Arrows denote the direction of net sand transport).

Figure 9 illustrates the method for determining the direction of net sediment transport adopted in the classification of beach profiles. The bottom figure shows two beach profiles surveyed at a time interval of three hours. From the difference between these two profiles, the rate of sediment transport in the onshore-offshore direction can be computed with the aid of the conservation equation of bottom sediment, given by Eq. (9),

$$\frac{\partial h}{\partial t} = \frac{1}{(1 - \lambda)} \frac{\partial q_s}{\partial x}, \quad (9)$$

in which h is the water depth, q_s is the sediment transport rate in the on-offshore or x direction, λ is the porosity of the bottom sediment, and t is the time. The distribution of the transport rate computed is given by the top figure. The dominant tendency of sediment transport inside and outside the surf zone in Fig. 8 was determined in connection with the beach profiles by calculation with Eq.(9).

Fig. 9 Method for determining transport rate.

EVALUATION OF THE PRESENT MODEL

The evaluation of the present model is made on the basis of shoreline migration from the initial position of each test run, because the shoreline of the TYPE II profile exhibits considerable migratory tendencies. When the shoreline advances, a beach is termed as an accretive profile, whereas when the shoreline recedes, it is termed an erosive profile (Sunamura and Horikawa, 1974).

The criterion for the type of beach profile, erosive or accretive, based on this study is shown in Fig. 10 in terms of $(H_0/L_0) \tan \beta$ and $w_s (d_{50})/gT$. In this figure, the results of many other laboratory experiments are included to cover a wide range of characteristics of waves and bed materials. Open and solid symbols represent the accretive and erosive profiles, respectively.

It is noticed from Fig. 10 that regions of occurrence of the two beach profiles are distinctly separated by the line of $C = 0.5$, although there exists a mixed region bounded by $0.3 < C < 0.7$. The existence of this mixed region seems to have a close connection with the migration tendency of break-point bars.

Fig. 10 Classification of erosive and accretive beach profile (Laboratory data).

Various kinds of light-weight bed materials have been widely used for movable bed experiments. Light-weight bed materials behave in very different ways under wave action from natural sand as a bed material (Nayak, 1970). Figure 10, however, indicates that the beach profile in the surf zone can be classified by the present model without respect to the specific gravity of bed materials. This implies that the fall velocity is a very important parameter controlling the beach transformation and sediment transport (Dean, 1973).

In applying results of model experiments to the prototype, we have to consider various factors resulting from the lack of dynamic similitude between the model and the prototype. Among these factors, the scale effect of model experiments and the effect of irregularity of wave characteristics on the onshore-offshore sand transport are examined in this study. Many previous studies have pointed out the importance of scale effects on the formation of beach profiles (Collins and Chesnutt, 1975; Noda, 1972). In the evaluation of the present model, experimental data obtained in a prototype wave tank by Saville (1957) are plotted on Fig 10 in order to obtain knowledge about the applicability of the present model to the prototype.

Tsuchiya et al. (1974) conducted a series of movable bed experiments in a wave tank installed in a wind tunnel. Their data, circles with a vertical bar, are plotted on Fig. 10 to examine the effect of irregularity of incident wave characteristics on beach profiles. In examining the irregularity effect of incident waves, the wave height in deep water in Eq. (6) is replaced with the mean wave height calculated from the significant wave height, which is calculated on the assumption that the wave height frequency distribution in the wave tank is expressible by the Rayleigh distribution function. It is noticed that the transformation of beach profiles under the action of irregular waves also is inferable fairly well from the criterion determined by the experimental results employing monochromatic waves.

The tendency for beach transformation due to changes in incident wave characteristics can be discussed with temporal variations of the C value of Eq. (6) and the shoreline position. The bottom figure of Fig. 11 shows the changes of C value with respect to the dimensionless cumulative time, t/T . The top figure is the time change in the relative displacement of the shoreline, X/L_0 (Fig. 2). The following statements are supported by the experiments: For cases of accretive beaches, $C_0 < 0.5$, the C -value tends to move progressively from the initial value to the value of 0.5. C_0 is the value at an initial stage of each test. For erosive beaches, $C_0 > 0.5$, the C -value also shifts toward the value of 0.5. It is therefore concluded that the line of $C = 0.5$ in Fig. 10 represents not only the criteria for the occurrence of beach profile type, but also the equilibrium condition of beach transformation in the surf zone.

When characteristics of both the incident waves and bottom sediment are prescribed, processes in beach transformations are represented by the vertical shift of data points on Fig. 10. It is apparent from Fig. 10 that the slope of an accretive beach becomes steeper due to the onshore sand transport in the surf zone in approaching an equilibrium beach profile, while the slope on the erosive beach becomes flatter due to the intensive offshore transport.

Fig. 11 Time changes of C-value and shoreline position.

BEHAVIOR OF BREAK-POINT BARS

In the classification of beach profiles, it was pointed out that the TYPE II profile occasionally exhibits unusual behavior, which may depend on the migratory tendency of a break-point bar. The occurrence and migratory tendency of break-point bars can be also discussed with the aid of the two parameters of this study. As seen in Fig. 12, a break-point bar is found both on the erosive and accretive profiles.

Most bars on the accretive profile migrate shoreward across the surf zone. Under constant wave conditions, this process is indicated by vertically upward shifts of data points in the accretive profile region of Fig. 12. In contrast, downward shifts of data points in the erosive region indicate the seaward migration of bars due to the intense sand transport beyond the breaking position. It is noticed from Figs. 10 and 12 that the mixed region, $0.3 < C < 0.7$, has a close connection with the growth and reduction of break-point bars, which depends on the direction of bar migration.

Fig. 12 Occurrence of break-point bars.

APPLICABILITY OF THE PRESENT MODEL TO THE PROTOTYPE

Figure 13 indicates the applicability of the present model to onshore-offshore sand transport in the prototype as well as to beach transformation. Analysis of previous field data, plotted in Fig. 13, is made on the assumption that two-dimensionality holds in shore processes. The examination of beach profiles, erosive or accretive, is decided by the shoreline displacement from its position at the beginning of each investigation term.

In examining the applicability of the model, the wave steepness in Eq.(6) is calculated by a method similar to that used in the examination of the effect of irregularities of wave characteristics as in Fig. 10. Some of the field data did not contain information on the characteristics of the breaking waves. In using such data, the breaking depth is calculated by using the breaker indices proposed by Goda(1970), and the surf zone width is estimated with the aid of a bathymetric chart. When the fall velocity was not prescribed in the data, it was calculated using the diagram for the fall velocity of quartz spheres (Sedimentation Engineering, 1975).

Fig. 13 Applicability of the model to the prototype.

In the analysis of the field data, the effect of time scale on the beach profile change was also included. Field data plotted on Fig. 12, except those of Hashimoto and Uda(1979), were obtained by investigations at intervals of three months or more. Hashimoto and Uda made weekly field surveys of the shoreline configuration and daily observations of the wave climate in the nearshore zone on Ajigaura beach facing the Pacific Ocean.

The long-term profile change appears to have good correlation with the wave height and period averaged over the field investigation. This implies that the beach profile change over the long-term depends on the mean energy level of the incident waves. On the other hand, the profile change over a short-term relates to the high-energy level wave climate during that term. It should be emphasized that the beach profile change in response to the wave field was found inferable from the same relation as that determined from the laboratory data.

CONCLUSIONS

In this study, a model describing onshore-offshore sand transport in the surf zone is developed on the basis of the concept of the balance of power expended on sand gains suspended by breaking waves. The derived relationship, Eq.(6), indicates that both the dimensionless fall-time parameter and the bottom slope in the surf zone, or the surf zone width, are very important parameters controlling on-shore-offshore sand transport.

To evaluate the present model, the authors classify beach profiles into accretive and erosive ones, which are determined by the shoreline migration from its initial position. According to experiments, the regions of occurrence of these two beach profiles are distinctly separated by the line of $C = 0.5$ (Fig. 10). This C -value also represents the equilibrium condition of profile change of two-dimensional beaches (Fig. 11).

The criterion obtained is as follows:

<	(onshore transport; accretive profile)
$C = 0.5$	(neutral; equilibrium profile)
>	(offshore transport; erosive profile)

From comparison with field data (Fig. 13), it is emphasized that this criterion is applicable to the prediction of the beach profile change in the prototype. The importance of the time scale involved in beach profile changes is revealed in the evaluation of the model.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude to Dr. T. Sunamura, Associate Professor of the University of Tsukuba, for valuable discussions. A part of this study was supported by Scientific Research Fund from the Ministry of Education.

APPENDIX
ON THE BEACH SLOPE IN THE SURF ZONE

The Shore Protection Manual(1977) provides a criteria for predicting the bar-berm profile in terms of the dimensionless fall time parameter, $F_0 = H_0/w T$. In this reference, the dimensionless fall time parameter is plotted against both wave steepness in deep water and wave height to grain size ratio (Figs. 4-29 and 4-30).

According to the results in SPM, the separation between bar-berm profiles, or erosive and accretive profiles, is given by a value of $F_0 = 1 \sim 2$, and the criteria in terms of F_0 is expressible as

$$\begin{array}{l}
 < & \text{(deposition onshore, accretive profile)} \\
 F_0 = 1 \sim 2 & \\
 > & \text{(deposition offshore, erosive profile)}
 \end{array}
 \tag{A.1}$$

On the other hand, the criteria obtained in the present study can be rewritten with respect to the dimensionless fall time parameter by using Eq.(7) and putting $C = 0.5$ as follows:

$$\begin{array}{l}
 < \\
 F_0 = \frac{0.08}{\tan\beta} \\
 >
 \end{array}
 \tag{A.2}$$

The effect of beach slope on the profile change can be evaluated by combining Eqs.(A.1) and (A.2). For the critical value of the beach profile classification, the beach slope in the surf zone becomes

$$\tan\beta = 1/12.5 \sim 1/25$$

The estimated beach slope is considered to be very reasonable in comparison with previous results obtained in laboratory experiments and in the field (SPM).

ON-OFFSHORE SEDIMENT TRANSPORT RATE
IN THE SURF ZONE

ABSTRACT

In this paper, models of the distribution of net on-offshore sediment transport based on two-dimensional equilibrium beach profiles and an equation of continuity of sediment transport are proposed. Various parameters of net on-offshore sediment transport in those models are discussed. Further, the relative importance of bed load and suspended load in the two-dimensional beach deformation are examined by measuring both of them on model beach experiments.

1. Introduction

A problem of fundamental importance to the mechanics of sediment transport on beaches under wave and wave-induced current system is the relative magnitude of the littoral sand drift and on-offshore sediment transport. In the previous report (Sawaragi et al., 1978), the authors have formulated the littoral sediment transport rate considering long-shore current as a sediment transporting flow. However, as to on-offshore sediment transport rate, the authors could not evaluate quantitatively because of the complexity of mechanics of sediment transport.

The purpose of this study is to examine the relation between on-offshore sediment transport and the deformation process of two-dimensional beach profile. The first half of this paper will be constructed around a model of the distribution of net on-offshore sediment transport rate based on experimental results about two-dimensional beach deformation which were conducted by many investigators. The final part of this paper will examine a relative importance of suspended and bed load in the two-dimensional beach deformation by measuring directly suspended and bed loads in two-dimensional model beach experiments.

2. Model of the distribution of net on-offshore sediment transport rate along a beach profile

As suggested by Tanaka et al. (1973) and Horikawa et al. (1974), beach profiles which seem to reach a quasi-equilibrium condition can be classified into three types as shown in Fig. 1. The distribution of net

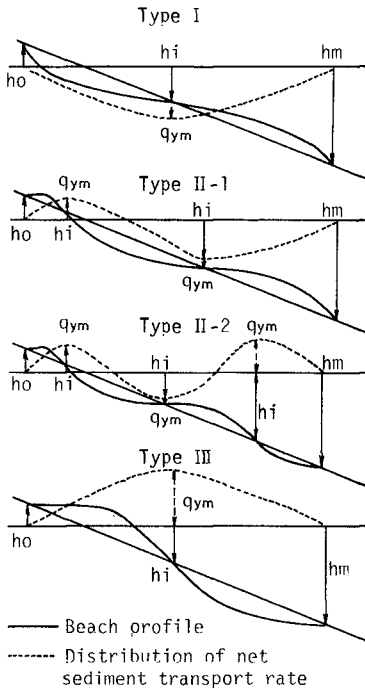

Fig.1 Model of the distribution of net on-offshore sediment transport rate

profiles, and calculated q_{ym} from the using the equation of continuity of sediment transport. In the following sections, these four characteristic quantities are analyzed by taking account of previous results obtained from the two-dimensional model beach experiments.

3. Analysis of h_0, h_m, h_i and q_{ym} which determine the distribution of net on-offshore sediment transport rate.

The four characteristic quantities will be expressed by the fluid density ρ , fluid kinematic viscosity ν , density of sediment ρ_s , median grain size d_{50} , wave height H , wave period T , beach slope i , gravity acceleration g , friction velocity u_* , wave running time t_s , and so on. Some important parameters such as the Shield's parameter

on-offshore sediment transport, which would have taken place in the processes of those beach deformation, can be modelled as dotted lines in Fig.1 from the equation of continuity of sediment transport. In Type I (erosion type), the direction of net on-offshore sediment transport is always toward offshore. In Type III (accretion type), onshore net sediment transport takes place in the entire range of beach profile. In Types II-1 and II-2, both onshore and offshore net sediment transport spring up.

The distribution of net on-offshore sediment transport rate can roughly determined by h_0, h_m, h_i and q_{ym} shown in Fig.1 where, h_0 and h_m : the critical height and depth of beach deformation, respectively, h_i : the depth of the point of intersection of two beach profiles measured in succession, i.e., the depth where the maximum net on-offshore sediment transport takes place, q_{ym} : the maximum net on-offshore sediment transport rate, and h_0 is taken upward, while h_m and h_i are taken downward from the still water level.

The authors rearranged about 80 experimental results on the two-dimensional beach deformation conducted by many investigators and evaluated h_0, h_m, h_i from the beach change of beach configurations by

$u_*^2/(\rho_s/\rho-1)gd_{50}$ and the surf similarity parameter $\xi=i/\sqrt{H_0/L_0}$ are already derived by combining above-cited variables to explain various phenomena in the surf zone. So far, however, there is no objective way to judge whether the beach profile reaches equilibrium or not. The authors, first, examine the time variations of h_o, h_m, h_i and q_{ym} to determine the wave running time for quasi-equilibrium beach profile.

3-1 Time-variations of the characteristic variables

Time-variations of h_o, h_m, h_i and q_{ym} of typical 2 cases in Type I and Type III are shown in Figs.2 and 3, respectively. In the figures, q_{ym} are calculated from differences of the water depth Δh , measured in succession with time interval Δt , by using the equation of continuity of the sediment transport. Therefore, they are given as average values taken over the time interval Δt . From Figs.2 and 3, the following results can be pointed out.

- 1) Net offshore sediment transport does not readily decrease even after a fairly long running time as seen in Fig.2. While, onshore net sediment transport decays soon, as seen in Fig.3.
- 2) In accordance with 1), h_o and h_m in Type I and h_m in Type II-1 increase after a large number of waves propagated. On the other hand, h_o and h_m

Fig.2 Time-variations of characteristic quantities of Type I

Fig.3 Time-variations of characteristic quantities of Type III

in Type III and Type II-2 almost remain constant or increase a little with increasing the running time.

3) h_i does not indicate significant changes with time.

Taking these results into account, beach profiles after 7.2×10^4 waves propagated were picked up to analyze h_o , h_m and h_i . In the case where the beach profile at this running time was not measured, we estimated those quantities by interpolating from the time-variations of them. The data, whose running time were less than $7.2 \times 10^4 T$, were omitted. However, experimental results of Saville (1957) who employed waves almost corresponding the full scale waves and Rector (1954) which have been quoted by many investigators were analyzed for reference, although they did not satisfy this limitation of running time.

On the other hand, we can assume the time-variations of q_{ym} expressed as Eq. (1) to clearly grasp the rate of decay of q_{ym} with running time.

$$q_{ym} = q_{ym0} \exp(-At_s/T) \quad (1)$$

where q_{ym0} is the initial value of q_{ym} and A is a constant. Here, q_{ym0} and A are calculated by the following procedure:

- 1) Select the data whose running times are more than $7.2 \times 10^4 T$ in which beach profiles were measured at least 3 times.
- 2) Let $t_s = 0, t_{s1}, t_{s2}, \dots$ be the times when the beach profile was measured and q_{ym1}, q_{ym2}, \dots be the maximum on-offshore sediment transport rate in the time interval $\Delta t_1 = t_{s1}, \Delta t_2 = t_{s2} - t_{s1}, \dots$
- 3) Calculate q_{ym0} and A by substituting $q_{ym} = q_{ym1}$ at $t_s = t_{s1}/2$ and $q_{ym} = q_{ym2}$ at $t_s = (t_{s1} + t_{s2})/2$.

In Figs. 2 and 3, Eq. (1) determined by the above-mentioned procedure are also shown by dotted curves. As can be seen from these figures, it is found that the time-variation of q_{ym} can be expressed fairly well by Eq. (1) and at $t_s/T = 7.2 \times 10^4$, the maximum onshore net sediment transport rate q_{ym} in Types III and II-2 almost diminish and the maximum offshore net sediment transport rate of Types I and II-1 become less than 25% of their initial value q_{ym0} .

3-2 Analysis of h_o

h_o will be determined by factors which control a wave run-up height and a change of shore line. The wave run-up height is said to be closely related to the surf similarity parameter ξ (Battjes, 1974). While, the change of shore line should be considered as one part of the whole beach deformation rather than related to local parameters near the shore line. Hence, the authors use the non-dimensional force, $N_s = H_o/T \sqrt{(\rho_s/\rho - 1)gd_{s0}}$ as the parameter to indicate the magnitude of the ability of the beach to deform. The derivation of N_s will be mentioned latter. Fig. 4 shows the relation between h_i/H_o and ξ with N_s as a parameter. From this figure, it is found that h_i/H_o increases with increasing ξ and that for the same value of ξ , h_i/H_o also increases with increasing N_s .

3-3 Analysis of h_m

In the initial stage of the beach deformation, h_m can not be deeper than the critical depth for an initial sediment movement. Generally,

Fig.4 Relation between h_o/H_o and ξ

Fig.5 Relation between $U_b^2 / (\rho_s / \rho - 1) g d_{50}$ and a_s / d_{50} at $h=hm$

the critical depth for the sediment movement is determined from the balance between the forces acting on a grain and the resistance force of the grain which can be given as follow:

$$(\pi/6)gd_{50}(\rho_s-\rho)\tan\phi = K(\pi/4)d_{50}^2\rho f u_b^2 \quad (2)$$

where $\tan\phi$ is the friction angle of the sediment, f the friction factor, u_b the maximum water particle velocity at the bottom, and K the coefficient. f is usually expressed by $u_b\delta/\nu$ or $u_b^2 T/\nu$ in a laminar region and a_s/Z_o in a turbulent region where $\delta=(\nu T/2\pi)^{1/2}$, $a_s=Tu_b/\pi$ and Z_o the equivalent roughness height. However, the effect of Reynold's number on the initial movement of sediment seems to be small compared with a_s/Z_o (Dingler,1975). Hence, Eq.(2) can be given as follow:

$$u_b^2/(\rho_s/\rho-1)gd_{50}\approx 1/f\approx F(a_s/Z_o) \quad (3)$$

Assuming that the same relation as Eq.(3) holds with h_m , the authors calculated $u_b^2/(\rho_s/\rho-1)gd_{50}$ and a_s/Z_o at $h=h_m$ by using the linear wave theory. The results are shown in Fig.5. In this calculation, Z_o is taken equal to d_{50} in order to take account of only the skin friction regardless of the bottom configuration according to Madsen(1976). As seen from Fig.5, the relation between $u_b^2/(\rho_s/\rho-1)gd_{50}$ and a_s/d_{50} at $h=h_m$ can be approximated fairly well by the following equations:

$$u_b^2/(\rho_s/\rho-1)gd_{50} = B(a_s/d_{50})^n \quad (4)$$

in which,

$$\begin{array}{ll} B = 0.18 & n = 1.1 \quad \text{for Type I and Type II-1} \\ B = 0.10 & n = 0.75 \quad \text{for Type III and Type II-2} \end{array} \quad (5)$$

By using the linear wave theory and $N_s = H_o/T/\sqrt{(\rho_s/\rho-1)gd_{50}}$, Eq.(4) can be modified as Eqs.(6) and (7).

$$\{(H/H_o)(1/\sinh kh_m)\}^{-1} = CN_s(d_{50}/L_o)^m \quad (6)$$

$$\begin{array}{ll} C = 400 & m = 0.6 \quad \text{for Type I and Type II-1} \\ C = 20 & m = 0.3 \quad \text{for Type III and Type II-2} \end{array} \quad (7)$$

The left hand side of Eq.(6) is the function of h_m/L_o only. And if N_s and d_{50}/L_o are given, h_m/L_o can be calculated from Eqs.(6) and (7). Fig.6 shows the comparison of h_m calculated from Eq.(6) with h_m measured from the beach profile. From this figure, it is found that Eq.(6) together with Eq.(7) give a sufficiently accurate estimate of h_m .

3-4 Analysis of h_i

h_i is defined as the depth where the maximum on-offshore sediment transport takes place. The limit depth of "D-profile" proposed by Swart(1970), "cut-depth" defined by Hallermeier(1977) seem to correspond to h_i of Types I and II-1. "Stable point" proposed by Raman et al. (1972) may also equivalent to h_i . Although the concept of "D-profile" or "cut-depth" can be applied only to the beach of Types I and II-1, h_i as defined above, can be applied extensively to all types of beach profiles.

In the consideration of h_i , it is necessary to take into account the difference of the mode of sediment transport between Type I and Type III. The causes of net on-offshore sediment transport have been studied for long time and may be summarized as follows:

- 1) stational flow such as mass transport current due to waves.
- 2) asymmetry of water surface profile, ie, asymmetry of the time-vari-

Fig. 7 Relation between Ubd_{50}/ν and $(\pi H/L)(1/\cosh kh)$ at $h=hb$ and $h=hm$

Fig. 6 Comparison of measured and calculated hm/Lo

ation of water-particle velocity.

3) effect of gravity, i.e., the existence of beach slope.

4) distorted profile of time-variation of the concentration of suspended sediment due to asymmetrical sand ripple or breaking waves.

Referring from theoretical and experimental results by Sato et al. (1962), Inman et al. (1963), Horikawa et al. (1974) and Bowen (1979), the necessary condition for the occurrence of net offshore sediment transport seems to be the existence of sufficient amount of suspended sediment, and net onshore sediment transport is mainly caused by bed load.

However, in the surf zone, although the asymmetrical property of time-variations of water-particle velocity increases, ripples usually disappear and the existence of the steady flow becomes dubious because of large turbulence brought by breaking waves. Hence, so far, the authors can not explain the reason why net onshore sediment transport can take place in the entire beach profile of Type III and net offshore sediment transport happens in the whole beach of Type I. Then, to begin with, the authors examine the direction of net on-offshore sediment transport in the offshore regions of three types of beach profiles by using two parameters proposed by Sato et al. (1962). They give the criteria for the occurrence of net on-offshore sediment transport on a horizontal bed by a function of sediment Reynold's number $u_b d_{50} / \nu$ and the amplitude of non-dimensional pressure gradient at the bottom by waves $(-1/\rho g)(\partial p/\partial x) = (H/L)(\pi/\cosh kh)$. They also found that asymmetrical ripples caused net offshore sediment transport by using radio active tracers. Although $u_b d_{50} / \nu$ is a non-dimensional parameter, it expresses a magnitude of drag force acting on a grain in a fluid and $(-1/\rho g)(\partial p/\partial x)$ indicates the relative magnitude of the acceleration of water-particle to that of the gravity. Fig. 7 shows the relation between $u_b d_{50} / \nu$ and $(H/L)(\pi/\cosh kh)$ at $h=h_b$, calculated from the new-breaker-index presented by Goda (1970), and $h=h_m$. Again, u_b and L were calculated by the small amplitude theory. Taking into account the direction of net on-offshore sediment transport of Type I and Type III, the direction of net on-offshore sediment transport can be distinguished by Eq. (8)

$$u_b d_{50} / \nu \begin{cases} < (H/L)(\pi/\cosh kh) \times 10^3 & \dots \text{ offshore} \\ > & \dots \text{ onshore} \end{cases} \quad (8)$$

Taking the ratio of $u_b d_{50} / \nu$ to $(H/L)(\pi/\cosh kh)$ and let the ratio be N_{sr} , the criteria of Eq. (8) can be written in a simple form,

$$N_{sr} = (u_b d_{50} / \nu) / \{(H/L)(\pi/\cosh kh)\} = g T d_{50} / 2 \pi \nu$$

$$N_{sr} \begin{cases} < 10^3 & \dots \text{ offshore} \\ > & \dots \text{ onshore} \end{cases} \quad (9)$$

However, as can be seen from Fig. 7, two data of Saville (1957) can not be classified by Eq. (8). He employed large waves as in the field and H_o/L_o of his experiments were larger than other cases. Therefore, to apply Eq. (8) or Eq. (9) to the large scale model beach as the field, some modifications including the effect of wave height itself or H_o/L_o explicitly seems to be required.

The direction of net sediment transport in Types II-1 and II-2 are also shown in Fig. 7, and they are classified by Eq. (9). This means that the change of the direction of net on-offshore sediment transport in

in these two types will occur in the surf zone.

As discussed above, the direction of net sediment transport in the offshore region can be determined by N_{sr} . On the other hand, h_i seems to be closely related to wave breaking as the first order action of fluid motion. So, the authors examine the relative depth of h_i to h_b , h_i/h_b of three types of beach profiles. Fig.8 shows the relation between h_i/h_b and N_{sr} . It can be seen from this figure that for the offshore net sediment transport of Types I and II-1, h_i/h_b ranges between $1.0 < h_i/h_b < 1.5$, for the onshore net sediment transport of Type III, $0.3 < h_i/h_b < 0.9$ and for the onshore net sediment transport of Type II-1, $-0.4 < h_i/h_b < 0.0$. This indicates that a longshore bar in a storm beach (Type I or Type II-1) has to be generated in the offshore region. For the beach of Type II-2, no significant tendency can be found out for the deficiency of the data.

Fig.8 Relation between h_i/h_b and N_{sr}

Because h_i of Types I and II-1 appears outside the surf zone, the procedure proposed by Hallermeier(1977) seems to be effective. Hence, the authors compared h_s calculated according to Hallermeier with h_i measured from the beach profile of Types I and II-1. As a result, the correlation between h_i and h_s is relatively high for small scale experiments, however, h_s seems to give smaller values of h_i for large-scale experiments. On the other hand, within the breaker zone, wave characteristics and wave-induced flow pattern are controlled by H_0/L_0 and \bar{i}

(Nakamura et al., 1966). Hence, h_i for onshore net sediment transport of Type III may also be controlled by H_o/L_o and i . The authors also discussed the relation between h_i of Type III and those two parameters. It is found that h_i/h_b have a tendency to decrease with decreasing H_o/L_o , however, i seems to have little influence on h_i/h_b .

3-5 Analysis of q_{ym}

Referring Madsen's presentation (1976), the time averaged rate of on-offshore sediment transport by bed load \bar{q}_y , i.e., the amount of sediment which have a capacity to be transported as net on-offshore sediment transport, can be expressed as follow:

$$\bar{q}_y / W_o d_{s0} = D (u_*^2 / (\rho_s / \rho - 1) g d_{s0})^n \quad (10)$$

where D is a coefficient, W_o the settling velocity of sediment and $n=3$. Assuming that the same kind of relation as Eq. (10) can be applied to suspended load and that the direction and the rate of net sediment movement can be expressed by N_{sr} , H_o/L_o and i , net on-offshore sediment transport rate q_y will be given as a first order approximation by

$$q_y / W_o d_{s0} \approx q F_1 (N_{sr}, H_o/L_o, i) \cdot F_2 (t_s/T) \\ = D (u_*^2 / (\rho_s / \rho - 1) g d_{s0})^n \cdot F_1 (N_{sr}, H_o/L_o, i) \cdot F_2 (t_s/T) \quad (11)$$

Further, it seems reasonable to assume the turbulent flow condition near $h=h_i$ and consequently a constant friction factor. Then, for Types I and II-1, u_* at $h=h_i$ ($> h_b$) can be replaced by $(H_o/T)(H/H_o \sinh kh)_{h=h_i} = (H_o/T)F_3(h_i/L_o)$, and h_i/L_o is also expressed by H_o/L_o according to Hallermeier (1977). Hence, the maximum net sediment transport q becomes

$$q_{ym} / W_o d_{s0} = q_{ym0} \exp(-At_s/T) \\ = E (H_o/T / \sqrt{(\rho_s / \rho - 1) g d_{s0}})^{2n} F (N_{sr}, H_o/L_o, i) \exp(-At_s/T) \quad (12)$$

where $N_s = H_o/T / \sqrt{(\rho_s / \rho - 1) g d_{s0}}$ and E is the coefficient of proportionality. N_s was already used to analyze h_o and h_m . The authors further consider that Eq. (12) can be applied to Types III and II-2.

Fig. 9 shows the relation between A in Eq. (12) and N_s . It can be seen that A is closely related to N_s and the direction of net on-offshore sediment transport. Namely, the larger, the N_s , the faster net sediment transport decays. And onshore net sediment transport decreases faster than offshore sediment transport.

Finally, Fig. 10 shows the relation between non-dimensional net on-offshore sediment transport rate q_{ym0}^* and N_s . Here, q_{ym0}^* is derived by taking four parameters in Eq. (12) into account as follow:

$$q_{ym0}^* = (q_{ym0} / W_o d_{s0})^{2n} (1/\lambda) (1/N_{sr}) (H_o/L_o) \quad (13)$$

where λ is the porosity of sand. From Fig. 10, it is concluded that q_{ym0}^* is proportional to N_{sr} regardless of the direction of net on-offshore sediment transport. And the exponent n in Eq. (10) is 3. The result corresponds to that obtained by Madsen et al. (1976).

Fig.9 Relation between A and Ns

Fig.10 Relation between q_{yrmo}^* and Ns

4. Experiments to measure on-offshore sediment transport rate in the two-dimensional model beach

Since net on-offshore sediment transport discussed above includes both bed and suspended loads, the relative magnitude of bed load and suspended load can not be examined. In this section, based on the experimental results, relative importance of bed load and suspended load in the deformation of two-dimensional model beach is discussed.

4-1 Equation of continuity of the sediment transport including suspended sediment

Consider the co-ordinate system taken X-axis horizontal to the shore line, positive y-axis shoreward, positive Z-axis vertically upward from the stillwater level. The diffusion equation for any arbitrary volume is

$$\partial C / \partial t = -\nabla \cdot (\vec{C} \vec{V}_s) \quad (14)$$

where C is the sediment concentration, \vec{V}_s the sediment-particle velocity vector. After taking time average and integrating Eq.(14) from $z=-h$ (bottom) to $Z=\eta$ (free surface), the equation of continuity can be obtained as follow:

$$\frac{\partial}{\partial t} \left(\int_{-h}^{\eta} C \, dz + (1-\lambda)h \right) + \frac{\partial}{\partial x} \int_{-h}^{\eta} q_x \, dz + \frac{\partial}{\partial y} \int_{-h}^{\eta} q_y \, dz = 0, \quad (15)$$

where $(q_x, q_y) = (u_s C, v_s C)$, $\vec{V}_s = (u_s, v_s, w_s)$, $(1-\lambda)\partial h / \partial t = [w_s C]_{z=-h}$

In the previous section, the authors consider Eq.(11) as a first order approximation of $q_y = v_s C$. In Eq.(15), $z=-h$ corresponds to bed load and $z>-h$ to suspended load, respectively.

Based on these consideration, the authors examine the relative importance of bed load and suspended load by measuring directly bed load and suspended load in model beach experiments.

4-2 Experimental procedure

Two wave tanks of different dimension were used. One is 26m long, 1.5m wide and 1.8m high, and other one is 51m long, 0.64m wide and 0.97m high. Two kinds of beach materials, i.e. $d_{50} = 0.54\text{mm}$, $\rho_s = 2.65\text{gr/cm}^3$ and $d_{50} = 0.34\text{mm}$, $\rho_s = 2.68\text{gr/cm}^3$ were used to form a model beach of 1/20 initial beach slope. The bed load was measured by a sand trap composed of an outer casing and inner box made of a tin plate. The inner box has two compartments to separately measure the amount of onshore and offshore sediment transport rate. The dimension of this inner box is 10cm in width, 10cm in length and 5cm in depth. While the beach profile was developed, the inner box was not installed and the outer casing was buried into the bottom sand bed. Just before the measurement was conducted, the outer casing was pulled up to the bottom surface and sands in it were taken out to replace them with the inner box. Bed load was measured at 10 different locations covering from swash zone to the offshore zone, and the measured time was from 2 to 6min. The average sediment transport rate Q_{bt} and net sediment transport rate Q_{bnet} were calculated from the sum and the difference of the amounts of sediment trapped in both shoreward and seaward compartments respectively in the unit of (dry weight/cm/sec). The suspended load was measured by collecting the water samples through siphons with intake nozzles as shown in Fig.11. the reasons why such a

primitive apparatus was used are as follows:

- 1) by the optical method, the direction of suspended load can not be distinguished,
- 2) small babbles brought into water by breaking waves decrease the accuracy of the measurement by optical method,
- 3) direct measurement of the amounts of sediments is possible by collecting the sediment laden water samples by siphons.

Fig.11 Sketch of the intake nozzles of siphon

The measurements of suspended sediment were done orienting the intake nozzle both toward onshore and offshore directions at each measuring point setting the lower part of the nozzle above 1mm from the bottom. Samples of 4 points distributed vertically at each measuring point were collected. Sampling time was from 40 to 80sec., and 200-400 CC was gathered. The concentration of suspended sediment \bar{C} and net on-offshore sediment transport rate q_{snet} are calculated from the following procedure. Let S_{ion} and S_{ioff} be weights of samples and dry net weights of sediments included in S_{ion} which was collected by orienting the intake nozzle offshore at $Z=Z_i$; height of the i th intake nozzle and S_{ioff} and S_{ion} be the amounts of those collected by orienting the intake nozzle onshore. The authors calculated \bar{C} at $Z=Z_i$ from

$$C(Z_i) = (S_{ion} + S_{ioff}) / (S_{ion} + S_{ioff}) \quad (\text{dry weight/weight}).$$

While net on-offshore sediment transport by suspension, q_{snet} was calculated from

$$q_{snet} = (1/T_s) [((S_{1on} - S_{1off}) / a_1) ((Z_2 + Z_1) / 2) + ((S_{2on} - S_{2off}) / a_2) ((Z_3 - Z_1) / 2) + ((S_{3on} - S_{3off}) / a_3) ((Z_4 - Z_2) / 2) + ((S_{4on} - S_{4off}) / a_4) (h - (Z_4 + Z_3) / 2)] \quad (\text{dry weight/cm/sec})$$

in which T_s is the sampling time and a_i is the area of i th intake nozzle. These method to separately measure the amount of onshore and offshore sediment transport by suspension is fundamentally based on the time-

variation of the velocity of fluid sucked through the intake nozzle which is calculated from the generalized Bernoulli's theorem; pressure equation. A head difference between the intake nozzle and the outlet was adjusted to coincide the intake velocity with the maximum water-particle velocity in both direction of offshore and onshore. However, when the orientation of intake nozzles directed onshore or offshore, a few sediments which were moving in the direction of offshore or onshore, seemed to be sucked. Consequently, the measured concentration might be little larger than the true concentration. Besides, due to an accuracy of weighing dry sands in the sample, the accuracy of concentration measured by this method decreases when C is less than 10^4 ppm.

The authors confirmed the reliability of the siphon by comparing the concentrations measured by the siphon with those of ductivity meter using an optical method.

Table-1 Experimental conditions

4-3 Experimental results

6 experiments were conducted. Their detailed conditions are shown in Table-1. In three cases of $N_{sr}=636$, suspended load will be expected to dominate and in the other three cases of $N_{sr}>1200$, bed load will be predominate.

H cm	T sec	d_{50} mm	ρ_s/ρ	N_{sr}
17.8	1.2	0.34	2.68	636
7.3	1.2	0.34	2.68	636
3.8	1.2	0.34	2.68	636
33.1	1.7	0.54	2.65	1431
12.4	1.7	0.54	2.65	1431
5.4	1.5	0.54	2.65	1263

i) Time-averaged on-offshore sediment transport by bed load Q_{bt} and suspended load Q_{st}

First, let's investigate the difference of the relative magnitude of Q_{bt} and Q_{st} between two beaches of different N_{sr} . Fig.12(a) and (b) show two examples of the distributions of Q_{bt} and Q_{st} . When $N_{sr}=636$, as shown in Fig.12(a), time-averaged suspended load Q_{st} clearly surpasses bed load Q_{bt} in amount. The ratio of the maximum time-averaged sediment transport rate Q_{st}/Q_{bt} is about 2.0. While in the case of $N_{sr}=1263$, as shown in Fig.12(b), suspended load is less than bed load and the ratio of the maximum transport rate Q_{st}/Q_{bt} is 0.5.

The authors also measured a bottom shear stress on a fixed flat bed by a shear meter. Details of the shear meter are described in the previous paper (Sawaragi et al., 1978). From Fig.12 and the results of the measured shear stress, it was found that Q_{st} was larger than Q_{bt} in the region of $U_* / W_0 > 0.8$, and Q_{bt} became larger than Q_{st} when $U_* / W_0 < 0.8$. However, U_* measured on a fixed bed, does not include the effect of the bottom roughness. So, in order to determine the strict criterion for the initiation of sediment suspension, it is necessary to clarify the sediment movements on the bottom which are closely related to the water-particle motion near the bottom.

ii) Relative importance of suspended load versus bed load to the beach deformation

Finally, the authors examine the relative importance of suspended load versus bed load to the beach deformation by investigating the relations among net sediment transport rate Q_{net} calculated from the time-variations of beach profiles, measured net on-offshore sediment transport rate by suspension Q_{snet} and bed load Q_{bnet} .

Fig.12(a) Distributions of q_{st} and q_{bt}
($N_{sr} = 636$)

Fig.12(b) Distributions of q_{st} and q_{bt}
($N_{sr} = 1263$)

Fig.13 shows one example of the distribution of q_{ynet} , q_{bnet} and q_{snet} together with the beach profile of $N_{sr}=636$. q_{bnet} and q_{snet} were measured in a relatively short time compared with running time $t_s/T=1.5 \times 10^3$, in which the beach profile in Fig.13 was developed. So, they might change with running time. q_{ynet} is given as an average over $t_s/T=0 \sim 1.5 \times 10^3$. In Fig.13, the distribution of q_{bnet} is similar to that of q_{ynet} , and q_{snet} has a sharp peak at $y/y_b=0.75$ which corresponds to the location of the bar. To examine the relative importance of q_{bnet} and q_{snet} in the beach deformation, the authors calculated the change of water depth caused by q_{bnet} and q_{snet} by using the equation of continuity of sediment transport without considering the effect of time-change of concentration of suspended sediment indicated by the first term in Eq.(15). The result is shown in Fig.14. In this figure, Δh shown by solid line is calculated from the difference of beach profiles between $t_s/T=0$ and $t_s/T=1.5 \times 10^3$, Δh_b , shown by heavy line, is calculated from q_{bnet} and represents the changes of mean water depth between two neighboring measuring points and Δh_s , shown by broken line is calculated from q_{snet} as well as Δh_b . As can be seen from this figure, the bar near $y/y_b=0.75$, the typical beach profile of this case, seems to be created not only by bed load but also by suspended load. However, Δh_s gives fairly large beach deformation compared with Δh in this region. According to Eq.(15), this difference between measured and calculated water depths have to be compensated by the increase of concentration of suspended sediment. On the other hand, the measured concentration increased about 6ppt at $y/y_b=0.75$ during $t_s/T=1.5 \times 10^3$. This increment of concentration only accounts for few millimeter of erosion near $y/y_b=0.75$. This indicates that, even in the case where suspended load dominates bed load, the first term of Eq.(15) becomes less than 1/10 of other terms.

Fig.15 shows the relation between q_{ynet} , q_{bnet} and q_{snet} in the case of $N_{sr}=1263$. In this case, q_{bnet} is in the direction of onshore through the entire range of the beach profile and the distribution of q_{bnet} almost coincides with q_{ynet} . While the direction of q_{snet} is mainly offshore and its magnitude is less than 1/2 of q_{bnet} . Fig.16 shows the relation between Δh , Δh_b and Δh_s . Same notations and symbols as in Fig.14 are used. From this figure, it can be found that the fundamental mode of the beach deformation of Type III with deposition in the shallower region and erosion in the deeper region as shown in Fig.1 is mainly created by q_{bnet} . However, q_{snet} also seems to contribute to the beach deformation of secondary mode in addition to the fundamental mode.

5. Conclusions

The authors analyzed experimental results about the two-dimensional beach deformation conducted by many investigators to propose the models of net on-offshore sediment transport rate and carried out two-dimensional model beach experiments to examine the relative importance of bed load and suspended load in the beach deformation. Following results are obtained.

- 1) When $N_{sr} = gT d_{50} / 2\pi v > 10^3$, the direction of net sediment transport is onshore (Type III) and when $N_{sr} < 10^3$, net offshore sediment transport is apt to take place (Type I). However, even when $N_{sr} < 10^3$, net onshore sediment transport may spring up near the shore line.
- 2) Net onshore sediment transport decays faster than that of offshore sediment transport. And when $N_s = H_o / T / \sqrt{(\rho_s / \rho - 1)} g d_{50}$ becomes large, net on-offshore sediment transport decays fast regardless of their direction.
- 3) The non-dimensional height of upper limit of beach deformation h_o / H_o increases with increasing $\xi = i / \sqrt{H_o / L_o}$ and N_s . And the non-dimensional depth of lower limit of beach deformation h_m / L_o can be expressed by Eq.(6).
- 4) The maximum net offshore sediment transport takes place in the offshore region and the maximum onshore sediment transport takes place in the surf and swash zones. Time-variation of the maximum sediment transport rate can be approximated by Eq.(1). And its maximum can be expressed by Eqs.(12) and (13).
- 5) When $N_{sr} > 1200$, time-averaged bed load surpasses time-averaged suspended load, and main beach deformation seems to be created by bed load.
- 6) When $N_{sr} < 640$, time-averaged suspended load surpasses time-averaged bed load, and beach deformation seems to be caused by both bed load and suspended load.
- 7) Suspended load becomes equivalent in amount to bed load when $u_* / W_o = 0.8$.

ABSTRACT

Forcing functions and sediment response were measured during two comprehensive surf zone experiments. The experiments included simultaneous measurements of waves and currents, and the movement of sediment as bed and suspended load. The longshore transport of suspended load was found to be about 10 to 20% of the tracer-measured load. Results from tracer measurements of the longshore transport of bed load indicate that previous measurements may have misestimated the effective "tracer layer thickness," and a more rigorous method is proposed.

1. INTRODUCTION

There is extensive competition for the use of nearshore areas for harbors, recreational beaches and swimming, as recipients of thermal and waste discharges, and for coastal construction. Therefore, understanding of sediment transport processes has become essential to coastal technology.

As a consequence, the Nearshore Sediment Transport Study sponsored by the U.S. Office of Sea Grant, NOAA, and funded in part by the Office of Naval Research, has been engaged in extensive field experiments since 1977. The overall objective of the study is the development of improved engineering prediction techniques for sediment transport by waves and currents in the nearshore region. The studies have been conducted jointly by research teams from five universities. The first field experiments were carried out at Torrey Pines Beach near San Diego, California, in March 1977 and November-December 1978 (Gable (ed), 1979; Seymour and Gable, 1980). Additional experiments have recently been conducted near Santa Barbara, California, in February 1980.

The purpose of this paper is to present the results from the two most comprehensive, high energy experiments conducted on 11 March 1977 and 6 December 1978. These experiments included simultaneous measurement of forcing functions (i.e., waves, winds and currents) from sensor arrays in and outside the surf zone, as well as sediment response in terms of bed and suspended load movement.

2. TORREY PINES BEACH SITE

A portion of Torrey Pines Beach in San Diego County, California, was selected as a site for this study. The site is located 5.5 km north of Point La Jolla, and 4 km north of the ocean pier of the Scripps Institution of Oceanography. A 3.0 km segment of this beach that has gently sloping offshore bathymetry and is terminated shoreward by 100 meter high sea cliffs was used for the beach and nearshore measurements (Figure 2-1). This beach satisfied the basic requirements for a straight beach with uncomplicated offshore bathymetry that is exposed to waves from all offshore quadrants. Chamberlain (1960) and State of California (1969) have estimated the net littoral transport in the vicinity of Torrey Pines Beach at about 200,000 m³ per year, to the south.

The study beach undergoes typical seasonal changes in configuration due to changes in wave climate. During summer wave conditions, the beach has a 30 to 60 meter wide backshore, a relatively steep upper foreshore, and a pronounced berm. Winter storm waves overtop the summer berm and erode the backshore, thus reducing the width of the exposed beach. Winter beach profile configuration is typified by a gently sloping beach foreshore that in places extends shoreward to the toe of the sea cliff. The beach profiles for the two experiments are shown in Figure 2-2. Generally the beach face slopes about 1:25, the surf zone 1:75, the section seaward to the 3 meter depth contour 1:35, while that portion from 3 to 10 meters depth slopes 1:50.

The sediments on the beach and shelf are predominantly fine quartz sand with minor amounts of feldspars and heavy minerals. Light minerals, that is those with a specific gravity of less than about 2.85, usually comprise 90% of the sample, while heavy minerals total about 10%. Of the light minerals approximately 88% is quartz, 10% feldspars and 2% shell fragments and miscellaneous material. Of the total heavy minerals hornblende is most plentiful, comprising about 60% (Inman, 1953). The size distributions for typical sediments obtained by grab samplers in the surf zone are listed in Table 2-1.

Table 2-1 Size distribution measures for sieved surf zone samples. Measures are from Inman (1952).

3. EXPERIMENT CONTROL

The dates and times of our tracer experiments were carefully selected to meet the following criteria: 1) fully operational status for the offshore wave array and other necessary sensors; 2) minimal change in tide elevation during a 3 hour period during daylight; 3) occurrence of dominant waves of sufficient height and breaker angle to generate a strong, unidirectional longshore current; and 4) absence of stationary rip currents across the sampling grid in the study area.

Figure 2-1 shows a stationary rip current pattern with separation between rip currents of 340 meters. In accordance with criterion 4, the injection line and sampling grid were placed within a 250 meter length of beach between rip currents. Reversal of longshore current during experiments resulted in the rejection of many of the experiments conducted on other days.

During the morning of the given day, Rhodamine-B dye was injected at several positions in the surf zone and observed from the cliff above the site. The dye dispersal patterns, such as that illustrated in Figure 4-4 indicated the approximate mean longshore current speed as well as the occurrence of complicating rip currents. If all conditions were satisfied, the injection location and sampling grid were determined appropriate to the current speed and direction, and flags marking the grid ranges were installed on the beach.

4. DRIVING FORCES

It is well known that the principal driving forces for longshore transport of sand in the nearshore waters are waves, currents, winds, and tides, in that order. Since strong winds did not occur during the two experiments described here, and because the experiments were scheduled to coincide with near still-stands in the tidal curve, neither wind nor tidal forces are considered to be important in these experiments. However, the stage of the tide may have some disequilibrium effect on the beach profile, as the water level during experiments was generally above mean sea level in order to cover the surf zone instruments. The tide in these waters is mixed, with a pronounced diurnal inequality. At the Scripps Institution of Oceanography pier the mean and spring tidal ranges are 3.6 and 5.2 feet (1.10 and 1.58 meters), and the mean tidal level is 2.7 feet (0.82 meters) above the datum of mean lower low water. During the experiments of 11 March 1977 and 6 December 1978 the water levels were about 20 cm and 60 cm respectively above mean tide level.

WAVES

The direction and flux of wave energy and momentum were measured from an array of wave pressure sensors placed parallel to shore in a water depth of 9.7 m below mean sea level, hereafter referred to as the 10 meter array. All data from it have been corrected to the actual depth of water at the times of the observations. Also, arrays of electromagnetic current meters, pressure sensors, and wave staffs were placed in and near the surf zone. Details of these near-surf arrays

are given in Guza and Thornton (1978, 1980) and Gable (ed 1979).

The spacings of the offshore line array were in a 1-2-4-5 and a 2-2-2-5 configuration with a unit lag of 33 meters and total array lengths of 396 and 363 meters respectively. The first was used on 11 March 1977 while the latter was used on 6 December 1978. The length of the array was designed for resolution of long period waves with directional peaks separated by 5° to 10° in ten meters of water. Data from the offshore array was telemetered back to the Shore Processes Laboratory of the Scripps Institution of Oceanography using the Shelf and Shore (SAS) system described by Lowe et al (1973).

The wave spectrum consists of the squares of the absolute values of the complex Fourier coefficients, which serve as estimates (having dimensions of length squared) of the energy density in each elemental frequency band. The sum of the energy densities under the spectral peak of the incident waves i.e., the variance, is the mean-square elevation $\langle \eta^2 \rangle$ of the water surface described by the time series. The mean wave energy per unit area of the water surface is given by the product of $\langle \eta^2 \rangle$ and the weight per unit volume ρg of the water,

$$E = \rho g \langle \eta^2 \rangle = \frac{1}{8} \rho g H_{\text{rms}}^2 \quad (4-1)$$

where H_{rms} is the root-mean-square wave height.

The energy spectrum was computed for time runs of about 17 minutes during which pressure was sampled two times per second ($\Delta t = 0.5$ sec), for a total number of data points $n = 2048$, which when transformed give 1024 elemental frequency bands. Energy and cross-spectra were computed from the summation of 8 ($q = 8$) elemental frequency bands, giving a total of 128 merged frequency bands and 16 degrees of freedom. The most important frequency bands were plotted, and examples are shown in Figures 4-1, 2.

Directional spectra were computed for every frequency band using the maximum likelihood estimator described by Capon (1969) and Davis and Regier (1977). Important frequency bands with high energy peaks were graphed, and examples are shown in the lower part of Figures 4-1, 2.

There is in general a flux of energy in the direction of wave propagation, which in the absence of refraction and dissipation is a constant per unit width of wave crest

$$ECn = \left[ECn \right]_{\infty} = \text{const} \quad (4-2)$$

where E is defined in relation (4-1), C is the wave phase velocity, and Cn is the wave group velocity.

Waves also transport momentum which is a tensor quantity consisting

Fig. 4-2 Examples of wave energy and directional spectra for 6 December 1978.

Fig. 4-1 Examples of wave energy and directional spectra for 11 March 1977.

of four components. The onshore flux of y -directed momentum S_{yx} has been shown to drive the longshore currents inside the surf zone (Bowen, 1969; Longuet-Higgins, 1972). Outside the surf zone S_{yx} is conserved, and is given by the relation

$$S_{yx} = En \cos \alpha \sin \alpha = (En \cos \alpha \sin \alpha)_0 = \text{const} \quad (4-3)$$

S_{yx} is obtained by integrating the energy, E , in the directional spectra with respect to $\cos \alpha \sin \alpha$ to obtain relation (4-3) for each 17-minute run.

The wave energy at the breakpoint was obtained by refracting each frequency band to an estimated breaker depth using Snell's law and relation (4-2). The actual breaker depth was then computed by combining equation (4-1) relating energy and wave height with the criterion for a breaking solitary wave, $\gamma_b = (H/h)_b = 0.78$ (Munk, 1949), and then recomputing the energy at the breakpoint, where h is the depth of water.

Wave heights at the breakpoint depth were then computed using equation (4-1); the radiation stress, S_{yx} , from equation (4-3). The phase velocities at the breaker depth were computed from the Boussinesq dispersion relation (Whitham, 1974, p. 462):

$$c_b^2 = \frac{9h_b}{1 + \frac{1}{3}(kh)_b^2} \quad (4-4)$$

It was then possible to estimate the power expended by the waves, $(CS_{yx})_b$, which has been related to the sand transport rate (Figure 6-1). Measured and computed wave parameters are summarized in Table 4-1.

CURRENTS

The general circulation of water in the surf zone, although complex, appears to follow patterns shown schematically in Figure 4-3. Early measurements showed that outside the surf zone, and between rip currents, water tended to move onshore from surface to bottom (Shepard and Inman, 1950). However, inside the surf zone, surface, mid-depth, and bottom waters have different net directions: the surface water moves onshore and longshore and has the greatest speed; the mid-depth water moves on-offshore with a net longshore motion; while the bottom water has a very slow net offshore motion, even though the highest velocities during the passage of a bore are decidedly onshore. There is also an upward circulation associated with the passage of the breaking wave and its bore (Inman and Quinn, 1952; Inman and Nasu, 1956; Inman et al, 1971).

Surf zone currents in these studies were measured by three separate methods: 1) dye injection into the water; 2) weighted drift bottles; and, 3) electromagnetic current meters mounted at mid-depths in the surf zone. The first method gives a pattern of water motion and was particularly effective in locating rip currents (Figures 4-4). Drift bottles give Lagrangian trajectories which can be plotted as current velocities representative of the upper layers of the surf zone. The current meters give continuous measures of values of x-y current components, and are most representative of the mid-depth motion of the surf zone (Figures 4-5, 6). They are more fully described by Guza and Thornton (1978).

5. SEDIMENT RESPONSE

The sediment response to the action of waves and currents is complex and not understood. For our purposes we will group these complex motions into bed and suspended load components. Bed load is arbitrarily defined as sand transported on and within 10 cm of the bed; while

Fig. 4-3 Schematic of surf zone circulation.

DYE DISPERSION IN THE SURF ZONE
6 DEC 78

Fig. 4-4 Dye pattern from 13:22 injection.

suspended load is that transported in the water column from 10 cm to the water surface. This definition is used because our present suspended load samplers do not function properly when operated closer to the bed than 10 cm.

TRACER TECHNIQUE FOR BED LOAD

The only known means of estimating the "instantaneous" bed load transport in the field is by tagging the sand in some detectable manner and injecting the tracer into the surf zone (e.g., Inman and Chamberlain, 1959). More recently, fluorescent dyed sand grains have been used as tracers by several investigators (Aibulatov, 1961; Ingle, 1966; Komar and Inman, 1970) to study the motion of sand in the nearshore environment. The longshore transport of sand has been estimated by multiplying the rate of advection of sand tracer by the depth in the bed to which the sand tracer mixes (Inman, et al, 1968; Komar and Inman, 1970).

If sand motion consisted of uniform advection, then a line source of tracer sand placed across the surf zone would move at a velocity calculatable directly by sampling the bed at the proper time and distance following injection. However, granular diffusion in the bedload transport, turbulent diffusion in suspended load transport, and non-uniform advection tend to disperse as well as advect the original distribution of tracer. In view of these processes, a concentration-weighted mean velocity must be calculated in order to estimate the true advection rate of tracer and its admixed sand aggregate.

Fig. 4-5 Longshore currents from current meter array for 11 March 1977.

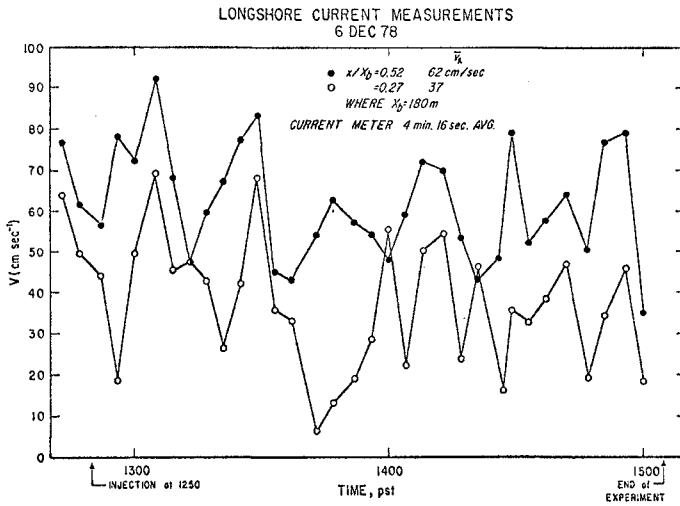

Fig. 4-6 Longshore currents from current meter array for 6 December 1978.

The tracer grain distribution was sampled following injection by two independent methods. The first method uses traditional "grab samplers" designed to sample the upper 2 cm of the sand bed, with the objective of surveying downcurrent as rapidly as possible to give a synoptic areal view of the tracer distribution at a given time. This method is referred to as "spacial sampling." The second method uses specially designed coring devices to repeatedly core the bottom along a fixed on-offshore range, downstream from the injection line and at constant intervals of time, and is analogous to sampling a dye plume in a river as it flows under a bridge. This method is called "temporal sampling." Each sample provides an estimate of the rate of advection. If a sample i is taken y_i meters from the injection line at an elapsed time t_i seconds after injection, then the sand velocity is given by $V_i = y_i/t_i$. If N_i is the tracer concentration of the sample, then a concentration weighted mean advection rate for sand in the longshore direction is given by

$$\bar{V}_L = \frac{\sum_{i=1}^n \left[N \frac{y}{t} \right]_i}{\sum_{i=1}^n N_i} \quad (5-1)$$

where n is the total number of samples. This definition of the advection rate V is also time weighted, thus freeing the transport calculation from bias introduced because all of the spacial samples cannot be taken at the same time. Spacial and temporal sampling concepts are shown schematically in Figure 5-1.

Tracer Layer Thickness

The vertical distribution of tracer in the cores was examined to determine the "tracer layer thickness," one of the most uncertain parameters in previous studies (Komar and Inman, 1970). Ideally the measured thickness is one which predicts the actual transport rate when multiplied by the advection rate and surf width. However, the determination of the tracer layer thickness from the core data has been highly subjective. In an effort to remove some of the subjectivity, we have chosen a concentration weighted depth to represent the "tracer layer thickness" Z_0 , defined as

$$Z_0 = 2 \frac{\int_{z=0}^{\lambda} N(z) z dz}{\int_{z=0}^{\lambda} N(z) dz} \quad (5-2)$$

Fig. 5-1

where z is the depth in the bed, $N(z)$ is the tracer concentration at depth z , and λ is a depth in the bed greater than any tracer penetrates. It has been assumed here that the surface of the bed ($z = 0$) is fixed, with no erosion or accretion occurring. We realize that this definition is itself highly subjective, but it is an effort towards standardizing the determination of the tracer layer thickness. It is to be noted that the actual value of Z_0 can be greater than the measured value, and the velocity V_0 must grade from a maximum at the surface to zero at the bottom of the layer.

The longshore series of cores taken with the center grab sample on 11 March 1977 were analyzed for tracer layer thickness Z_0 using several systems including relation (5-2), and the results are plotted in Figure 5-2. The upper curve showing maximum thickness of tracer penetration more closely approximates the thickness used in previous studies (Komar and Inman, 1970); while the lower curve represents a more conservative cut-off thickness where the tracer concentration is 1 grain/gm or less.

BED LOAD TRANSPORT

The product of the tracer layer thickness Z_0 , the advection rate of sand and tracer V_0 , and the surf zone width X_b , results in an estimate of the longshore bed load sediment transport rate. This procedure is schematically depicted in Figure 5-1.

Tracer injections and bed load sampling

Tracer injections and bed load sampling were made on 11 March 1977 and 6 December 1978. On 11 March 1977, since only spacial sampling was attempted, a grid of $10 \times 18 = 180$ grab samples were recovered and 21 core samples. The grid is shown in Figure 2-1 and the contours of tracer concentration in Figure 5-3. On December 1978 two spacial and a temporal sampling were made, and the results are shown in Figure 5-4, 5. This procedure permits three independent estimates of transport, but with the same number of personnel, necessarily results in fewer samples per run.

The tracer layer thickness Z_0 as a function of surf zone width for both days is plotted in Figure 5-6. It is apparent that Z_0 is greatest in the swash zone and least in the central portion of the surf zone, and again increases towards the breakpoint. Separate investigation, not reported here, confirms this bimodal distribution of Z_0 , i.e., minimum values in the center of the surf zone. This bimodality was used to estimate transport rates near the breakpoint on these high energy days where breakpoint samples were not obtained.

Fig. 5-2 Longshore variation of Z_0

Fig. 5-3 Distribution of grab sample tracer concentrations on 11 March 77.

Fig. 5-4 Distribution of grab sample tracer concentrations on 6 December 78.

Three types of estimates for the transport rate were made in order to demonstrate the effect of the conceptual models in the interpretation of field data. The first estimate used the tracer layer thickness, Z_0 , as defined in eq. 5-2 and assigned the mid-surf value of Z_0 to the unsampled outer portion of the surf zone. The second estimate extrapolated the tracer layer thickness to the unsampled portion of the surf-zone using a bimodal distribution as described above. The final estimate equated Z_0 to the maximum thickness of tracer penetration and applied a bimodal distribution for the tracer layer thickness.

The percent recovery of tracer was calculated for both spacial and temporal methods. For the spacial method, each sample yields an estimate for the total amount of tracer in the region from which it was taken. These estimates can be summed over the experimental grid and compared with the known quantity of tracer injected over the same area. For the temporal method, the amount of tracer which advected across the sampling line is estimated, and compared to the amount of tracer injected in that portion of the surf zone covered by the temporal sampling line.

Table 5-1. Sediment Response

	11 March 77	6 December 78		
		Spacial		Temporal
		Run #1	Run #2	
Sampling Start (min. after inj.)	85	41	92	15
Sampling End (min. after inj.)	170	71	109	135
Tracer Recovery (%)	65	39	77	48
Immersed Wt. Longshore Transport Rate, I_b (nt/sec)

SUSPENDED LOAD

Suspended sediment samples were collected on 11 March 1977 and 6 December 1978 during the period between tracer sand injection and the start of grab sampling. The 11 March 1977 samples were collected at the offshore positions shown in Figure 5-7. Six sample series were collected below the crest of the bore, five series between bores, and five just before passage of the bore. On 11 March 1977 samples were taken where bore heights ranged from 30 cm to 102 cm. The breaker type on 11 March 1977 ranged from spilling to plunging, with some strongly plunging.

During the 6 December 1978 experiment suspended sediments were collected at four stations from under the passing crest of the bore. Because of high plunging breakers, these samples did not extend beyond the inner surf zone (Figure 5-8). Samples were collected under bores ranging in height from 49 to 72 cm on that day, with a total range of heights during the November-December 1978 experiments of 15 to 131 cm.

The suspended load was integrated over depth to give the suspended load in grams over a square meter of bed. The product of this load and the average longshore current was then assumed to give an estimate of the suspended load transport rate for that portion of the surf zone. These estimates, when integrated across the surf zone, give the estimates of total suspended load transport rate. The 11 March 1977 experiment provides data on the variation of suspension over a wave cycle. On this day the average suspended load over a wave was used to estimate the total suspended load transport rate. The 6 December 1978 rates were corrected using information from the 11 March 1977 experiment. The total suspended load transport rates are listed in Table 5-1.

FIELD AND LABORATORY PROCEDURES

The tracer experiment used natural Torrey Pines Beach sand dyed with either Florescein (green) or Rhodamine (red) dye. Plastic bags of wetted tracer sand were placed on the sand bed along the injection range to approximate a line source of tracer across the surf zone; then each bag was emptied simultaneously at the time of injection.

The grab samples were collected using a hand-held, scissors type, box grab sampler with the sample volume of 7.5 x 12.5 and 2.1 cm deep. The samples were transferred to plastic bags and labeled with date and grid location. Grab and core samplers were designed for both simplicity of operation in the surf zone and for recovery of sediment cores with undisturbed vertical structure, described in Waldorf and Zampol (in prep).

In the period between injection of tracer and grab sampling, the suspended load was sampled at a number of points across the surf zone. At each sample location a vertical series of 3 or 4 suspended load samples were taken using a "water-coring device" (Waldorf and Zampol, in prep). The swash was sampled with a mechanically closed "plastic bag" sampler.

After fresh water rinsing and drying, 10 gram sub-samples from each grab sample were spread to a single grain layer thickness on a counting grid. The fluorescent tracer grains in the sample were counted using a long-wave ultraviolet light in a completely darkened room. Using these techniques, tracer concentrations as low as 100 grains/kg are measured.

Fig. 5-8 Representative suspended load, profiles, and sampling locations for 6 December 78.

6. DISCUSSION

The bed and suspended load measurements presented here were made under the most intensely monitored forcing conditions yet reported for moderately high energy, dissipative beaches (gentle slope, wide surf zone). As a consequence more surf zone variables and their ranges are known than for previous field investigations. The measurements also showed some trends suggesting that previous simplistic models and methods of calculation should be revised.

FORCING FUNCTIONS

The surf zone width X_b varies with breaker height and type, and a rigorous definition is not generally possible. However, the old concept of a "significant surf zone width" determined by the average of the one-third highest breakers seems appropriate from the standpoint of energy and momentum fluxes.

The complex nature of the longshore and the on-offshore currents was clearly demonstrated by the three methods of current measurement employed, and portrayed schematically in Figure 4-3. The strongest currents were always near the midpoint of the surf zone, and no dyed water passed seaward of the breakpoint except in rip currents. Rip currents may be stationary (Figure 2-1), or may progress down current through the experiment area as in Figure 4-5. The effect of rip currents on the overall transport is not known, but must be considered as an important mechanism in the overall transport processes.

SEDIMENT RESPONSE

The on-offshore bimodality of the tracer layer thickness Z_0 was an unexpected finding, and clearly emphasizes the shortcoming of basing transport estimates on limited core information. The concepts of "tracer layer thickness" are of sufficient importance to merit much of the discussion in Section 5, and resulted in the definition given in relation (5-2). The differences between this definition and others is shown graphically by Figure 5-2. The upper curve of maximum tracer penetration more closely approximates the value of tracer layer thickness used previously by Inman et al (1968) and Komar and Inman (1970). Since the interpretation of sand tracer data depends upon the conceptual models of the processes involved, we have interpreted the data in accordance with several models in order to demonstrate the ranges in sand transport rates to be expected. For purposes of comparison, transport estimates are plotted together with the previous data of Komar and Inman (1970) in Figure 6-1.

The difference in transport rates between the spacial and temporal sampling on 6 December 1978 is not clear. However, the persistence of rip currents moving through the sampling grid (Figure 4-5) suggest tracer was lost offshore. This effect would be more pronounced in the spacial sampling which is sensitive to the entire grid length, than to the temporal sampling which was relatively close to the injection point (Figure 5-4). If this is the cause for the different transport rates, then the temporal sampling is the more accurate value.

Fig. 6-1 Wave power vs. sediment transport rate (after Komar and Inman, 1970). Ranges of values for 11 March 77 and 6 December 78 are indicated.

Suspended load measurements emphasized the complex nature of suspension processes and demonstrate the need for continuous monitoring sensors vs. the discrete type samplers employed here. Even so, these data show the importance of the changes in concentration as a function of the phase of the bore. Other data taken during the 1977-78 period by this laboratory indicate the importance of the type of breaking wave. Plunging waves suspend much more sediment than spilling waves, especially near the breakpoint. There also appears to be a bimodal distribution of suspension, with maxima in the swash zone and near the breakpoint. The ratio of suspended transport rate to tracer-determined transport rate is 10 to 20% on 11 March 1977 and 6 December 1978. Thus, a comprehensive model of longshore transport as well as on-offshore transport will need to incorporate suspended load as a fundamental component of the total load.

AN APPROACH TO UNDERSTANDING COASTAL PROCESSES

A.D. Gordon, B.E., M. Eng. Sc., Engineer Coastal Process Investigation Section, N.S.W. Department of Public Works, Coastal Engineering Branch, Sydney, Australia.

D.B. Lord, B.E., Engineer Coastal Process Investigation Section, N.S.W. Department of Public Works, Coastal Engineering Branch, Sydney, Australia.

ABSTRACT

The approach adopted in N.S.W. for investigating coastal processes leading to development of a numero-descriptive model for management purposes is outlined. The technique involves the formation of a regional coastal model and its adaptation to site specific cases. This site specific conceptual model is then tested and modified on the basis of theoretical calculation and field data collection. Two specific case histories are outlined.

1. INTRODUCTION

With increasing pressure for development of the coastal zone, a growing community awareness of the nearshore environment, and the harsh economic realities of man's attempts to do battle with the sea, there has been a rapidly growing need for greater understanding of coastal process systems. Both planning and environmental impact requirements have necessitated the development of regional coastal process models to facilitate the assessment of factors which pattern the coastline.

It is desirable that such models be based on rigorous analytical solutions of mathematically described mechanisms. However, both the complex nature of coastal processes, and the recency of scientific endeavour in this field, have resulted in simplifying assumptions and empirically derived relationships being substituted for the more rigorous approach so that pressing problems may be attacked within an acceptable time frame.

In developing coastal models which can describe the historical coastal formation, determine present beach response and predict future trends, an accounting type philosophy has been adopted. "Sediment Budgeting", an expression of the conservation of mass principle, provides a useful framework within which a variety of techniques may be used to determine the coastal processes of a particular region. One further advantage offered by the flexibility of this budget philosophy is that the degree of sophistication to which mechanisms are described and calculations executed, can be tailored to the requirements of a particular study.

2. COASTAL PROCESS ANALYSIS

Two types of coastal process models have been developed for the New South Wales coastline; the criteria for categorisation being that of time scales.

- (i) Engineering/planning time scale (1-100 years)
- (ii) Geological time scale (100 + years).

While it is recognised that far shorter time scales must be employed when considering specific mechanisms of the coastal processes within the sediment budget, it is argued that for the purpose of engineering/planning and environmental impact analyses, the time scales nominated above are most appropriate for model development.

Both the engineering time scale model (site specific), and the geological time scale model (generalised coastal), are developmental; each supplementing and complementing the other.

The remainder of this paper will be devoted to:

- . Outlining the generalised N.S.W. coastal model and demonstrating its relevance.
- . A documentation of the methodology used in developing site specific models and illustration of the strengths and shortcomings of the approaches and techniques employed.

GENERALISED COASTAL MODEL

FIG. 1.

3. GENERALISED COASTAL MODEL

This is an overall coastal model which explains the historic development of the observed present day coastal features and is invaluable basic information for any site specific engineering study.

The methodology adopted in formulating the generalised coastal model is shown in Figure 1. In simplistic terms the resulting model for the New South Wales coastline can be presented as follows:

Three major natural factors have contributed to the present day coastal morphology.

- (i) Bedrock outcrops and sediment deposits which pre-date the Holocene sea level rise.
- (ii) The onshore movement of sand which accompanied the Holocene sea level rise.
- (iii) The alongshore and onshore/offshore re-working of coastal deposits by wind wave and current action.

While the contribution of the first factor may be obvious, the subtle inter-relationship of the other two is not so obvious. It is however essential that an understanding of this inter-relationship be developed in order that an apparent existing anomaly may be explained.

GENERALISED COASTAL DEVELOPMENT MODEL

FIG. 2.

Thom et. al. (1978) have shown at many locations along the N.S.W. coastline, that the development of beach ridges and barrier deposits followed the Holocene sea level rise and still stand (ref. Figure 2).

These accretionary features have resulted from the onshore movement of sand in response to the "new" sea level condition. Radio carbon dating carried out by Thom on N.S.W. beach ridge plains indicates that they were formed during the period approximately 8,000-2,000 years B.P. A decreasing rate of ridge formation is evident with time. Little evidence exists past 2,000-1,500 years B.P. of any general coastal accretion and in fact the reverse, a state of beach recession is now apparent on a majority of N.S.W. beaches. Hence an anomaly exists - coastal accretion having occurred approximately 8,000-2,000 years B.P., coastal erosion 2,000 years B.P. to the present.

Competing theories have been advanced to explain this apparent reversal in shoreline behaviour. The first is that there has been a major shift in weather patterns. The second theory which is favoured by the authors is that while longshore and aeolian redistribution mechanisms have operated throughout the 6,000 year still stand, during the period up until 2,000 years B.P., the onshore movement of sand dominated coastal development. The diminishing quantities of onshore moving sediment in the period 6,000-2,000 years B.P. reflected the decreasing availability of sand in the offshore region. By approximately 2,000 years B.P. the offshore source had been depleted to such an extent that longshore redistribution due to wave obliquity and onshore movement of sediments under aeolian processes dominated. In coastal compartments where longshore redistribution is possible, and the sediment losses to the compartment due to this redistribution exceed the onshore supply, a state of beach erosion exists.

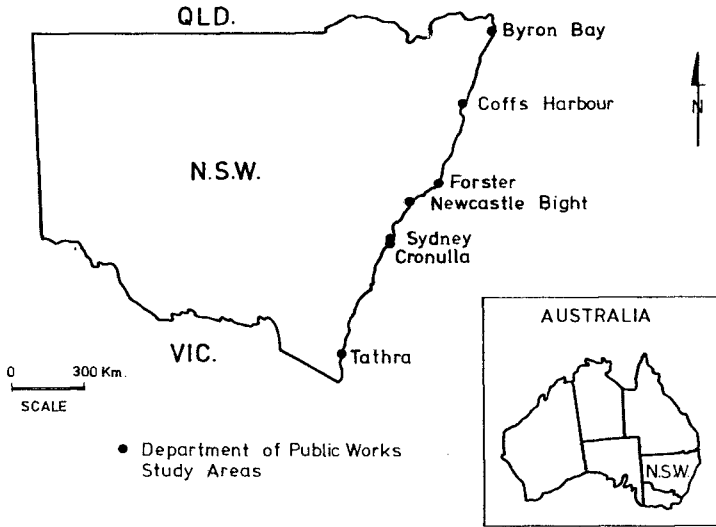

Thus the generalised coastal model predicts that at the present time, where there is no new source of suitable sediments, the beaches will be:

- (i) In a state of dynamic equilibrium where no longshore or aeolian losses occur.
- (ii) Undergoing long term erosion where either aeolian and/or longshore losses occur.

4. SITE SPECIFIC MODELS

Site specific models have been developed at a number of locations on the New South Wales coast (ref. Figure 3). While the aims of individual investigations may vary, the underlying philosophy of analysis adopted in each case is the sediment budget approach. Further, the application of this approach has taken a particular form:

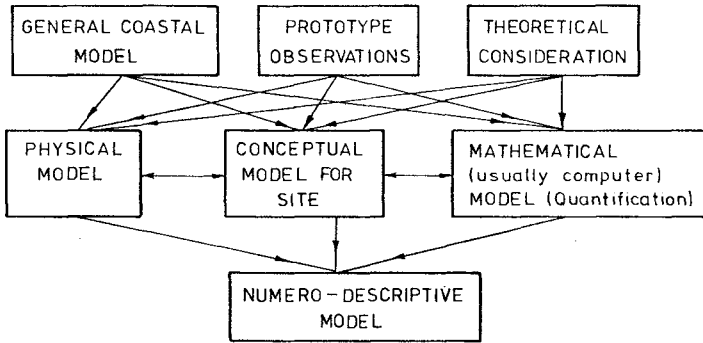

- . Development of a conceptual model.
- . Quantification of that model.
- . Formulation of a numero-descriptive (predictive) model.

LOCATION OF STUDY SITES

FIG. 3

An outline of this methodology is shown in Figure 4.

SITE SPECIFIC MODEL

FIG. 4

Boundary determination precedes model development. The onshore boundaries are usually obtained from morphological considerations while longshore boundaries are based on geomorphological criteria. Offshore boundary delineation is more complex as it is necessary to take into account sedimentological and/or bathymetric discontinuities as well as the hydrodynamic factors.

The final form of a site specific conceptual model is only obtained following a period of rigorous testing and modification. To facilitate this process of model development an extensive prototype data programme is required.

Data collection programmes have included:

- . Sea and swell data - height, period from Datawell Waverider Buoys, and directions from ship and shore observations supplemented by hindcast analysis.
- . Wind records - speed, duration and direction using Lambrecht anemometers at fixed locations and Ventimeters - hand held anemometers - for mobile stations.
- . Currents - Lagrangian patterns obtained by drogus tracking and Eulerian information using ONO directional and, more recently, Marsh McBirney X-Y electro-magnetic current meters. Rip currents - metered, surveyed and aerially photographed.
- . Bathymetry - 5.5 metre long twin hull boats powered by two 115 h.p. outboard engines give surf zone capability. These have been equipped with Raytheon type DE914 Fathometers and Motorola Miniranger Mk III position fixing equipment to enable accurate bathymetric data collection. This data is then reduced by a reduction/plot programme presently based on a VARIAN V75 computer.
- . Erosion history - including differential longshore, onshore and offshore movements. Standard terrestrial survey techniques are used onshore, and the technique outlined above is used offshore. Historical survey data collection from existing plans and photogrammetric analysis using stereo restitution instruments on present and historical photography. The latter is usually restricted to vertical aerial photography with a 60% overlap and scales typically in the range 1:4,000 to 1:50,000.
- . Sediment distribution patterns - spatial distribution of onshore and offshore sediment types, grain size parameters and lithology. This data is obtained from - dredge samples (a 75 mm x 300 mm steel tube with towing yoke at one end and sealed at the other is lowered to the sea floor and dragged a short distance by the survey boat); core samples up to 2 metre length obtained by divers using both suction coring equipment and hammer corers, diving is usually carried out from the survey boat; side scan sonographs produced using a Klein model 400 side scan unit operated from 15-25 metre trawlers. All position fixing is based on the

Motorola Miniranger system. Sand samples are examined under binocular microscopes to determine the composition and texture, and grain size characteristics are determined by both sieving and settling tube analysis. Further research is under way as to methods of classifying sediments under turbulent conditions (Smith and Gordon, 1980).

Geological and geomorphological history - analysis and age structure of sediment and bedrock: Sparker, boomer and magnetometer surveys to develop seismic profiles of both bedrock and the various sediment interfaces. The equipment is operated from the trawlers used for side scan operations with the same position fixing procedure. Auger boreholes are used to obtain material for dating from the back beach barrier ridge systems and to provide a check on seismic interpretation.

Bedforms - spatial and temporal distribution of ripples and dunes, their height, wave length, composition and direction of orientation. Data is collected by diver operations and from interpretation of side scan sonographs.

The quantification of the conceptual model requires an analysis of the various sources and sinks coupled with a mathematical description of the sediment movement between them. The techniques employed to quantify these sources and sinks will be illustrated in part in the following sections which deal with two site specific studies.

It is the quantification of sediment movements within the model boundaries which, of the coastal sciences, suffers most from the lack of adequate theoretical development. Hybrid modelling techniques have been employed in an attempt to offset these theoretical limitations.

Refraction and diffraction of waves provide particular problems. The accuracy of calculated longshore transport rates reflect to a considerable degree the ability to determine correctly the coastwise inshore wave energy distributions. Physical models, computer based mathematical models and prototype observations have been combined to synthesise inshore wave energy conditions. Because of inaccuracies in the available recorded wave data, particularly with respect to direction spectrum, the reliability of calculated values has been appraised by undertaking sensitivity analyses on the refraction and transport studies. Geomorphological and sedimentological indicators are also employed as independent references.

Sediment transport equations; the relationships between the driving forces and the sediment reaction to those forces, are in their infancy from the viewpoint of theoretical understanding.

The Bijker (1967) approach of increased bed shear under waves, represents a significant contribution to attaining a more scientific description of coastal sediment transport. However its inherent simplifications when applied to a beach system of complex morphology; rip cells and multiple offshore bars, has resulted in the continued

use of the more simplistic empirical approach outlined in the Shore Protection Manual (CERC, 1977); better known as the C.E.R.C. equation. More recent work by Longuett Higgins (1970, 1972) has lent some degree of theoretical credence to this relationship between wave thrust and longshore sand transport.

A mathematical model, at present based on a modified C.E.R.C. philosophy, has been adapted to local conditions and placed on a P.D.P. II computer for ease of calculation, alteration and testing against prototype data.

To illustrate the methodology employed in site specific model generation, and to highlight the shortcomings and strengths of both this approach and the theoretical considerations upon which it is based, two typical studies will be discussed. Both studies are from regions of the New South Wales coast which are believed to be undergoing long term recession.

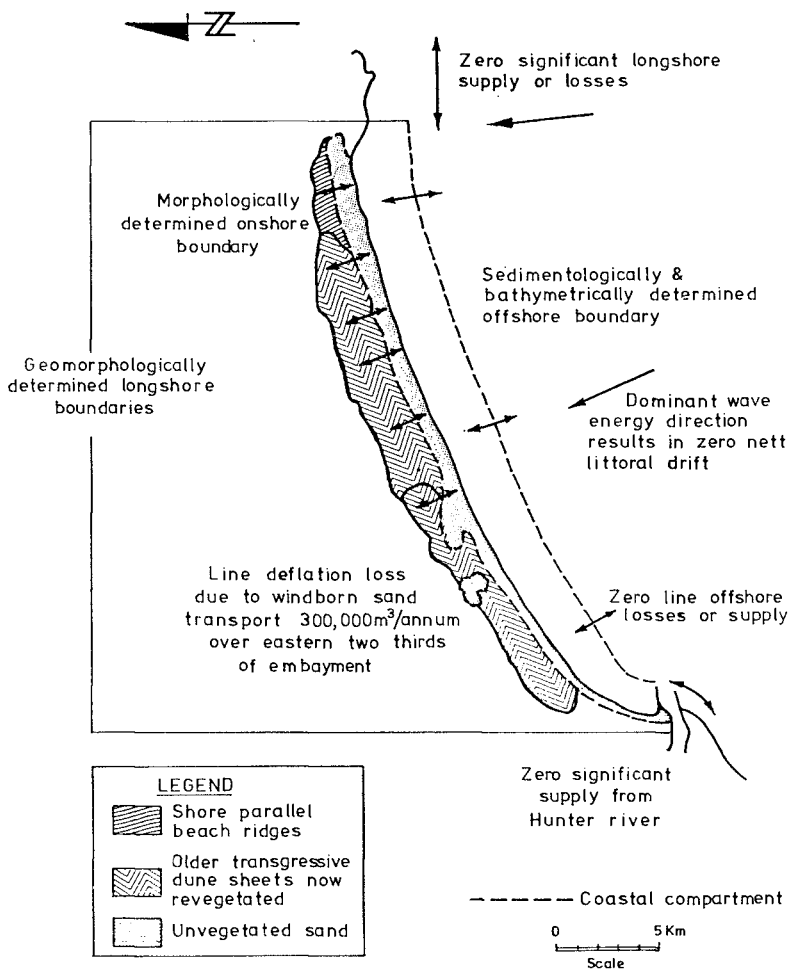

- . Newcastle Bight (Figure 3), a 30 kilometre long embayment located 120 kilometres north of Sydney. This is an example of a shoreline which is eroding due to aeolian losses.
- . Byron Bay - Hastings Point (Figure 3), a 30 kilometre long stretch of coastline located 750 kilometres north of Sydney. This is an area which is eroding due to an imbalance between overall coastal alignment and dominant wave energy approach direction. An interesting offshore loss mechanism intensifies the erosion problem.

4.1 Newcastle Bight

Newcastle Bight has a long history of beach erosion. It is backed by a massive transgressive dune sheet which is moving inland over forest and farming areas. Interest in the area followed a proposal to excavate a large new harbour in the transgressive dunes and to construct a breakwater protected entrance through the beach and surf zone.

The numero-descriptive model for Newcastle Bight has been summarised in Figure 5. It is not intended to discuss the study (Gordon and Roy 1977, D.P.W. 1977) in detail, but rather a number of interesting points have been singled out for presentation:

- . A major N.S.W. river discharges into the southern end of the coastal compartment. Calculations based on Colby's work (Colby 1964) showed that during major flood events the river had the capability to transport sand to the coast. Sand of suitable size was known to be present in the upper reaches of the river. Compositional and textural sedimentological studies showed no significant contribution of these terrestrial sands to the coastal sediment system. Further analysis of the flood data indicated that these events were infrequent, and that dry weather flows were incapable of transporting the material. The river was thus eliminated as a present day source of significant quantities of coastal sediments.

NUMERO-DESCRIPTIVE MODEL
NEWCASTLE BIGHT

FIG. 5

Initial calculations using hindcast wave statistics, the wave refraction programmes and sediment transport calculations gave a nett northerly drift of 200,000 cubic metres per year. Analysis of wave rider data showed that the hindcast statistics overestimated the frequency of waves of heights above 2-3 metres whilst underestimating the frequency of smaller waves. Using the waverider statistics, the calculated nett littoral drift was 135,000 cubic metres per year to the south (Table 1). Following doubts as to the accuracy of the recorded wave direction data, and particularly with respect to the assignment errors between True and Magnetic North (12 degrees), a sensitivity analysis was carried out on the effects of wave direction on transport volumes. It was found that a 7.5 degree shift in the nett energy flux pattern applied to the refraction programme resulted in a zero nett littoral drift condition for the embayment. Sedimentological evidence supported this latter finding (Gordon and Roy, 1977). As it was felt that at best, the wave directional data which was recorded to sixteen compass points was only accurate to ± 11.25 degrees, a model which predicted a zero nett littoral drift condition was adopted. The model was calibrated accordingly and the gross littoral drift quantities were adjusted.

TABLE 1

Deepwater Wave Approach Direction	Average Annual Sand Transport (m^3/yr) and Direction of Transport	
	From Wave Statistics based on True North	From Statistics based on Magnetic North (12° shift)
E	224,000 South	242,000 South
ESE	345,000 South	262,000 South
SE	235,000 South	86,000 South
SSE	212,000 North	304,000 North
S	457,000 North	396,000 North
Gross Drift	1,473,000	1,290,000
Nett Drift	135,000 South	110,000 North

The numero-descriptive model confirmed that the measured 1 to 2 metre per year (long term average) shoreline recession could be accounted for by the deflation losses associated with the landward moving transgressive dunes. The initial numerical analysis did not, however, produce this result. Aeolian transport was assessed by the Bagnold approach (Kadib, 1964) using long term wind data from anemometers located at both the southern end and the centre of the embayment. This formula was applied in the form:

$$Q = 1.8 \times t \times 3.6 \times 10^3 \sqrt{d/D \cdot \gamma/g \cdot U_*^3}$$

and

Q = total transportation in kg/year/metre

t = wind duration in hours/year

d = d_{50} diameter of sand in millimetres

D = 0.25 mm Bagnold standard sand particle size

γ = Specific weight of air kg/m³

g = gravitational acceleration m/sec²

U_* = shear velocity in m/sec

These calculations showed that some 20 cubic metres/year/metre of beach (long term average) was moving in an offshore direction. This resultant was 120 degrees opposed to the known landward transport obtained by direct measurements and aerial photographic interpretation which gave a landward encroachment of the transgressive dune sheet of from 5 to 10 metres per annum, landward transport of some 25 to 50 cubic metres/metre of beach. Examination of this anomaly showed that as the onshore movement was into a well vegetated region, the trapping effect of the trees, and their local modification of the wind field resulted in their acting as a 'sand diode'; selectively modifying the aeolian mechanism. Thus it was concluded that the nett movement was chiefly dependent on the onshore component of wind energy, and hence the aeolian transport calculations were modified accordingly.

Monthly surveys (D.P.W. 1977) and sand samples taken in the offshore zone produced evidence of a break in sediment characteristics and movement at depths of 12 to 14 metres throughout the Bight; shallower at the southern end in the hook of the zeta curve. This break was interpreted as being the base of the highly active inner nearshore zone and as such was useful in the further development of the "generalised model" and provided information relevant to the development of sediment transport models.

The quantity of material involved in the onshore-offshore movement during storm events was estimated from the profiling data. In March 1973 a 3 day storm occurred. The peak significant wave height from wave rider records was 6.2 metres while the maximum wave height was 9.9 metres. The recurrence interval of this storm

was estimated as 1 in 1 year. The storm produced an average 35 metre recession of the mean water mark and between 100 and 150 cubic metres/m of beach were removed from the sub aerial beach and placed on the offshore bar. Experience at other locations on exposed ocean beaches in N.S.W. indicate that for a more intense storm with wave heights of 10 to 12 metres this storm demand may be of the order of 200 to 400 cubic metres/metre of beach.

The accuracy of the final numero-descriptive model (Figure 5) constructed for Newcastle Bight was enhanced by the adoption of the approach outlined in Section 3 - the quantification of a conceptual model with emphasis on testing against prototype information and observations.

4.2 Byron Bay - Hastings Point

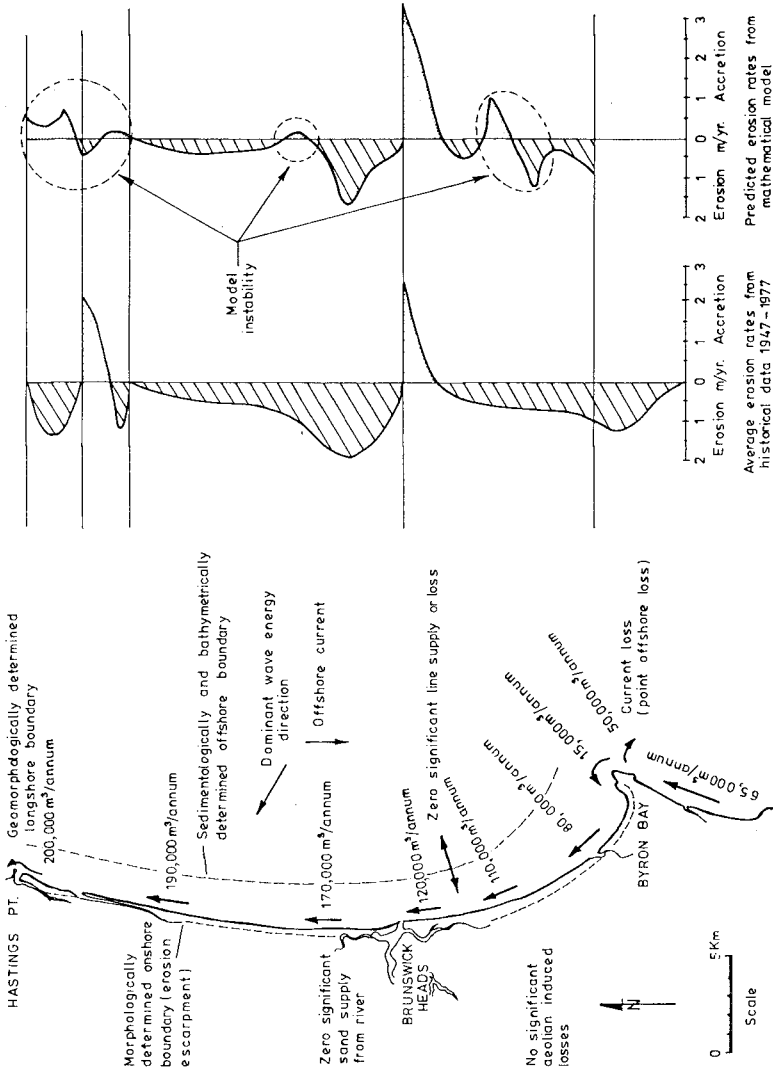

Shoreline recession in the Byron Bay - Hastings Point region was drawn to public attention dramatically with the loss of houses during the late 1960's and the severe damage to a small village located mid way along this stretch of coast. In 1972, after further severe cyclone activity, this village of 17 houses had to be totally abandoned. To provide a basis for future management and planning of the area, a site specific coastal study was undertaken (Gordon, Lord and Nolan, 1978).

This study showed that a time averaged nett longshore drift occurs from south to north throughout the Byron Bay - Hastings Point embayment, which is an open ended compartment. Throughout the embayment an unfavourable coastal alignment promotes a differential littoral drift situation which results in a greater quantity of sand leaving the compartment to the north than is entering it at the southern end.

The existing coastal sediments have responded to this increasing sediment demand, resulting in recession of the shoreline. This recession can be viewed as a "line source" of littoral drift material.

The numero-descriptive model which resulted from the study has been summarised as Figure 6. This study provided interesting insights into offshore loss mechanisms, and methods by which longshore transport formulae can be calibrated and used to reproduce time histories of differential shoreline recession.

Although it was recognised that littoral drift imbalance within the compartment was a major contributing factor to shoreline recession, it became apparent during the investigation that a significant offshore loss mechanism was active off the southern headland. Current studies, sedimentological evidence, and unusual bathymetric features (ref. Figure 7) off Cape Byron were examined to facilitate description and then quantification of this loss.

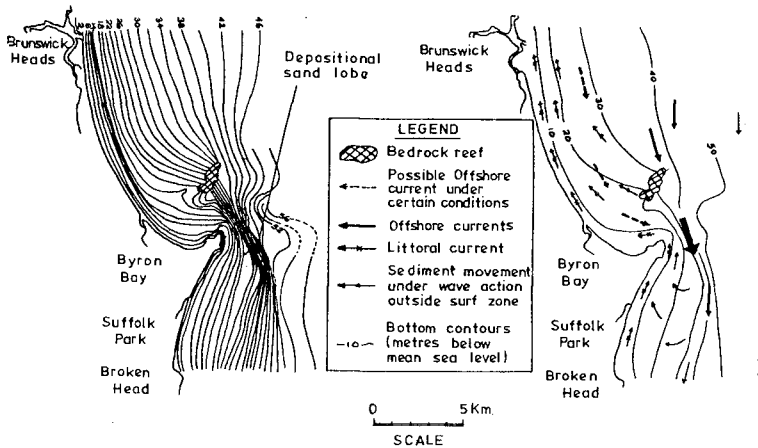

NUMERO-DESCRIPTIVE MODEL
BYRON BAY - HASTINGS POINT

FIG. 6

Intermittent excursions of the East Australia Coast Current onto the continental shelf in this region at certain times produce south bound currents in excess of 0.5 m/s close to the Cape where wave reflection from the near vertical cliffs ensure that sediment suspension occurs even under low wave conditions. Thus northerly drifting sand in the littoral stream which would normally bypass Cape Byron may, under certain conditions, be intercepted and transported offshore and to the south where it forms a prominent bathymetric feature; a sink for littoral material in some 30 to 50 metres water depth (ref. Figure 8). Using sedimentological

OFFSHORE BATHYMETRY
BYRON BAY

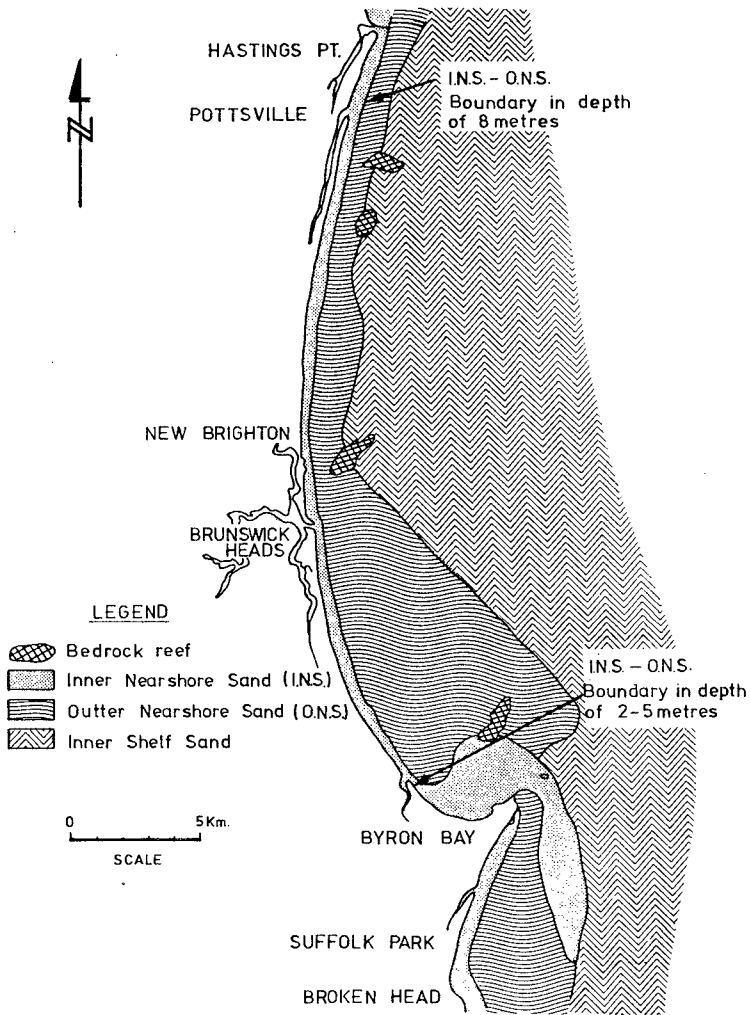

FIG. 7

OFFSHORE CURRENTS
AROUND CAPE BYRON

FIG. 8

analyses to define the extent of this feature, and bathymetric evidence to calculate the quantities of sediment lost to the sink, it was estimated that 50,000 cubic metres per annum of sand had been removed on average from the littoral drift system over the last 6,000 years. The assumption that this loss has occurred at a steady rate over 6,000 years is tentative. Further work is required to examine the validity and implications of this assumption.

To examine and predict the pattern of shoreline recession, a computer based transport model was adapted and extensively modified to this location. The model divided the coastal compartment into a number of shore normal elements (Figure 9). The wave refraction programme, sediment transport formula and local wave data were combined to calculate the longshore transport rate into and out of each element for discrete time steps. At each time step the "budget" of the individual elements

OFFSHORE SEDIMENT TYPES
BROKEN HEAD TO HASTING POINT

FIG. 9.

was assessed and sediment deficits or excesses were distributed to the adjacent elements. The onshore element boundary was flexible and reflected overall sediment gains or losses as beach erosion or accretion (Gordon, Lord and Nolan, 1978).

Instabilities occurred in the model at discontinuities such as breakwaters and in regions where refraction/diffraction patterns were complex or interacted (Figure 6). These instabilities were mainly associated with inappropriate selection of element size and the techniques employed to assign refraction, diffraction and bypass coefficients.

Model calibration was carried out by comparing the resulting shoreline recession patterns with those obtained historically from survey and photogrammetric analyses. The structure of this model, enabling it to be run both backward and forward from any point in time, allowed verification of the model against prototype data prior to its usage as a predictive tool for shoreline recession.

The model employed the C.E.R.C. formula in the form:

$$Q = K.C_g \frac{\rho g H^2}{8} \cdot \sin \alpha \cdot \cos \alpha$$

where

Q = longshore transport rate

K = an empirical coefficient which involves a number of parameters

C_g = wave group velocity

$\frac{\rho g H^2}{8} \cdot \sin \alpha \cdot \cos \alpha$ = wave thrust

Initial results using a K value obtained from the Shore Protection Manual (C.E.R.C., 1977) produced erosion and transport rates approximately three times those measured in the prototype. The K value was adjusted accordingly and the model was then used to predict future trends.

As with the Newcastle Bight study, offshore sediment patterns provided data on offshore boundary considerations. A marked change in sand type was noted at a depth of 8 metres in the exposed regions of the embayment, shallowing to 2-5 metres in the sheltered hook of Byron Bay.

The offshore boundary for the model elements was taken as the break in sediment patterns referred to above. The inner boundary was the back of the beach at the base of the erosion escarpment; typically +3 metres to +4 metres above I.S.L.W. In a fully

3-dimensional model, profile changes due to varying input data should be modelled as well as plan form changes in shoreline. It is argued that in a long term erosion situation, it is reasonable to assume that whilst dramatic day to day changes in profile shape may occur, the nett result is a mean profile which migrates landward as erosion progresses. Obviously, this is a gross simplification for the convenience of model operation. However it is believed that profile changes between depths of between 50 metres and 10 to 8 metres are subtle on an engineering time scale. It is further believed that no significant modification to the profile solely due to wave induced effects occurs at depths greater than 50 metres, although wave penetration to the bed may exceed this figure on certain occasions. Thus, the eroded volume per unit time, per unit length was obtained as illustrated in Figure 10.

ACTIVE ZONE ZONE

FIG 10

Sensitivity of the model to directional wave data was investigated by generating 100% occurrence nett transport rates along the embayment for three major offshore directions (Figure 11). It was then a simple process to test the effects of various directional distributions on the longshore transport rates and, hence, the erosion patterns.

100% OCCURENCE NETT TRANSPORT RATES
CAPE BYRON TO HASTINGS POINT

FIG 11

TABLE 2 - Sediment Budget

SOURCE	VALUE (m ³ /year)	SINK	VALUE (m ³ /year)
Q ⁺ ₁ (offshore point supply)	0	Q ⁻ ₁ (offshore current loss)	50,000
Q ⁺ ₂ (rivers and creeks)	0	Q ⁻ ₂ (inlet loss)	0
Q ⁺ ₃ (beach nourishment)	0	Q ⁻ ₃ (sand extraction)	0
Q ⁺ ₄ (longshore transport in)	65,000	Q ⁻ ₄ (longshore transport out)	200,000
q ⁺ ₁ x (offshore line supply)	0	q ⁻ ₁ x (offshore line loss)	0
q ⁺ ₂ x (dune and terrace erosion)	180,000	q ⁻ ₂ x (overwash and wind loss)	0
q ⁺ ₃ x (beach erosion and shell production)	0	q ⁻ ₃ x (beach storage and shell loss)	0
TOTAL of Sources	245,000	TOTAL of Sinks	250,000

The quantified conceptual model is presented in traditional sediment budget terms as Table 2. Emphasis has been placed on the use of point sources/sinks (Q) and line sources/sinks (q) because of their significance in this particular study. The total sediment budget therefore took the form:

$$\sum_{i=1}^4 Q_i + \sum_{i=1}^3 \left(\sum_o q_i x_i \right) = \sum_{i=1}^4 Q_i - \sum_{i=1}^3 \left(\sum_o q_i x_i \right)$$

In the Byron Bay - Hastings Point study, the adaptation of the methodology outlined in Section 3, enabled a model to be constructed which showed not only the total sediment budget of the coastal compartment, but also enabled predictions to be made concerning future differential shoreline movement throughout the compartment.

5. CONCLUSIONS

By invoking a conceptual model/numerical model approach the concept of sediment budgeting has been expanded to provide an insight into processes operating within the coastal compartment under study. The use of geomorphological and sedimentological indicators has assisted in quantifying and testing the models. The development of a general coastal model has provided an invaluable frame of reference and starting point for any site specific studies.

The modelling process is an ongoing development. Recognition that generalisation is dependent on mechanism understanding has resulted in increasing emphasis being placed on the methods used to calculate actual sediment movement paths.

Accuracy and confidence in results have been increased by the carrying out of sensitivity analyses and a process of constantly reviewing proposed mechanisms and transport paths against prototype observations and data.

Notwithstanding the above, it is plainly apparent that there exists a compelling need for greater understanding of sediment transport mechanisms, and hence the development of more appropriate formulae for both the aeolian and littoral regions of the coastal zone. In concert with this, far more sophisticated data collection is required, particularly with respect to inshore wave directional spectra, current information, and sediment characteristics.

The results of any computation are only as good as the input data and the validity of the assumptions used.

Relationship Between Alongshore Wave Energy and Littoral Drift
in the Mid-West Coast at Taiwan

HO-SHONG HOU, ph.D., M., ASCE*

CHUNG-PAN LEE**

LUNG-HUI LIN**

ABSTRACT

Based on the wave pattern, the geographical location and the disposition of rivers, the littoral drift moves predominantly from NE to SW direction in section II as shown in Fig. 1. Seven rivers of rapid stream bring tremendous amount of sediments from the high mountain to the nearshore of this section in typhoon season (i.e. from June to September). But for the winter monsoon season, i.e. from October to the next April, the waves induced by NE monsoons migrate littoral drift from North toward South.

Applying the energy approach for unidirectional steady flow derived by Bagnold(1963), the theoretical relationship between the littoral immersed weight transport rate and the alongshore breaking wave energy is found out. It reveals that the relationship is not strictly linear, i.e. the larger part of the alongshore breaking wave energy is supplied for transporting the sediment as the former increases. But for a coast having a steady oceanographical condition, the relationship could be considered as linear relation since the alongshore breaking wave energy is not varying very much.

In this paper, the study of littoral drift vs wave energy at the Taichung Coast from the Ta-Chia River to the Ta-Tu River will be carried out. Using the wave records gained by the ultrasonic wave gauge at 19m depth and the littoral drift quantity obtained from long-term observation, the relationship between alongshore breaking wave energy and littoral immersed weight transport rate is found out.

First, the waves which have the same direction are summed up. Then from "THE WAVE CHARACTER COMPUTING PROGRAM", the incident directions of these wave groups at 19m depth are determined. Then the alongshore breaking wave energy per unit time per unit length of beach could be calculated by the same PROGRAM. Finally the relationship between alongshore breaking wave energy and littoral immersed weight transport rate of this coastal condition is obtained as $I_i = 0.55 (P_i)_b$

1. Introduction

The littoral transport rate is defined as the transport rate passing through a cross section which is perpendicular to the shoreline or contour line and the range of movement is considered between the threshold depth of sediment and the height of wave run-up.

To evaluate the littoral transport rate are classified into four different methods as follows:

(1). Using the littoral transport rate of neighbor coast, and considering the local conditions such as the shoreline configuration, the grain size and the source of sand, then modifying the neighbor littoral transport rate as the interest littoral transport rate.

(2). Using the nearshore bathymetry to evaluate the volume change of the total sediment along the shore, and estimate the littoral transport rate by groin or spit activity.

(3). Using the long-shore current to estimate the littoral transport rate.

(4). Using the along-shore breaking wave energy to compute the littoral transport rate.

Galvin(1972) derived the formula $Q_s = 2H^3$, where Q_s in unit 10^5 yd³/year and H (ft) is the mean breaking wave height of one year. But the formula is good only for suspended load due to its hypothesis. In fact, the quantity of the bed load is much larger than that of the suspended load.

Method (1) is more practical than the others, but the data of littoral transport rate are so few, therefore, the other methods are need to try. If the study area has not groin, break-water or spit to block completely the littoral transport, then the littoral transport rate is not easily to

Figure 1. The sketch of the prevailing direction of littoral drift at Taiwan sandy coast.

estimate. The alongshore current is changing from place to place, from time to time, it is very difficult to find out a dominate value of alongshore current. Therefore, it is more often to use the alongshore breaking wave energy to estimate the littoral transport rate. If there is no wave records then the wave characters could be predicted from wind records.

Bagnold (1963) use the littoral immersed weight transport rate I_i to represent the littoral transport rate, where I_i has the same unit with the alongshore breaking wave energy $(P_i)_b$.

2. The theoretical consideration

2.1. The relationship between the bed load and the available power of fluid under wave action

Under wave action, the forces acting on the sand element (i.e. the free body m_b of containing sufficient sand particles) include the total driving force of fluid T_F , the tangential reactive force T_t due to collisions, the normal reactive force P_n due to collisions and its own gravity. T_F includes drag force, lift force and the pressure gradient stress. T_t and P_n is defined as shown in Fig. 2, where $\tan \phi' = T_t/P_n$ is the friction coefficient of solid phase. ϕ' is almost equal to the repose angle of sand, ϕ . Then

$$T_t = P_n \tan \phi \dots \dots \dots (1)$$

As shown in Fig. 3

$$T_t = \left[\left(\frac{\rho_s - \rho}{\rho_s} \right) g m_b \cos \alpha_B - T_{FV} \sin \beta \right] \tan \phi$$

where β is the angle between T_F and the bed. Since the sand moves up and down. From Newton's second law, i.e.

$$\left[\frac{(\rho_s - \rho) + \rho C_M}{\rho_s} \right] m_b \frac{du_{bb}}{dt} = T_{FV} \cos \beta - \left(\frac{\rho_s - \rho}{\rho_s} \right) g m_b \sin \alpha_B - \left[\left(\frac{\rho_s - \rho}{\rho_s} \right) g m_b \cos \alpha_B - T_{FV} \sin \beta \right] \tan \phi$$

and

$$T_{FV} = \left(\frac{\rho_s - \rho}{\rho_s} \right) g m_b \left\{ \frac{1}{\cos \beta + \sin \beta \tan \phi} \left[\frac{1}{g} \left(1 + C_M \frac{\rho}{\rho_s - \rho} \right) \frac{du_{bb}}{dt} + \sin \alpha_B + \cos \alpha_B \tan \phi \right] \right\} \dots \dots \dots (2)$$

Similarly

$$T_{FD} = \left(\frac{\rho_s - \rho}{\rho_s} \right) g m_b \left\{ \frac{1}{\cos \beta + \sin \beta \tan \phi} \left[\frac{1}{g} \left(1 + C_M \frac{\rho}{\rho_s - \rho} \right) \frac{du_{bb}}{dt} - \sin \alpha_B + \cos \alpha_B \tan \phi \right] \right\} \dots \dots \dots (3)$$

Figure 2. The diagram of definition of frictional coefficient in solid phase.

Figure 3. The force system acting on the bed load.

where T_{FV} is the upward driving force, T_{FD} is the downward driving force, u_{bb} is the velocity of sand and C_M is the virtual mass coefficient, while the volume concentration of sand is C_v .

$$C_M = \frac{1}{2} (1 + 1.59 \frac{C_v}{\pi}) \dots\dots\dots(4)$$

Then, as the sand element move up and down, the work done by fluid is

$$\begin{aligned} & |T_{FV} \cos \beta| |(u_{bb})_u| + |T_{FD} \cos \beta| |(u_{bb})_d| \\ &= \frac{\rho_s - \rho}{\rho_s} g m_b u_{bb} \left\{ \frac{2 \cos \beta}{\cos \beta + \sin \beta \tan \phi} \left[\frac{1}{g} (1 + C_M \frac{\rho}{\rho_s - \rho}) \right. \right. \\ & \quad \left. \left. \frac{du_{bb}}{dt} + \cos \alpha_B \tan \phi \right] \right\} \dots\dots\dots(5) \end{aligned}$$

where $(u_{bb})_u$, $(u_{bb})_d$ represent the upward and downward velocity of sand element respectively. Part of the force in Eq.(5) brings the sand away from the original place, i.e. to cause the net sediment transport, which is

$$\begin{aligned} & (\frac{\rho_s - \rho}{\rho_s}) g m_b \bar{u}_{bb} \left\{ \frac{\cos \beta}{\cos \beta + \sin \beta \tan \phi} \left[\frac{1}{g} (1 + C_M \frac{\rho}{\rho_s - \rho}) \right. \right. \\ & \quad \left. \left. \frac{dU_{bb}}{dt} + \sin \alpha_B + \cos \alpha_B \tan \phi \right] \right\} \dots\dots\dots(6) \end{aligned}$$

\bar{u}_{bb} is the net velocity of bed load. Set

$$i_b = (\frac{\rho_s - \rho}{\rho_s}) g \cdot m_b \cdot \bar{u}_{bb} \dots\dots\dots(7)$$

where i_b is the immersed weight transport rate. If ω is the available power of fluid, ϵ_b is the effective coefficient which is used to cause bed load. Then from eq.(6) and eq.(7), the relationship between the immersed weight transport rate of the bed load and the available power of fluid is as

$$\begin{aligned} & i_b \left\{ \frac{\cos \beta}{\cos \beta + \sin \beta \tan \phi} \left[\frac{1}{g} (1 + C_M \frac{\rho}{\rho_s - \rho}) \frac{du_{bb}}{dt} + \sin \alpha_B \right. \right. \\ & \quad \left. \left. + \cos \alpha_B \tan \phi \right] \right\} = \epsilon_b \omega \dots\dots\dots(8) \end{aligned}$$

Assume the sediment transport has completely developed, and the resultant force acts normal to the bed is in equilibrium, i.e. $P_t = 0$. Then

$$T_F \sin \beta = (\frac{\rho_s - \rho}{\rho_s}) g m_b \cos \alpha_B$$

$$T_F = \frac{1}{\sin \beta} (\frac{\rho_s - \rho}{\rho_s}) g m_b \cos \alpha_B \dots\dots\dots(9)$$

The work done by fluid to take sand element move up and down is

$$2 T_F \cos \beta u_{bb} = 2 \frac{\cos \alpha_B}{\tan \beta} \left(\frac{\rho_s - \rho}{\rho_s} \right) g m_b u_{bb} \dots \dots \dots (10)$$

But cause the net sediment transport is only equal to

$$T_F \cos \beta \bar{u}_{bb} = \frac{\cos \alpha_B}{\tan \beta} \left(\frac{\rho_s - \rho}{\rho_s} \right) g m_b \bar{u}_{bb} = \epsilon_b \omega$$

or

$$i_b \frac{\cos \alpha_B}{\tan \beta} = \epsilon_b \omega \dots \dots \dots (11)$$

It simply represents the relationship between the immersed weight transport rate of bed load and the available power of the fluid. Since T_F might change periodically, the equilibrium state of the assumption is existing temporarily and the sediment move up and down occasionally. But when the sediment transport has completely developed, the particles move up and down is considered as the same rate. Therefore, eq.(11) is quite reasonable.

2.2. The relationship between the suspended load and the available wave power

Since the suspended load is away from bed, its wall effect is less than that of bed load. The transport of suspended load is mainly caused by the mass transport due to nonlinear waves and the alongshore current. The motion of suspended load is considered as the resultant of the horizontal velocity u_s and the settling velocity w . The collision effect between suspended particles is ignored since the concentration of suspended load is low. The only external force on the suspended load is the driving force of fluid including the drag force, the lift force and the pressure gradient stress. It is shown in Fig.4. and yields

$$T'_F \cos \beta' = \left(\frac{\rho_s - \rho}{\rho_s} + C_M \right) m_s \frac{du_s}{dt} \dots \dots \dots (12)$$

where m_s indicates suspended load while u_s is its horizontal velocity, T'_F is the driving force of the fluid, β' is the angle of T'_F from horizontal direction. Fluid transports the suspended load by doing two actions. One is to make m_s move in the horizontal direction, the other is to keep m_s from falling with settling velo-

Fig.4 The force system on suspended load.

city w . Therefore, the power worked by fluid to transport the suspended load with net transport velocity \bar{u}_s is

$$[T'_F \cos \beta'] \bar{u}_s + [T'_F \sin \beta'] w = \epsilon_s (1 - \epsilon_b) \omega \dots (13)$$

If the sediment transport is fully developed, the suspended load may be considered statistically as move in the horizontal direction. Then

$$T'_F \sin \beta' = \left(\frac{\rho_s - \rho}{\rho_s} \right) g m_s \dots \dots \dots (14)$$

and

$$T'_F \cos \beta' = \left(\frac{\rho_s - \rho}{\rho_s} \right) g m_s \frac{1}{\tan \beta'} \dots \dots \dots (15)$$

From eq.(13), (14) and (15), then

$$\left(\frac{\rho_s - \rho}{\rho_s} \right) g m_s \bar{u}_s \left[\frac{1}{\tan \beta'} + \frac{w}{\bar{u}_s} \right] = \epsilon_s (1 - \epsilon_b) \omega \dots \dots (16)$$

is obtained, where i_s is the suspension efficiency, and next by

$$i_s = \left(\frac{\rho_s - \rho}{\rho_s} \right) g m_s \bar{u}_s \dots \dots \dots (17)$$

as the immersed weight transport rate of suspended load. Therefore,

$$i_s \left[\frac{1}{\tan \beta'} + \frac{w}{\bar{u}_s} \right] = \epsilon_s (1 - \epsilon_b) \omega \dots \dots \dots (18)$$

is the relationship between the suspended load and the available power of the fluid as the sediment transport is fully developed.

The total transport rate i is expressed as

$$i = i_b + i_s \dots \dots \dots (19)$$

$$i = \left[\frac{\epsilon_b}{\cos \alpha_s / \tan \beta} + \frac{\epsilon_s (1 - \epsilon_b)}{1 / \tan \beta' + w / \bar{u}_s} \right] \omega \dots \dots \dots (20)$$

Eq.(20) is derived from eq.(11) and (18). Let K be as follows.

$$K = \frac{\epsilon_b}{\cos \alpha_s / \tan \beta} + \frac{\epsilon_s (1 - \epsilon_b)}{1 / \tan \beta' + w / \bar{u}_s} \dots \dots \dots (21)$$

Eq.(20) represents the relationship between the immersed weight transport rate and the available power of the fluid. Because the action between sand bed and water mass is different as breaking wave type is changed, ϵ_b and ϵ_s will be affected by the breaking wave parameters. It is believed that the plunging wave causes seriously erosion than that of the other type of breaking wave. The settling velocity increases as grain size increases, therefore K will decrease as sand grain size increases. It is shown in eq.(21). Besides that, K becomes large as the net transport rate of suspended load increases.

Therefore, the littoral transport will be strengthened in the direction of alongshore current if there is a permanent or semi-permanent alongshore current. The parameter β (or β') reveals the magnitude of fluid acting on moving sediment, it grows up as the vertical fluctuation increases. Therefore, it will be larger in the shallower water or under the action of the bigger waves. And the K value will be larger in the shallower water and for the higher wave energy. The above reasons show that the K value is not always a constant. But, for the long-term climate, if the weather is steady at the same coast, the K value could be considered as a constant.

2.3. The definition of the available wave power

By Using the Airy wave theory, the energy density of a wave with wave height H is E

$$E = 1/8 \rho g H^2 \dots\dots\dots(22)$$

The power P transmitted between wave rays with distance Δb is

$$P = E \cdot C_g \cdot \Delta b \dots\dots\dots(23)$$

where C_g is group velocity, as shown in Fig.5, the angle between contour line and wave crest line is α and the power transmitted in the longshore direction is

$$P \sin \alpha = E \cdot C_g \cdot \Delta b \sin \alpha$$

where Δb is in term of the coast length Δl as

$$\Delta b = \Delta l \cdot \cos \alpha$$

Then, the alongshore wave energy per unit length of the coast is

$$P_l = E \cdot C_g \cdot \sin \alpha \cos \alpha = \frac{1}{8} \rho g H^2 \cdot C_g \cdot \sin \alpha \cdot \cos \alpha \dots\dots(24)$$

Fig.5. The diagram of the alongshore wave energy.

Eq.(24) is called the available alongshore wave power for transporting the coast sediment.

3.The experimental investigation

3.1.The estimate of littoral transport

At a straight sandy coast of infinite length, if characteristics of waves and characteristics of shore are kept the same along the straight sandy coast, then there is neither erosion nor accumulation. Because the movement of sediment transport is continuous. To estimate the littoral transport rate from the nearshore bathymetry, the groin or breakwater or spit is necessary installed to block the littoral transport. Therefore, the accumulation in the upstream area is the total littoral transport of this sandy coast.

The littoral transport rate of the Taichung coast is illustrated as follows.

There are the Ta-An and the Ta-Cha rivers in the north side of Taichung Harbor, while the Ta-Tu river is in the south side. In the typhoon season (From May to Oct.), Ta-Cha river bring about $1.13 \times 10^6 \text{ m}^3$ per year and Ta-Tu river bring about $1.20 \times 10^6 \text{ m}^3/\text{yr}$ into the coast. The orientation of the coastline from the Ta-Tu river to the Ta-Cha river is N 21.5 E and that of the Ta-Cha river to the Ta-An river is in the direction of N 42.5 E. This means that the neighborhood of the mouth of Ta-Cha river act as a spit which block a part of the littoral transport.

The bottom slope of depth contour from -0 m to -20 m is 1/75 in the neighborhood of the mouth of the Ta-Cha river and the slope of the Ta-Tu estuary is 1/100; the bottom slope from -20 m to -50 m is 1/80 in the mouth of the Ta-Cha river and it is 1/20 in the mouth of the Ta-Tu river. The width of the inter-tidal zone becomes wider from the Ta-Cha river to the Ta-Tu river. It reveals that the injecting flow of Ta-Tu river blocks the littoral transport and carries sediments toward offshore.

From the wind records, during winter season, wind blows from N to NE direction which is the predominant wind and occurs 80 % per year, and the speed is often beyond 10 m/sec. The induced wind wave is mainly $H=1 \sim 2 \text{ m}$, $T=6 \sim 6.4 \text{ sec}$. In summer, wind which blow in S to WSW direction occur 13 % Per year, and its speed is always below 5 m/sec unless in typhoon. The induced wind wave is always less than 0.7 m. Therefore, the littoral drift will migrate from north to south. The plot of the mean grain size distribution of the sediment confirms the result, as shown in Fig.6.

From the continuous bathymetry, using the mesh method, the volume change of the total sediment in the study area is found out as

$$\Delta V = \frac{A}{4} \left[\sum h_1 + 2 \sum h_2 + 3 \sum h_3 + 4 \sum h_4 \right] \dots \dots \dots (25)$$

where A is the grid area and h_j is the fluctuation of water depth at the point co-related to the i number of grids, as shown in Fig.7.

Fig.6. The distribution of the mean grain size.

After 1975, the north breakwater of Taichung Harbor has extended to the water depth of -5m, which is usually deeper than that of wave breaking, the north breakwater is completed at the October of 1976, the head of the north breakwater reached to the depth of -20m, as shown in the Table.

From Fig.8, it is found out that sea bottom fluctuated seriously before the head of the north breakwater reached -20m. This means that the littoral drift still passes through the north breakwater and moves southward before the time of July 1976. After the length of the north breakwater is prolonged, the area effected by the moving sediment to the place about 6Km south from south breakwater, which is always the change of erosion and accumulation, the littoral transport rate of the study area is equal to the accumulation between the Ta-Chia river and the place which is 6Km south from the south breakwater before July, 1976. The littoral transport rate is equal to the accumulated sand volume of the north side of the north breakwater after July, 1976.

Fig. 7. The plot of the meth method.

Date		4, 1974	10, 1974	10, 1975	10, 1976	10, 1977
north breakwater	progress	+ 0 m	+ 142 m	+ 479 m	+ 462 m	+ 310 m
	the head's depth	± 0 m	- 3 m	- 5 m	- 10 m	- 20 m
north groin	progress	+ 0 m	+ 319 m	+ 6 m	+ 287 m	+ 200 m
	the head's depth	± 0.4 m	- 0.8 m	- 2 m	- 4 m	- 6 m

For computing the sand volume change rate by the mesh method, the yearly littoral drift of this area is shown as follows.

1971, 6 - 1972, 7	:	1,340,000 m/yr	
1972, 7 - 1973, 7	:	1,636,000 "	
1973, 7 - 1974, 7	:	1,458,000 "	
1974, 7 - 1975, 7	:	1,406,000 "	(26)
1975, 7 - 1976, 7	:	1,386,000 "	
1976, 7 - 1977, 8	:	2,028,000 "	
1977, 8 - 1978, 8	:	1,313,000 "	
1978, 8 - 1979, 8	:	1,307,000 "	

By representing the above results as the immersed weight of littoral transport rate, and using the formula

$$I_1 = (\rho_s - \rho) g a' Q \dots \dots \dots (27)$$

then the quantity of I_1 is, ($a' = 0.6$)

1971, 6 - 1972, 7	:	1.277 x 10	Kg m /sec/m-yr
1972, 7 - 1973, 7	:	1.588 x 10	"
1973, 7 - 1974, 7	:	1.389 x 10	"
1974, 7 - 1975, 7	:	1.339 x 10	"
1975, 7 - 1976, 7	:	1.320 x 10	"
1976, 7 - 1977, 8	:	1.929 x 10	"
1977, 8 - 1978, 8	:	1.251 x 10	"
1978, 8 - 1979, 8	:	1.245 x 10	"

Figure 8.1. The change of the bottom slope at the north side of the north breakwater.

Figure 8.2. The change of the bottom slope at the north side of the north breakwater.

3.2 The calculation of the alongshore breaking wave energy :

The wave data are recorded by the ultrasonic wave gauge at the depth -19m per 2 hours from July 1972 to June 1976.

The wave is affected by the effects of shoaling, refraction, bottom friction and percolation. By neglecting the effects of bottom friction and percolation as wave is propagating toward the surf zone, there the breaking wave height is equal to

$$H = H_0 K_r K_s$$

where K_r and K_s are refraction coefficient and shoaling coefficient respectively. The mathematical representation is as follows

$$k_r = (B_0 / B)^{1/2}$$

$$k_s = (C_{g0} / C_g)^{1/2}$$

where B is the separation of the wave rays and prefix "0" represents the characters of deep water. As the bottom slope is smaller than 1/10, then K_r and K_s could be calculated from the four equations derived by Chao, Y.Y. (1970) as follows

$$C^2 = \left(\frac{g}{k}\right) \tanh kh$$

$$\frac{d\theta}{ds} = \frac{1}{c} \left(\sin \theta \frac{\partial c}{\partial x} - \cos \theta \frac{\partial c}{\partial y} \right) = -\frac{1}{c} \frac{dc}{dB}$$

$$H_0 (C_g)_0 B_0 = H^2 \cdot C_g \cdot B = \text{constant}$$

$$\frac{d^2 B}{ds^2} - P^{(1)} \frac{dB}{ds} + P^{(2)} B = 0$$

$$P^{(1)} = \frac{1}{c} \left(\cos \theta \frac{\partial c}{\partial x} + \sin \theta \frac{\partial c}{\partial y} \right)$$

$$P^{(2)} = \frac{1}{c} \left(\sin^2 \theta \frac{\partial^2 c}{\partial x^2} - 2 \sin \theta \cos \theta \frac{\partial^2 c}{\partial x \partial y} + \cos^2 \theta \frac{\partial^2 c}{\partial y^2} \right)$$

Where D is water depth, θ is the angle between X axis and wave direction, S is the distance along wave ray and C is the phase velocity. Use numerical method to get

$$D_{n+1} = D_n + \left(\frac{\partial D}{\partial x} \right)_n dx + \left(\frac{\partial D}{\partial y} \right)_n dy + \frac{1}{2} \left(\frac{\partial^2 D}{\partial x \partial y} \right)_n dx dy + \left(\frac{\partial^2 D}{\partial x^2} \right)_n dx^2 + \frac{1}{2} \left(\frac{\partial^2 D}{\partial y^2} \right)_n dy^2$$

$$P_{n+1} = \left[(4 - 2P_n^{(2)} \Delta s^2) / (2 - P_n^{(1)} \Delta s) \right] B_n - \left[(2 + P_n^{(1)} \Delta s) / (2 - P_n^{(1)} \Delta s) \right] B_{n-1}$$

The subscript "n" represents the value of the nth calculation, as shown in Fig.9, where X axis is taken parallel to the shoreline. Developing these numerical calculations to get "THE WAVE CHARACTER COMPUTING PROGRAM", the wave characters such as K_r , K_s , H , C_g and θ could be found out at any water depth $h=D$. Since $\theta = \frac{\pi}{2} - \alpha$ as shown in Fig.9, then

$(P_1)_b = \frac{1}{8} \rho g H_b^2 (C_g)_b \cos \theta_b \sin \theta_b$
is the alongshore breaking wave energy.

Figure 9.1. The diagram of the wave refraction.

Since there is no records of wave direction at -19m depth, the incident wave direction is found out by the above program using the deep water incident wave direction which is the wind direction as the wave gauge serves.

Consider only the waves which are moving onshore could cause littoral transporting. The waves which is the same incident direction is summed up. The root mean square value of their heights and the mean value of their periods are found out. Therefore, the total onshore acting waves are compiled to 8 equivalent waves which have the "rms" wave height H_{rms} , mean wave period \bar{T} . This is because

$$(P_i)_b \propto H^2 \cos \theta \sin \theta \propto H^2 \sin 2 \theta$$

$$\sum_{i=1}^M (P_i)_b \propto \left(\sum_{i=1}^M H_i^2 \right) \sin 2 \theta = M H_{rms}^2 \sin 2 \theta$$

Where M_j is the number of the waves which have the same wave direction θ_j , and H_{rms} is represented as

$$H_{rms}^2 = \frac{1}{M} \sum_{i=1}^M H_i^2$$

To compute the alongshore breaking wave energy, the input data including the water depths of the grid points, the water depths and the coordinates of the incident points, the H_{rms} values and the \bar{T} values of the equivalent waves with the incident wave direction θ at the depth -19m, are all considered.

The output results are $(SUM)_j$ which is the summation of the alongshore breaking wave energy of MN wave rays. Then the total alongshore breaking wave energy per unit beach length of one year is expressed as

$$(P_i)_b = \frac{7200}{MN} \sum_{j=1}^8 [M_j (SUM)_j]$$

where 7200 sec is the 2 hr wave acting duration.

The result of each year from July 1972 to June 1976 is shown as the Table 2,3,4 and 5.

3.3 The relationship between I_i and $(P_i)_b$

Equation (21) shown that the relationship between I_i and $(P_i)_b$ is not exact linearly proportional to each other, this is proved by Fig.10. which is originally prepared by Komar and Inman (1970) there is a upper limit $K=0.77$. Adding the data of equation(28) and Table 2 - 5 into Fig. 10, re-analyze the total data by the least square method to get a regression line which is expressed as $I_i = 0.154 (P_i)_b^{1.0695}$

Figure 9.2. The diagram of the wave refraction.

where I_i and $(P_i)_b$ are in units of cgs system.

But for the Taichung coast where the climate is so steady that the alongshore breaking wave energy fluctuate slightly, the relationship between I_i and $(P_i)_b$ could be expressed as

$$I_i = K(P_i)_b$$

where K is constant and is equal to 0.55. The equation is suitable for any unit system.

4. Conclusion and Discussion

Applying the energy approach for unidirectional steady flow (Bagnold, 1963), derive out the relationship between the alongshore breaking wave energy and the littoral immersed weight transport rate as $I_i = K(P_i)_b$. K is function of wave height, bottom slope, the grain size and the sediment transport pattern. It increases as the grain size decreases or it does either there exists an ocean current in the predominant littoral transport direction or under the action of the bigger waves. This reveals that the larger part of wave energy is supplied to transport sediment as the wave energy becomes larger. This is shown by the empirical relationship $I_i = 0.154 (P_i)_b^{1.0000}$. But for a coast, such as the Taichung coast, where the oceanographic condition is so steady that the alongshore breaking wave energy fluctuates slightly, the relationship between I_i and $(P_i)_b$ could be written as $I_i = K(P_i)_b$, where K is constant. Then the Taichung coast has the relation of $I_i = 0.55 (P_i)_b$. This equation could be applied for the coast of similar oceanographic conditions and beach characteristics to estimate the littoral transport rate. Such that the harbor planning and the shore protection could be based on.

Figure 10. The relationship of the alongshore breaking wave energy and the immersed weight transport rate.

5. Acknowledge

The authors are grateful to the Taichung Harbor Bureau, Taiwan, R.O.C. for the observational wave records. Also the appreciation is given to Mr. Sen-Ho Chen, M.S., Harbor and Oceanic Engineering Institute, National Taiwan College of Marine Science and Technology, for his assistance to the computer program, and working personnel of The Computer Center at N.T.C.M.S.T.

ID,JD: number of the grids for x-axis, y-axis, respectively
MN : number of the incident wave rays
DP : water depth of the grid point
XI,YI: the initial coordinates of x and y axis respectively
X,Y : the coordinates of the position for calculating wave character
D : water depth
BD : water depth to output
BT : the separation of wave direction ray
NN : the index of waves
H : wave height
T : wave period
WL : wave length
C : celerity
CG : wave group velocity
PL : wave energy of each incident wave ray
SUM : the total wave energy of all beach for each wave
TH : the angle between x axis and the wave direction
II : the order of incident wave rays
N : the index of calculating step
KR,KS: the refraction coefficient and shoaling coefficient respectively

CHAPTER 77

LONGSHORE WATER AND SEDIMENT MOVEMENT

by

D.H. Swart* and C.A. Fleming**

ABSTRACT

The mean sediment transport rate obtained by using six known longshore transport formulae, for which the input variables are determined consistently, is used as best estimate of the transport. A good comparison is obtained when this package deal approach is compared with a prototype situation where the transport rates are inferred from quarterly bathymetric surveys over two years. The accuracy of the input variables is reviewed theoretically and the results are used to perform a sensitivity analysis.

1. INTRODUCTION

The Inman/Bagnold/Komar formula (referred to below as the SPM formula) for the prediction of total longshore transport rates is suggested in the Shore Protection Manual (SPM, 1973) for use in the coastal environment. In the design of large coastal structures, such as the breakwaters for a harbour which can accommodate oil tankers and ore carriers, the length of the breakwaters is determined largely by navigational requirements and the longshore transport is important only for the determination of the method of sediment by-passing, if that should be required. In such instances the output as given by the SPM formula, that is, a total annual transport rate without any indication about the area within which this transport takes place, is mostly sufficient. However, the present-day trend is for more and more smaller coastal structures to be built, such as small fishing harbours or small-craft harbours. Navigational requirements only demand a water depth of, say, 7 m at the entrance to such harbours. This depth could quite easily fall within the active coastal transport zone, which implies that the sediment transport determines the entrance depth to the harbour. Therefore it is important to have both the longshore transport rate, as predicted by the SPM formula, and the distribution normal to shore of this transport. For this reason it is imperative that the longshore transport distribution normal to shore is predicted in terms of the local hydraulic parameters. Such formulae, which were called detail predictors by Swart (1976a), use the wave characteristics, hydraulic bed roughness and local longshore current velocity to predict instantaneous longshore transport rates. The accuracy of predicted sediment transport rates for given hydraulic input parameters is, even under steady-flow conditions, strongly dependent on the accuracy of the input variables. Even a small inaccuracy in the input velocity can, for example, cause substantial errors in the predicted transport rates. The input variables used for the prediction of longshore transport rates are usually also predicted, either because of difficulties in measuring the required parameters in the coastal environment, or because of the impracticability of measuring over a long period of time, say one year, to deduce seasonal trends from the input data. If the techniques used to predict the input variables, which are in

* Coastal Engineering and Hydraulics Division, National Research Institute for Oceanology, Stellenbosch, South Africa.

** Sir William Halcrow and Partners, Consulting Engineers, Swindon, U.K.

turn to be used to predict sediment transport rates, are not quite accurate, the computed longshore transport rates could be in error by an appreciable margin. For this reason it seems a sound practice to use as many reliable predictors for the longshore transport rate as are available, and to infer the best estimate of the longshore transport rate from the results of all these formulae. In addition, it is imperative to always use the same method of predicting the input variables, to eliminate the possibility of differences in predicted transport rates because of the use of different techniques to predict the input variables. This paper describes the elements of such a 'package deal' approach. The following *input variables* are required to allow the application of the package deal approach.

(1) *Wave data* are needed in either intermediate or deep water over the period for which transport rates are required (mostly one year to allow an evaluation of seasonal effects), that is,

- significant wave height $(H_s)_I$
- peak energy wave period T_p
- angle of incidence θ_I
- fraction of the time that every wave condition occurs f

Subscript I signifies 'input'.

(2) The following details of the *bed topography* are required:

- the topography of the whole area to allow the construction of wave refraction diagrams;
- beach profiles at the locations where transport computations are to be performed, to decide on the depths d_i in which transport rates are needed and to find the representative widths of the transport zones thus defined;
- the mean bed slope in the breaker zone at the locations where longshore current velocities are to be calculated.

(3) The *characteristics of the sediment* (bed material) influence the longshore sediment transport rates, namely,

- the relative apparent density $\Delta_s = (\rho_s - \rho_w)/\rho_w$ where ρ = mass density, subscript s refers to 'sediment' and subscript w to 'water';
- the distribution of grain sizes; $D_{10}, D_{16}, D_{35}, D_{50}, D_{65}, D_{90}$.

With the aid of the above input variables a comprehensive set of output variables is produced.

(1) The standard output of a *refraction study* is obtained, namely,

- significant wave height H_s
- wave length λ
- angle of incidence θ

in all water depths d_i , as chosen above in the area between the water line and a depth equal to four times the maximum depth in which wave breaking can occur. This area is referred to below as the 'test area'.

(2) A wide range of *wave characteristics* is calculated for water depths d_i in the test area. Included are, for example, the horizontal orbital velocity at the bed u_{bc} and the orbital amplitude a_0 at the bed. All computations regarding wave characteristics are at present performed with linear wave theory.

(3) *Bed-form characteristics* are computed at depths d_i in the test area by using the technique outlined by Swart (1976a) and are then used to compute the following:

- the hydraulic bed roughness $r = 25\Delta_r^2/\lambda_r$, see Swart (1976a) where Δ_r and λ_r are the bed-form height and length respectively;
- the wave friction factor f_w , found empirically by Swart and Loubser (1980) from 640 data sets for turbulent flow in the boundary layer, namely,

$$\text{For } a_o/r < 7 \quad f_w = \frac{0.30}{1+0.28\left(\frac{a_o}{r}\right)^{1.1}}$$

$$\text{For } 7 \leq a_o/r \leq 160 \quad f_w = 0.0066 + 0.483\left(\frac{a_o}{r}\right)^{-0.91}$$

$$\text{For } 160 < a_o/r \quad f_w = 0.0146\left(\frac{a_o}{r}\right)^{-0.157} + 0.483\left(\frac{a_o}{r}\right)^{-0.91} \quad \dots (1.1)$$

- the chezy roughness coefficient C_h , and
- the friction factor C_{LH} as used by Longuet-Higgins (1970) in his theory for the prediction of longshore current velocity.

(4) *Wave-induced properties* which are also functions of the bed roughness r are computed at depths d_i in the test area, namely,

- bed shear stresses, and
- wave power.

(5) *Longshore current velocities* v_i are computed for depths d_i in the test area, with the technique outlined in Section 2.

(6) At the same depths *longshore transport rates* are computed for five different detail longshore transport formulae, namely, the formulae of

- B yker (1971)
- Fleming (1976, 1977)
- adapted Engelund-Hansen (Swart, 1976b)
- Nielsen (1978, 1979)
- adapted Ackers-White (Swart and Lenhoff, to be published in 1980).

In addition the total longshore transport, as predicted by the SPM formula, is also obtained.

(7) *Statistical properties* of the computed transport rates are calculated, namely,

- the mean total transport μ obtained from the six formulae listed under (6), as well as the standard deviation σ around the mean,
- the mean transport/unit width normal to shore obtained from the five detail predictors listed under (6), as well as the standard deviation around the mean.

Similar means and standard deviations are also calculated for the gross transport and the total upcoast and downcoast transport.

The individual items of the package deal approach outlined above have mostly been reported on by various researchers in literature and are therefore not repeated in detail in this paper. The only exceptions are

the prediction of longshore current and the adaptation of the Ackers-White formula for the prediction of sediment transport under steady-state flow conditions. These two aspects are therefore discussed in more detail in Sections 2 and 3 below before the package deal approach is applied to a prototype example.

2. LONGSHORE CURRENT VELOCITY

The momentum balance in the longshore direction determines the strength and distribution of the longshore current, that is

$$\frac{\partial R_{yx}}{\partial y} - (B_x + \frac{\partial D}{\partial y}) = 0 \quad \dots (2.1)$$

where the x- and y-axes are assumed to be parallel and normal to the (straight) coastline, R_{yx} is the flux of longshore momentum across a line parallel to the shoreline, B_x is the bed shear in the direction of the longshore current and $(\partial D/\partial y)$ is the exchange of momentum due to horizontal turbulent eddies. The radiation stress term represents the driving force whereas the bed shear and the lateral mixing are the dissipative forces.

Longuet-Higgins (1970) formulated equation (2.1) and found a solution to this equation for regular waves breaking as spilling breakers on a gently sloping beach. The lateral mixing, which is the key factor in the determination of the shape of the velocity profile, that is, in the distribution of velocity across the breaker zone and beyond the breaker line, is difficult to determine quantitatively. Longuet-Higgins assumed the lateral mixing to increase with the distance offshore to the power 1.5, even outside the breaker zone. The lateral mixing depends to some degree on the rate of change of wave energy dissipation as the wave approaches the shore, that is, on the type of breaker that occurs, or stated differently, on the shape of the velocity profile itself. The area within which the wave energy is dissipated is greater in the case of irregular waves with a spectrum of wave heights (extends further offshore) than is the case for regular waves and in addition the local rate of energy dissipation is also lower for irregular waves than for regular waves. It therefore seems probable that the effect of lateral mixing on the velocity profile will be less in the case of irregular waves. Furthermore it is truer to nature since, although the assumption of spilling breakers will still be required, a spectrum of wave heights is assumed. With this in mind Swart (CSIR, 1978) developed an explicit formula for the prediction of longshore current which is valid for long-crested irregular waves. The main points of this derivation are outlined below.

The following *assumptions* are made:

- (1) Linear wave theory is used for all wave properties.
- (2) Random long-crested waves with a Rayleigh distribution of wave heights are assumed.
- (3) All waves in the spectrum break as spilling breakers with a constant breaker index $\gamma =$ ratio of wave height at breaking to mean water depth.
- (4) Each wave is assumed to retain a height equal to γ times the local water depth as it approaches the shoreline, that is, its wave height decreases at the same rate as the water depth in the breaker zone. In this manner a truncated wave height spectrum is formed, as assumed by Battjes (1974) in his treatment of random breaking waves.

- (5) Wave set-up is neglected.
- (6) The bed slope α in the breaker zone is assumed to be constant.
- (7) The friction coefficient is assumed constant over the breaker zone.
- (8) Lateral mixing is neglected.

Except for assumption (8), the other assumptions are the same as those made by Longuet-Higgins (1970). The resulting form of the three components in the momentum balance equation, based on these assumptions, is given below.

Radiation stress term ($\partial R_{yx} / \partial y$)

Longuet-Higgins (1971) showed that the radiation stress R_{yx} is given to the second order of approximation by

$$R_{yx} = En \sin \theta \cos \theta \quad \dots(2.2)$$

where E is the wave energy per unit surface area, n is the ratio group velocity to wave celerity and θ is the angle of wave incidence. Battjes (1974) showed that the wave energy in a breaking wave spectrum is reduced to a fraction q_b of the value it would have attained if shoaling and refraction had taken place uninterrupted, that is, if no breaking had taken place, when a fraction $(1-q_b)$ of the waves are breaking. It follows from the definition of the Rayleigh distribution that

$$q_b = 1 - \exp(-H_b^2 / H_{f,rms}^2) \quad \dots(2.3)$$

where H_b is the local breaker height ($= \gamma d$) and $H_{f,rms}$ is the root-mean-square wave height that would have been attained in the absence of wave breaking. Since the wave height cannot exceed a value (γd) this wave height is fictitious.

It therefore follows from equation (2.2) that the radiation stress R_{yx} is reduced to a fraction q_b of its fictitious value R_{yxf} in the absence of wave breaking, that is,

$$R_{yx} = q_b R_{yxf} \quad \dots(2.4)$$

where subscript f refers to 'fictitious'.

Since it is assumed that the fictitious waves do not break, R_{yxf} is independent of the distance offshore. Therefore

$$\frac{\partial R_{yx}}{\partial y} = R_{yxf} \frac{\partial q_b}{\partial y} \quad \dots(2.5)$$

With the aid of equations (2.2) to (2.5) it can be shown in an analogous manner to Longuet-Higgins' derivation for regular waves that

$$\frac{\partial R_{yx}}{\partial y} = \frac{5}{16} \rho \gamma^2 g d \exp\left(-\frac{\gamma^2 d^2}{H_{f,rms}^2}\right) \sin \theta \cos \theta \tan \alpha \quad \dots(2.6)$$

Bed shear term B_x

Longuet-Higgins (1970) showed that, provided that the longshore transport velocity v is much less than the maximum horizontal orbital velocity u_{bc} at the bed, the bed shear B_x can be approximated by

$$B_x = \frac{2}{\pi} C_{LH} \rho u_{bc} v \quad \dots(2.7)$$

For shallow-water waves the orbital velocity u_{bc} reduces to

$$u_{bc} = \frac{1}{2} \left(\frac{\bar{H}}{d} \right) (gd)^{\frac{1}{2}} \quad \dots(2.8)$$

$$\text{and therefore } B_x = \frac{1}{\pi} \rho C_{LH} \left(\frac{\bar{H}}{d} \right) (gd)^{\frac{1}{2}} v \quad \dots(2.9)$$

where \bar{H} is the mean wave height of the breaking wave spectrum in a water depth of d .

Solution

Since the lateral mixing is neglected, it follows from equations (2.1), (2.6) and (2.9) that the longshore current velocity v equals:

$$v = \frac{5\pi}{16} \frac{\gamma^2 (gd)^{\frac{1}{2}}}{C_{LH}} \left(\frac{\bar{H}}{d} \right)^{-1} \exp \left\{ \frac{-\gamma^2 d^2}{H_{rms}^2} \right\} \sin \theta \cos \theta \tan \alpha \quad \dots(2.10)$$

An example of the velocity profile as predicted by equation (2.10) is given in Figure 1. Both axes are non-dimensionalized, the vertical axis by dividing by a scaling velocity v_{OR} and the horizontal axis by dividing by the distance from the shoreline to the location in the profile where the significant wave height will start breaking, that is, where 13.5 per cent of the waves in the spectrum will have started to break. Also shown in this figure is the solution for regular waves of Longuet-Higgins, applied with a lateral mixing which can be shown to be the average of the possible mixings. The agreement between the two solutions is very good. This indicates that the assumption to neglect lateral mixing is justified for irregular waves and therefore equation (2.10) is used for the prediction of longshore current velocity in the package deal approach.

Longshore velocity friction factor C_{LH}

The magnitude of the friction factor C_{LH} must be known before equation (2.10) can be used to determine longshore current velocities. Galvin and Nelson (1967) compiled all available longshore current data. Each of these data sets can be used to determine a value for C_{LH} . Longuet-Higgins (1970) evaluated this information and concluded that C_{LH} is 'of order 0.01'. It is suggested in the Shore Protection Manual (SPM, 1973) that C_{LH} is actually less than 0.01. A value of $C_{LH} = 0.0071$ is suggested as the best estimate of C_{LH} . Using the same data, Komar and Inman (1970) found that

$$C_{LH} = 0.15 \tan \alpha \quad \dots(2.11)$$

Swart suggested that the friction factor should also be a function of the bed roughness r (CSIR, 1978). He showed theoretically that

$$C_{LH} = \Phi \left(\frac{f_{wb} g}{2C_{hb}^2} \right)^{\frac{1}{2}} \quad \dots(2.12)$$

where Φ is an unknown coefficient and subscript b refers to the significant breaker line.

Galvin and Nelson's data were then used to find a value for Φ , namely,

$$\Phi = 25 (\tan \alpha)^{0.85} \quad \dots(2.13)$$

that is,

$$C_{LH} = 25 \left(\frac{f_{wb} g}{2C_{hb}^2} \right)^{\frac{1}{2}} (\tan \alpha)^{0.85} \quad \dots(2.14)$$

Galvin and Nelson's data are plotted in Figure 2 for each of the above suggestions for the friction factor C_{LH} . From the four one-to-one plots of velocity listed in Galvin and Nelson's paper to predicted longshore current velocity it is quite apparent that the last alternative for C_{LH} , that is, equation (2.14), as given by Swart and Fleming (in CSIR, 1978) yields by far the best agreement between data and prediction, followed by Komar and Inman's equation (equation (2.11)). The value of C_{LH} as predicted from equation (2.14) is therefore used in the package deal approach.

3. PREDICTION OF LONGSHORE TRANSPORT RATES

As stated in Section 1, there are two types of formulae for the prediction of longshore transport rates, namely, overall predictors and detail predictors. Of the one overall predictor and five detail predictors listed in Section 1 only the adapted Ackers-White formula (Swart and Lenhoff, to be published in 1980) has not been reported on in the international literature. Therefore only a short summary is given of the first five transport equations, whereafter the adapted Ackers-White formula is discussed in more detail.

SPM formula (SPM, 1973; Swart, 1976a)

This formula is based on an empirical relationship between the longshore component of the energy flux due to wave action and the total longshore transport rate. No distribution is given of transport across the breaker zone. The formula for the total transport rate for each wave condition i is:

$$S_{SPM} = K(D) f_i T_p H_{OS}^2 K_{rb}^2 \sin 2 \Theta_b \quad \dots(3.1)$$

(in $m^3/year$)

where H_{OS} is the deep-water significant wave height, K_{rb} is the refraction coefficient at the significant breaker line and Θ_b is the angle of incidence at the significant breaker line. Swart (1976a) showed that the proportionality factor $K(D)$ is not a constant but is a function of the median grain size D_{50} of the bed material, namely,

$$K(D) = 91 \times 10^4 \log_{10} \left\{ \frac{0.00146}{D_{50}} \right\} \quad \dots(3.2)$$

Bijker formula (Bijker, 1971)

Bijker's formula, developed in 1967, was the first detail predictor and at the time constituted a major breakthrough in the prediction of longshore transport rates. It is built up of two components, namely, a bed load component and a suspended load component. The bed load formula was adapted from the Frýlink formula for sediment transport rates under riverine conditions by adapting the shear stress terms:

$$S_{bB} = 5 D_{50} \frac{v}{C_h} g^{\frac{1}{2}} \exp \left\{ \frac{-0.27 \Delta_s g D_{50}}{\mu(\tau_{wc}/\rho)} \right\} \quad \dots(3.3)$$

(in $m^3/m/s$)

where μ is a ripple factor defined by Bijker and the bed shear stress due to waves and current τ_{wc} is:

$$\tau_{wc} = \rho \frac{v^2 g}{C_h^2} \left(1 + \frac{1}{2} \left(\frac{\xi u_o}{v} \right)^2 \right) \quad \dots(3.4)$$

Swart (1976b) subsequently showed that $\xi = C_h (f_w / (2g))^{1/2}$. The suspended load was found from the Rouse-Einstein distribution of suspended material from bed to free surface and integrating the product instantaneous velocity times concentration of bed material with depth, resulting in:

$$S_{SB} = 1.83 S_{bB} \{ I_1 \ln \left(\frac{33d}{r} \right) + I_2 \} \quad \dots(3.5)$$

where I_1 and I_2 are elliptic integrals, for which Býker determined quantitative values by numerical integration. The total transport per metre in any given water depth d_i is then

$$S_B = S_{bB} + S_{SB} \quad \dots(3.6)$$

(in $m^3/m/s$)

Although the formula contains no incipient motion criterion, the transport rates predicted for velocities below the threshold velocity are very low.

Fleming formula (Fleming and Hunt, 1976; Fleming, 1977)

Fleming developed a transport formula by which the total load (bed plus suspended load) for wave action can be predicted. He defined a reference concentration C_e close to the bed (a small distance e above the bed). He used the force balance of bed particles to derive a theoretical expression for C_e , which contains an incipient motion criterion. Fleming assumed that the concentration at the bed cannot exceed 0.52 and that the eddy diffusivity is constant over the whole water mass above the elevation $z = e$. A simple one-seventh power rule was assumed for the variation with distance from the bed of the longshore current velocity. The following equations must be integrated numerically to find the total longshore transport at any water depth d_i :

For $0 \leq z \leq e$

$$C(z) = 0.52 \left(\frac{C_e}{0.52} \right)^{z/e} \quad \dots(3.7)$$

$$v(z) = \frac{8}{7} v \left(\frac{z}{d_i} \right)^{1/7} \quad \dots(3.8)$$

where z is the distance above the bed.

For $e < z \leq d_i$

$$C(z) = C_e \exp \{ J_m (1 - (z/e)^{0.75}) \} \quad \dots(3.9)$$

The velocity $v(z)$ is again determined from equation (3.8). Fleming presented equations for the finding of J_m and e . The resulting transport is given in $m^3/m/s$.

Adapted Engelund-Hansen formula (Swart, 1976b)

Swart adapted the original formula by Engelund and Hansen (1967) for the prediction of total sediment transport rates in any depth d_i under steady flow conditions in an analogous manner to the Býker formula. The resulting equation is:

$$S_{EH} = \frac{0.05 v C_h (\tau_{wc}/\rho)^2}{g^{5/2} \Delta_s^2 D_{50}} \quad \dots(3.10)$$

(in $m^3/m/s$)

Obviously, equation (3.10) contains no incipient motion criterion. For longshore current velocities below the threshold velocity the formula predicts longshore transport rates which are higher than those predicted by the Býker formula.

Nielsen formula (Nielsen et al., 1978)

Nielsen determined the distribution of suspended sediment with distance from the bed for breaking (spilling breakers) and non-breaking wave conditions in the laboratory. He used the data to determine empirically quantitative predictors for the eddy diffusivity ϵ , which he found is constant with distance from the bed for non-breaking waves and increases strongly with distance from the bed for breaking waves, and the concentration of suspended material at the top of the bed forms C_0 , which contains an incipient motion criterion. The effect of the spilling breakers was to increase the eddy diffusivity at the bed by two orders of magnitude. The variation of concentration of suspended material with distance from the bed for a nonuniform material is given by

$$C(z) = C_0 \left(\frac{1}{1+\sigma V} \right)^{1/V} \dots(3.11)$$

where $V = \text{var}(w)/w_{s0}^2$, with $w =$ fall velocity of bed material; and $\sigma =$ parameter including the eddy diffusivity. In the package deal approach the product of the concentration in equation (3.11) and the velocity in equation (3.8) is integrated numerically with respect to z to find the total load in any given depth d_i . The appropriate value of the eddy diffusivity (with or without wave breaking) is used inside and outside the breaker line.

Adapted Ackers-White formula (Swart and Lenhoff, to be published, 1980)

The original formula for the prediction of sediment transport rates under steady-state conditions was as follows (Ackers and White, 1971):

$$S = 1.45 v D_{35} C \underbrace{\left(\frac{P_{fg}/\rho}{v_* fg} \right)^n \left(\frac{P_{cg}/\rho}{v_* cg v_r} \right)^{1-n}}_{\text{efficiency term}} \left(\frac{F_{gr}}{A} - 1 \right)^m \dots(3.12)$$

where C , n , m and A are grain size dependent parameters, for which empirical relationships are given by Ackers and White; F_{gr} is the sediment mobility $= (v_{fg} v_{cg}^{1-n}) / (\Delta_s g D_{35})^2$; P is the stream power; v_r the resultant velocity $= v$ for steady state) and v_* is the shear velocity $= (\tau/\rho)^{1/2}$; subscripts 'fg' and 'cg' respectively denote the 'fine grain' and 'coarse grain' versions of the properties. The value for fine-grained sediment is obtained by using the actual bed roughness r , as described before, whereas the value for coarse-grained sediment is obtained by using the grain size D_{35} instead of r in the appropriate equations. For steady-state conditions the efficiency term reduces to $(v/v_* fg)^n$. At present there are four adapted versions of equation (3.12) which are used in coastal engineering application, each containing different assumptions.

(1) SWANBY-version (Swart, 1976b)

Only the fine grain component of the shear terms was adapted to include the effect of wave action, which has now been found to be incorrect. Both the fine grain and the coarse grain components should be adapted.

(2) Willis-version (Willis, 1978)

Willis concluded that the critical (incipient motion) value A of the mobility number is different for combined wave and current action from the value for current action alone. To compensate for this difference he

multiplied the wave-induced shear stresses by an empirical coefficient w_c^2 , where w_c^2 is a function of the grain size. Willis adapted both the fine grain and the coarse grain components of the shear stress to include the effect of wave action, but he used an erroneous equation for wave power $\{c_g \tau_{wc}$ (where c_g = group velocity of the waves) and the power was treated as a scalar instead of finding the mean value of the product (instantaneous resultant velocity at the bed times instantaneous bed shear stress)}, which yielded too high values for the power. The effect of this mistake on the predicted transport rates is masked because w_c^2 was computed by using the equation for longshore sediment transport rate with the erroneous expression for the wave power.

(3) V.d. Graaff and V. Overeem-version (V.d. Graaff and V. Overeem, 1979)

V.d. Graaff and V. Overeem added the effect of waves on the shear stresses to both the fine- and coarse-grain components, but used the same critical mobility number as for steady-state conditions and also used the steady-state version of the efficiency term instead of the actual wave power.

(4) Swart and Lenhoff-version (to be published, 1980)

All three versions discussed above are therefore erroneous in one way or another. Swart and Lenhoff therefore defined a fourth version, in which all previous shortcomings are eliminated. Three points are important.

a. The *instantaneous sediment mobility* $F_{gr}(t)$ for waves and currents is given by:

$$F_{gf}(t) = \frac{v_{*fg}(t)^n v_{*cg}(t)^{1-n}}{(\Delta_s g D_{35})^{1/2}} \quad \dots (3.13)$$

The 't' denotes time variation.

Instead of adapting the fine and coarse grain components of the shear stress individually by integrating each separately with respect to time, it is more logical to compute the average effect of the inclusion of waves on the mean mobility number by integrating the instantaneous mobility number with respect to time, that is

$$F_{wc} = \overline{F_{gr}(t)} = \frac{1}{T} \int_0^T F_{gr}(t) dt \quad \dots (3.14)$$

where F_{wc} is the mean sediment mobility for combined current and wave action.

b. Similarly, the *instantaneous value* $E_f(t)$ of the *efficiency term*, as given in equation (3.12), is averaged to obtain the mean value E_{fwc} of the efficiency term for combined current and wave action, namely,

$$E_{fwc} = \overline{E_f(t)} = \frac{1}{T} \int_0^T E_f(t) dt \quad \dots (3.15)$$

$$\text{where } E_f(t) = \left(\frac{P_{fg}(t)/\rho}{v_{*fg}(t)^3} \right)^n \left(\frac{P_{cg}(t)/\rho}{v_{*cg}(t)^2 v_r(t)} \right)^{1-n} \quad \dots (3.16)$$

$$P(t) = v_r(t) \tau(t) \quad \dots (3.17)$$

Values for the instantaneous resultant velocity at the bed $v_r(t)$ and the instantaneous shear stress at the bed $\tau(t)$ are found by vector addition of the contributions by the waves and the currents.

When applying the formula for sediment transport rates (equation (3.12)), values for F_{wc} and E_{fwc} are found by numerical integration.

c. A new empirical relationship for the *critical mobility number* A was determined from more than 800 data sets of four different types, namely:

- observed incipient motion data on a flat bed for waves only;
- observed incipient motion data on a rippled bed for waves only;
- observed incipient motion data on a flat bed for combined current and wave action;
- sediment load data over rippled beds for waves only as well as combined wave and current action.

In the case of the first three types the mobility number could be determined directly from the data. For the fourth type, however, all variables in equation (3.12) were known, except the critical mobility A , which could then be easily computed. The results are presented in Figure 3 in the form of a Reynolds number R_* ($= (\bar{\tau}_{cr}/\rho)^{1/2} D_{50}/v$, where $\bar{\tau}_{cr}$ is the mean shear stress at incipient motion and v is the kinematic viscosity) versus a dimensionless grain size D_* ($= (g\Delta_s/v^2)^{1/3} D_{50}$). This figure indicates that all four types of data follow the same relationship between R_* and D_* , namely,

$$\log_{10} (R_*) = 0.092 (\log_{10} D_*)^2 + 1.158 \log_{10} D_* - 0.367 \quad \dots(3.18)$$

The critical mobility is now simply

$$A = R_* D_*^{-1/2} \quad \dots(3.19)$$

This implies that equation (3.12) is in fact universally applicable to all types of flow, namely, to waves only, current only and combined waves and currents. Since the incipient motion data and sediment load data are completely independent and have been treated completely differently, it also implies that this fourth adapted version of the original Ackers-White formula is indeed correct. It is consequently also the only adapted version of Ackers-White which is included in the package deal approach.

4. PROTOTYPE APPLICATION

An example is now given to illustrate the results obtained with the package deal approach for a prototype application. The input variables are summarized in Figure 4. It can be seen that the location under consideration is situated on a high-energy coastline. Quarterly bathymetric surveys over a two-year period indicated that the beach under consideration was in overall equilibrium (see Figure 5) although a substantial seasonal variation took place in the total volume of sediment in the control area. Fleming (1976) showed that the offshore-directed transport through the seaward boundary of the control area was negligible and that the volumetric changes depicted in Figure 5 are associated with a distinct sloshing of the material in the bay. During the summer months with persistent southerly winds and wave conditions, accretion took place in the northern half of the control area and (less) erosion occurred in the southern half of the control area. The opposite process took place during the winter months when northerly winds and wave conditions are more predominant. The data therefore indicate a clear wave-driven sloshing in the bay, with a corresponding average transport residual per year maintained over two years of $1.45 \times 10^6 \text{ m}^3/\text{yr}$ (see Figure 5). The results obtained from the package deal approach are summarized in Figure 6. The data indicate that the

volume of material in the control area will increase during periods of northbound transport and will decrease during periods of southbound transport. This result agrees with the prototype data. The average value of the difference in transport capacity at the up- and down-coast boundaries of the control area is predicted to be $1.65 \times 10^6 \text{ m}^3/\text{yr}$ plus or minus about 20 per cent of this mean value, which agrees well with the observed value of $1.45 \times 10^6 \text{ m}^3/\text{yr}$. Furthermore, the theoretical results also indicate that the volume of material in the control area will return approximately to its initial value after each year ($+ 1.7 \times 10^6 - 1.6 \times 10^6$), which also agrees with the prototype data. Since the wave climate has a marked seasonal component, the package deal approach therefore indicates a wave-driven sloshing mode of the same magnitude as observed in prototype. Figure 7 indicates that the prediction of the distribution of longshore transport with distance offshore is very consistent for the five detail predictors. The 95 per cent confidence band of the mean predicted longshore transport rate is approximately twice the standard deviation, which means that it is possible to predict the mean annual transport rate from the six predictors with 95 per cent certainty to within plus or minus 40 per cent. *It can therefore be concluded that the six formulae used to predict annual longshore transport rates are consistent with the given input variables.*

5. POSSIBLE SOURCES OF INACCURACY IN THE INPUT VARIABLES

In order to investigate whether this consistent answer obtained by means of the package deal approach is necessarily the correct one, a few possible sources of inaccuracies in the input variables that have to be specified for the application of the package deal approach are discussed briefly below.

Wave characteristics

The wave height H , which is a very significant parameter in the determination of every wave-induced process, could have been obtained from measurements in either shallow or deep water. In both instances the obtained wave height could be inaccurate.

For waves *measured in shallow water* the method of analysis of the records determines the extent of the possible inaccuracies. The actual waves are non-linear, that is, they are not sinusoidal anymore. For that reason a random wave train in shallow water consists of a number of non-linear components. By assuming that all these non-linear components can be represented by Vocoidal waves (see Swart and Loubser, 1978) it can be shown that a normal Fourier analysis, that is, an analysis in the frequency domain, will underestimate both the significant wave height H_s and peak wave period T_p of wave records measured in shallow water (see Swart, 1980). This is the result of the decomposition into their higher-frequency components of the non-linear waves in the spectrum. An example of this behaviour is given in Figure 8a for a random shallow-water wave record, simulated by the random superposition of Vocoidal component waves. The input values for the example shown are the root-mean-square wave height $H_{rms} = 0.711 \text{ m}$ and the peak wave period $T_p = 14.621 \text{ s}$. The results of the normal Fourier analysis are denoted by a subscript '1' and are $H_{rms1} = 0.49 \text{ m}$ and $T_{p1} = 5.686 \text{ s}$. Also shown in this figure is the result of a higher-order analysis, developed by Swart (1980), in which the Vocoidal components (instead of the

sinusoidal components) are extracted from the original wave record. In the normal Fourier analysis the wave height can be underpredicted by up to 50 per cent, whereas the wave period can be underpredicted by up to 70 per cent. On the other hand, a Draper-analysis, in the time domain, of the same simulated record also underpredicts both height and period to the same extent as a normal Fourier analysis, in this instance as a result of the fact that the component waves are not symmetrical around the mean water level but do in fact have more pronounced crests. For the specific example shown in Figure 8a the Draper results are H_{SIGD} = 0.581 m and TZ (zero-crossing period) = 3.617 s.

Waves *measured in deep water* can be analysed properly, because all component waves are either sinusoidal or closely resemble sinusoidal waves. In this case it is the method of transfer (via shoaling/refraction) of the wave from deep to shallow water which determines the extent of the inaccuracies. Figure 8b shows the error, at the location where $H/d = 0.6$, in the wave height obtained from linear shoaling and refraction of a wave with a deep water angle of incidence of 20° , when compared to Vocoidal theory. This is a valid way of determining the errors, since Swart and Loubser (1979) have shown that Vocoidal theory shows both a good agreement with measured wave data and adheres closely to the theoretical boundary conditions. The wave height is consistently underpredicted by linear (Airy) wave theory. For the whole range of values of $T(g/d)^{1/2}$ given in Figure 8b the error in the angle of incidence at $H/d = 0.6$ is about -0.13 for the example under consideration, again as compared to Vocoidal theory. The corresponding errors in the radiation stress components R_{yx} (used in the determination of longshore current velocity) and R_{xx} (which determines the mean water level but is not as yet part of the package deal approach) are given in Figures 8d and 8c respectively. It is shown that linear theory consistently overpredicts the radiation stresses. The error in R_{yx} does not necessarily reflect the possible error in the longshore current velocity v , since the friction coefficient C_{LH} is determined empirically. Since it is, however, possible that the formula for longshore current is applied outside the area of empirical determination of the friction factor C_{LH} , the extent of errors in R_{yx} point to a very possible source of inaccuracy in the current velocity v .

Bed roughness

The bed roughness is determined by the geometry of the bed forms, which can consist of wave-induced ripples and completely three-dimensional dune and bar patterns. In the package deal approach only the wave-induced ripples are used for this purpose, because they are the only predictable bed forms. Although this approach has to date given quite satisfactory results, it is obvious that it is an obvious source of error in the determination of the roughness, which in turn affects the friction factors C_{LH} and f_w and therefore also the longshore current velocity and ultimately the predicted longshore transport rate.

Breaking waves

The package deal approach is applied throughout the whole sediment transport zone, that is, also in the breaker zone. This is for a few reasons not correct:

- (1) The wave characteristics inside the breaker zone, such as orbital velocities and wave profile, are definitely non-sinusoidal.

(2) The expressions for the determination of bed roughness and wave-induced bed forms, derived for non-breaking waves, are not necessarily valid inside the breaker zone.

(3) The amount of sediment in suspension is determined, not only by the bed-related turbulence structure, but also by the turbulence induced by wave breaking. Figure 8e contains an example of the sediment load in the breaker zone, as predicted by the technique of Nielsen et al. (1978) by alternatively assuming breaking and no breaking for the same wave conditions. Although for the example shown the case with breaking leads to a total load which is 173 per cent more than in the case without breaking, the average percentage underprediction due to the fact that the effect of breaking waves on the turbulence was not taken into account would have amounted to 33 per cent for the annual transport in the example in Section 4. This is significant, since the Nielsen formula is the only one of the five detail predictors which includes the effect of wave breaking in his formula.

(4) The longshore current profile across the breaker zone is determined to a large extent by the type of wave breaking which occurs. At present the computation performed in the package deal approach assumes, as is done by everybody else, that the waves break in the spilling mode.

Longshore current velocity

The effect of the bed roughness, friction factor C_{LH} and breaker type on the longshore current velocity have already been touched upon in the above discussion. The beach profile itself also affects the longshore current. At present a representative constant beach slope is assumed for the longshore current determination. In reality the beach profile is often of the bar-type, which contains a well-developed trough landwards of the breaker bar, in which the longshore current will tend to concentrate. Recent research by Dette (1980) is the first step towards understanding this phenomenon.

It is therefore apparent that all input variables could be subject to possible inaccuracies, which could affect all six longshore transport predictors used in the package deal approach.

6. SENSITIVITY ANALYSIS

For this reason a sensitivity analysis was carried out to establish the extent of the influence of inaccuracies in the prime input variables (that is, wave height H longshore current velocity v and bed roughness r) on the average annual longshore transport rate, as predicted for the situation outlined in Section 4 with the five detail predictors. These three input variables were allowed to vary in the following ranges, namely, $0.5 < r_r < 5.0$; $0.2 < r_v < 1.0$; and $0.5 < r_H < 2.0$. The definitions for r_r , r_v and r_H are given in Figure 9, which also contains the results of the sensitivity analysis. Two graphs are given in Figure 9 for each input variable (r , v , H). In each case the left-hand graph indicates the variation of S/S_{pm} with the ratio r_r (or r_v or r_H), where S is the mean computed transport for the five detail predictors and S_{pm} is the transport given by the SPM formula in the original package deal approach. The right-hand graph represents the

relative standard deviation σ/μ for the five detail predictors in terms of the ratio r_r (or r_v or r_H), where μ is the mean transport (equal to S in the left-hand graph) and σ is the standard deviation of the five elements of which μ is made up. Figure 9 indicates a few interesting things:

(1) The package deal approach, that is, $r_r = r_v = r_H = 1$, seems to yield the best correspondence with the SPM results of all ratios (of r_r , r_v and r_H) tested.

(2) The relative standard deviation σ/μ reaches a minimum value for $r_r = r_v = r_H = 1$, that is, for the package deal approach.

It can therefore be concluded that the package deal approach for the detail predictors yields the same annual transport rate as the SPM formula, which in a way contains empirically all the physical influences on the input parameters mentioned in Section 5, that is, the bed form and bed roughness, wave breaking and bar profiles. It is therefore reasonable to assume that the results obtained via the package deal approach at present represent the best estimate of annual longshore transport rates. Since both the overall and the detail predictors depend on the predicted wave characteristics, which have been shown to be possibly in error, the package deal results could be in error. The extent of the error will depend on the empirical relationships for the longshore friction factor C_{LH} and for the parameter $K(D)$ in the SPM formula, if both of these are determined from available data by using a good non-linear wave theory, for example, Vocoidal theory, for the prediction of shallow water wave characteristics instead of linear Airy wave theory.

7. CONCLUDING REMARKS

We have therefore at present got a *package deal* approach that yields consistent transport rates and distributions across the breaker zone, but we should do further research to improve our input variables, namely, (1) wave characteristics; (2) bed forms and bed roughness; (3) longshore current velocity and distribution across the breaker zone for bar-type beaches; (4) breaking wave phenomena in general; and (5) the effect on sediment suspension of increased turbulence due to breaking.

CRITERION FOR STABILITY OF SHORELINE PLANFORM

JOHN D. WANG, Ph.D., Associate Professor
 BERNARD LE MEHAUTE, Ph.D., Professor and Chairman
 Ocean Engineering Division, Rosenstiel School of
 Marine and Atmospheric Science, University of Miami,
 4600 Rickenbacker Causeway, Virginia Key, Miami,
 Florida 33149, U.S.A.

INTRODUCTION

The problem of beach planform stability has been known for a long time: When does a small perturbation on a straight beach tend to grow with time and when does it tend to be flattened out? The interest in this problem arises from evidence of instabilities occurring in nature, but perhaps more importantly it is a problem that must be taken into account when formulating models for beach evolution and erosion. Existing mathematical models describing shoreline changes assume that the beach planform is stable and in equilibrium. It is therefore important to establish the range of wave conditions for which instabilities could occur, thereby invalidating such models. In the present case our interest is specifically directed towards determining conditions for which a model for shoreline evolution is intangible because of development of local instability.

Grijm (1960) gave an approximate mathematical analysis indicating that at the point where the longshore sediment transport Q as a function of wave angle is maximum the shoreline must either be straight or form a cusp. Under his assumption that Q is proportional to $\sin 2\alpha$ the maximum occurs for $\alpha = 45^\circ$. Le Mehaute and Soldate (1977) summarizes other studies that essentially arrive at the same results, viz. when the deep water wave angle is greater than 45° the shoreline is unstable. This result did not seem to be substantiated by field or laboratory observations.

In this study of shoreline planform we first derive a criterion for instability of straight beaches. Then assuming that longshore sediment transport is proportional to the alongshore wave energy flux component at the point of breaking we determine the range of deep water wave characteristics and beach slopes which would cause unstable situations to occur.

We consider only the longshore transport and exclude effects of on-offshore transport.

PLANFORM STABILITY CRITERION

Consider a straight beach along which an x-axis is defined, see Fig. 1. We shall take the usual definition of instability as a condition under which an initial infinitesimal disturbance grows in time. Accordingly, we introduce an infinitesimal protuberance on a straight shoreline, which is initially in equilibrium with

$\partial Q/\partial x = 0$. A mass balance on the control volume also shown in Fig. 1 is performed. The seaward boundary of the control volume is chosen at a depth large enough so that the longshore transport is zero there.

Two situations may arise:

- a) The longshore transport Q increases across the disturbance, i.e. $\partial Q/\partial x > 0$. To satisfy conservation of mass the increase in transport must come from erosion within the control volume and hence the protuberance is eroded until it disappears. The beach is stable for $\partial Q/\partial x > 0$.
- b) In the case of decreasing longshore transport, sediment accumulates in the control volume and the protuberance grows. The beach is unstable for $\partial Q/\partial x < 0$.

The above analysis applies to the case of a protuberance from the beach, the opposite conclusions would be derived for a recession. It is therefore useful to generalize the results by considering Q as a function of the breaking wave angle, i.e. $Q = Q(\alpha_b)$. According to our earlier assumption Q is also a function of deep water wave height, H_0 ; wave period, T ; and beach slope, S ; however these can be assumed unaffected by the small disturbance and independent of x .

We can then write

$$\frac{\partial Q}{\partial x} = \frac{\partial Q}{\partial \alpha_b} \frac{\partial \alpha_b}{\partial x}$$

and considering the sign for $\partial \alpha_b/\partial x$, which is positive for the protuberance and negative for the recession the criterion for stability becomes

$$\frac{\partial Q}{\partial \alpha_b} > 0 \quad \text{STABLE} \quad (1)$$

and similarly

$$\frac{\partial Q}{\partial \alpha_b} < 0 \quad \text{UNSTABLE} \quad (2)$$

Since α_b is a function of H_0 , T , S , and the deep water incident wave angle, α_0 , the condition $\partial Q/\partial \alpha_b = 0$ can also be given as a critical value of α_0 for given H_0 , T , and S . Expressing the stability criterion in terms of deep water wave characteristics makes it easier to determine whether given wave conditions would cause instability. In the following we use linear and nonlinear wave theories to determine those critical values of α_0 .

Figure 1. Local instability of a straight shoreline.

LINEAR THEORY

In the case of initially straight parallel contours, the deep water wave characteristics can easily be transformed into breaking wave characteristics by assuming conservation of energy flux between wave orthogonals.

If linear theory is used to express energy flux conservation, one obtains the following:

$$\frac{H_b}{H_o} = \sqrt{\frac{c_{go}}{c_{gb}}} \cdot \sqrt{\frac{\cos \alpha_o}{\cos \alpha_b}} \quad (3)$$

c_g = wave group velocity

Sub index o refers to deep water values and index b refers to breaking. By adding Snell's law; the dispersion relationship and the equation relating wave group velocity to wave phase velocity, c,

$$\frac{L_b}{L_o} = \frac{\sin \alpha_b}{\sin \alpha_o} \quad (4)$$

$$\frac{L_b}{L_o} = \tanh \frac{2\pi h_b}{L_b} \quad (5)$$

$$c_{gb} = \frac{1}{2} \frac{L_b}{T} \left(1 + \frac{\frac{4\pi h_b}{L_b}}{\sinh \frac{4\pi h_b}{L_b}} \right) \quad (6)$$

where h_b is the depth at breaking and L is the wave length, one has 4 equations to determine the 5 unknowns: H_b , h_b , L_b , c_{gb} and α_b . The fifth equation consists of a breaking criterion for which we use the empirical relation proposed by Le Mehaute and Koh (1967).

$$\frac{H_b}{H_o} = 0.76 \cdot S^{1/7} \left(\frac{H_o}{L_o} \right)^{-1/4} \quad (7)$$

Equation (7), which was derived for normal incident waves is modified to make it applicable to obliquely incident waves. The deep water wave height, H_o , is replaced by its unrefracted value

$$H_o \rightarrow H_o \frac{\cos \alpha_o}{\cos \alpha_b}$$

and the bottom slope is replaced by the slope

$$S \rightarrow S \cos \alpha_b$$

leading to the result

$$\frac{H_b}{H_o} = 0.76 \left(\frac{H_o}{L_o S^{4/7}} \right)^{-1/4} \cos^{3/8} \alpha_o \cos^{-13/56} \alpha_b \quad (8)$$

By straightforward manipulation of Eqs. (3) - (8), one obtains the following implicit equation for determining the breaking wave angle as a function of incident wave angle, α_o and the parameter $H_o/L_o S^{4/7}$

$$\begin{aligned} & 0.76 \left(\frac{H_o}{L_o S^{4/7}} \right)^{-1/4} \cos^{3/8} \alpha_o \cos^{-13/56} \alpha_b \\ &= \left(\frac{\sin \alpha_o}{\sin \alpha_b} \right)^{1/2} \left(\frac{\cos \alpha_o}{\cos \alpha_b} \right)^{1/2} \left\{ 1 + 2 \ln \left(\frac{\sin \alpha_o + \sin \alpha_b}{\sin \alpha_o - \sin \alpha_b} \right) \right. \\ & \left. \left[\frac{4 \sin^2 \alpha_o \sin^2 \alpha_b}{\sin^2 \alpha_o - \sin^2 \alpha_b} \right]^{-1} \right\}^{-1/2} \quad (9) \end{aligned}$$

The equation is solved numerically and the results are shown in Fig. 2.

LINEAR STABILITY CRITERION

The usual assumption is that longshore transport is proportional to the longshore component of wave energy flux at the point of breaking:

$$Q \propto H_b^2 c_{gb} \sin 2\alpha_b \quad (10)$$

We can normalize this expression with the constant $H_o^2 c_{go}$ to give the remarkably simple result

Figure 2. Breaking wave angle as a function of α_0 and $\frac{H_0}{L_0 S^{4/7}}$ linear theory.

$$\begin{aligned}
 Q &\propto \left(\frac{H_b}{H_o}\right)^2 \frac{c_{gb}}{c_{go}} \sin 2\alpha_b \\
 &= \frac{c_{go}}{c_{gb}} \frac{\cos \alpha_o}{\cos \alpha_b} \cdot \frac{c_{gb}}{c_{go}} 2 \sin \alpha_b \cos \alpha_b \\
 &= 2 \cos \alpha_o \sin \alpha_b
 \end{aligned} \tag{11}$$

Using Eq. (11) and (9) we can determine the critical value of α_o for which $\partial Q/\partial \alpha_b = 0$. This is again calculated numerically and the results are shown in Table 1. For each value of $H_o/L_o S^{4/7}$, two critical values of α_o are found. For incident wave angles between these two values the beach is unstable, otherwise it is stable.

The lower limit of the unstable region is almost invariant to the parameter $H_o/L_o S^{4/7}$ with a value of $\alpha_o = 42^\circ$ while the upper limit decreases with increasing $H_o/L_o^{4/7}$. The upper limit in terms of α_o varies between $59^\circ.8 \leq \alpha_o \leq 63^\circ.5$.

NON-LINEAR WAVE THEORY

It is well-known that linear wave theory underestimates the wave height near breaking. Since we are using an empirical breaking criterion derived from observations of real waves, we would expect that the predicted breaking depth is smaller than the real depth and thus the predicted limits for α_o and α_b are also smaller than the real waves. Wang and Le Mehaute (1980) have shown that better results can be obtained for large deep water wave steepness using a non-linear hybrid wave theory which uses cnoidal theory to predict wave height and linear theory for wave length. A detailed description of the rationale and verification of this model is given in that paper. Here, we use the hybrid theory with the breaking criterion (8) to determine critical values of α_o .

A problem arises because wave energy flux is not properly defined for the hybrid theory. We carried out the stability analysis using both the linear expression (11) and the normalized cnoidal energy flux given by

$$Q \propto \left(\frac{H_b}{H_o}\right)^2 \frac{L}{L_o} B \sin 2\alpha_b \tag{12}$$

B is a function of elliptic integrals:

Table 2

Lower and upper limits for unstable shoreline regimes. I is computed using linear wave energy transport Eq. 11. II is computed using cnoidal wave energy transport Eq. 12.

$$B = B(m) \equiv \frac{1}{m^2} \left[\frac{1}{3} (3m^2 - 5m + 2 + (4m - 2) \frac{E(m)}{K(m)} - (1 - m - \frac{E(m)}{K(m)})^2 \right] \quad (13)$$

$K(m)$ and $E(m)$ are complete elliptic integrals of the first and second kind respectively. The parameter m is given by, see e.g. Svendsen and Brink-Kjaer (1973):

$$m K^2(m) = \frac{3}{16} \frac{HL_c^2}{h^3} \quad (14)$$

where L_c is the cnoidal wave length parameter.

The critical values of α_0 and α_b corresponding to $\partial Q/\partial \alpha_b = 0$ are presented in Table 2. Again two values for α_0 are found indicating a bounded region of instability.

It is seen that as expected the critical values are somewhat greater than those computed using linear theory. The difference between using linear wave or cnoidal wave energy flux is small and only influences the lower limit. The upper limit is not affected by the choice of energy flux expression because it is determined practically by the maximum value of α_b for given S and H_0/L_0 .

Of greater importance is the fact that the non-linear theory predicts a larger zone of instability since the upper limit is significantly higher than predicted by linear theory. For large deep water wave steepness the upper limit for α_0 is greater than 85° , however, this may be due to the fact that we are outside of the region for which the breaking criterion and wave theory are verified. Another source of uncertainty derives from the empirical relationship between longshore transport and energy flux used in this study. When better parameterization of transport rates becomes available the same methodology can however be used to investigate for instabilities.

CONCLUSION

As part of our effort to develop useful models for the prediction of long term shoreline evolution we have investigated the practical limitations imposed on the models by the external conditions. The local instability phenomenon considered in this study is an example of such a limitation. Other areas that need further research involves the definition of an equivalent monochromatic wave from a multi-directional spectrum and the temporal discretization of an observed wave record.

ZETA BAYS, POCKET BEACHES AND HEADLAND CONTROL

by

R. Silvester,⁽¹⁾ Y. Tsuchiya⁽²⁾ and Y. Shibano⁽³⁾

ABSTRACT

The now familiar equilibrium shape of bay sculptured by waves between headlands can indicate to man the direction he could follow in stabilizing shorelines. The characteristics of these crenulate or zeta shapes are known and can be applied in design or defining limits of erosion. Some natural settings are discussed which introduce difficulties in identifying the correct bay shapes for applying these tools. The application of headland control to specific cases of instability is presented. The final requirement is emphasised of aiding Nature to protect the coastline by the formation of the offshore bar and its subsequent return to the beach without concurrent downcoast drift. The method currently receiving widespread support of placing offshore breakwaters in close proximity to each other is discounted as a viable protective alternative.

INTRODUCTION

The occurrence of crenulate or zeta shaped bays between natural headlands when persistent swell approaches the coast obliquely is now observable and well known (1)(2)(3). These may be in dynamic equilibrium with the sediment supply and wave climate or in static equilibrium when no further littoral drift is taking place. (See Figure 1) In either condition the bay will have a curved section of logarithmic spiral form and some indentation dimension (a) that is some fraction of the space (b) between the headlands.

It is seen that the angle of wave crests to the line joining the headlands equals that between the tangential coast and this same alignment. Even when not in static equilibrium this beach extremity is very close to this final angle (β).

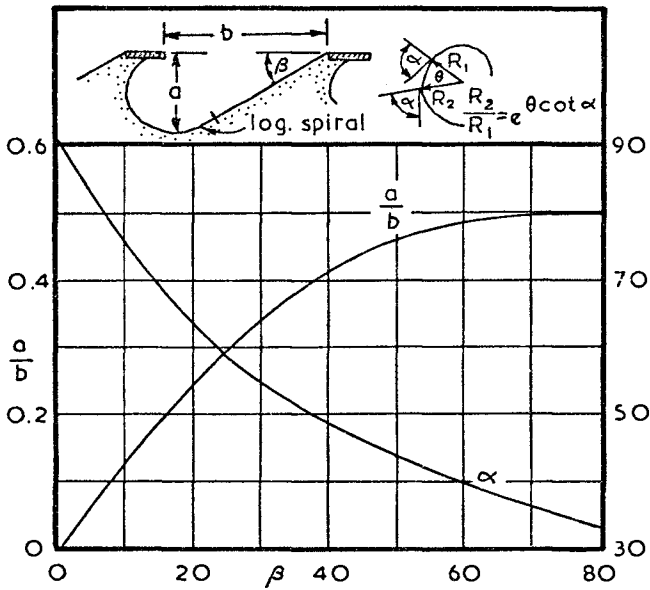

In the final stable form certain characteristics of the plan shapes are known from model tests and observations of prototype bays that are in this condition. (2)(4) As can be seen in Figure 2 the ratio of maximum indentation (a) to headland spacing (b) is fixed for a given obliquity of incident wave to headland alignments (β). In the same figure the relationship is shown between the constant (α) for the logarithmic spiral that the curved section of beach assumes.

With the above tools the stability of a bayed coast can be assessed, or the limit of erosion that can take place in the event of no further sediment being supplied, either from upcoast or from within the bay from

2. Parameters relating to bays in static equilibrium

a river. Such yard sticks can also be employed in designing headlands to stabilize an eroding bay or general coastline. In this final equilibrium condition persistent waves will be arriving normal to the complete periphery of the bay. At the tangential downcoast section waves will refract slightly but within the curved zone they suffer both diffraction and refraction before breaking parallel to the beach. Any wave thus breaks simultaneously around the complete bay shoreline.

POCKET BEACHES

There are situations where a deep indentation occurs and there is insufficient sand to saturate the bay and cause transport around the downcoast headland. These might be termed "pocket beaches", where it is more difficult to identify the control line from which the zeta bay can be tested for its stability. Extra variables entering the problem will be discussed to show how the true crenulate shape can be checked.

Protruding downcoast headland

Where the downcoast beachline does not reach the extremity of its headland (as pictured in Figure 3) due to lack of sediment, the control point should be the shoreline extremity. The figure shows the direction of the predominant or persistent waves, which determine the ultimate bay shape. The control line runs from the tip of the upcoast headland (on the left of the figure) to the intersection of the beach and the downcoast headland. This provides the measure of (β') from which (a'/b') and the logarithmic spiral constant (α') is determined from Figure 2. Since (b') is known the indentation (a') can be computed and the bay drawn.

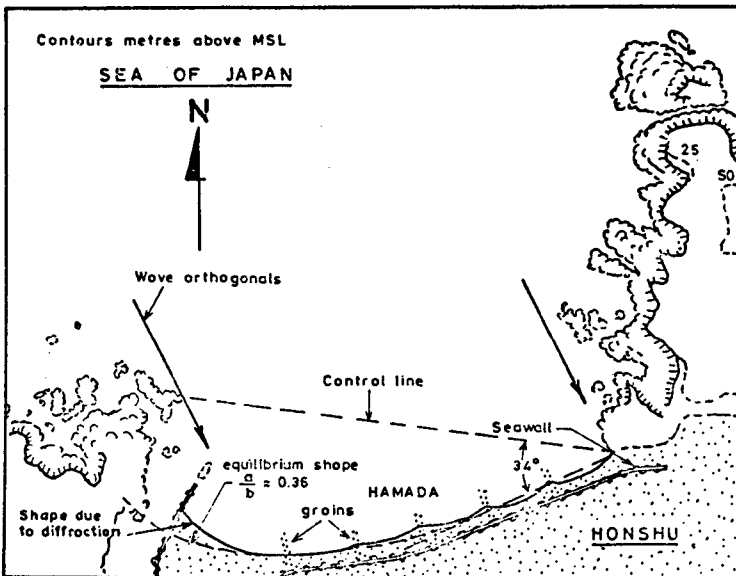

If renourishment by natural or man-made means were effected a new shape would emerge with a new contact point of the beach with the downcoast headland, as exhibited by angle (β) and indentation ratio (a/b) . A different value of (α) will also apply. Further addition of sediment will decrease the value of (β) which, as seen in Figure 2, will decrease (a/b) and make the curvature of the beach closer to that of a circular arc. After passing through the stage of a straight beach normal to the wave orthogonal, further accretion would result in a new bay shape which would be dictated by some headland or control point further upcoast.

The set-up as illustrated in Figure 3 would be ideal for further model verification of (a/b) and (α) , perhaps with a wave guide parallel to the downcoast headland to prevent reflection from this other headland.

An example of this situation is contained in Figure 4, which is a bay of the Honshu coast facing the Sea of Japan. The wave orthogonals are normal to the tangential downcoast section of the bay. That on the left determines the control point of the upcoast headland whilst the control line intersects the meeting of the beach with the downcoast headland. The value of $\beta = 34^\circ$ gives $a/b = 0.36$ from which the equilibrium bay shape can be sketched, as shown dotted. It is seen that at the upcoast end extra accretion has occurred due to wave diffraction around the jetty constructed at a river outlet. Otherwise the existing coast is in static equilibrium or nearly so, which calls into question

3. Bays with no by-passing of downcoast headland.

4. Bay exhibiting downcoast control of beach with headland.

Bay with double curvature due to wave diffraction.

the need for the seawall and groynes constructed along the tangential section of beach. This is a case where sand renourishment might have solved the erosion problem.

Double curvature of bays

It has already been shown in Figure 4 that deviations from the logarithmic spiral curve can take place if a secondary headland, in this case a jetty causes local wave diffraction. Another example at the down-coast end of a bay is illustrated in Figure 5, where waves sculpture an almost circular beach which is asymptotic to the end of the log-spiral section. Any such change in curvature should indicate this extra control condition. As noted in the figure, the wave orthogonal must be normal to the tangent at the transition, from which β is obtained. The control line from which (b) is measured then provides the indentation (a) by which the static equilibrium shape can be assessed.

An example of this problem is given in Figure 6 which is a bay on the Shikoku coast of Japan facing the Pacific Ocean. The increased curvature at the western end of this pocket beach indicates diffraction by the protruding downcoast headland. The wave orthogonal must be normal to the transition tangent giving the control line shown. The resulting equilibrium bay can be drawn and compared to the existing shoreline for testing its stability. It is seen that the bay can be continued into the upcoast headland complex even though it cannot exist there.

Multiple upcoast headlands

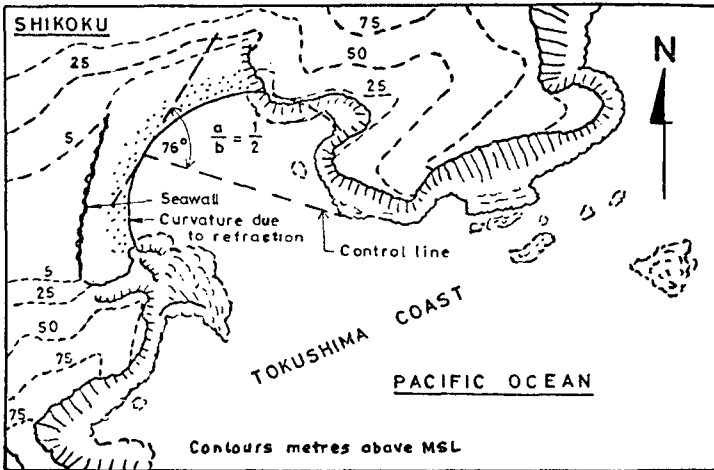

Figure 7 shows the complication of more than one headland in the upcoast region. It is necessary to determine which one controls the shape of the bay. The orthogonal of the persistent waves is normal to the tangential downcoast beach. This same orthogonal applies to the upcoast region as illustrated. In the absence of headland B point A becomes the control point and AC the control line by which β' is measured. This gives the indentation and curvature for the equilibrium beach from these controls. If this orthogonal intercepts the tip of headland B if it exists the new control line BC gives a new β value and completely different bay shape. It is obvious that the presence of headland C, even with A effecting control of the bay will cause greater curvature within its lee due to secondary diffraction.

In Figure 8 a bay on the Japanese coast is shown where the control point for the upcoast zone must be determined. It is another case of double curvature at the downcoast end so that a transition point must be determined to assess the line of the wave orthogonal. Once this is done the same alignment of wave approach indicates the protruding headland as the upcoast control point. The resulting equilibrium bay is much further inland than the existing coast indicating a great potentiality for erosion. This is displayed by the extensive seawalls shown, which have been provided to protect the road and rail links on the coast, a necessary feature around most of the Japanese coastline. A method of stabilizing this bay is indicated by headlands but will be discussed later.

Orientation of headlands

It is convenient for considering bay characteristics to align headlands with the line joining the tips, about which waves diffract as in Figure 1. Natural conditions are never so easy and hence alignments as in Figure 9 must be accounted for. The original situation is presented by alignments A and E where the control line and spacing (b) fixes indentation (a) once (β) has been measured. If other headland orientations still have the same (b) the same plan form results. However, with alternatives B, C and D for the upcoast structure part of the bay will not exist. Even so the drawing of the remainder of the bay may help the determination of (a) within the hypothetical section in order that it, with portion of the logarithmic spiral, can be assessed.

Similarly the orientation of the downcoast headland at G or F has no influence on the equilibrium bay formed by the control line as pertains to E. It is only when this structure protrudes into the bay, as with alternative H shown dotted in Figure 9, that a new control point is established. As seen a new (b') is operative as well as a different (β), from which a new (a) is derived and, of course, a changed log-spiral for the curved section of bay.

6. Example of bay with double curvature.

7. Bays formed by different upcoast headland control

8. Example of defining control by upcoast headland.

9. Effect of headland orientation on bay formation.

10. Influence of wave reflection on smooth beach line.

It is interesting to compare alternatives of breakwaters running parallel to the coast, as with A and E in Figure 9, to groynes running normal to it, as with C and between G and F. With the former a complete bay exists for a given spacing (b) between structures whereas only a fraction of it can result from the latter or groyne solution. Not only is a longer beachline possible with the breakwaters A and E, but material is prevented from being dispersed seawards during storm events. Any longshore drift during these sequences is forced into the deeply indented zone with perhaps deposition offshore. With the groyne alternative a rip current will form along the face of C in the figure and much material is thrown out to sea, possibly to return to the beach much further down-coast(5).

Influence of wave reflection

The crenulate shaped bays resulting from persistent waves from one direction will produce a uniformly curved beach of log-spiral form. Any deviation from this should indicate some secondary influence on the waves or the sediment motion. One of these could be a rocky shoal offshore which refracts the waves to produce a slight protuberance of the beach with possibly adjacent denudation. These aberrations should be smoothed out when determining indentation (a) or the log-spiral (α) value.

Another source of shoreline deviation would be reflection from headlands, two types of which are depicted in Figure 10. At the down-coast end orthogonals are drawn which show the extent of the reflected waves. The short-crested system so produced by these and incident waves is very conducive to sediment transport parallel to the wall, or headland in this case.(6)(7) Outside the bounding orthogonal of the reflected wave accretion will occur so that the shoreline shown dotted in the figure results. Using the intersection of this waterline with the headland as the control point is erroneous (as illustrated) as it should be derived from the smooth curve of this tangential or log-spiral curve.

The upcoast headland is also shaped to give the possibility of reflection. The incident orthogonals from the headland extremity will have varying angles of reflection but the bounding orthogonal is as shown. Here again material will be scoured and produce a shoreline as dotted in Figure 10. The deviation in the correct log-spiral curvature may cause a wrong assessment of indentation (a') instead of (a).

Figure 11 does not provide an example of reflected wave influence but it does indicate the need to extrapolate a bayed shoreline across a river mouth to the downcoast headland control point. It can be seen from the (β) measured and the (a/b) derived that the bay is in equilibrium except for a short length at the southern end where excess material is apparent. This is unlikely to be stable, as indicated by the presence of the seawall very close to this margin.

Changing control points

Figure 12 gives three examples of alterations in control points, those in A and C are man-induced whilst B could be a natural phenomenon.

11. Extrapolation of bay across river mouth to determine control line.

12. Examples of natural or man-made features that influence bay shape.

It is unfortunately a common practice to extend an upcoast headland in order to provide calmer water for the construction of a port in its lee. As seen in A of Figure 12, a control point is shifted from point A to point B, about which the persistent waves must now diffract. This results in accretion in the port location, probably before construction is commenced. In the case of the bay being close to equilibrium this siltation is at the expense of the adjacent beach.

The sand spit illustrated in B of Figure 12 will also produce a new control point B which will cause accretion in the lee of the breakwater, perhaps by denuding the adjoining beach by littoral drift being held within the spit.

In diagram C of the figure the reshaping of the coastline by the intrusion of a large structure, such as an airport runway, is illustrated. Between A and B reflection of waves can re-orient the beach as shown dotted. Downcoast of the new feature accretion will occur adjacent to it with concomitant erosion a little distance away, particularly if there is no sediment input into the bay.

HEADLAND CONTROL

Bays which are not in equilibrium can be stabilized by the installation of headlands within them. This results in smaller bays being sculptured by the persistent swell or predominant wave system. This is depicted in Figure 13 where the existing unstable shoreline is shown, together with the static equilibrium shape which would ensue in the event of all sediment supply being stopped (an eventuality quite possible in these days of dredging substantial channels to ports). To prevent the obvious loss of valuable land, which could be highly developed for commercial or recreational purposes, the suggested headlands could be located to give no net loss or complete gain of land area.

In determining (β) for each segment or bay it should be recognised that the persistent wave orthogonals at each headland location must be normal to the tangent at that section of the static equilibrium bay. The angle between the orthogonal and the normal to the control line joining adjacent breakwaters is (β) which gives indentation (a) from the value of (a/b) derived from Figure 2. Values are indicated in the figure. The bay can be sketched in by starting with the tangential section parallel to the static equilibrium section of coast and making the indentation line tangential to the curved section of the new bay. In the case of bay erosion the newly formed bays will be oriented in the same direction as the main bay, with the tangential sections to the right, for example, in Figure 13.

Another situation may arise where a bay is still building out to its static equilibrium limit. This possibility is displayed in Figure 14 where a deep indentation between two mountain structures has been virtually cut-off by a sand spit supplied from a source which is indicated is at the recognised downcoast zone of the bay being formed. The sediment still filling the bay will travel in the direction shown, towards the curved section of the coast. With the control points and (b) known, the angle (β) can define (a) and the log-spiral (α) so that the equilibrium bay can

be drawn. Whilst material is available for filling the coast will remain dynamically stable, with siltation continuing in the curved section of the bay. If however the supply is insufficient for the wave energy arriving, erosion will take place at the tangential downcoast end which is normally the most stable section.

An example of this is given in Figure 15 which is a bay in Honshu facing the Sea of Japan. The Hino river in its natural state has over geologic time supplied an abundance of material to form the sandy spit reaching the Shimane Peninsular. However, the static equilibrium bay is far seaward of the existing shoreline, indicating the need for much more sediment before stability is reached. Since the river has been harnessed by dams upstream the discharge of sand has diminished substantially resulting in erosion near the Kaika coast.

A method of stabilizing this coast by headlands is suggested in Figure 14, in which the indentations of each bay is determined from the angle between the wave othogonals (normal to the static equilibrium line) and the normal to the control line of each bay (as detailed in Figure 13). It can be seen in this rather unique case that the stabilizing bays are oriented in the opposite direction to that of the major bay, due to this silting situation.

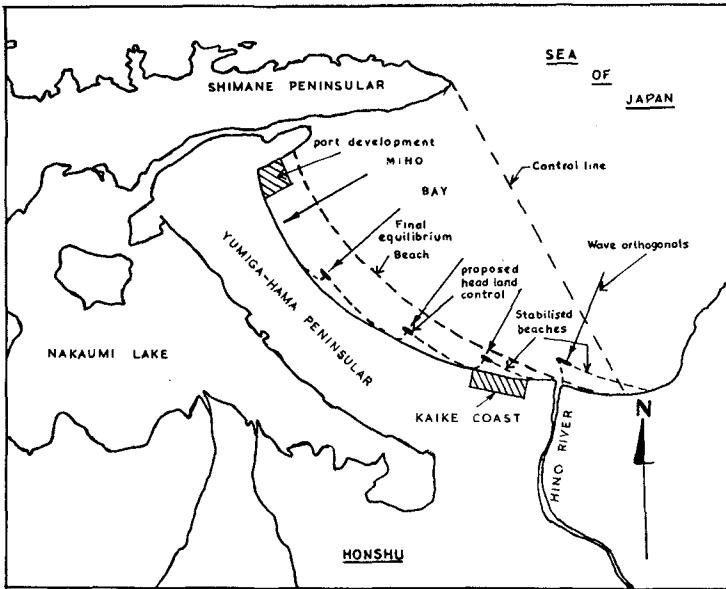

The solution proposed by Toyoshima (8), as in many other locations in Japan (9), is the installation of offshore breakwaters parallel to the coast but spaced very close together. The openings were, in fact, one quarter the length of the individual structures placed echelon fashion. This was after attempts at stabilisation by groynes and seawalls had failed. Figure 16 shows three of these breakwaters behind which tombolos have formed. However, also apparent are defensive blocks found necessary, in line with the openings between breakwaters. This indicates too close a spacing of the structures from the beachline desired. Although it was concluded that tombolo growth occurred during storm conditions, it would be during these events that a strong rip current would be generated through the openings as overtopping water and storm wave water entering the circular bays must return to the sea through these limited spaces. Toyoshima (9) suggests that counter-measures will always be necessary in this exposed zone.

13. Headland stabilization of an eroding bay.

14. Situation of a bay still filling to non-littoral drift state.

15. Example of bay accreting to equilibrium and method of stabilizing by headlands.

The sand finding its way behind the breakwaters will be that scoured by the reflected and incident waves seaward of these structures. The result of this can best be expressed in the conclusion of Toyoshima(8): "The most important problem is subsidence of the breakwaters".

The writer's concept of coast stabilization by headlands does not countenance offshore breakwaters placed so close together. It envisages a spacing in the order of ten times the length of each structure, in order that a zeta shape of coast can be sculptured. The alternative suggested by Toyoshima virtually constitutes a continuous wall being constructed offshore at great cost. The excessive reflection by oblique waves accelerates the transport of sediment that results in scouring of the bed and a resulting maintenance problem. The spacing of headlands from the existing shoreline can be such as to exchange some beach zone for accretion elsewhere or beach aggradation at all points. A renourishment scheme accompanied by headland installation will provide stable bays very quickly with no erosive effects downcoast of the system.

The suggested plan in Figure 8, to stabilize a highly developed coastal plain, contemplates (at first look) three headlands which would have cost much less than the seawalls finally constructed, even when nourishment of the bays is considered. It is worthy of note that such headlands only need to break the waves under the worst storm conditions. Even natural reefs have achieved the same results of maintaining sandy prominences leeward of such submerged features.

NATURE'S DEFENSE MECHANISM

The essence of the problem is to maintain a supply of sand for offshore bar construction by storm waves without the waterline continually receding. This implies that the bar material is brought back to the beach by subsequent swell exactly from whence it came. This is the case for bays in static equilibrium since persistence waves around their periphery arrive normally. Even with littoral drift occurring in a dynamic equilibrium situation, fluctuations in sediment supply will not be accompanied by such large beach recessions as for a long straight coast controlled by headlands at much greater spacing. The limiting indentation for no sand supply at all is predictable.

Man can do no better than observe natural processes and emulate them in his marine structures or operations, or by helping Nature to be more efficient. In this way he is copying natural scientists who try to enhance the productivity of Nature.

BEACHES: PROFILES, PROCESSES AND PERMEABILITY

Michael R. Gourlay

Department of Civil Engineering
University of Queensland, St Lucia, Australia.Abstract

Equilibrium beach profiles have been investigated in the laboratory for two beach materials, 0.22 mm marine sand and 1.55 mm crushed coal. Analysis of the results confirms that the dimensionless fall velocity H_0/Tw is an important parameter influencing both surf zone hydraulics and the form of the resulting equilibrium profile. Beach permeability also significantly influences the hydraulics within the beach face and it has been found that both H_0/Tw and the parameter w_f/w , the ratio of the fluidising velocity to the fall velocity, influence the form of the equilibrium profiles of permeable beaches.

1. INTRODUCTION

The problems involved in the interaction between waves and beaches are complex and while much research has been undertaken in this field, it is still not yet possible to predict on empirical grounds, let alone theoretical grounds, the shape of a beach after it has been subjected to given wave conditions. This situation applies both in the apparently simple two dimensional case where waves approach the beach with crests parallel to the shoreline and in the three dimensional case where matters may be further complicated by offshore wave refraction and geographical features such as headlands, rock bars, etc, as well as man made structures.

Investigation of this problem in the field involves an extremely complicated interacting system with many variables virtually none of which can be controlled. Moreover, the simultaneous measurement of all relevant variables over a sufficiently large area is in most cases completely impossible. On the other hand, investigation in the laboratory encounters problems concerning the reproduction of a sufficient number of the relevant variables in correct relationship to one another. Thus the laboratory investigator is confronted with the problems of

scale effects and of too simplistic a representation of the phenomena. Nevertheless, it is possible in the laboratory to investigate certain aspects of beach processes in a systematic manner so that the general behaviour may be established. For example, the work of Kemp and Plinston (1968) has shown the significance of the surf zone conditions, as expressed in terms of the ratio of uprush time to wave period, in determining the interaction between breaker type and beach profile. Again, the general influence of the height of a sand dune upon the amount of shoreline recession during a storm has been established by van der Meulen and Gourlay (1968), confirming what had been suspected but could not be proven from available field data.

While laboratory investigations provide a means for gaining further understanding of beach processes under controlled conditions, the solution of many practical coastal engineering problems cannot wait until complete understanding of these processes is obtained. Consequently a second very important purpose of laboratory beach profile investigations is to compare the behaviour of various model beach materials at laboratory scale with prototype conditions so that model scale relationships may be established for the design of movable bed coastal models used in the solution of real engineering problems involving coastal sediment transport. It has been a common procedure to use lightweight sediments in such movable bed models on the assumption that, because these materials are more easily moved by the flow or waves in the model, they will reduce the influence of scale effects. It has also been long recognised that such materials often give grossly distorted beach profile shapes particularly on the beach face and in the surf zone. The investigation described in this paper began as a study of the use of crushed coal as a model beach material to represent natural beaches of quartz sand but subsequently developed into a more general study of the processes which determine the shape of beach profiles formed in beach materials with different permeabilities.

2. FACTORS INFLUENCING BEACH PROFILE SHAPE

A large number of factors influence the shape of beach profiles in nature. These may be divided into active factors and passive factors. The former produce the actions which mould the latter into a given profile shape. At the same time changes in the profile shape modify the mechanisms by which the active forces mould the profile. The following are the more common factors involved:

Active factors

- waves, tides, winds, rainfall, temperature;
- duration of influence of active factors.

Passive factors

- beach material, initial profile shape;
- geology and/or other constraints.

In practice most model investigations neglect the effects of tides, winds and rainfall and reproduce only the action of waves upon various beach materials. The constraints of geology and/or artificial constructions are usually not included in tests but are replaced by the constraints imposed by the model test basin. The latter at one and the same time may both exclude prototype three dimensional effects produced by nearshore oscillations and circulation systems and introduce spurious three dimensional effects characteristic of the model basin. Moreover, wave generators producing regular waves in shallow water also generate parasitic secondary waves which can affect the form of the beach profile (Hulsbergen 1974).

Even with the very limited number of factors normally considered in model tests, still further simplifications are generally made. Most laboratory investigations of beach processes have been made with regular waves of constant height and period. Only a few investigations have involved irregular and/or wind generated waves (e.g. van der Meulen and Gourlay 1968, Kraai 1969, van de Graaff 1977 and Vellinga 1978). While numerous tests have been made with both quartz sand and various light-weight materials of different median sizes, systematic tests of the effects of variations in the grading and shape of beach sediments are very few (e.g. Collins and Chesnutt 1975). Opinion is divided as to whether the slope (and/or shape) of the initial profile affects the shape of the final equilibrium profile although it is recognised that it certainly affects the time taken to reach equilibrium. The fact that water temperature cannot be controlled in outdoor model basins and often has not been controlled in indoor ones means that many investigators have had difficulty in obtaining equilibrium profiles with fine sands whose motion relative to the fluid, as expressed by their fall velocity, is significantly affected by temperature (Chesnutt 1975).

3. BEACH PROCESSES AND SURF ZONE HYDRAULICS

3.1 The Equilibrium Beach Profile

The equilibrium beach profile is that profile shape which when subjected to a given wave condition dissipates and/or reflects all the wave energy reaching it in such a manner that no net transport of the beach/bottom sediment occurs anywhere along the profile. The sediment transport mechanisms involved in this process are complex and vary in nature along the profile. For instance offshore of the breakpoint sediment transport is initiated and maintained by the orbital motion of the waves which exerts a shear stress on the bottom material through the oscillatory boundary layer created by the waves. The process is complicated by the development of ripples on the bottom and the occurrence of complex interactions between the oscillatory flow and vortices formed in the lee of the ripples. At the breakpoint relatively large amounts of sediment may be thrown into suspension, particularly by plunging breakers, and the flow becomes highly aerated. High aeration and suspension of sediment particles may continue within the surf zone as the bore from the broken wave travels landward. At the shoreline

the uprush deposits its remaining sediment on the beach face as it percolates into the porous beach material before the backwash and/or outflow from the beach face mobilises the sediment again. The sediment transport processes acting to form the equilibrium beach profile are thus complex and cannot be related to a single simple model.

It has long been recognised that there are two basic forms of equilibrium beach profile (figure 1).

- (i) The step profile or swell profile formed when the waves are of low steepness (H_0/L_0 small) and/or the beach material is coarse.
- (ii) The bar profile or storm profile formed when the waves are of high steepness (H_0/L_0 large) and/or the beach material is fine.

The two profile types generally correspond with the concepts of reflecting and dissipative beaches as described by Short (1978). Transition profiles between these two limiting cases may exhibit rhythmic alongshore variations such as crescentic bars and beach cusps. In such situations the beach profile varies significantly in shape depending upon its location with respect to these rhythmic features.

Futhermore a bar profile may have one or more bars depending upon the wave steepness and/or the beach slope.

Figure 1

3.2 Dimensionless Fall Velocity H_0/Tw

In the search for model scale laws for beach process modelling, increasing attention is being paid to the use of the dimensionless fall velocity as a scaling parameter. For instance, Saville and Watts (1969) and Saville (1980) implicitly used this parameter in an investigation in which fine crushed coal was used to model larger scale beaches formed in fine to medium sand. Gourlay (1968) proposed the use of the parameter H_0/Tw for describing beach processes, pointing out that H_0/w represented "the time taken for a sand particle to fall a distance equal to the wave height. If this time is large compared with the wave period, any material stirred up by the breaking waves is likely to remain in suspension and to move as suspended load. If it is of the same order of magnitude or less than the wave period, bed load motion will predominate". Thus it was suggested that not only was the parameter H_0/Tw important in beach processes but that a value of the order of unity could be critical in determining the different sediment transport processes which lead to different profile forms.

Some time earlier Iwagaki and Noda (1962) had shown that the occurrence of the two main profile types, step profiles and bar profiles, depended upon the two parameters H_0/L_0 and H_0/d . Bar profiles occurred at relatively large values of both parameters and step profiles at small values. Subsequently Sitarz (1963) showed that the profile type depended upon the following parameter:

$$\frac{H}{T\sqrt{g(s-1)}d} < 0.6 \quad \text{step profile}$$

$$> 0.6 \quad \text{bar profile}$$

with bar profiles always occurring if $H_0/L_0 > 0.03$. This parameter is very similar to H/Tw since $w \propto \sqrt{g(s-1)d}/C_D$ where C_D , the drag coefficient of the sediment particles, is a function of the Reynolds number (wd/ν). Subsequently a number of researchers using data from various sources found that step and bar profiles could be separated on the basis of $H_0/Tw(d_{50})$.*

e.g. Dean (1973)	$H_0/Tw \lesssim 0.85$
C.E.R.C. (1973) based upon Kohler and Galvin	$\lesssim 0.6$ to 2.0 depending upon H_0/d
Gourlay (unpublished)	$\lesssim 1.55$ for fine sand (0.2 to 0.3 mm)
	$\lesssim 0.4$ for coarse sand/ fine gravel (2 mm)

In the last case the critical value of H_0/Tw decreased with increasing sediment size, indicative of the possible influence of beach permeability on profile shape.

* Unless otherwise specified the value of w used to calculate H_0/Tw is $w(d_{50})$, the fall velocity of the median sediment size.

More recently van Hijum (1974) found that for coarse material with $d_{90} \geq 6$ mm bar type profiles were formed when

$$\frac{H_o}{L_o} > 2.5 \frac{d_{90}}{H_o}$$

Assuming $C_D \approx 1.3$ for coarse natural sediments and $s = 2.65$ this reduces to

$$\frac{H_o}{T w(d_{90})} \lesssim 0.48$$

where $w(d_{90})$ is the fall velocity corresponding to the d_{90} size. In fact the beach material was very uniform and this relationship is probably equivalent to

$$\frac{H_o}{T w(d_{50})} \lesssim 0.54$$

which is the same order as that established for coarse material from the present author's earlier unpublished analysis.

A change in profile type also implies a change in beach slope. Kemp and Plinston (1968) found that the beach slope was a function of $H_b/Td^{3/2}$ which parameter is essentially the same as that used by Sitarz. Kemp and Plinston used the breaker height which is a more relevant wave height than H_o when the mechanics of the actual surf zone processes are being considered. For small values of $H_b/Td^{3/2}$ the beach slope decreased as $H_b/Td^{3/2}$ increased up to a critical value, above which the beach slope was constant. They also found that the critical value of $H_b/Td^{3/2}$ at which the beach slope changed significantly corresponded to the transition from surging/collapsing breakers to plunging breakers which occurred when the relative uprush time T_u/T , or "phase difference" of the uprush, was 0.7. Subsequently Nayak (1970) found that both the beach slope and the reflection coefficient decreased with increasing values of H_o/Tw . Moreover, reflection was smaller for coarser beach materials with the same value of H_o/Tw , apparently because of the increased permeability of the coarser materials. More recently Dalrymple and Thompson (1976) using data from a number of sources found that the beach slope at still water level decreased with H_o/Tw for step type beach profiles but tended to become constant for values of $H_o/Tw > 1$ when bar profiles were present.

Considering the problem of model scale relationships for dune erosion during a storm surge, van de Graaff (1977) and Vellinga (1978) have found that beach processes may be modelled using very fine sand, if H_o/Tw has the same value in both model and prototype. If this criterion cannot be met, then it is necessary to distort the model profile scales.

3.3 Initial Beach Slope

There has been some difference of opinion as to whether the initial slope of the beach profile affects the final equilibrium profile shape. For instance Dalrymple and Thompson (1976) found that initial slopes from 1:5 to 1:10 had no significant effect upon the equilibrium shape of beaches formed from 0.4 mm sand. Similarly van Hijum (1974) found the same result for the same initial slope range when the beach material was fine gravel. Earlier Nicholson (1968) claimed a similar result for 2 mm quartz sand with initial slopes from 1:5 to 1:20. On the other hand, Chesnutt (1975) found that equilibrium beach profiles formed in 0.2 mm sand may be affected by initial profile slopes when the latter was changed from 1:10 to 1:20. Sunamura and Horikawa (1974) found that initial profiles of 1:10, 1:20 and 1:30 influenced the final profile shape formed in 0.2 and 0.7 mm sands and proposed that profiles be classified on the basis of whether they resulted in erosion or accretion of the original beach face. Recently Hattori and Kawamata (1980) combined this concept of eroding and accreting profiles with a parameter which includes both the initial beach slope and the fall velocity, i.e.

$$\frac{(\frac{H_o}{L_o}) \tan \alpha}{w / g T} = 2\pi \frac{H_o}{T w} \tan \alpha$$

< - onshore transport
 = 0.5 - neutral (equilibrium)
 > - offshore transport

It is difficult to generalise on the effect of initial slope upon equilibrium profiles at the present time, but it seems possible that initial slope does not significantly affect the equilibrium profile when the initial profile is steep and no significant wave energy is dissipated offshore of the breakpoint. Under such conditions the breakers will normally be surging or plunging during the initial stages of profile development. On flat initial slopes where significant energy is dissipated offshore of the breakpoint and/or the breaking waves are spilling, it is possible that no equilibrium can be developed.

4. EXPERIMENTAL INVESTIGATION

The purpose of the present investigation was to compare the equilibrium beach profiles and associated processes produced by different kinds of breaking waves in two beach materials with very different permeabilities. The experimental work was divided into two parts:

- (i) the determination of all relevant properties of the beach materials;
- (ii) the formation of equilibrium beach profiles in a wave basin for each beach material for various wave heights at a constant wave period.

The two beach materials used in this investigation were:

- (i) a fine marine sand, $d_{50} = 0.22$ mm, typical of the beach sands on the exposed beaches of southern Queensland;
- (ii) a coarse crushed coal, $d_{50} = 1.55$ mm, with a similar relative particle size distribution to the sand.

The sediment properties determined were of two types:

- (i) those describing the sediment itself, e.g. specific gravity s , size distribution, porosity ϵ and angle of repose;
- (ii) those describing hydraulic characteristics associated with the sediment, e.g. fall velocity w , fluidising velocity w_f and permeability k .

The values of some of these properties are shown on figures 2 and 3 while the complete data is given in a separate report (Gourlay 1980).

The beach profile tests were made in a two dimensional wave basin 14.7 m long, 3.05 m wide, and 0.6 m deep equipped with a suspended paddle type wave generator. In each case the beach material was formed to an initial slope of 1 in 13. The water depth offshore of the beach h_i was 0.368 m. The wave period was 1.9 s for all tests and 8 or 10 tests were made for each material with deepwater wave heights varying from 23 to 183 mm.

Tests were run for sufficient time to reach equilibrium, the test durations varying from 4 to 30 hours. Equilibrium was taken as being reached when the wave uprush limit and breakpoint location did not alter position significantly with time. Once the profile had reached equilibrium the following quantities were measured:

- (i) incident wave heights and reflection coefficient along 10 equally spaced lines offshore of the beach;
- (ii) wave height transformation along centre profile, including crest and trough elevations, from offshore through the surf zone to the beach;
- (iii) location, height and type of breakers; location of plunge point, if any; location of uprush limit and time of travel of broken wave from breakpoint to uprush limit;
- (iv) wave set-down and set-up along centre profile from offshore to landward of uprush limit;

and after the wave generator was turned off:

- (v) beach profiles along 10 equally spaced lines over the full extent of the wave formed profile.

5. EXPERIMENTAL RESULTS

5.1 Beach Profiles and Mean Water Level

The experimental profiles measured along the centre of the wave basin together with wave heights and mean water levels are given for selected tests on figure 2 (sand) and figure 3 (coal). Steep reflective beaches with step type profiles were developed by low waves on both beach materials, while flat dissipative beaches with offshore bars were developed with the highest waves. In both cases the smallest waves produced erosion of the profile offshore of the breakpoint and accretion of the beach in the form of a large berm. Waves of intermediate height produced erosion of the offshore profile with accretion both on the beach and further offshore. Only the highest waves produced erosion of both the beach and inner surf zone and consequent deposition further offshore. The accreting, transition and eroding beaches generally corresponded with the occurrence of surging, plunging and spilling breakers respectively. For both beach materials the offshore profile seaward of the breakpoint was steepest just before the breakers changed from plunging to spilling.

Significant differences in detail were also evident between the profiles formed in the two different beach materials. All the beach profiles formed in sand had an almost constant beach face slope of 12° between the still water line and the berm crest (uprush limit). The sand beach behaved as an almost impermeable surface with both the uprush and the backwash flowing parallel to the beach face. Beach profiles in sand showed a breakpoint bar with plunging breakers. In contrast the beach profiles formed in the coal were much smoother in shape and a bar was not formed with plunging breakers. The most obvious feature of the coal beach profiles formed by low wave heights was the very steep berm which was built up at the uprush limit. With surging breakers this berm was very high and had a very steep face above the mean water level with a slope approaching 55° , the critical angle for stability of this beach material. On the other hand, the slope of the beach face at the still water line was very much less than this value, i.e. of the order of 4° for the higher waves. It is quite evident that the permeability of the coal beach was very important and the mechanism whereby this large berm was built up involved the uprush percolating into the steep berm face, draining vertically downwards through the deposited material, and then emerging as the backwash as the base of the beach below the mean water level.

Offshore of the breakpoint, the mean water level was almost horizontal with comparatively little wave set-down, particularly for the coal beach. Mean water level started to rise at the plunge point and the maximum elevation of mean water level (maximum wave set-up) occurred within the beach landward of the uprush limit. For the spilling breakers occurring with the largest waves, mean water level rose at a very flat slope between the outer and inner breakpoints. The mean water level gradient inshore of the inner breakpoint was significantly steeper than offshore but flatter than that for the lower wave heights.

Marine sand

$d_{50} = 0.22 \text{ mm}$
 $e = 0.415$

$\sigma_g = 1.24$
 $w(d_{50}) = 27 \text{ mm/s}$

$s = 2.67$
 $w_f = 0.41 \text{ mm/s}$

Figure 2

$d_{50} \approx 1.55 \text{ mm}$
 $\epsilon \approx 0.51$

Crushed coal
 $\sigma_g \approx 1.27$
 $w(d_{50}) \approx 46 \text{ mm/s}$

$s \approx 1.34$
 $w_f \approx 2.7 \text{ mm/s}$

Figure 3

5.2 Beach and Surf Zone Parameters

The basic experimental data measured just before the end of each test and from the profiles surveyed just afterwards is presented elsewhere (Gourlay 1980). The parameters are breaking wave height H_b , wave reflection r , maximum wave set-up $\bar{\eta}_m$, berm crest/dune foot height z_c , surf zone width x_d , relative uprush time or "phase difference" T_u/T and beach slope at still water line $\tan \alpha_{swl}$. These parameters are plotted as functions of the basic independent variable, deepwater wave height H_0 on figure 4.

In virtually all cases the magnitudes of the various parameters are greater for the impermeable sand beach than for the very permeable coal beach. The quantity with the least difference is the breaker height but in most other cases the magnitudes of the coal beach parameters are about half those of the sand beach. In most cases the breaker type is seen to influence the form of the relationship. For instance the maximum berm height occurs when the surging breakers are just changing to collapsing breakers. Both plunging and spilling breakers dissipate more energy offshore of the beach with a consequent reduction in the wave uprush which determines the berm/dune foot height. The maximum wave set-up or wave induced groundwater level behind the beach also varies with breaker type but its maximum value appears to be associated with profile shape rather than breaker type. Both the surf zone width and maximum uprush time are different for each beach material with surging and plunging breakers but tend to similar values with spilling breakers.

As discussed earlier, the dimensionless fall velocity H_0/Tw is an important parameter influencing beach processes and beach profile shape. Its significance is shown on figure 5 where H_b/H_0 , $\bar{\eta}_m/H_0$, z_c/H_0 , x_d/L_0 and T_u/T are all plotted as functions of H_0/Tw or in actuality H_0/w since T is constant for these experiments. The following results are obtained:

- (i) The maximum wave set-up occurs at about $H_0/Tw = 1$ for both beach materials.
- (ii) $T_u/T = 0.5$ when $H_0/Tw = 1$ and profiles for $H_0/Tw < 1$ are definitely step type profiles. Bar type profiles are not formed until $H_0/Tw \approx 1.4$ to 1.5 .
- (iii) The relative berm height z_c/H_0 has a maximum value for the coal beach when $H_0/Tw < 0.6$.
- (iv) Both the relative surf zone width x_d/L_0 and the relative uprush time T_u/T are unique functions of H_0/L_0 for both materials except for the highest spilling breakers. The shapes of these functions indicate that x_d/L_0 is a function of T_u/T as shown by Sunamura and Horikawa (1974).

Since the wave period was not varied in these experiments, any parameter involving T or L_0 ($= gT^2/2\pi$) has not yet been justified. A detailed analysis of data from other sources has not yet been made, but

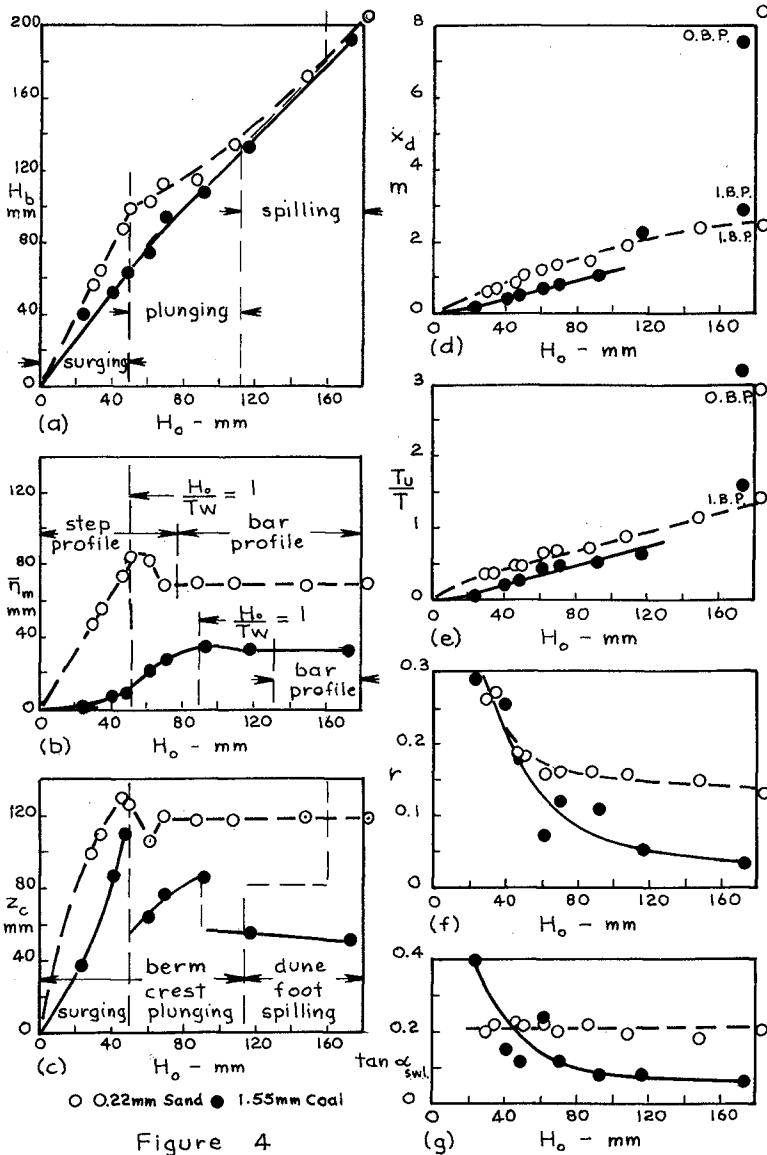

Figure 4

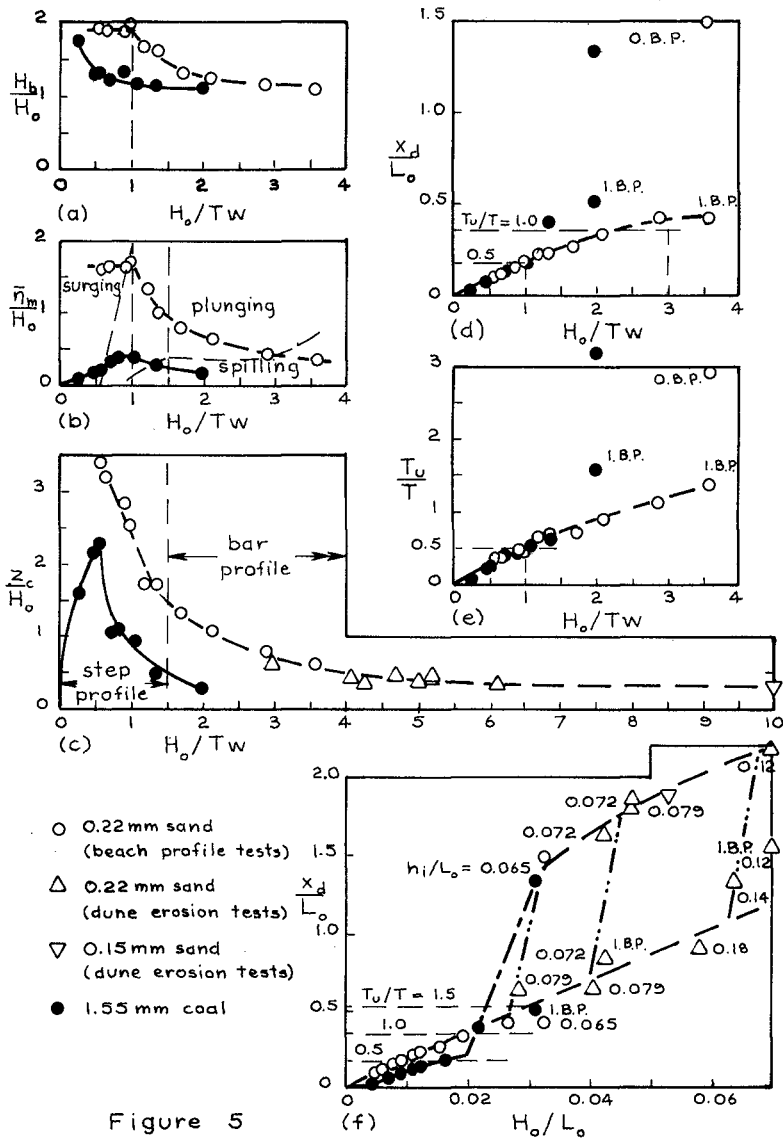

Figure 5

some data from earlier experiments on the erosion of sand dunes (Gourlay 1968, van der Meulen and Gourlay 1968) has been examined. This data is for 0.22 mm sand very similar to that used in the present tests, with one test with 0.15 mm sand. Wave periods varied between 1.04 and 1.63 s while wave heights were such that wave steepness H_0/L_0 was generally greater than the largest steepness used in the present tests. The only quantities conveniently available were dune foot height (uprush limit) z_c and surf zone width x_d . As indicated on figure 5c the relationship between z_c/H_0 for the dune erosion data and H_0/Tw is quite consistent with that for the present tests.

When x_d/L_0 for the dune erosion data was plotted as a function of H_0/Tw (not shown on figure 5d), no clear picture was presented since all the additional data was for $H_0/Tw \geq 3$ which was the region where this parameter tended to separate rather than unify the data from the present tests. On the other hand, it was found if x_d/L_0 were plotted against the deepwater wave steepness H_0/L_0 then a reasonably consistent pattern emerged (figure 5f). For $H_0/L_0 < 0.03$, x_d/L_0 is a simple function of H_0/Tw . For $H_0/L_0 > 0.03$ there are two possible surf zone widths. The narrower surf zone (small x_d/L_0) is an extension of the low wave steepness sand curve. It also includes surf zone widths inshore of the inner breakpoint on wide surf zones. Wide surf zones (large x_d/L_0) occur when significant deposition occurs on the level bottom of the wave basin seaward of the initial sand slope in the present tests or on a horizontal section of the offshore profile seaward of an approximately 1 in 10 slope in the dune erosion tests. Thus there appears to be an effect of initial profile shape present in the form of different values of h_i/L_0 where h_i is the depth offshore of the initial plane beach or the depth of the horizontal section of the initial profile in the dune erosion tests. As indicated on figure 5f the critical steepness of 0.03 for the initiation of a wide surf zone in these tests corresponds to $h_i/L_0 = 0.065$. About half the dune erosion tests have values of $h_i/L_0 = 0.072$ or 0.079 and those with $H_0/L_0 > 0.04$ have relatively wide surf zones. On the other hand, tests with $h_i/L_0 = 0.14$ and 0.18 lie on the narrow surf zone line with the former possibly on the point of transition to a wide surf zone at $H_0/L_0 \approx 0.06$. Certainly a test with $h_i/L_0 = 0.12$ and $H_0/L_0 > 0.06$ has a wide surf zone.

It appears from the preceding that the initial profile shape as typified by the ratio h_i/L_0 in these tests does affect the shape and particularly the surf zone width of the equilibrium profile when waves reach a certain critical steepness, the value of which increases with the magnitude of h_i/L_0 . This effect is possibly a consequence of significant energy dissipation occurring offshore of the original breakpoint during early stages of tests with relatively steep large waves. As suggested earlier, such an effect could be expected to occur on flat plane beaches, but not on steep ones. Hence the above results tend to confirm the idea that the initial profile shape affects the shape of the equilibrium profile when the former is flat but not when it is steep.

5.3 Beach Permeability

While it is evident that the parameter H_0/T_w is of considerable significance in representing the beach profile data particularly for x_d/L_0 and T_u/T when the latter parameter is less than 1.0, it is also evident from figure 5 that there are significant differences between the impermeable sand beach and the permeable coal beach with regard to other beach and surf zone parameters. These effects are almost certainly related to the differences in permeability of the two beach materials. In fact the magnitudes of these differences are in most cases directly related to the ratio between the fluidising velocity w_f and the fall velocity w as can be seen in figure 6 where w_f/w has been introduced as a multiplier to the various dependent variable parameters z_c/H_0 , \bar{r}_m/H_0 , etc. With the exception of figure 6a for H_b/H_0 , where the independent variable parameter H_0/T_w has been multiplied by w_f/w , all the other figures show that when the dependent variable is multiplied by w_f/w , the data points for both sand and coal beaches lie on the same curve when $H_0/T_w > 1$. Moreover there is a tendency for the modified parameters to become constant when $H_0/T_w > 3$.

The data plotted on figure 6 shows that there is no qualitative difference in behaviour between the two beach materials when $H_0/T_w > 1$, only a quantitative one. On the other hand, when $H_0/T_w < 1$ there are significant differences in the nature of the hydraulic processes within the surf zone, which is in fact confined to the uprush-backwash cycle, between the impermeable sand beach and the very permeable coal beach. The nature of these differences has been already indicated in the discussion on beach profiles. For the sand beach the hydraulic parameters involving H_b and \bar{r}_m are independent of H_0/T_w when the latter is less than 1.0 while the beach slope is essentially constant for all values of H_0/T_w . Both the modified wave reflection coefficient r_w/w_f and the modified surf zone similarity parameter $[(\tan \alpha_{sw})/\sqrt{H_0/L_0}]w_f/w$ appear to follow similar trends with H_0/T_w . Unfortunately the scatter of the data is too much to compare the relationship between these two parameters with that for a fixed plane beach.

The exact significance of the above results and particularly the ratio w_f/w has not yet been worked out in theoretical terms, but it seems quite certain that w_f is a very important sediment property which determines the shape of beach profiles formed in relatively large light weight sediments. w_f has been described as the fluidising velocity, that is it is the overall upward velocity of flow through a bed of sediment which just causes that sediment to be fluidised or to become unstable. It is related to the permeability k by the relationship

$$w_f = k i_c$$

where $i_c = (s-1)(1-\epsilon)$ is the critical hydraulic gradient at fluidization. On the other hand, w_f may be interpreted as the fall velocity of the sediment at maximum concentration of sediment particles. Under such conditions particle interference is a maximum and the fall velocity is very much less than that for widely separated particles in still water.

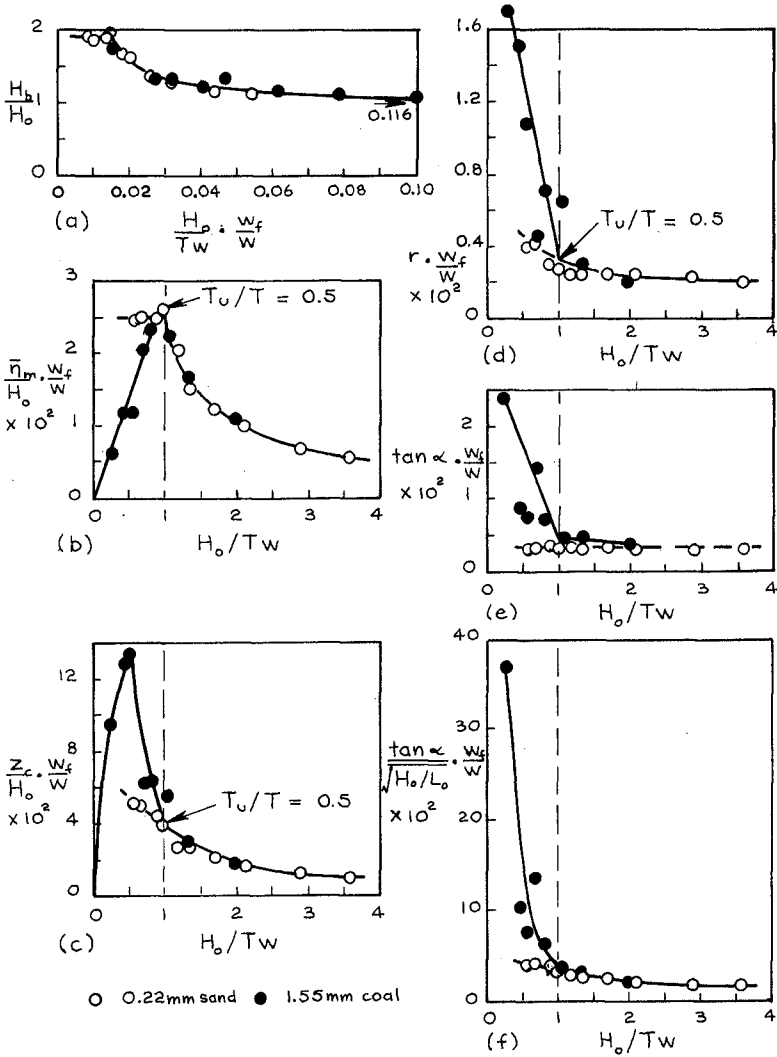

Figure 6

For spherical particles w_f/w is a constant for both very small and large particles, the magnitude of this ratio being a function of the dimensionless particle size $g^{1/3}(s-1)^{1/3}d/v^{2/3}$ and the porosity ϵ of the deposited sediment. This ratio w_f/w is smaller for small particles than large ones since the permeability and hence w_f of sediments decreases both as the porosity decreases and as the specific surface (surface exposed to fluid per unit volume of solid) increases.

6. SUMMARY AND CONCLUSIONS

(i) The dimensionless fall velocity H_0/Tw , which represents the behaviour of the sediment particles stirred up by the breaking waves in the surf zone, is an important parameter influencing surf zone hydraulics and the form of the equilibrium beach profile inshore of the breakpoint. In particular the wave set-up has a maximum value when $H_0/Tw = 1$ and both the relative surf zone width x_d/L_0 and relative uprush time T_u/T are unique functions of H_0/Tw when $T_u/T < 1$.

(ii) While H_0/Tw is a necessary and probably sufficient parameter for defining similarity conditions for model beaches formed in relatively impermeable sand, it is not sufficient for defining similarity conditions for model beaches formed in relatively permeable materials, particularly lightweight materials such as crushed coal. For permeable beaches the ratio w_f/w , which is the ratio of the maximum possible flow velocity within the deposited sediment to the maximum particle velocity in still water, is also important.

(iii) Similarity of the beach profile with respect to the beach face and its associated hydraulics is determined by both H_0/Tw and w_f/w as follows:

$H_0/Tw < 1$ - Hydraulic conditions within the beach face are significantly different for impermeable and permeable beach materials and no similarity is possible.

$1 < H_0/Tw < 3$ - Both H_0/Tw and w_f/w determine the similarity of the beach face.

$H_0/Tw > 3$ - Beach face parameters become independent of H_0/Tw and w_f/w is sufficient for similarity.

(iv) The shape of the initial profile does not appear to affect the shape of the equilibrium profile when the former is steep and offshore accretion is confined to the initial plane profile surface. If the initial slope is flat and/or offshore accretion occurs on the horizontal bottom of the wave basin or on an offshore horizontal section of the initial profile then either a wide or a narrow surf zone is possible. The occurrence of a wide surf zone depends upon the magnitude of both H_0/L_0 and h_1/L_0 .

(v) The results presented in this paper concerning the importance of w_f/w need to be extended with further experimental data for other beach materials including a permeable very coarse sand/fine gravel and a finer crushed coal. Further tests at various wave periods and initial profile slopes/shapes are also required to define the limits of the influence of H_0/T_w upon surf zone hydraulics and equilibrium beach profiles.

7. ACKNOWLEDGEMENTS

The author gratefully acknowledges the assistance of Jennifer Hacker, Peter Melloy, Warren Moreton and Shane Pearce in obtaining and analysing the experimental data for the beach profile tests.

The dune erosion test data was obtained by the author while working at the "de Voorst" laboratory of the Delft Hydraulics Laboratory, The Netherlands.

The beach profile tests were supported by a grant from the Australian Research Grants Committee.

SAND BED-FORM LENGTHS UNDER OSCILLATORY MOTION

ARTHUR BREBNER*

ABSTRACT

Tests were carried out in the oscillating water tunnel to determine the bed-form lengths of sand ranging from 0.1 mm to 0.55 mm subjected to oscillatory motion of various orbital diameters ranging from 0.15 m to 1.5 m and of various periods ranging from 3 to 15 s. The relationship for the bed-form length is given in the accompanying graph in dimensionless form.

INTRODUCTION

Oscillatory motion over an initially flat bed can, under certain conditions, cause the formation of relatively stable bed-forms of trochoidal shape having a definite "wave-length" from crest to crest of Λ m and wave-height from crest to trough of Δ m. The purpose of the tests described herein is to provide more information on the bed-form lengths for fine sands of median diameter D of 0.1 and 0.2 mm and of density ρ_s (water density ρ) to compare these results with the results of previous tests. A test bed 15 m long and 0.15 m thick of sand was screeded off flat in the oscillating tunnel and the piston throw set to give a fixed value of orbital diameter Λ m. A starter from which the bed-forms would grow was created by heaping up a small quantity of the sand approx. 1 cm high across the tunnel normal to the oscillating motion.

This starter was not essential since the bed-forms would grow from any slight discontinuity, especially from the ends of the test section, but made the measurement of growth easier to record.

The oscillatory motion was then imposed on the bed with a very long period T s such that the maximum velocity just above the boundary

$$U_{\max} \left(= \frac{\pi \Lambda}{T} \right) \text{ m/s}$$

was incapable of creating motion. As the period was slowly decreased striations of negligible height and of about 5 cm wave length appeared, giving a mottled appearance to the bed. Bed-forms do not form until the mobility number

* Professor of Civil Engineering,
Coastal Engineering Laboratory,
Queen's University at Kingston, Canada.

$$\frac{U_{\max}^2}{g(\rho_s/\rho - 1)D}$$

(which is essentially the ratio of drag force to inertia force or Shields' parameter) is greater than 3. Under such conditions the bed-form will grow on either side of the starter, spreading to both ends of the test section, gradually growing in length and height until a stable form is attained. The number of oscillatory cycles, n , to achieve a sensibly constant length is a direct function of the value of the mobility number. The growth of the bed-form length with cycles is as shown on Fig. 1.

FIGURE 1

When a bed-form has been created and is sensibly stable if the period is reduced, so increasing the mobility number, the bed-form can be wiped out such is the amount of turbulence and material in suspension above the bed.

The author's results have been plotted on Fig. 2, as have the test results of Mogridge and Kamphuis (1) and Lofquist (2) for differing densities and sizes of bed material using the dimensionless group

$$\left(\frac{\gamma_s D^3}{\rho v} \right)^{1/2}$$

(proposed by Yalin and Russell (3)) to show why the bed-form length decreases with increasing mobility number for fine sands. Here γ_s is the submerged specific weight and v the kinematic viscosity of water. This group is essentially a fall velocity Reynolds Number.

FIGURE 2

With regard to the ratio of bed-form "wave height" Δ to bed-form "wave-length" Λ , this ratio is given by $(\Delta/\Lambda)_{\max} = 0.14$ and the crest angle at this maximum steepness is 120° . These numbers are either remarkable or fortuitous — by water-wave theory for deep-water conditions the maximum water-wave steepness at breaking is 0.14 (i.e. $\pi - 3$) and Stokes' angle is 120° . Also, using typical soil mechanics figures for the natural angle of repose for loose sand, namely about 30° , this gives the internal angle of the crest as $(180^\circ - 2 \times 30^\circ) = 120^\circ$. The author leaves the explanation of this remarkable similarity of the two systems to erudite applied mathematicians such as Professor Longuet-Higgins.

In trying to relate this work to the extremely difficult task of modelling sea-bottom and beach processes one has firstly to keep in mind Fig. 1 where it is seen that the process is very time dependent. A 10 s prototype wave at a high mobility number will produce bed-forms in many less cycles than a 1 s model wave at perforce a smaller mobility number. Secondly, the model mobility number must be at least 3 to achieve any chance of bed-form formation — and hence material movement during the cycle. Lastly, for small sizes of sand (0.1 to 0.2 mm) which are very common on the world's best recreation beaches, a high prototype mobility number may result in no bed-form whatsoever and only massive amounts of sand in suspension above the bed which are easily moved by littoral or other currents. This may be impossible to reproduce in a model at lower mobility numbers unless one uses extremely lightweight material since the use of smaller model sizes of cohesionless material is not feasible. It is impossible for the same mobility number, by using say lightweight material in the model, to simultaneously have the same fall velocity Reynolds Number. Thus strict modelling of the motion of small size sand bed-forms under wave action is virtually impossible.

ABSTRACT

Shoreline development and shore-zone sediment transport on the Alaskan North Slope are dependent upon levels of wave energy, sea ice conditions, and the ice-sediment characteristics of eroding tundra cliffs. Considerable variation exists between the coastal processes and the shore-zone morphology of the Chukchi and Beaufort Sea beaches, (respectively west and east of Point Barrow). The supply of coarse sediments (sands or gravels) and the volumes of material eroded from tundra cliffs are a function of the initial character of the cliff sediments and of the ice content of the exposed cliffs. As cliff heights decrease, the ice content of the cliff increases, erosion rates increase but the sediment supply rates decrease. Wave-energy levels are relatively high and maintain a constant level on the Chukchi coast. The transport system on this coast is continuous and is augmented by storm events. On the Beaufort coast, energy levels are much lower, transport processes discontinuous, and storm events are therefore more significant. Sediments supplied to the coastal zone on the Chukchi coast are derived largely from the erosion of tundra cliffs and the barriers are continuous, linear, and stable. Rivers are the primary source of coastal sediments on the Beaufort coast and the more variable energy levels produce unstable barriers that are subject to aperiodic transport processes.

INTRODUCTION

The shoreline processes and coastal form of the Alaskan North Slope between Cape Beaufort and Demarcation Point are characterized by considerable variability. These differences can be explained in terms of regional variations in geology, sediment supply, and sediment transport processes. This paper discusses the results and interpretations of work carried out since 1975 by the authors and by other workers in this area. The emphasis throughout is on the interaction between the sediments available for redistribution by shoreline processes and on the energy levels which control the redistribution of the littoral-zone sediments.

Although the same processes operate in the shore zone of the North Slope as in lower latitude regions, the role of ice is a key element in understanding the coastal geomorphology and the sediment dispersal patterns. The open-water season is less than 3 months each year and the shore zone is a low wave-energy environment due to the small fetch distances imposed by the perennial polar pack-ice. An additional role of ice is related to the ice content of the cliff sediments which is a critical factor in controlling the volume of sediments available to the shore zone for beach development. The ice content, which is a function of regional variations in cliff height, affects the rates of sediment supply and the construction of beach or barrier systems.

GEOLOGY

The geology of the Alaskan North Slope north of the Brooks Range is characterized by a series of thick (10-40 m) Quaternary sediments which form a low coastal plain. Outcrops of bedrock along the shoreline are limited to a few short sections of the Chukchi coast where Cretaceous sedimentary rocks outcrop at or near sea level. Apart from

these relatively few sections of bedrock, the remainder of the Alaskan North Slope coast is composed of unconsolidated materials. Relief is higher along the Chukchi coast than on the Beaufort Sea coast (Table 1). On the Chukchi shorelines 44.3% of the relief is greater than 5 m, whereas, on the Beaufort Sea coast only 11.3% of the relief is greater than 5 m (Hartwell, 1973). The primary effect of this regional variation in relief is that the drainage is predominantly towards the northeast. Although approximately 40% of the North Slope is adjacent to the Chukchi coast, about 80% of the drainage is into the Beaufort Sea (Walker, 1974). This drainage pattern, which results from the greater relief in the western coastal plain, is dominated by the Colville system which drains the majority of the hinterland area.

In terms of the surficial sediments it is possible to distinguish two major units that are found to the east and to the west of Oliktok Point. To the east there is a series of predominantly coalescing alluvial or glacial-outwash fans (sandy, gravel material), or outcrops of the Flaxman Formation (Hopkins and Hartz, 1978). The latter is a sandy, mud Pleistocene deposit which contains pebbles, cobbles and boulders. West of Oliktok Point, the Cubik formation, a Pleistocene marine deposit, is a pebbly sand which contains up to 65% of silt-clay in some sections; elsewhere the stoney muds of the Flaxman Formation outcrop. In all areas, these post-Pleistocene surficial sediments are mantled by a 2-3 m thick layer of thaw-lake sediments, which are predominantly peats and muds (Hopkins and Hartz, 1978).

In terms of broad characteristics, the Chukchi Sea has a coast of relatively high relief and straight shorelines with no large river systems or deltas. The more irregular coast of the Beaufort Sea is a

result of (i) shoreline erosion in this area of thaw lakes and low relief, and (ii) possible contemporary submergence (Hartwell, 1973). The Beaufort Sea coast has many sections of low cliffs, barrier islands, thaw lakes, and numerous large deltas.

The primary geological features of the North Slope that influence coastal zone processes and sediment transport systems are:

- (i) the near-surface bedrock on the Chukchi coast that affects relief, drainage and thaw subsidence,
- (ii) the variation in surficial sediments, with a higher fine fraction in the unconsolidated deposits on the Beaufort coast,
- (iii) the greater coastal relief on the Chukchi coast, and
- (iv) the greater number and size of the rivers that drain into the Beaufort Sea.

This geological background is essential to an understanding of the sediment sources and, therefore, of the sediment dispersal patterns on the North Slope.

The major sources of the sediments that accumulate in the beaches and in the lagoons of the North Slope are: (1) material eroded from tundra cliffs, and (2) sediments supplied to the littoral zone by rivers. Erosion of the barrier islands themselves may provide additional material to the nearshore system. The relative contributions from coastal and fluvial sources differ significantly between the Beaufort and Chukchi coasts. This difference can be attributed largely to: (a) the regional variation in tundra cliff characteristics and in the character of the unconsolidated deposits, and (b) the North Slope drainage pattern.

TUNDRA CLIFFS AND SEDIMENT SUPPLY

Tundra cliffs, comprised of unconsolidated Quaternary deposits and cemented by frozen interstitial pore water, are distributed widely along the Chukchi and Beaufort Sea coasts and are found on exposed outer shorelines as well as along lagoon shorelines. Estimates indicate that 50% to 75% of the coastline is backed by tundra cliffs.

Despite the geographical proximity of the two regions, fundamental differences in cliff morphology, stability and composition exist between the Chukchi and Beaufort Sea coasts. The major morphologic differences are caused by the regional variation in topography that has resulted from a stable to emergent coast with higher relief and near-surface bedrock, hence relatively high coastal cliffs, on the Chukchi Sea coast (Table 1) and from a submergent coast with widespread thaw

subsidence, hence relatively low coastal cliffs, along the Beaufort Sea coast (Table 1). This regional variation in relief between the two regions has important consequences to the coastal stability and littoral sediment supply.

Sediments become enriched with pore ice at the tundra surface as a result of normal periglacial processes. Ice contents are typically 75% ice-by-volume near the surface and decrease exponentially with depth to values of 40% at the six-meter depth (Sellman *et al.*, 1975). This means that near the tundra surface much of the bulk volume is actually comprised of ice, whereas, in sediments at lower depths only the normal void space is filled with ice. The important consequence of this phenomena is that the ice content of low cliffs is very high ("ice-rich") and of high cliffs is relatively low ("ice-poor"). Due to regional variations in topography (Table 1), the low, ice-rich cliffs are found primarily along the Beaufort coast and the high, ice-poor cliffs occur along the Chukchi coast.

The ice content of tundra cliffs is an important control on cliff stability, both in terms of rates of change and in terms of the mechanisms responsible for change. Surveys have shown that cliffs along the Chukchi coast are retreating at an average rate of 0.3 m/yr. (Harper, 1978), whereas along the Beaufort coast Lewellen's data (1977) indicate a mean cliff retreat rate of 2.7 m/yr. with local long-term retreat rates as high as 20 m/yr. Much of this order of magnitude difference in retreat rates can be attributed to the excess ice effect discussed above. In addition, large volumes of material may be eroded from low cliffs but these volumes would produce only small amounts of sediment for potential redistribution as these cliffs are largely comprised of

ice. The effect of excess ice is illustrated in Figure 1 which shows the relationship between cliff height, retreat rates and the volume of sediment produced by erosion. From this figure, a 2-m high "ice-poor" cliff retreating at 0.5 m/yr. would supply one cubic meter of sediment to the littoral zone. An "ice-rich" cliff of the same height would have to retreat at a rate of 0.9 m/yr. to produce the same volume of sediment. An important point illustrated in this figure is that the effect of ice content on sediment supply rates is most pronounced for

Figure 1. Cliff heights and cliff retreat rates required to produce $1 \text{ m}^3/\text{year}$ of eroded sediment from "ice-rich" cliffs (dashed line) and from "ice-poor" cliffs (solid line).

low cliffs (less than 3 m in height). The second important effect of the ice content in cliff sediments is a disproportionately high retreat rate for the low-relief, ice-rich cliffs.

An additional factor contributing to the large differences in retreat rate is lithology (Table 1). The Beaufort Sea cliffs are comprised primarily of silt; the sediment produced by erosion of these unconsolidated, fine-grained materials is rapidly transported offshore and lost from the littoral system. By contrast the gravel component of the Chukchi cliffs forms protective beaches at the cliff bases and can be reworked into constructional spits and bars.

As a result of the differences in cliff heights, ice-contents, and lithology between the two coasts, the rate of sediment supply from cliff erosion also differs significantly. Along the Beaufort Sea coast low, silty, ice-rich, rapidly retreating cliffs yield small amounts of sediment for reworking into constructional landforms, whereas on the Chukchi coast, high, gravelly, ice-poor, slowly retreating cliffs yield relatively large amounts of material which is available for redistribution into beaches, bars, spits and barriers.

The other major sediment source is from river input; this also differs significantly between the two coasts. Although the Beaufort Sea coast is 50% longer than the Chukchi Sea coast (Chukchi, 811 km; Beaufort, 1343 km; Hartwell, 1973) over 80% of the drainage of the North Slope is into the Beaufort Sea (Walker, 1974). The major river systems on the North Slope are the Colville, Sagavanirktok and the Canning, all of which drain into the Beaufort Sea. Preliminary estimates (Cannon, 1978) for the Beaufort Sea coast suggest that 82% of the material deposited in the lagoon system is derived from fluvial

input and that the remaining 18% is contributed from erosion of the tundra cliffs and of existing barrier islands. Sediment budget calculations for one section of the Chukchi coast indicate that less than 10% of the nearshore sediments are derived from fluvial input and that greater than 90% are contributed by erosion of the tundra cliffs (Harper, 1978).

Significant regional variations exist in terms of sediment sources. Material supplied from cliff erosion accounts for approximately 90% of the total sediment input to the Chukchi coast, whereas less than 20% of the sediment input on the Beaufort coast is from cliff erosion and over 80% is thought to be contributed by rivers. The effects of excess ice in the sediments and, to some extent, lithology are important in controlling these relative contributions.

No estimates are available on the absolute amounts of sediment input to the nearshore budget, however, knowledge of the relative contributions from cliff erosion versus fluvial input and observations of regional morphology suggest that total supply rates (in terms of reworkable material, i.e., sand or gravel) are much lower along the Beaufort than the Chukchi coasts. The net result is that: (1) erosion is exceeding supply along the Beaufort and the coastal system is experiencing a net sediment deficit, and (2) accretion is matching or exceeding erosion along the Chukchi and the coast is relatively stable. These regional variations in supply have important consequences to the stability and morphology of the constructional coastal landforms, particularly the barrier islands.

COASTAL PROCESSES

The single most important factor that controls shore-zone processes is the presence of sea ice on the adjacent coastal waters. The average open-water season on the North Slope decreases towards the northeast from Cape Beaufort to Point Barrow, from approximately 3 months to 1 month at Barrow, and increases to 2 months along the Beaufort Sea coast from Barrow towards Demarcation Point. In addition to open-water data, it is also important to consider the fetch distances and the presence of pack ice on the adjacent sea areas. Due to the location of the edge of the permanent polar pack the Chukchi Sea coast, which is exposed towards the west, has fetch distances in the order of 50-200 km during the open-water season. By contrast, fetch distances on the Beaufort Sea coast vary between 10 and a maximum of 200 km. Figure 2 presents the mean annual position of the 10% ice-cover line. The fetch areas adjacent to the coast are reduced from the southwest towards the northeast and into the Beaufort Sea area. In addition, pack ice assumes an increasingly important role in dampening existing waves. These factors combine to greatly reduce and limit the duration of the open-water period in the Beaufort Sea.

Although wave heights are low and wave periods are generally short throughout the entire area, there is a significant difference in shore-zone wave-energy levels between the Chukchi Sea and the Beaufort Sea due to the differences in potential wave generation. The coasts of the North Slope are low wave-energy environments and the role of storms is, therefore, significant as large pulses of energy are introduced to the shore zone in what would otherwise be relatively quiescent energy conditions. In particular, the southwest winds that affect the Chukchi

coast are characterized by frequent short periods of high wind velocities (Short, 1979). Onshore winds on the Chukchi coast occur between 30% and 40% of the open-water season. The relatively short duration of these onshore winds is offset by the higher velocities during storms that occur on this coast and by the longer fetch distances when compared to the Beaufort coast.

Wind data from Barter Island on the Beaufort Sea coast indicates that northeast winds occur between 60% and 70% of the duration of the open-water season. Although the frequency of onshore winds is greater than on the Chukchi coast, the velocities are lower and the fetch distances are smaller, so that overall wave-energy levels at the shoreline are considerably reduced. Although data are scarce for this region,

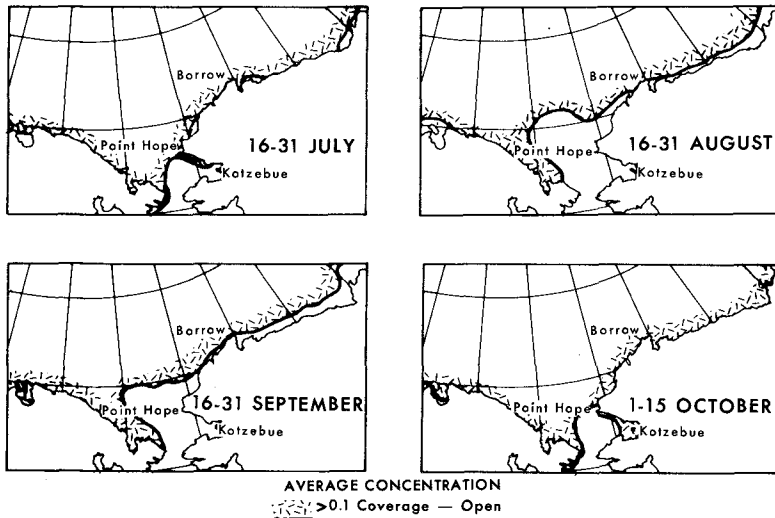

Figure 2. Mean position of the 0.1 (10%) ice-cover boundary for four different summer periods (from Selkregg, 1975).

wave heights greater than 1 m occur for approximately 10% of the open-water season on the Chukchi coast but for only 3% of the open-water season on the Beaufort coast. Brower *et al.* (1977) provide data on mean monthly wave heights for the Beaufort Sea which give values of 0.39 m for July, 0.48 m for August and 0.77 m for September. A secondary characteristic of the Beaufort Sea wave environment is that the angles of wave approach are generally high, due to the elongate nature of the wave generating zone. In addition to an increase in wave-energy levels from east to west along the Beaufort coast, which is a function of wind direction, the high-angle waves result in an east to west shore-zone sediment transport system.

Wave hindcasts for sites along the North Slope coast have been computed (Table 2) based on fetches derived from maps of the mean ice-margin position (Fig. 2). The wind speeds required to generate a fully arisen sea were determined for each of the fetch distances, based on Neumann (1953). The wave characteristics of the fully arisen sea were then related to wind velocities and the value \bar{H} is the mean wave height of the spectrum. The wave heights are therefore the theoretical maxima possible for each of the onshore directions. These data are summarized diagrammatically in Figure 3.

Figure 3. Hindcast maximum wave heights for September (data from Table 2).

TABLE 2. Measured fetch distances (F_m - in nautical miles) and mean wave heights (\bar{H} in meters) hindcast by the Pierson-Neumann-James method, for typical summer ice conditions on the Alaskan shore of the Chukchi and Beaufort Seas.

As these are low wave-energy environments storms assume an important role on both coasts in terms of shoreline wave-energy levels and of sediment transport. Storm-induced water level changes are greater than the astronomical tides. The tidal range is less than 50 cm on all coasts, whereas, storm-induced water level changes can reach 3 m (Reimnitz and Maurer, 1978). Under normal circumstances the tidal range is slightly greater on the Chukchi than on the Beaufort Sea coast, whereas, the storm surges are greater on the Beaufort Sea coast.

The computation of shore-zone energy levels provides an approximate guide to relative variations alongshore. Short (1979) indicates that approximately twice as much wave energy acts upon the Chukchi as upon the Beaufort Sea coast (Table 3). Of equal importance to the higher energy levels is the fact that wave processes are more continuous on the Chukchi Sea coast due to higher wind velocities (Owens, 1977). Energy levels on the Beaufort Sea coast are lower and the frequency and intensity of storm-generated waves are also lower. Therefore sediment transport in the shore zone is a relatively continuous process on the more exposed Chukchi Sea coast and transport is more intermittent and more variable on the Beaufort Sea coast. These differences in energy levels are reflected in the character of the beaches and the barriers. On the more exposed Chukchi coast the beaches are both straighter and higher, with better defined berm systems. On the Beaufort Sea coast, beach sediments are generally poorly sorted and often the berm is either low or not present. These basic differences in the profile characteristic of the beaches can be attributed directly to variations in both the frequency and the magnitude of peaks in the wave-energy spectrum.

SHORELINE DEVELOPMENT AND BEACH MORPHOLOGY

The regional variations in the geological and process parameters discussed above are clearly reflected in the character of the barrier beaches and in the sediment transport systems. Owens (1977) noted that the barriers of the Beaufort Sea coast have an irregular plan form, rarely have dunes, and are overwashed during storms. By contrast, the barriers between Point Hope and Barrow on the Chukchi coast are continuous, straight, and commonly have low dunes in the backshore. These differences are related directly to variations in both the frequency and magnitude of peaks in the wave-energy spectrum. Owens noted that longshore sediment transport processes on the more exposed Chukchi Sea coast are relatively continuous during the open-water season, whereas, energy levels on the Beaufort Sea coast are both lower and more variable.

The geometry of the barrier systems can be compared by referring to barrier height and barrier width values. Averages taken from survey profiles indicate that barrier heights on the Chukchi coast generally range between 1 and 3 m, whereas, barrier heights on the Beaufort coast greater than 1.5 m are rare. Similarly, barrier width values decrease from 150-350 m on the Chukchi coast to 100-200 m on the Beaufort coast. These morphological differences are a result of a combination of factors related to both wave-energy levels and sediment supply rates.

The paucity of sediments on the Beaufort Sea coast has given rise to a series of discontinuous and relatively unstable barriers which are generally crescentic in shape, are separated by wide tidal inlets, and are highly transgressive (Nummedal, 1979). Sediment transport on this coast takes place primarily as a series of storm-related pulses rather than as a continuous process. The Beaufort coast barriers are transgressive, with an average landward movement in the order of 3-5 m/yr. In response to the east-west sediment transport system (Short, 1979), many of the islands are also migrating towards the west at rates in the order of 20-30 m/yr. This overall sediment transport direction and migration pattern is not uniform, with frequent reversals related to storm winds. Due to the existence of wide inlets between many of the islands, many of the barrier islands are independent, self-contained systems rather than part of a longshore sediment transport continuum. This is in direct contrast to the long, continuous barrier systems of the Chukchi coast which form part of an integrated series of three large sediment transport cells.

The decrease in shoreline wave-energy levels towards the northeast and east along the coast of the North Slope results in an increasing

complexity of beach profile morphology and in an increasing variability of beach plan morphology. These trends are a simple reflection of the changes in wave-energy levels alongshore and in the change from a continuous to an aperiodic sediment transport system. Overall sediment transport rates range from 5,000 to 20,000 $\text{m}^3/\text{yr.}$ on the Chukchi Sea coast to 2,000 to 5,000 $\text{m}^3/\text{yr.}$ on the Beaufort Sea coast (Wiseman, *et al.*, 1973). Measured longshore sediment transport rates at Point Barrow (Nummedal, 1979) provide values in the order of 1,500 m^3 of sediment transport per day during a three-day storm in 1977 (Fig. 4). Thus this storm alone could have transported approximately 5,000 m^3 of sediment during that single event. Based on field observations and theoretical calculations, the entire annual sediment transport volume on the Beaufort Sea coast could be confined to one or several storm events.

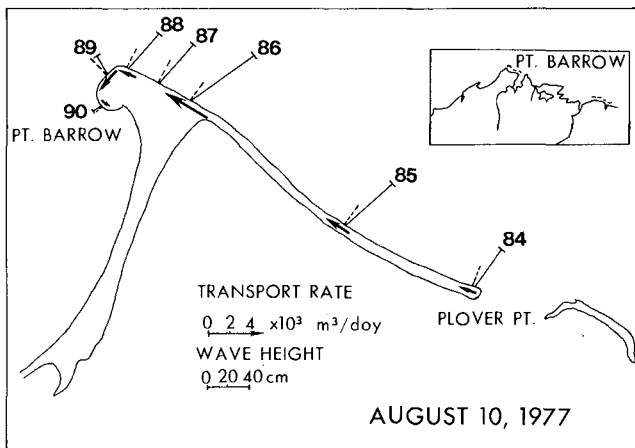

Figure 4. Sediment transport rates (arrows) based on measured longshore wave power and measured wave heights and wave orthogonal angles (bars) at Point Barrow. Numbers (84-90) refer to station codes (from Nummedal, 1979).

DISCUSSION

The assessment of the potential impacts of man's activities is important in engineering design studies. Sediment transport in the shore zone, cliff erosion rates, and the redistribution of beach materials are all critical and sensitive elements of the natural dynamics of the North Slope coasts. Many of the small, narrow, barrier islands of the Beaufort Sea coast are subject to major changes during large storms. The erosion and redistribution of sediments by overwash and by longshore transport can cause erosion and/or deposition on a large-scale during a period of only a few days. Site selection analyses for nearshore and onshore facilities must take into account the potential for such natural dynamic changes in morphology and in shoreline location on barrier islands as well as on the more obvious eroding tundra cliff coasts.

A knowledge and understanding of coastal processes can be used to advantage in the design process. For example, the orientation and shape of artificial islands placed in the nearshore zone can be varied to take into account local transport processes. Figure 5 provides a schematic example of this point. In this scenario an island oriented east-west would have a net shore-zone transport to the east, whereas, a 30° change in orientation to a northwest-southeast alignment would result in net transport towards the northwest. In both cases the calculated net transport rates are in the order of $10^5 \text{ m}^3/\text{yr}$. (Nummedal, 1979).

CONCLUSIONS

- (a) The supply of sand-sized sediments from cliff erosion for barrier development on the North Slope is controlled by wave-energy levels, cliff lithology, cliff height, and by the ice content of the exposed cliffs. Ice plays an important role in coastal process and in sediment supply variations.

Figure 5. Sediment transport rates on hypothetical deep-water artificial islands.

- (b) Shore-zone wave-energy levels are controlled primarily by the distribution of sea ice which limits fetch distances. The ice content of exposed cliff sections is a function of cliff height due to periglacial processes that concentrate ice near the surface.
- (c) Variations in barrier and beach morphology between the Chukchi and Beaufort Sea coasts are dependent on the modifying effects of ice, both on the adjacent sea surface and, to some extent, within the cliff sediments.
- (d) The Chukchi coast has high tundra cliffs which supply comparatively greater volumes of sediment to the shore zone. Wave-energy levels are higher and barriers are straight, continuous, and stable.
- (e) Cliff heights, sediment supply rates and wave-energy levels are lower on the Beaufort coast. The barriers are more crescentic, complex, discontinuous, and transgressive.
- (f) Previous studies of arctic coasts have noted the important effects of ice in limiting shore-zone physical processes. On the Alaskan North Slope the effects of variations in ice content within the tundra cliffs also play a critical role in limiting sediment availability for barrier beach development.

ACKNOWLEDGEMENTS

The data discussed were derived primarily from research projects funded by the Geography Programs, Office of Naval Research, Arlington, Virginia, under a contract with the Coastal Studies Institute, Louisiana State University (Owens and Harper), and by the Outer Continental Shelf Environmental Assessment Program of NOAA (Nummedal).

SEDIMENT DISPERSAL ON THE N.S.W. CONTINENTAL SHELF

Ron Boyd

Geology Department, University of Sydney,
N.S.W., 2006, Australia

ABSTRACT

This paper presents a semi-empirical model for describing sediment dispersal on the central New South Wales (N.S.W.) continental shelf. Results from a program of field experiments identify wind speed and direction, wave height and frequency distribution of near-bottom currents as being the dominant factors influencing near-bottom current asymmetry on this shelf. A combination of theoretical prediction and field experiment has been used to define the seaward limits for onshore/offshore sediment exchange and the modes of sediment transport operating within this active zone.

INTRODUCTION

A unified theoretical basis for continental shelf sediment dispersal is yet to be fully established. In such a situation, empirical models may provide useful tools in interpreting sediment dispersal patterns for specific shelf regions. This contribution presents such a model for the central N.S.W. shelf. Field data is used to identify the basic nature of the near-bottom flow field and resulting sediment transport on this shelf. The model also represents a framework from which future local investigations of sediment dispersal may be planned.

SIMPLIFICATIONS

A number of simplifying assumptions have been made which consist of eliminating those elements which account for only relatively minor contributions to the local sediment budget. These assumptions are:

- (i) Coastal streams do not supply significant quantities of sand-sized sediment to the shelf at the present time.
- (ii) Longshore transport is an ineffective dispersal mechanism along much of the compartmentised central N.S.W. coast.

- (iii) Coastal estuaries do not act as sinks for sediment derived from the adjacent shelf.
- (iv) The major contribution to the shelf sediment budget comes from onshore/offshore exchange.

FRAMEWORK OF THE MODEL

The model developed to document onshore/offshore exchange operates by rationalising the spectrum of atmosphere/ocean/substrate interactions into a finite number of categories. The resulting classification system is derived from four years of ocean observations in the Sydney region. These observations suggest a classification system based on parameters of average wave period (T_{av}), significant wave height (H_s), swell approach direction, wind speed and orientation to the coastline (Table 1). The wave period and height parameters define a number of alphanumeric

TABLE 1. SHELF WEATHER CLASSIFICATION

WAVE PARAMETERS	WIND PARAMETERS
<u>Average Wave Period (T_{av})</u>	<u>Wind speed</u>
A. $T_{av} \leq 7$ seconds	< 20 km/hr (av)
B. $7 \text{ seconds} < T_{av} \leq 10$ seconds	> 20 km/hr (av)
C. $T_{av} > 10$ seconds	
<u>Significant Wave Height (H_s)</u>	<u>Orientation of Wind to coastline</u>
1. $H_s \leq 1$ m	- Onshore (including S)
2. $1\text{m} \leq H_s < 3\text{m}$	- Offshore (including N)
3. $3\text{m} \leq H_s \leq 5\text{m}$	
4. $H_s > 5\text{m}$	
<u>Swell Direction</u>	<u>Key:</u>
- Arriving from the NE quadrant (including E)	< less than
- Arriving from the SE quadrant (including S)	> greater than
	\leq less than or equal to

divisions (A1-C4). Swell direction and wind parameters account for a further numeric subdivision (categories 1 to 49). The classification is informally referred to herein as the Inner Shelf Process-Response Model (I.S.P.R.M.)

EXPERIMENTAL PROGRAM

An experimental program was conducted at Palm Beach, some 30 km north of Sydney, to identify characteristic responses in the near-bottom current field and patterns of sediment transport for each category in the model. Data collection utilised a mechanical current meter based on a design by Summers *et al.* (1969).

NEAR BOTTOM CURRENT ASYMMETRY

Onshore/offshore sand transport depends on near-bottom current asymmetry. Initiation of sediment motion on wave-dominated coasts such as that of central N.S.W. depends on orbital velocities resulting from oscillatory wave currents. Rates and directions of sediment transport are determined by unidirectional currents superimposed on oscillatory wave motion (Bagnold, 1963). Unidirectional currents may be produced by the waves themselves (e.g. Longuet-Higgins, 1953) or they may result from other mechanisms such as wind stress (e.g. Murray, 1972), tidal motion (e.g. Huthnance, 1972), rip currents (e.g. Cook, 1970), or backwash (e.g. Kemp, 1975).

Under conditions such as those experienced during the Palm Beach field experiments, net water transport is expressed as inequality of onshore and offshore surges. For each cycle under shaling conditions, non-linear wave theories (e.g. Stokes theory) suggest onshore surges should become stronger while offshore surges should occupy a longer time interval. The field data from Palm Beach did not conform with these predictions. Current meter records exhibited current maxima in both the onshore and offshore directions. Similar variations occurred in the relative amount of time occupied by onshore and offshore flow. This data therefore indicates that other factors in addition to wave motion determine near-bottom currents at Palm Beach. To identify any other contributing factors, a statistical correlation analysis was performed on the data. In particular, investigations were made of the relationship between near-bottom currents and the parameters which define the I.S.P.R.M. such as wind velocity, wave height and wave period. Other parameters considered likely to influence near-bottom currents such as tidal motion or bedslope were also included for analysis.

Net bottom drift was the dependent variable chosen for correlation. This parameter is derived by summing individual current speed and direction values over an entire record. The resultant thus takes into account both current velocity and duration. Statistical tests for this analysis consisted of a diagonal correlation coefficient (D.C.C.) designed to identify relationships between directional parameters (such as net bottom drift and wave direction) and a rank correlation (R.C.) to identify relationships between parameters whose magnitude could be compared (such as wave height and net bottom drift).

The most significant correlations occurred between net bottom drift, wind and wave parameters. In particular, the direction of bottom drift correlated strongly with wind direction. Bottom drift magnitude correlated best with wave height and spectral distribution of near-bottom currents. Poor correlation resulted from the other parameters considered, including tidal motion and sea floor topography (Table 2).

1. Wind-Induced Effects

Wind direction and wind speed both showed good correlation with net bottom drift. A D.C.C. value of 0.77 (the highest value for all parameters investigated)

TABLE 2

PARAMETER	TEST	LEVEL OF SIGNIFICANCE	CORRELATION COEFFICIENT
Wind Direction	DCC	-	0.77
Wave Height	RC	>90%	0.56
Wind Velocity	RC	>90%	0.55
Spectral Distribution	DCC	-	0.50

Bed Slope	RC	<90%	0.30
Bed Roughness	RC	<90%	0.30
Depth	RC	<90%	0.30
Wave Period	RC	<90%	0.21
Tidal Direction	DCC	-	0.09
Wave Direction	DCC	-	0.02

FIGURE 1
WIND VELOCITY VERSUS NET BOTTOM DRIFT

was found to exist for correlation between wind direction and the direction of net bottom drift. The R.C. test indicated a dependence existed between wind speed and net bottom drift magnitude at greater than the 90% level of significance. The correspondence between wind parameters and net bottom drift is graphically illustrated in Fig. 1. Data values tend to cluster in the upper right and lower left quadrants of the graph, with a further tendency to be along the diagonal between the two. This indicates onshore winds are associated with near-bottom currents directed offshore while offshore winds are associated with near-bottom currents directed onshore. Stronger winds tend to produce higher values of net bottom drift.

The above results are in agreement with comparable studies conducted by Cook and Gorsline (1972) and Murray (1972). A simple, steady-state model proposed by Jeffries (1923), adequately accounts for the observed generation of near-bottom currents by wind stress. On the N.S.W. coast, Jeffries' model predicts onshore-directed bottom currents to result from westerly winds and offshore-directed bottom currents from easterly winds on the inner shelf. Wind stress control over near-bottom currents may be generalised via the Jeffries model for inclusion in the I.S.P.R.M. classification. Strong offshore-directed current asymmetry, derived from wind stress effects, may

be found in Categories 5, 6, 11, 12, 17, 18, 23, 24, 29, 35, 36, 41, 42 and 49. Strong onshore-directed current asymmetry from the same source occurs in Categories 3, 4, 15, 16, 21, 22, 33, 34, 39, 40 and also 49.

2. Wave-Induced Effects

Wave height, wave period and water depth are the variables which occur in the expression for volume transport resulting from wave motion in both Stokesian and solitary waves (Inman in Shepard, 1963). Inspection of the Palm Beach data revealed wave height to be the most significant of these variables in determining net bottom drift. The magnitude of net bottom drift in the direction of wave advance increased exponentially with wave height (Fig. 2).

Values of net bottom drift also tended to increase with increasing wave period but here the relationship was less well established (Fig. 3). A similar result has been reported by Cook and Gorsline (1972). However, this result does not conform with theoretical predictions, such as the Longuet-Higgins mass transport concept (Longuet-Higgins, 1953), which suggest net bottom drift is inversely related to wave period. Several factors may help to interpret the Palm Beach results.

- a. Long average wave period is commonly associated with larger waves on the central N.S.W. coast. This was the case for all Palm Beach experiments. It was difficult (especially using in situ recording techniques) to monitor occasions where wave height remained constant over a range of wave periods.
- b. Conditions of low average wave period are commonly associated with a wide frequency distribution of wave energy rather than the monochromatic swell conditions for which theoretical relationships are derived. This is reflected in the high correlation found to exist between frequency distribution of near-bottom currents and direction of bottom drift. Narrow-band frequency distributions were associated with stronger onshore bottom drift. Wide-band frequency distributions often resulted in low and offshore-directed values of bottom drift. In addition, under field conditions, low average wave period is frequently the result of shorter-period wind waves generated by an onshore wind and superimposed on pre-existing swell.

3. Relationship of Current Asymmetry to the I.S.P.R.M.

Insufficient data has been collected during the present study to accurately determine the quantitative contribution of individual processes to current asymmetry. The value of the present work lies in identifying the parameters controlling current asymmetry and incorporating

FIGURE 2
NET BOTTOM DRIFT VERSUS WAVE HEIGHT
(positive values only)

FIGURE 3
NET BOTTOM DRIFT VERSUS WAVE PERIOD
(positive values only)

these parameters into a qualitative model (the I.S.P.R.M.). The present form of the model is suitable for constructing a conceptual framework for shore-normal shelf dynamics which predicts the relative effectiveness of individual processes.

Wind stress provides the most effective control of current asymmetry. In the absence of a significant wind stress contribution, waves control the near-bottom current field. Wave control is most effective for conditions of larger waves which produce a concentration of near-bottom currents at low frequencies. Therefore, strong, onshore, near-bottom currents result from strong offshore winds, high energy swell conditions which produce oscillatory flows dominated by low-frequency components, and combinations of these two mechanisms. Such situations are present chiefly in I.S.P.R.M. Divisions C4, C3, C2 and B2, in Categories 49, 46, 44, 43, 40, 39, 38, 37, 34, 33 and to a lesser extent 20 and 19. Onshore flow extends to lower categories such as 22, 21, 16, 15, 4 and 3 under strong offshore wind conditions. Offshore near-bottom currents result from strong onshore winds and wide spectral distribution of oscillatory currents in Categories 5, 6, 11, 12, 17, 18, 23, 24, 29 and 30. Weak and variable near-bottom currents occur in the absence of higher energy swell or strong wind conditions such as in Categories 1, 2, 13 and 14, or when strong winds negate higher energy swell conditions. The above situations are summarised in Fig. 4.

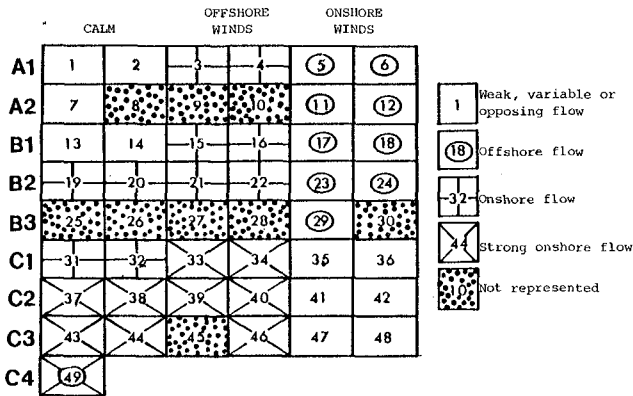

FIGURE 4
I.S.P.R.M. CLASSIFICATION OF NEAR-BOTTOM FLOW

SEDIMENT DYNAMICS

As a first step in determining sediment dynamics on the central N.S.W. shelf, the seaward limit to the zone of sediment activity resulting from wave processes was established for the range of shelf weather situations covered by the I.S.P.R.M. classification system. In addition, the modes of sediment transport operating within the active zone were observed and recorded during the field experiments at Palm Beach.

These field experiments conformed with a conceptual model of wave-generated sedimentary structures presented by Clifton (1976). Clifton recognised a typical shoaling sequence of structures resulting from wave-induced oscillatory flow. Beginning offshore and moving landward, these are (1) an inactive zone, (2) active symmetric ripples, (3) long-crested asymmetric ripples, (4) irregular asymmetric ripples, (5) asymmetric cross-ripples, (6) megaripples and (7) flat bed. This same sequence was commonly observed at Palm Beach.

Three important divisions exist within Clifton's model. These are:

- (1) A division between active and inactive zones. This division corresponds to the shelf location where initiation of sediment motion begins.
- (2) A division between symmetric and asymmetric bedforms. In the Palm Beach examples, this division also separated migratory and non-migratory bedforms. In the zone of symmetric bedforms, sediment was transported by grain translation close to the bed during each wave cycle and by intermittent suspension in ripple-lee vortices, formed as the oscillatory motion changed direction. In the zone of asymmetric bedforms, sediment transport was dominated by migration of individual bedforms and by the translation of a highly-concentrated, near-bed layer of suspended sediment.
- (3) A division between rippled beds and flat beds. This division corresponds to the appearance of a sheet flow mode of sediment transport.

It was decided to use the Clifton model as a basis for providing a conceptual documentation of sediment transport zones on the central N.S.W. continental shelf.

Sediment Transport Zones

For simplicity, Clifton's model was based on dimensional parameters derived from the work of Dingler (1974) and Komar and Miller (1973). It is generally accepted (see for example

discussion by Komar (1976)) that sediment transport criteria are best described by a shear stress concept, such as that proposed by Shields (1936). Therefore shear stress criteria have been used to construct continental shelf "fences" defining the initiation of sediment motion and the onset of sheet flow for each division of the I.S.P.R.M. Following the methods of Nielsen (1979), a non-dimensional shear stress

$$\theta' = \frac{\tau'_{\max}}{\rho(s-1)gd} \quad \text{eqn. 1}$$

has been used to calculate the sediment transport depth zonation. Here ρ is density of water, s is grain density, g the acceleration due to gravity and d is grain diameter. Nielsen found that the concentration of moving sediment is related more closely to the skin friction (τ') than to the total shear stress. τ'_{\max} may be calculated from the relationship;

$$\tau'_{\max} = \frac{1}{2} \rho f_w (a\omega)^2 \quad \text{eqn. 2}$$

where $\omega = \frac{2\pi}{T}$, a is water semi-excursion and f_w , a friction factor, is derived from Swart's (1976) formula

$$f_w = \exp [5.213 \left(\frac{k}{a}\right)^{1.94} - 5.977] \quad \text{eqn. 3}$$

Here k is the hydraulic roughness. Nielsen gives the critical θ' values for initiation of motion and onset of sheet flow as 0.045 and 1.0 respectively. An iterative solution was then developed (from eqn. 1) for critical water depths corresponding to θ' values of 0.045 and 1.0.

Bedform asymmetry is a function of near-bottom flow asymmetry. In Clifton's model, the transition between symmetric and asymmetric bedforms took place at velocity difference values between 1 and 5 cm/sec. Velocity difference is here defined as the sum of the maximum velocity under the wave crest in the direction of wave propagation (positive vector) plus the maximum velocity under the trough of the wave (a negative vector). In six of the seven examples of asymmetric bedforms observed at Palm Beach while simultaneously recording currents, the velocity difference lay between 1.1 and 9.5 cm/sec. It was thus concluded that the range of velocity difference between 1 and 5 cm/sec, proposed by Clifton, adequately defined the transition between symmetric and asymmetric bedforms. At present it is only possible to accurately predict the flow asymmetry derived from wave

shoaling. In the following discussion other controlling influences of the near-bottom current field (such as wind stress) will not be considered. Velocity difference (V_d) values were quantitatively estimated from the Stokes second-order wave equations whereby

$$V_d = \frac{14.8H^2}{LT \sinh^4 kh} \quad \text{eqn. 4}$$

These values were used to construct a further continental shelf fence (for the development of asymmetric bedforms) in each I.S.P.R.M. division. The location of the three sediment transport zones defined by fences for the initiation of sediment motion, development of asymmetric bedforms and onset of sheet flow are shown for each I.S.P.R.M. division in Fig. 5.

A combination of low θ' values and a seaward increase in grainsize for sand on the inner shelf generally restricts

FIGURE 5

active bedform development to the shoreface, above the 30m isobath, for I.S.P.R.M. divisions A1, B1 and C1. Bedform activity in Divisions A2, B2 and C2 may extend onto the inner shelf while Divisions C3 and C4 create active sediment motion in all areas of the inner shelf and extend into the midshelf zone, below the 60m isobath. Fine sand modes (less than 0.5mm grainsize) in inner shelf sands are entrained at significantly deeper depths and under lower energy conditions than the coarser sand and gravel modes. Asymmetric bedforms are virtually restricted to the shoreface except for Divisions C2, C3 and C4. Sheet flow under flat bed conditions is entirely restricted to the shoreface except for extreme events in Division C4. In Divisions A1, B1 and C1 sheet flow is restricted to the vicinity of the surf zone.

DISCUSSION

The model which has been presented above contains several important implications for sediment dispersal on the central NSW continental shelf.

1. The dominant parameters identified as controlling near-bottom current asymmetry on this shelf are wind speed and direction, wave height and frequency distribution of near-bottom currents.
2. The active zone of sediment exchange, as defined in the fence diagrams, extends further offshore than is usually acknowledged on this coast. This is because the active zone limit has been previously correlated with a sharp sediment textural discontinuity at depths of 20-25m. Theoretical predictions for initiation of sediment motion, distribution of the asymmetric bedform zone (which contains migratory bedforms) together with corroborative data derived from bottom photographs and sediment volume measurements (Boyd, 1980) all indicate onshore/offshore sediment exchange may occur between the surf zone, the shoreface and the inner shelf on this coast.
3. The relative frequency of constructive versus destructive conditions (as defined in figure 4) is the primary determinant of both the short-term and long-term exchange budgets.

CONCLUSION

In its present form, the above model may be used to indicate direction and relative magnitude of near-bottom currents. For a wave-induced flow field, the model also indicates the modes of sediment transport and their areal distribution on the inner shelf. It thus represents a conceptual framework with which to interpret the general nature of sediment dispersal on the central NSW continental shelf.

FLUID MUD DYNAMICS AND SHORELINE STABILIZATION:

LOUISIANA CHENIER PLAIN

John T. Wells and Harry H. Roberts

Coastal Studies Institute, Louisiana State University

Baton Rouge, Louisiana 70803, U.S.A.

Abstract

The coast of western Louisiana is presently receiving a new influx of fine-grained sediment from the Atchafalaya River to the east, the first such sediment pulse in recorded history. The major effect of this sediment, which accumulates as fluid mud in the nearshore and at the shoreline, is to attenuate incoming wave energy, thus providing conditions favorable for further sedimentation. Examination of color infrared photography and comparison of observations from aerial overflights and information from ground reconnaissance undertaken periodically since 1969 indicate that mudflat sedimentation is increasing and appears to be moving to the west. When muds move ashore and begin to dewater after becoming "shore attached," they gain strength rapidly and can resist subsequent fair-weather wave scour if their bulk density exceeds $1.20-1.25 \text{ g/cm}^3$. An understanding of why and how these fluid muds accumulate and move subaqueously may provide us with the ability to predict areas of future erosion and accretion along the western Louisiana shoreline.

Introduction

The shoreline of Louisiana is extremely dynamic, and its history is complex. In contrast to the sandy beaches of the east and west coasts of the United States, shoreline sediments in coastal Louisiana are composed mainly of silts and clays that have entered the Gulf of Mexico via the Mississippi River. The predominance of fine-grained coastal sediments, particularly the soft gel-like "fluid muds," play a major role in many of the geologic and oceanographic processes on the inner continental shelf and at the shoreline, such as rate of wave attenuation and rate of shoreline erosion and accretion. This paper examines the source, transportation, and site of accumulation of fluid muds in western Louisiana and their importance to shoreline stabilization.

Traditionally, the coast of Louisiana has been eroding faster than that of any other state (USACOE, 1971), primarily because of the natural processes of wave and current scour, subsidence and consolidation of sediments, and sea level rise. Average annual rates of shoreline change for the period 1812-1954 were determined by Morgan and Larimore (1957) from 1:20,000 aerial photography and are given in Figure 1 for the western half of the state. Only three areas of accretion were reported by Morgan and Larimore, and two of these were the result of sediment entrapment by jetties east of both Calcasieu and Sabine ship channels (Fig. 1). In a third area, west of Marsh Island in the vicinity of Chenier au Tigre, coastal accretion had occurred naturally; much of this accretion resulted from new mudflat development initiated by an influx of muds during the 20-30 years prior to 1954.

Evidence provided in a detailed account of sedimentation on the western Louisiana coast (Morgan et al., 1953), along with results of the present study, indicates that the erosional trend is reversing and that the western half of the state is receiving a new pulse of sediment. This reversal in trend (stabilization and even progradation) is attributed to an influx of fine-grained sediment from the Atchafalaya River, a distributary of the Mississippi River which now carries 30 percent of total flow from the Mississippi. As will be discussed in the following paragraphs, an understanding of the dynamics of this new "fluid mud" in the nearshore and on the inner continental shelf may provide us with the ability to predict areas of future erosion and accretion at the shoreline.

Background and Study Area

The western half of the Louisiana coast, referred to as the chenier plain, has been dominated periodically by pulses of fine-grained sediment from the Mississippi River during the past 5,000 years (Howe et al., 1935; Russell and Howe, 1935). Development of the chenier plain and adjacent shelf was traced stratigraphically from cores using radiocarbon dating techniques (Gould and McFarlan, 1959) and is summarized below. As sea level rose from -5 m to its present level, a transgressive sequence of marine sediments was deposited over the dissected Pleistocene Prairie formation, first filling estuaries, then later spreading across shallow-bay and marsh environments (Fig. 2). High-resolution seismic profiles, such as that reproduced in Figure 2, provide thickness and location of Holocene sediments, older underlying channel fill deposits, silt horizons, and

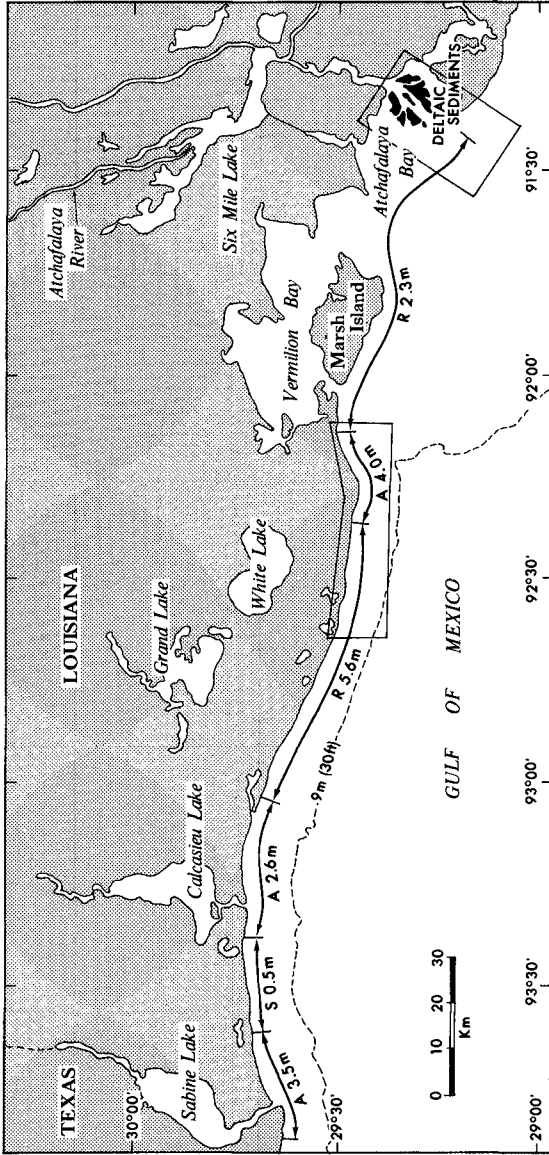

Figure 1. Coast of central and western Louisiana showing average annual rates of shoreline change from 1812 to 1954 (from Morgan and Larimore, 1957). A = accretion, S = stable, R = retreat. Enclosed areas of shoreline are major study sites.

Figure 2. High-resolution seismic profile (E. G. and G. BOOM operated at 300 joules) across the western Louisiana shelf, approximately 10 km seaward of the shoreline south of White Lake. Note that Holocene clays and silty clays are approximately 6 m thick in this area. (Profile courtesy of Jim Hauser, Odom Offshore).

shell lenses.

During the final stage of post-glacial rise in sea level some 3,000 years ago, the chenier plain began to prograde rapidly, and eventually a wedge of recent sediments 6-8 m thick (Fig. 2) was deposited to a distance of 24 km offshore, thus placing the shoreline roughly where we see it today. Pulsations of sediment from the Mississippi River, transported by coast-parallel currents, were responsible for the progradational stage of development. At times when the Mississippi River introduced sediment in the vicinity of the present chenier plain, the shoreline shifted seaward; during periods when its course took the discharge farther east, sediment influx to the chenier plain was low and wave attack was able to slow or halt the advance (Could and McFarlan, 1959). Cheniers formed during these latter periods and now stand as "islands" in the marsh.

A new pulse of sediment, the first in some 1,000 years, began adding soft muds to the shoreline near Chenier au Tigre in the late 1940s, coincident with the subaqueous development of a new delta in Atchafalaya Bay (Morgan et al., 1953). Although the delivery of sediments from the Mississippi River down the Atchafalaya River had been in progress since the mid-1500s (Fisk, 1952), it was not until the mid-1900s that sedimentation in the bay and areas offshore became noticeable. This large-scale introduction of silts and clays to the coast occurred when the Atchafalaya basin to the north became essentially sediment filled and sediment began bypassing these basin-lakes for areas to the south. In the early 1950s Morgan et al. (1953) documented the occurrence of mud deposition along approxi-

mately 50 km of coast from Marsh Island to Rollover Bayou which, in places, formed broad mudflats up to 2 m thick. Today, the chenier plain is backed by extensive brackish and saline marsh and is fronted by ephemeral mudflats along the eastern one-third of its length (Fig. 3). Whereas the coastline and inner continental shelf may appear monotonous to a casual observer, they are in fact, on a small scale, extremely active morphologically.

Present Studies

Shoreline variations and areas of mudflat accumulation were determined from color infrared photographs taken in October 1974 and October 1978 (NASA Missions 74-293 and 78-148, respectively), from 1974 orthophotoquads, and from aerial and ground reconnaissance in 1974 and 1979. Color infrared photography is particularly useful for delineating vegetation/mudflat/open water boundaries since color enhances the vegetation, which during times of low primary productivity is difficult to distinguish from exposed mudflats or turbid water.

Results of these photo and ground comparisons, together with data given in Adams et al. (1978) for the period 1954-1969, are shown in Figure 4. Over the 10-year period from 1969 to 1979 the following patterns have been recognized: 1) simultaneous erosion and accretion at the shoreline,

Figure 3. Mudflat exposed at low tide, Louisiana chenier plain east of Rollover Bayou.

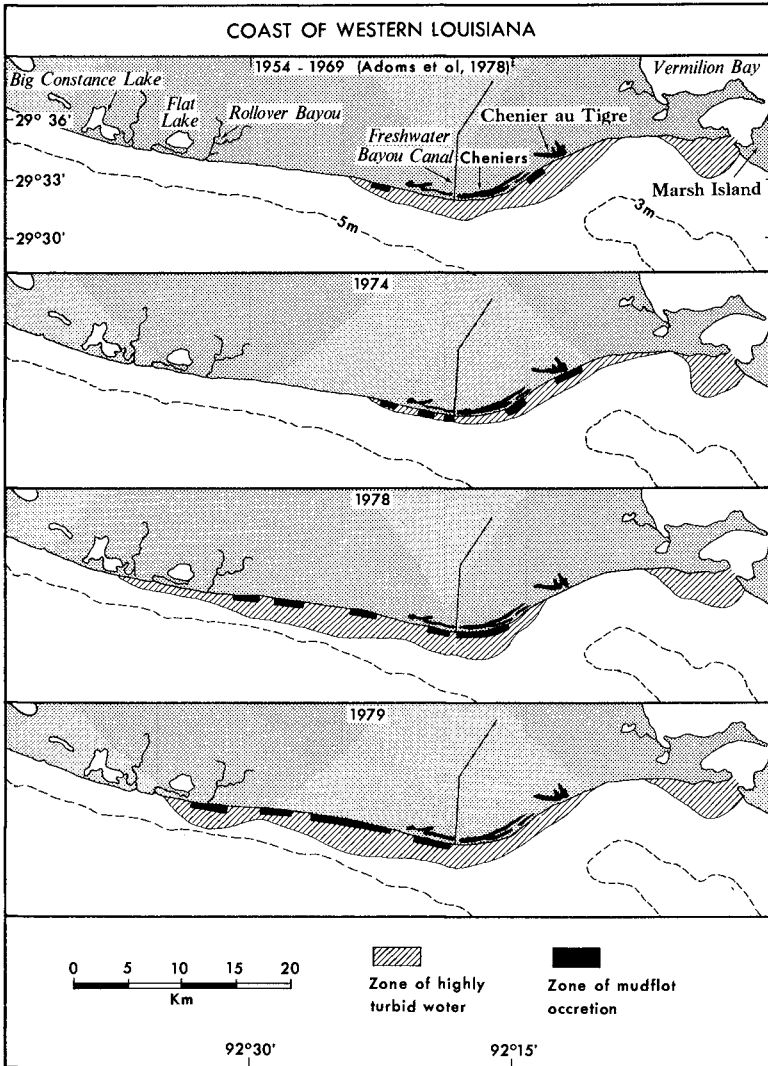

Figure 4. Areas of mudflat accretion from 1969 to 1979, Louisiana chenier plain. Segments of coast between mudflats are generally eroding. Note shift in sedimentation to the west.

2) increasing length of shoreline fronted by mudflats, and 3) shift in the locus of sedimentation to the west. No attempt has been made to plot previous shorelines, and our contention is simply that the presence of mudflats indicates a prograding shoreline. The basic question from an engineering standpoint, given the fact that simultaneous erosion and accretion do occur and that the system of mudflats is enlarging and spreading to the west, is, "How can future sites of erosion and accretion be predicted?" To begin answering that question requires field data from the sediment source, the pathway along which the sediment is carried, and the segments of coast that receive the sediment. To date we consider our findings in these areas to be of a reconnaissance nature.

Sediment source: Atchafalaya River. Field research in Atchafalaya Bay has been in progress for several years (Roberts et al., 1980), with emphasis presently on circulation and sediment transport. Earlier reports by Thompson (1955), Cratsley (1975), Shlemon (1975), and Rouse et al. (1978) have provided additional information on processes and rates of sedimentation, environments of deposition, and the initial phase of subaqueous delta growth. Information used in this and subsequent sections was gathered from many sources, including publications and files of the U.S. Army Corps of Engineers (USACOE), suspended-sediment analysis, current meter moorings, and aerial and ground surveys.

The volume of water delivered to the continental shelf from Atchafalaya River and the concentration of sediment in that water are factors presumed to be important to the growth of mudflats on the chenier plain. At present, nearly all of the sediment supplied to the chenier plain appears to be derived from the Atchafalaya River. Figure 5 shows the volume of sediment-laden water carried down the Atchafalaya River from 1956 to 1975. Mean monthly discharge averaged 5,126 cms from 1938 to 1972 (USACOE, 1974) and average annual peak flow, as shown by the dashed line (Fig. 5) is approximately 12,000cms.

Abnormally high waters were characteristic of the years 1973-1975. Average discharge was 8,864 cms with peak flows of approximately 20,000 cms in April 1973 and 18,000 cms in April 1975 (USACOE, 1975). During this period of high discharge, the Atchafalaya Delta emerged subaerially and evolved rapidly (Fig. 6).

Sediments that enter Atchafalaya Bay consist of fine sand, silt, and clay. Suspended-sediment concentrations at five stations within the bay (Fig. 6) taken during high-water discharge in 1980 show typical values of 200-300 mg/l, with highest concentrations occurring in bottom water (Table 1). Size analysis from USACOE data (Roberts et al., 1980) shows that 75-78 percent of suspended sediment in the river near its diversion point from the Mississippi River is silt and clay, whereas 63 percent of the sediment that eventually enters the bay is silt and clay sized.

Over the past 20 years sediments entering the bay have changed from a dominance of silt and clay to silt and fine sand. It is important to note, however, that, despite the increase in coarse sediment (sand) entering the bay, the volume of fine sediment (clay) also increased, but at a slower rate. The annual load of silt and clay to the bay is 61×10^6 metric tons,

Figure 5. Mean monthly discharge from Atchafalaya River at Simmesport, Louisiana. Dashed line is average annual peak discharge.

or $146 \times 10^6 \text{ m}^3/\text{yr}$, using a mass to volume conversion of 425 kg/m^3 . Volumetrically, if one assumes that 80 percent of silt and clay leaves the bay for the inner shelf, then the shelf waters receive $117 \times 10^6 \text{ m}^3$ of fine-grained sediment each year.

The 3 years of abnormally high discharge (1973-1975) were also years of extreme sediment flux into and through the Atchafalaya system (Fig. 7). On average, annual suspended sediment (including sand) into the bay during

these 3 years was 11.1×10^6 metric tons ($261 \times 10^6 \text{ m}^3$), nearly double that during the period 1965-1971. These flood events may be important in the subsequent development of mudflats on the chenier plain in that they provide perturbations to the already enormous sediment supply.

Sediment transport: coastal mud stream. Evidence that sediments which enter the Gulf of Mexico from Atchafalaya Bay are transported to the

Figure 7. Total suspended load and silt and clay in suspended load during high discharge years 1973-1975.

west is provided by satellite imagery and current meter moorings. Figure 8 shows an ERTS Band 5 image that extends from Atchafalaya Bay to the eastern margin of the chenier plain. A turbid plume of water, shown as white, extends out from Atchafalaya Bay to a water depth of 5-10 m, then moves as a band along the south shore of Marsh Island and the western Louisiana coast. Similar bands of muddy water that originate from large rivers with high discharge of fine-grained sediments, such as those from the Mississippi, Amazon, and Po Rivers, have been referred to as mud streams (McCave, 1972) and we have applied this terminology to the Atchafalaya waters.

Current meter data taken at two stations seaward of Atchafalaya Bay in the spring of 1980 show residual currents to the southwest (parallel to the navigation channel) near the Point au Fer shell reefs and to the northwest farther out on the shelf (Fig. 9). Data at both stations are from mid-depth current meter moorings and were taken with Endeco 174 ducted-impeller, magnetic-recording current meters. Thirty-five days of data were obtained at station 1 and five days at station 2. Current speeds at station 1 are typically 10-30 cm/sec; direction of flow, although setting to the northwest, is influenced strongly by the passage of cold fronts every 5-7 days, which produce winds first from the southwest, then from the northwest. Current speeds at station 2 are 10-50 cm/sec and occur as well-defined pulses related to stage of the tide. Direction, however, does not reverse from tidal effects, but reflects a general flow to the south from Atchafalaya Bay with a strong westerly drift component from coastal waters.

Volume flux of silt- and clay-sized sediment into Atchafalaya Bay and onto the inner shelf is shown in Figure 10. To obtain an order-of-magnitude estimate of sediment transported northwest to the chenier plain, mass transport was calculated as

Figure 8. ERTS image (Band 5) of Atchafalaya Bay and central Louisiana coast taken in 1977.

$$T_M = \bar{c} \cdot \bar{v} \cdot A \quad (1)$$

where \bar{c} = average concentration of suspended sediment, \bar{v} = average velocity of residual current, and A = cross sectional area of the mud stream. Taking reasonable estimates of concentration (0.2 kg/m^3) and velocity (0.1 m/sec) through a 16-km-wide cross section normal to the coast resulted in a mass flux parallel to the coast of 640 kg/sec . To obtain an estimate of volume transport from mass transport,

$$T_v = T_m / \rho_c \quad (2)$$

was calculated, where ρ_c is sediment concentration of fluid muds in the nearshore and exposed as tidal flats (375 kg/m^3). When converted to transport per year, the volume of sediment moving in the Atchafalaya mud stream is $53 \times 10^6 \text{ m}^3$. This represents nearly one-half of the total sediment that leaves Atchafalaya Bay and is nearly an order of magnitude larger than longshore volume transport rates on high-energy sandy beaches.

Figure 9. Examples of current speed and direction taken seaward of Atchafalaya Bay (see Fig. 10) in spring 1980. Residual currents are shown on the inset.

Sediment accumulation: chenier plain. Upon reaching the chenier plain, sediments accumulate as mudflats and subaqueous pools of fluid mud in the nearshore region. The initial accumulation of muds in the 1940s was attributed by Morgan et al. (1953) to a decrease in current strength in the vicinity of Chenier au Tigre as a result of the NE-SW shoreline configuration (see Fig. 4). Whereas the early mudflats were concentrated near Chenier au Tigre, they did extend as far west as Rollover Bayou. However, during the following 15 years (1954-1969) the intensity of mudflat progradation appeared to decrease, and, according to Adams et al. (1978), only two small segments of coast showed progradation in this time period (Fig. 4). The rapid mudflat progradation began again between 1969 and 1974.

The time correlation between years of abnormally high river discharge (1973-1975) and renewed mudflat development suggests that accretion, at least at the shoreline, follows sediment pulses from Atchafalaya River flood waters. During the time period between major flood events, sediment reaching the chenier plain may be deposited more gradually on the inner shelf as a blanket of silts and clays. If one computes the volume of a typical mudflat as $1-2 \times 10^6 \text{ m}^3$, then 25-50 such mudflats could form each year from the $50 \times 10^6 \text{ m}^3/\text{yr}$ of sediment derived from the Atchafalaya mud stream. Since new mudflats do not form at this rate, much of the sediment from the Atchafalaya River may be deposited as a uniform thin veneer over a

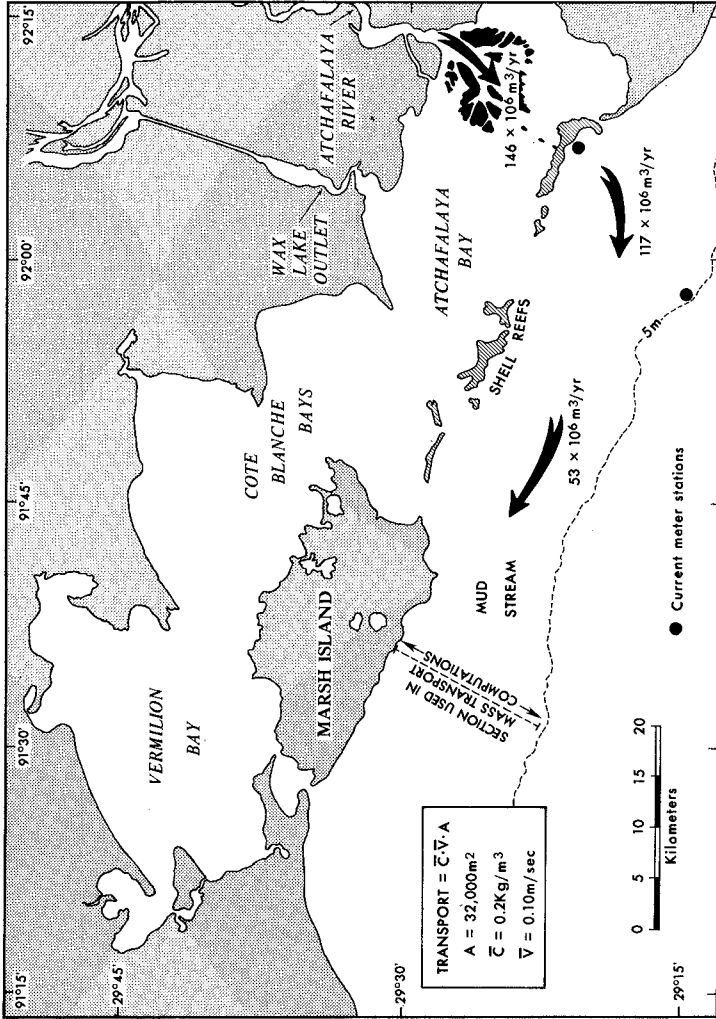

Figure 10. Central Louisiana coast showing computed values of volume flux of sediment into and through the Atchafalaya system. The coastal mud stream carries approximately 50×10^6 m³/yr of silt and clay to the chenier plain.

longshore distance of perhaps 100 km or more.

Longshore currents are responsible for transporting the muds to the west, as shown in Figure 4. These currents are driven by waves arriving at the shoreline from an angle. The most frequently occurring waves on the Louisiana shelf are from the southeast: 42 percent of all waves are 1-1.5 m high and arrive from the southeast with periods of 4.5-6.0 sec (Becker, 1972). Longshore transport of sediment to the west is consistent with currents induced by waves that arrive from the southeast quadrant. Generally, the wave climate is one of low wave energy at the shoreline (Fig. 11).

The clouds of turbid water that can be seen in color infrared photography, ERTS imagery, and aerial overflights are the result of soft, fluid mud which remains partly in a suspended state, even under low wave activity. Because of their low bulk density and high water content (Table 2), new muds are easily eroded and are often ephemeral features. Samples taken in May 1980 show that suspended-sediment concentrations between Freshwater and Rollover Bayous range from 25 to 200 mg/l in surface waters. The input of suspended sediment from local sources on the eastern chenier plain is low, and the sediments in suspension, in addition to being caused by wave scour, reflect the high turbidity of the Atchafalaya mud stream. Field reconnaissance and sampling have revealed areas of dense suspension near bottom and, on occasion, a poorly defined water-sediment interface.

Predicting Future Trends

The basic hypothesis proposed in this study is that, if the dynamics of fluid muds in the inner-shelf environment can be understood, particu-

Figure 11. Spectrum of 6-sec waves from the southeast off Freshwater Bayou.

TABLE 2.--PROPERTIES OF COASTAL MUDS, LOUISIANA CHENIER PLAIN

larly the question of where they accumulate and why they move, then areas of future erosion and accretion can be predicted. This hypothesis is based on the following rationale. First, wave energy is strongly attenuated when waves propagate over fluid muds; therefore, accumulation of muds on the inner shelf, such as at the "mud hole" (Morgan et al., 1953), will result in less wave attack at the shoreline itself (Fig. 12). Thus, segments of coast landward of fluid-mud accumulations should be areas of accretion as a result of the more favorable environment for fine-grained sedimentation. Second, fluid muds in the nearshore may periodically move onshore to become "shore-attached," thus causing the shoreline to prograde.

The rate of loss of wave energy on the inner shelf has been quantified from a similar environment in northeastern South America, where fluid muds blanket the bottom in layers 0.1-1.0 m thick (Wells, 1977). Figure 13 shows wave spectra constructed from simultaneous wave records taken at 22, 11, and 4 km offshore. By the time waves reach the station 4 km from shore in a water depth of 1.6 m, 94 percent of their energy has been lost. The shelf gradient in northeast South America is 0.0008, very close to the 0.001 gradient on the western Louisiana shelf. Often, waves never reach the shoreline, but are simply attenuated to nonexistence, without breaking (Wells, 1977; Wells et al., 1979). This sediment-water interaction is a true process-response relationship; muds attenuate waves,

Figure 12. Small waves propagating over a mudflat west of Freshwater Bayou.

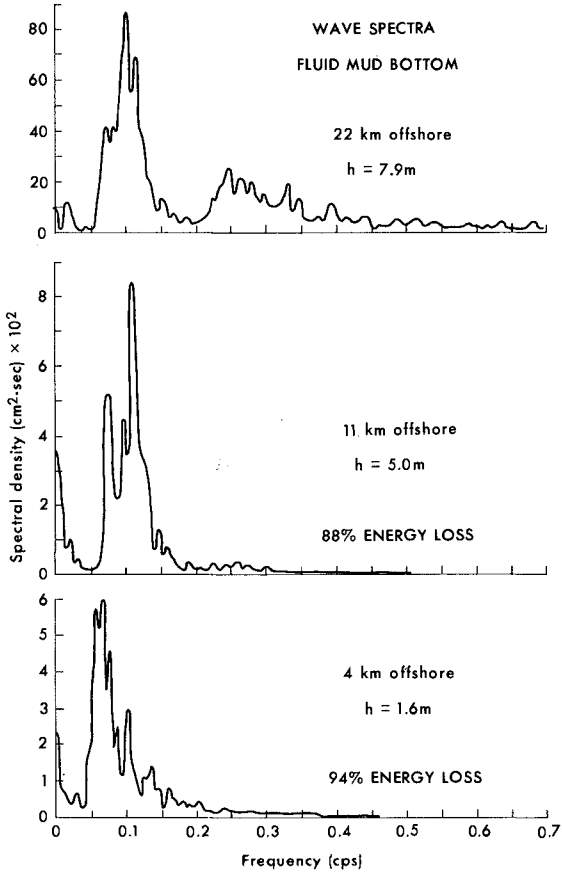

Figure 13. Wave spectra from simultaneous wave records taken off the coast of Surinam, South America. Bottom was blanketed by fluid muds similar to those in Louisiana.

which, because of their energy loss, allow even further sedimentation.

The mechanics of the process whereby muds move ashore are unknown, but have been suggested from results of research in other similar environments. Wells et al. (1979) have proposed that nonlinearity of shallow-water waves over soft muddy bottoms may produce a net drift in the direction of wave travel, thereby moving mud toward shore. The angle of wave

approach controls the magnitude of the longshore component, hence the ability to translate muds alongshore, even if waves do not break as spilling or plunging breakers. Others have suggested that inner-shelf circulation may carry highly turbid bottom water shoreward and less turbid surface water seaward, thus "trapping" muds in the nearshore (Cibbs, 1976), and still other researchers have explained mud accumulation on tidal flats as a result of settling lag (Postma, 1954) and scour lag (Van Straaten and Kuenen, 1957).

Once muds are exposed subaerially and begin to dewater, they gain strength rapidly. Figure 14 shows a plot of bulk density versus apparent viscosity for fluid muds in northeastern South America. A small linear increase in density as a result of dewatering and consolidation can lead to a large (exponential) increase in viscosity, which is related to sediment strength (Krone, 1963; Owen, 1970). If muds are exposed to conditions of drying and continue to dewater until density reaches 1.20-1.25 g/cm³, then shear strength may be sufficient to withstand normal wave attack. Coincident with this early stage of consolidation, vegetation becomes established. Barring catastrophic storm events, vegetation will flourish, and within a year the new mudflat will become permanently attached to form a wedge of Holocene sediments.

Figure 14. Plot of bulk density versus apparent viscosity in fluid muds from northeastern South America.

The process of mudflat sedimentation described above is altered significantly during major storms and the passage of hurricanes. For example, storm waves associated with Hurricane Audrey in 1957 caused higher than normal retreat rates on the western chenier plain, yet produced in only a few days' time near Freshwater Bayou two mud arcs 300 m wide, 2 m thick, and a total of 7200 m long (Morgan et al., 1958). At present we are unable to predict the effects of storms and hurricanes on coastlines fronted by fine-grained sediments.

Segments of coast between mudflats are typically eroding (Fig. 15), and the processes of erosion and accretion are cyclical in both time and space. Because of this cyclical nature of mudflat development, areas of future erosion and accretion have been predicted with moderate success in northeastern South America (Delft Hydraulics Laboratory, 1962; NEDECO, 1968) by studying locations of fluid mud accumulations. As in coastal Louisiana, conditions that favor fine-grained sedimentation in northeastern South America are 1) large supply of fine-grained sediments, 2) prominent westward drift, 3) strong wave attenuation, 4) shoreward movement of fluid muds, and 5) consolidation and increase in shear strength. Using this knowledge, studies are presently underway in Louisiana to locate and track fluid muds in the nearshore, and it is anticipated that future research into details of how fluid muds move will refine our predictive capabilities.

NEARSHORE SEDIMENT TRANSPORT STUDY EXPERIMENTS
R. J. Seymour* and C. G. Gable**

INTRODUCTION

The Nearshore Sediment Transport Study (NSTS) is a multi-institutional research program with the objective of developing improved engineering predictive models for transport of sediment, both longshore and cross shore, by waves and currents. The program is sponsored by the Office of Sea Grant (OSG), an agency of the National Oceanic and Atmospheric Administration (NOAA). A general introduction to the objectives, schedule and organization of the NSTS program was presented at the 16th ICCE by Seymour and Duane (1979). Shortly after the Hamburg Conference, the first major field experiment was conducted at Torrey Pines Beach, California, in November, 1978. The second major experiment was conducted 14 months later in February, 1980 at Leadbetter Beach, in Santa Barbara, California. Each of these experiments involved levels of measurement intensity that appear to exceed by a large factor those of any similar work. Because of the large data sets obtained and the importance of these data to other investigators in coastal processes, the NSTS project is making them available promptly. In the following sections, a general description will be given for each of these experiments and information supplied on how the data may be obtained.

TORREY PINES BEACH EXPERIMENT, NOVEMBER, 1978

Torrey Pines Beach, north of the Scripps Institution of Oceanography (SIO) in La Jolla, CA, is a straight and regular beach, as shown in Figure 1. This regularity was considered a significant advantage for the initial experimental site, as was its proximity to SIO. The wave climate and beach response characteristics had been well studied and it was possible to select a month for the experiment when there would be a high probability of large waves, but prior to the extreme winter storms.

An instrumentation plan was developed by E. B. Thornton of the Naval Postgraduate School, R. T. Guza and S. S. Pawka of SIO to define the dynamics of the shoaling waves and of the surf zone. The arrangement adopted for Torrey Pines is shown in Figure 2. In this figure, the mean sea level intersection with the beach is at approximately 90 meters offshore of the arbitrary origin, and the typical breaker line is at about 180 meters during high tide. Therefore, it can be seen that the instrumentation extended several surf zone widths seaward, but with the highest density of instruments in the breaking zone and shoreward.

The incident wave climate was measured with a 5 element linear array of pressure sensors at a depth of about 10 m. The array spacing was 2-2-2-5 with a 33 m. unit spacing. The linear array allowed the calculation of a directional spectrum so that the wave field could be refracted shoreward to any desired location. A main shore normal instrument line was established that is labelled SID4 in Figure 2. A shore normal array of pressure sensors, wave staffs and two-axis electromagnetic current meters was installed which extended shoreward to include a resistance type runup meter in the swash zone. A second, shore parallel, array of current meters was installed at a depth of approximately 0.6 m below MSL. A total of 22 current meters was employed, 20 of them in fixed locations within the instrument grid. Two current meters were arranged in portable frames which could be installed in locations suitable for obtaining measurements of rip currents. These measurements were made by R. A. Dalrymple of the University of Delaware. Ten pressure sensors and seven wave staffs were deployed, as well as an anemometer mounted on a tower on the beach. These instruments, as well as the 20 fixed current meters and the runup meter, were installed and operated by Thornton, Guza and Pawka.

During the experiment, R. W. Sternberg of the University of Washington deployed two prototype instruments for measuring suspended sediment. One operated on the principle of changing the natural frequency of a vibrating element with changing sediment concentrations. The second unit measured concentrations by determining the number of sediment grain impacts with a small sensing whisker. A third experimental suspended sediment meter was evaluated by D. L. Inman and R. E. Flick of SIO. This instrument measured backscatter from a polarized laser.

The data gathering and recording system used at Torrey Pines was developed by the Shore Processes Laboratory (SPL) at SIO. Signals from the deep water instruments were telemetered directly to SPL using a battery powered shelf and shore station at the linear array. Other instruments were cabled to the beach and then telemetered to SIO. Data were sampled at 64 hz from all instruments and were PCM encoded. The PCM data were transmitted by telemetry link and recorded on a 7 track tape recorder at SIO. Data runs were approximately four hours in duration on each of the 20 experiment days. When the data were converted to computer compatible tapes at a later time, the sampling rate was reduced to 8 hz by block averaging 8 adjacent data values. This resulted in a data output of nearly one-half billion words.

The principal emphasis of the Torrey Pines experiment, in contrast to later field work, was on characterizing the surf zone dynamics. However, a number of sediment

transport observations were made as well. D.L. Inman of SIO conducted three longshore transport experiments using dyed sand tracers which were timed to coincide with data runs. These experiments covered a variety of wave conditions. Suspended sediment measurements were made using a water column coring device. The amount of tracer in the bed, and its depth of burial, was determined from analysis of sediment cores taken using various spatial and temporal sampling schemes. Some results of this work are contained in Inman et al. (1980). Both the water column and the bed coring devices were developed by SPL.

Beach morphology changes were measured by R.J. Seymour of SIO. The ten ranges shown on Figure 2 were surveyed to wading depth every second day. The main range (SIO4) was surveyed daily. In addition, these ranges were extended to a depth of 10 m twice during the experiment using a boat mounted fathometer with electronic navigation. All of the beach profile and bathymetric data were digitized and recorded on magnetic tape. The beach changes included a number of erosional and accretional events associated with variations in the incident wave climate. These provide a data set on cross shore transport which can be correlated with the forcing functions obtained from the surf zone dynamics measurements.

Drift kelp was a major problem in this experiment. Particularly after an event of large waves, the mats of kelp could exceed 100 kg in weight and were capable of damaging or destroying any of the surf zone instrumentation. Guza and Thornton developed a breakaway mount for the current meters which allowed them to survive the kelp onslaughts and also devised a scheme for rapidly reinstalling and realigning the meters after the kelp was removed. Precise alignment of the two axis meters was critical in shallow water since wave approach angles are quite small, approaching the directional resolution of the meter. A storm midway through the experiment carried away all of the wave staffs and they were not replaced. However, all of the current meters were returned to service.

THE TORREY PINES DATA

One of the guiding policies of the NSTS program is that the experimental data be made available to the public promptly. The investigators are allowed 18 months after the completion of an experiment to analyze their data and to publish their findings. A large fraction of this time is spent in sorting out the records and editing the raw data. In July, 1979, NSTS sponsored a workshop at La Jolla in which the preliminary results of the Torrey Pines experiment were presented. In December, 1979, a comprehensive experiment report was published (Gable

[1979]). This report contained complete descriptions of the experiment site, the environmental conditions, the instrument locations, types and calibrations, and sufficient information to allow other investigators to extract meaningful data from the data tapes. In March, 1980, an announcement was made at the 17th ICCE that the data tapes were available to the general public. This was accomplished on schedule, 18 months after the experiment. The data require eight 2400 foot 9-track magnetic tapes. They include the profile data and the suspended sediment data from Sternberg's instruments as well as all of the surf zone dynamics measurements. The data from Inman's tracer studies, which could not be readily presented on tape, are included as an appendix to the experiment report.

Investigators wishing to acquire the Gable report or copies of the tapes should contact

THE SANTA BARBARA EXPERIMENT

A site selection study, conducted by R.G. Dean of the University of Delaware, recommended that the second NSTS experiment be conducted at Leadbetter Beach in Santa Barbara, CA. The second experiment was to place heavier emphasis on the measurement of sediment transport than the first, and Santa Barbara was selected principally because of the very satisfactory sediment trap provided by the harbor. As shown in Figure 3, Leadbetter Beach is a feeder beach for the sandspit formed in the shadow of the breakwater. The accumulation of sediment within the harbor is bypassed by intermittent dredging. The Santa Barbara experiment began in September, 1979 with the initiation of a year long trap study. The intensive experiment period, comparable to the Torrey Pines experiment, was conducted during the month of February, 1980. The experiment was directed by R.G. Dean for the sediment transport measurements and by R.J. Seymour for the wave climate measurements. The accumulation of sediment was measured at approximately six week intervals with profiles extending from the dry beach to a depth of approximately 10 m. These profiles were run at 50 m spacing along the feeder beach, the breakwater and the sandspit, as shown in Figure 4. Wading surveys were made on the shallow end of the profiles with the deep water portion conducted by fathometer surveys using an electronic location system on the boat. The incident wave climate was measured at least every six hours for the one year period of the experiment. Two slope arrays of the type described in Seymour et al. (1980) were

AERIAL VIEW OF SANTA BARBARA,

NSTS EXPERIMENT IN FEBRUARY 1980
AS SHOWN ABOVE THE HARBOR.

FIGURE 3

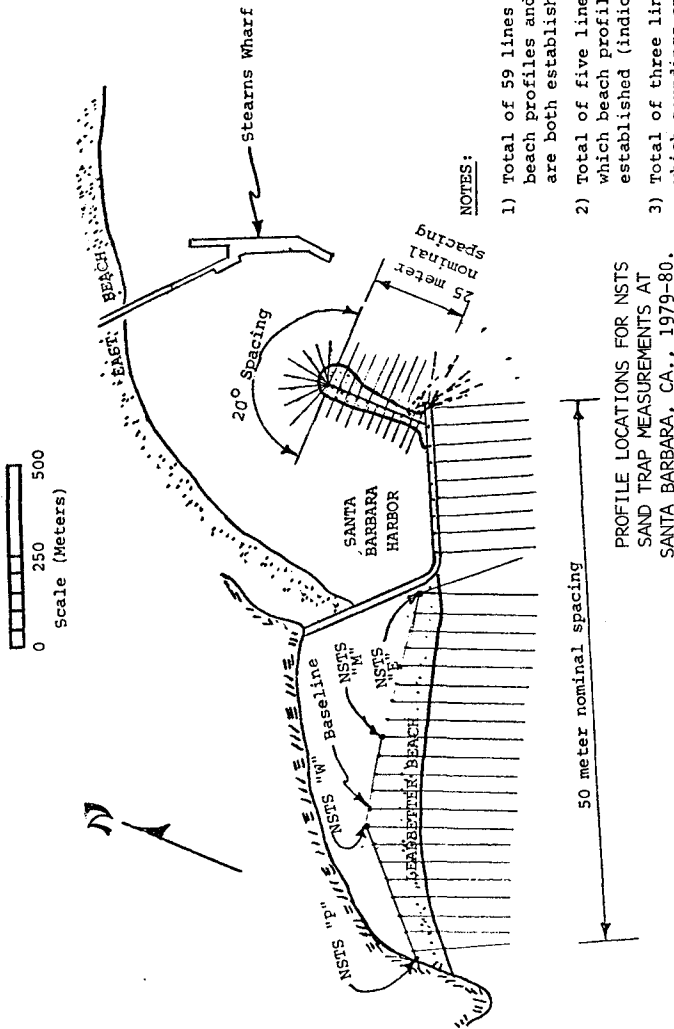

FIGURE 4

installed. These directional arrays provide a moderately well defined directional spectrum and well defined estimates of the longshore radiation stress. The wave data is collected automatically over telephone lines using the system described in Seymour and Sessions (1976) and is recorded at La Jolla.

During the February intensive experiment the instrument location plan followed the Torrey Pines scheme as shown in Figure 5. R. T. Guza and E. B. Thornton were again responsible for the surf zone dynamics measurements with R. A. Dalrymple making the rip current measurements. Twelve current meters were installed in the main cross shore range line and five meters were used in the longshore line. One other current meter was permanently installed, two were moveable for rip current measurements, and three were used for swash zone measurements. In addition to the eight pressure sensors in the slope arrays shown in Figure 5, there were seven additional pressure sensors in the cross shore main range line. Two still water level reference gauges were also installed in this line to measure setup.

In the Santa Barbara experiment, particular emphasis was placed on measurements in the inner third of the surf zone. Special portable space frames were developed to support instruments in very shallow water. These frames are shown in Figure 6. Typically, one frame would mount a two-axis current meter, a resistance type wave height probe, and two types of sediment concentration meters developed by R. W. Sternberg. The first of these was a refinement of the impact whisker type deployed at Torrey Pines. The second was a new miniaturized optical backscatter instrument with five sensors mounted at various heights off the bottom.

Measurements of integrated longshore current were obtained by R. E. Flick using a conventional metallic conductor GEK system and also a prototype seawater conductor unit. D. L. Inman and R. L. Lowe of Scripps Institution of Oceanography deployed a prototype bedload sensor employing three downward looking sonars. One sonar senses the bed thickness by discriminating the horizons at the sand surface and at the bottom of the moving bed. The other two, which look at the bottom at an angle, detect bedload speed components by Doppler shift. In addition to the swash zone instruments described earlier, R. W. Sternberg deployed two stacked 5 element suspended sediment meters of the backscatter type in deeper water.

Beach profile changes were measured by R. J. Seymour and by D. G. Aubrey of Woods Hole Oceanographic Institution. Five ranges were surveyed at least daily using wading survey techniques. In addition, an automatic profiling tractor was deployed to obtain continuous surveys to depths of 6 m. This vehicle is described in Seymour, et al. (1979).

The first two weeks of the month long experiment were characterized by moderate to low waves with high angles of incidence so that the longshore currents tended to be strong at all times. Midway in the experiment a storm of very unusual intensity attacked the site for about one week, resulting in severe erosion to the beach as shown by the profiles in Figure 7. During the high wave episode, which was also marked by exceptionally strong longshore currents, drift kelp necessitated the removal of all but the deepest instruments. The wave measurement system continued to function throughout the experiment.

D.L. Inman and R.E. Flick conducted seven tracer studies during this experiment. Four were before the storm and three were in the week following the storm when the beach had been flattened and narrowed considerably. These studies followed the methodology utilized at Torrey Pines.

At Santa Barbara, the data were all cabled directly to the recording system which was housed in a trailer adjacent to the beach. Because of increase in the number of channels of instrumentation and because of longer data runs, almost a billion words of data were recorded -- roughly twice that at Torrey Pines.

SANTA BARBARA DATA

An experiment report and copies of the raw data tapes are expected to be available through the National Oceanographic Data Center in August 1981 for this experiment.

FUTURE EXPERIMENTS

The NSTS program plans one more major field experiment, patterned on the one at Santa Barbara, but on the eastern coast of the United States. The intensive portion of this experiment is tentatively scheduled for the fall of 1981. This third major experiment is expected to add a valuable data set on a barred coastline with steeper waves.

A SEDIMENT TRAPPING EXPERIMENT AT SANTA CRUZ, CA.

R. J. Seymour*
G. W. Domurat**
D. M. Pirie***

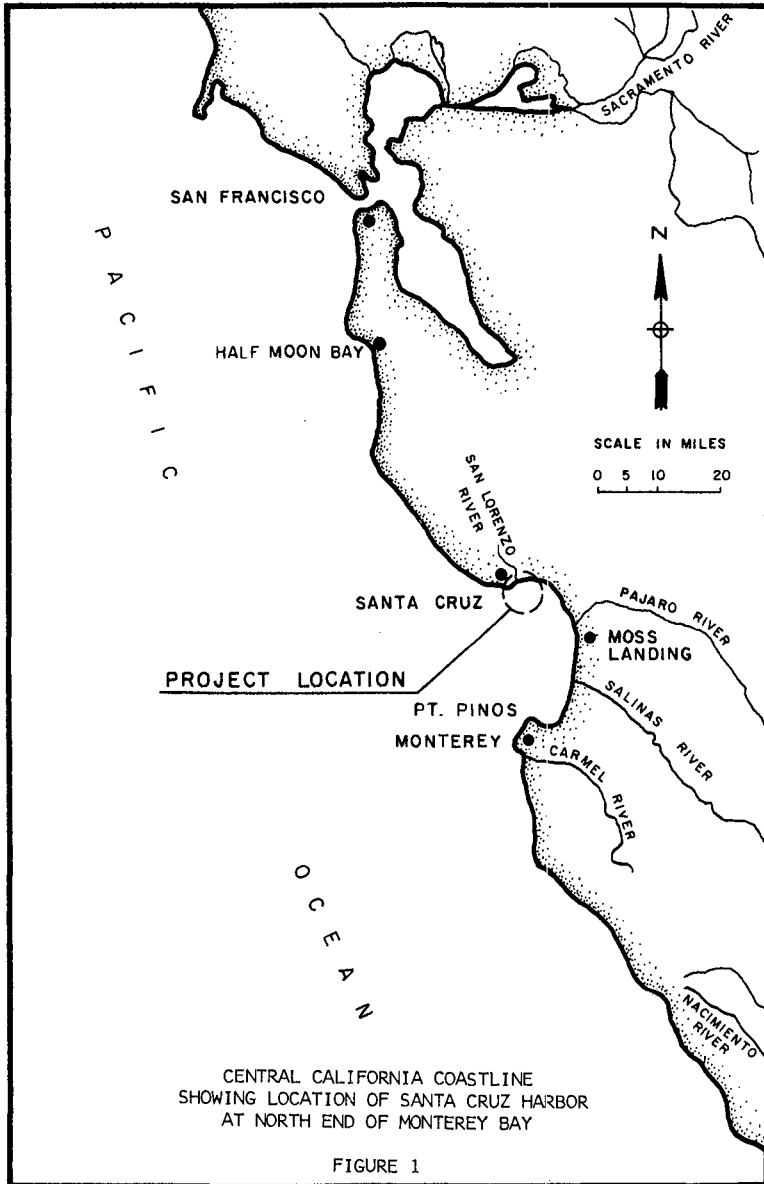

INTRODUCTION

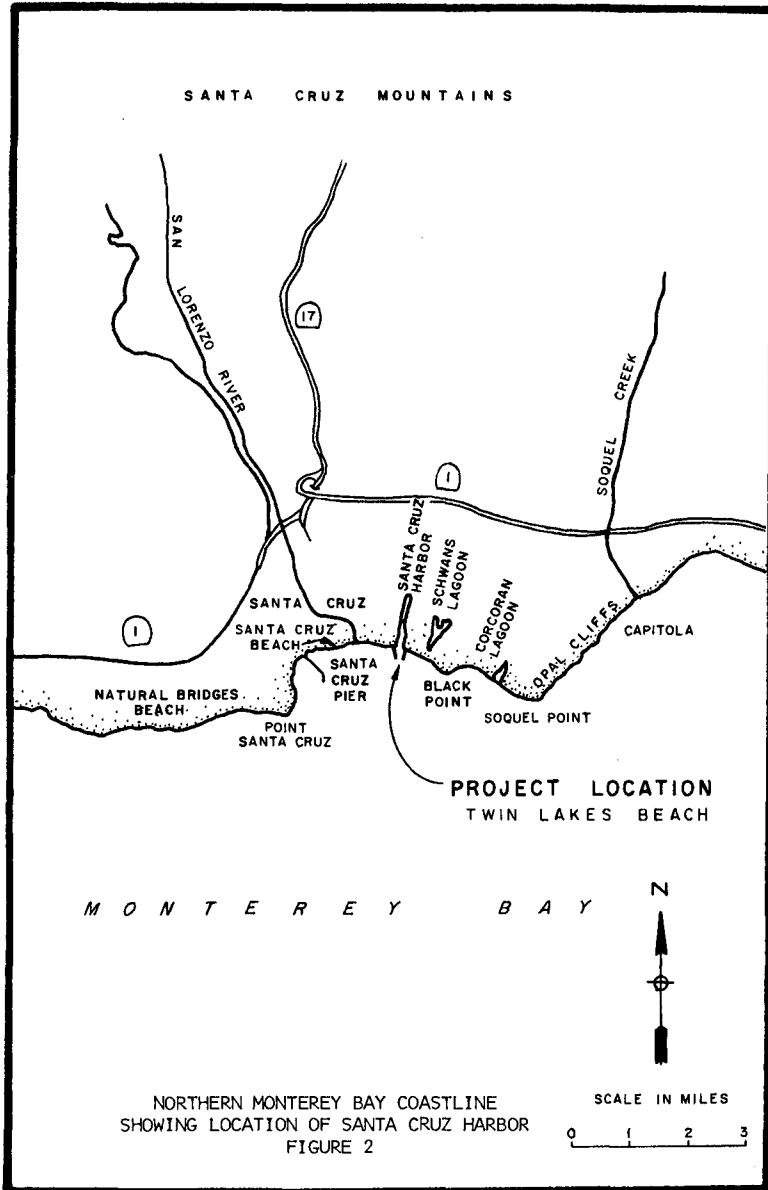

Santa Cruz Harbor is located on the northern coast of Monterey Bay, California, approximately 104 kilometers south of San Francisco and 22 kilometers north of Moss Landing, as shown in Figures 1 and 2.

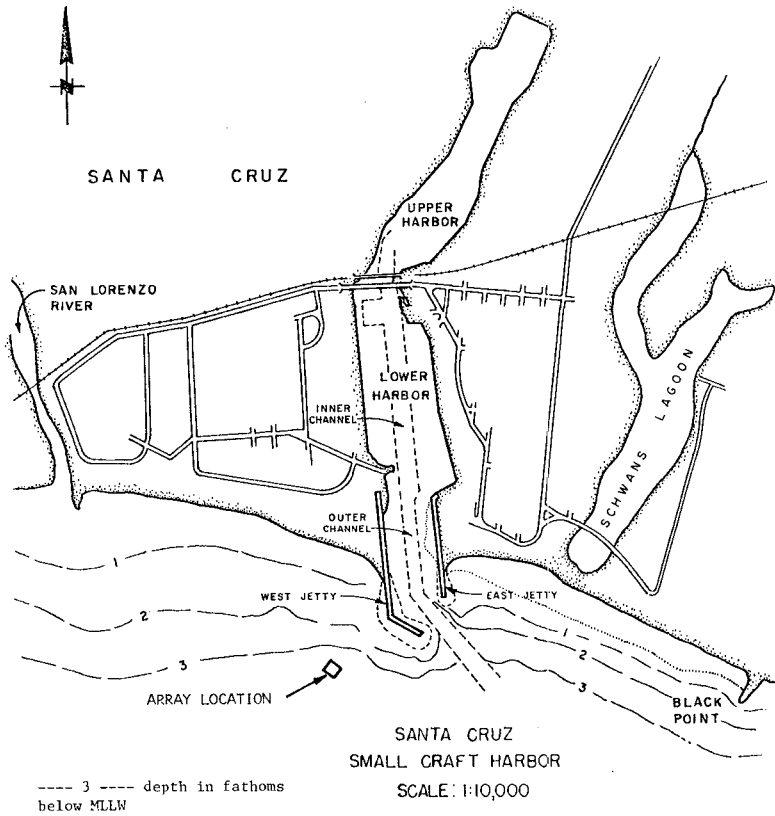

Harbor construction was authorized by Congress under the Rivers and Harbors Act of 1958, which provided for a harbor to accommodate light-draft vessels in Woods Lagoon at the eastern boundary of Santa Cruz. The authorized improvements included two rubblemound jetties 360 meters long and 243 meters long, on the west and east sides of an entrance channel, respectively -- an entrance channel approximately 270 meters long, 30 meters wide and 6 meters deep, reducing to 45 meters in depth at the same width for an additional 111 meters -- an inner channel, 240 meters long, 45 meters wide, 45 meters deep, reducing to 3 meters in depth at the same width for an additional 100 meters -- a turning basin approximately 90 meters long, 75 meters wide, and 3 meters deep, and a sand-bypassing plant. Figure 3 shows the project features. The armor units of the seaward side of the west jetty are 28-ton quadripods. The west jetty also has a concrete cap extending to elevation +4.8 meters MLLW.

Construction of the harbor was initiated in February of 1962 with the dredging of Woods Lagoon and the start of work on the west jetty. The west jetty was completed in February 1963. Then work began on the east jetty, and it was completed in April 1963. The entrance channel was dredged to the project dimensions in the summer of 1963. Construction of Santa Cruz Harbor was completed in November 1963, with the exception of the sand-bypassing plant. Construction of the sand-bypassing plant was deferred until the littoral drift rate could be more accurately determined.

PLAN OF SANTA CRUZ HARBOR
SHOWING WAVE GAGE ARRAY LOCATION

FIGURE 3

During and subsequent to construction of Santa Cruz Harbor jetties, the beach west of the jetties experienced rapid accretion, building out from the 1962 pre-project shoreline about 75 meters by 1965 and about 150 meters by 1977. The growth of the beaches has protected the bluffs along East Cliff Drive from rapid erosion by wave action. Soon afterward, substantial littoral transport during winter months would shoal the entrance to the harbor closing it to all vessel traffic.

In 1977, the U.S. Corps of Engineers undertook a study of the shoaling problem with the purpose to develop and evaluate alternative methods of mitigating the shoaling effects. The study defined the coastal processes and the resultant shoaling mechanism at the harbor entrance. The littoral processes study led to the conclusion that the net littoral transport rate was 230,000 cubic meters to 382,000 cubic meters per year from west to east. Shoaling of the channel has required annual maintenance dredging reported to be on the order of 76,400 cubic meters per year since 1965.

Estimated littoral transport rates used by Walker, et al. (1978) indicated that a potential for reversals in transport exists but that shoreline east of the harbor was so oriented that these reversals during the winter months were not likely to cause significant shoaling in the channel.

DEEPWATER WAVE CLIMATE

The waves arriving at Santa Cruz can be divided into three categories according to origin:

Northern Hemisphere swell, Southern Hemisphere swell, and seas generated by local winds.

The geometry and bathymetry off Santa Cruz allow swell to approach from the south clockwise through west-northwest, whereas locally generated seas can approach from the east clockwise through west-northwest. The following description of the wave climate is taken from Marine Advisors (1961).

Northern Hemisphere Swell. Most of the wave energy reaching Santa Cruz is from Northern Hemisphere swell generated primarily by extra-tropical cyclones in the northern Pacific. These cyclones, also referred to as Japanese-Aleutian storms, typically originate in the vicinity of Japan and move eastward across the higher latitudes to the Gulf of Alaska. These storms are most prevalent and intense during the winter and spring seasons. Infrequently, storms originating in the vicinity of the Hawaiian Islands move eastward across the mid-latitudes and

produce swell that reaches Santa Cruz. However, this southwesterly swell is rarely as large as that produced by the Japanese-Aleutian storms. Tropical storms and hurricanes, called chubascos, which develop off the coast of Mexico, during the months of July through October, rarely move as far north as Southern California, although they do generate moderate swell that reaches most of the California coast.

Southern Hemisphere Swell. During the austral winter, storms of great intensity and size occur in the high and mid-latitudes of the southern Pacific. The storms are comparable with the extra-tropical storms of the Northern Hemisphere but are often more severe. Swell generated by these storms occur from May through October, but are most common during August and September. Because of the great decay distances, these waves have low heights and long periods when they reach Santa Cruz. Typical southern hemisphere swell has heights between 0.3 and 0.9 meters and periods ranging from 13 to 21 seconds. These waves approaching Santa Cruz are from the south through southwest.

Data collected by the wave gage array for 1978 is summarized in Figure 4. This figure presents the measured height and period distribution functions.

POTENTIAL SEDIMENT SOURCES

The shoreline region lying northwest of Santa Cruz, extending from Half Moon Bay to Point Santa Cruz, comprises sea cliffs and small pocket beaches which occur mostly at the mouths of small creeks. Wave-induced erosion of the sea cliffs is a possible source of littoral material at Santa Cruz. Sea cliffs comprise shale and cretaceous sediments in most of the southern two-thirds of this reach. However, these sediments may not be the significant contributors of beach material at Santa Cruz. Marine terrace deposits overlay the sea cliffs along the southern two-thirds of the region and may be the primary contributors of beach material.

Drainage in the region is typified by short, steep-gradient streams originating in the Santa Cruz mountain range. Near the ocean, the rivers have the character of drowned river valleys. The streams have small drainage areas, and flows are characterized by flash floods. No deltas are found offshore because the wave climate rapidly removes sediment and distributes them along the beach and offshore.

The reach of shoreline between Point Santa Cruz and Soquel Point includes Santa Cruz Beach, the San Lorenzo River, and stretches of sea cliffs. The San Lorenzo River, 0.8

SANTA CRUZ HARBOR JAN-DEC 1978

kilometers west of Santa Cruz Harbor, has a drainage basin of 355 square kilometers and an annual runoff of 0.1541 cubic kilometers. The heaviest runoff occurs during the winter months, October through April. Estimates made by the Corps of Engineers (1974) indicate that the annual sediment discharge of the San Lorenzo is between 67,232 and 101,612 cubic meters. Of this total, 20 percent, or 13,725 to 20,628 cubic meters was assumed to be of sand sizes found on beaches in the study area.

Offshore of the project site is a narrow continental shelf which drops off into the Monterey Canyon located in the middle of Monterey Bay. Figure 5 shows the general bathymetric features of the Santa Cruz embayment. The beach slopes steeply to the 6 meter depth contour, then slopes very gently to the south. The bottom comprises hard rock outcroppings which are partially overlain with unconsolidated sediment.

WAVE MEASUREMENT SYSTEM

In February, 1978 a directional wave measurement array was installed near the harbor entrance to assess the forcing function for longshore transport. Scripps Institution of Oceanography (SIO), under contract to the San Francisco District, U.S. Army Engineers, added this installation to the network of wave measurement stations as described in Seymour and Sessions (1976). The point of measurement is at a depth of 7 meters approximately 100 meters west, or updrift, of the jetties.

The wave measurement system consists of a directional array, a shore terminal containing suitable electronics to allow for remote automatic data logging and analysis, and the necessary interconnecting cable. The array is a square steel space frame, 6 meters on a side, with short vertical risers at the corners. At the top of each riser is a cylindrical container capable of storing approximately 15 meters of three conductor waterproof cable. Attached to these cables are pressure sensor instruments in waterproof housings. External pressure is transmitted to the instrument by means of an oil filled diaphragm. The use of the long cable allows divers to bring the pressure sensors to the surface, remove them for service or replacement, and reconnect the new instrument using reliable connectors that cannot be reconnected under water. The diaphragms are protected from marine growth by a pad of copper gauze coated with antifouling paint and contained in a perforated cap. The frame, which is made of steel pipe, serves as conduits for all branch cabling so that no cables are exposed after the system is installed. The main power and signal cable is polyurethane jacketed with internal steel armor and is strain relieved at the frame. The density of the cable is sufficient to insure rapid self burial under

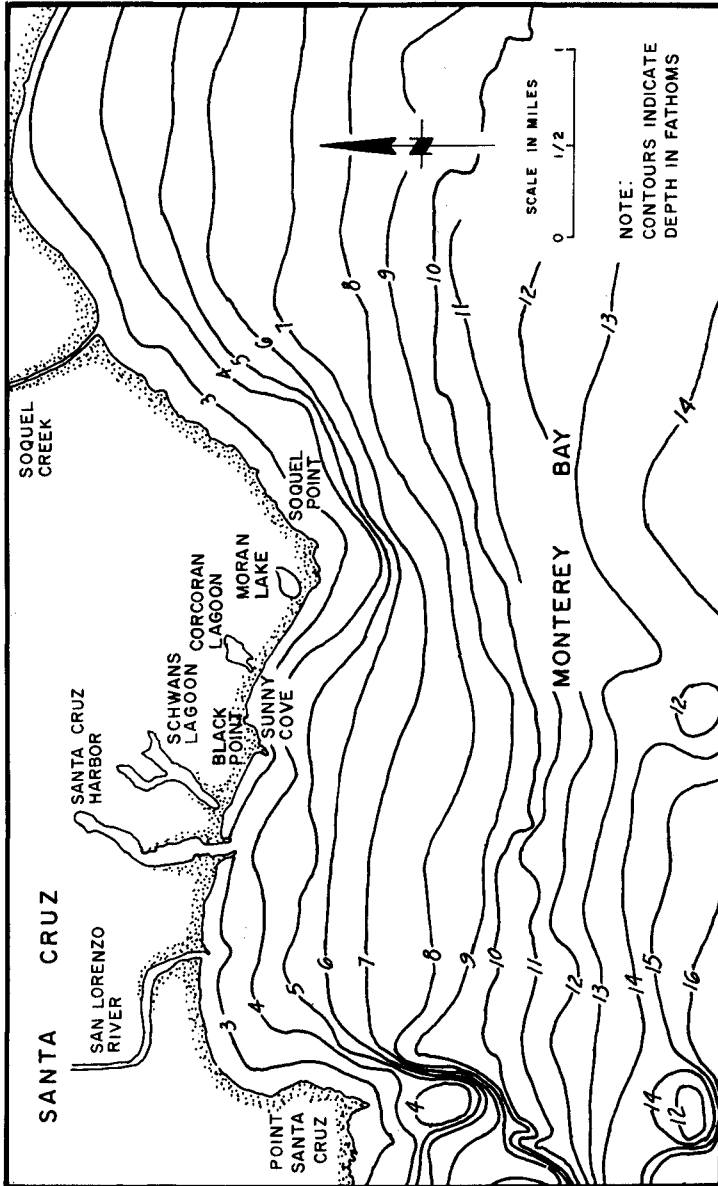

FIGURE 5 BATHYMETRIC FEATURES IN SANTA CRUZ REGION

even moderate wave conditions. Experience during several severe winter storms has shown that the cable will remain buried even during periods of gross beach erosion. The cable is trenched into the sand with a backhoe above the high water line. Figure 6 shows an array frame on the stern of a LARC amphibious truck prior to being towed to its installation site.

The shore terminal is a weatherproof enclosure, approximately one meter square containing the interface electronics. The analog output of each pressure sensor is converted to a frequency modulated signal within the sensor housing so that there are no line losses or distortion to contend with in the cable. This FM signal is then converted to a digital output sampled at 1 hz within the shore terminal for each sensor output. All sensors are sampled simultaneously so that phase relationships are accurately preserved for directional analysis. The digitized pressure values are stored in solid state memory using a pushdown scheme that retains the most recent 1024 values. This allows for storing slightly more than 17 minutes of data for each sensor.

The shore terminal is connected to an ordinary telephone line with a data coupler. When the assigned telephone number is dialed, the control circuitry locks the data in the memories, and transmits an identifying code followed by the data stream. The entire contents of the four memories are transmitted in less than one minute. Data are received by a dedicated computer at SIO and, after transmission quality checks, are written to magnetic tape. If the computer detects unusable data it will recall the station. If telephone company circuit overloads prevent a completed call after three attempts, the system will move that station to the end of the calling queue for a later attempt.

Wave data were collected at ten hour intervals during 1978 and part of 1979. During the fall of 1979, the interval between data runs was reduced to 6 hours.

DATA ANALYSIS METHODS

Longuet-Higgins, et al. (1963) shows that an estimate of the longshore component of the radiation stress, S_{xy} , can be obtained from knowledge of the surface elevation and the components of sea surface slope at a point. This methodology was developed for use with a pitch and roll measuring buoy in deep water but is equally applicable to shallow water if a method exists for measuring the slope components. In the present scheme, the components of sea surface slope are obtained from the differences between pairs of sensors. The components are rotated to a

DIRECTIONAL WAVE ARRAY FRAME
MOUNTED ON LARC VEHICLE PRIOR TO
BEING TOWED INTO POSITION. OIL
DRUMS ARE TEMPORARY FLOTATION.

FIGURE 6

coordinate system based upon the local onshore and longshore directions as determined by smoothing the bathymetry in the vicinity of the array. Since the estimate of S_{xy} is formed by cross-spectral analysis, the difference fourier coefficients can be corrected from pressure differences to surface elevation differences by linear wave theory, as described in Seymour and Higgins (1978).

Each data run obtained from the slope array is analyzed using the computer at La Jolla. The analysis products include:

- Significant wave height
- Period of peak energy
- Distribution of energy by frequency (energy spectrum)
- Distribution of S_{xy} by frequency

These statistics are published monthly and are made available to any investigators concerned with the study area. Figures 7 and 8 show typical examples of the analysis summaries for wave energy and S_{xy} .

The most commonly used estimator for longshore transport is the Bagnold-Inman-Komar model which is reported with the most recent values of the empirical coefficient in the CERC Shore Protection Manual. Seymour and Higgins (1978) shows that this formulation can be readily transformed so that transport is proportional to S_{xy} and to the square root of the significant wave height, resulting in an equation of the form:

$$Q = k S_{xy} (H_s)^{1/2} \quad (1)$$

where Q is the longshore mass transport,
 k is the proportionality coefficient,
and H_s is the significant wave height.

The assumptions embodied in Eq. (1) include:

1. The bathymetry between the measurement point and the breaker line is regular. Since the measurement point is in relatively shallow water, this is a reasonable approximation on almost all beaches. This assumption allows for conservation of S_{xy} .
2. S_{xy} is conserved to the break point.
3. The depth at breaking can be estimated from the significant wave height at the measurement point.

The advantage of the slope array for applications where sediment transport estimates are required is immediately

TYPICAL DATA ON WAVE DIRECTIONAL
CHARACTERISTICS AT SANTA CRUZ
HARBOR. FROM APRIL 1980 MONTHLY
REPORT OF CALIFORNIA COASTAL
DATA COLLECTION PROGRAM.

FIGURE 8

apparent. This system produces an unbiased estimate of S_{xy} which can be readily converted to estimates of longshore transport by eq. (1). In theory, S_{xy} can be calculated from a knowledge of the directional spectrum. However, as shown in Higgins, Seymour and Pawka (1980), linear arrays designed to give good definition of directional spectra yield biased estimates of S_{xy} . Since linear arrays are characteristically much larger than the slope array and cannot be prealigned on the shore, they tend to be much more expensive to install. The slope array system offers, therefore, an inexpensive alternative which sacrifices some definition of the full directional spectrum to achieve the best definition of S_{xy} .

MODEL FOR SEDIMENT IMPOUNDMENT

Since the harbor is dredged to contract limits approximately at yearly intervals, at the end of the winter maintenance dredging season, the total amount of dredged material removed is a reasonable estimate of the annual amount of material impounded by the jetties. It has been assumed by many, including the authors, that a significant amount of the longshore transport is bypassed during the intervals when the harbor entrance is severely shoaled. Walker, et al. (1978), in a study of the dredging problem at Santa Cruz Harbor, suggest that the amount of material bypassing the entrance is much larger than the amount impounded. Nevertheless, in the present work, it was hypothesized that there was a correlation between the apparent longshore transport, as estimated by eq. (1), and the observed impoundment, derived from the dredging workload.

The period chosen for testing this hypothesis lays between two occasions when the dredging had been completed to design depth in the harbor entrance. The baseline was after the dredging completion in mid-March, 1978. This was assumed to be a zero level of accretion. The study extended to the next such event which occurred 15 months later at the end of May, 1979.

In the period including these events, from February 1978 to June, 1979, the slope array was sampled approximately 2500 times, or over 700 hours of actual wave data were collected. Each data run was analyzed to produce values of S_{xy} and H_s . These were then employed in Eq. (1) to provide a time history of estimated longshore transport. This series can be summed in a variety of ways to provide estimates of net or gross transport. In Figure 9, the transport estimates have been summed for complete months. It can be seen that the drift towards the east is dominant, but that intervals of small westward transport are predicted during the summer months.

ESTIMATION OF LONGSHORE TRANSPORT AT SANTA CRUZ HARBOR, CA.

FIGURE 9

The authors then postulated a simple model for sediment impoundment in the harbor. Since the feeder beach to the west was characteristically full, it was assumed that all eastward transport would be trapped between the jetties. Conversely, since the eastern beach was usually stepped well shoreward of the jetty, it was assumed that the small amounts of westward transport would be stored in the eastern feeder beach and would not be carried around the jetty. The impoundment load in this model was then, simply, all of the eastward transport and none of the westward transport.

The impounded sediment volume, as a function of time, was then calculated by this scheme for the period between the two baseline dredging events. During this interval, there were two other dredgings. These were not made to the contract limits, but by subtracting their output volumes at the appropriate times, the accumulation time history could be made more realistic. The final accumulation volume was then reduced by the amount of the last baseline dredging episode. The residue or deficit volume would then represent the difference between the estimate of the impounded sediment and the actual value, since a perfect estimate of the accumulation would be exactly balanced by the dredging removals and the final volume would be zero.

Figure 10 shows the result of this estimation of the impounded volume. The estimate provided a residue of approximately 3000 cubic meters, which is about 5 percent of the total dredging load for the period. Therefore, the simple model for impoundment, and the closely spaced intervals of directional wave observation, provided a gratifyingly close estimate of the actual accumulation in the harbor entrance.

These same data can be employed to construct an annual net transport rate. The longshore transport estimate for the period from February, 1978 through January, 1979 is 62,000 cubic yards. It is interesting to compare this with an estimate made in Walker, et al. (1978). In this report, longshore transport was estimated by using deepwater wave statistics inferred from ships' observations and hindcasts from meteorological records. The deepwater waves were then refracted into shore and the same basic transport equation used to estimate a net longshore drift of 373,000 cubic meters. Since the transport relationships utilized were the same, this indicates that the hindcast thrust of the waves was six times that actually measured by the slope array.

OBSERVATIONS AND CONCLUSIONS

The slope array provides a convenient method for estimating the gross and net longshore transport of sediment in the

PREDICTION OF HARBOR SHOALING
AT SANTA CRUZ, CA.

FIGURE 10

vicinity of the measuring point. For a particular 15 month period at Santa Cruz Harbor, CA, the net transport in the eastward, or dominant, direction provided a very efficient estimator of the sediment volume impounded in the harbor entrance.

There appeared to be little, or no bypassing of sand around the harbor entrance. During this particular winter storm period, staged dredging kept the harbor mouth from closing completely. This was not true during other winters, when there may have been substantial bypassing.

The longshore transport appears to be substantially less during the winter of 1978-79 than is predicted by using average deepwater wave climates refracted into this location.

The results suggest that a nearly complete trap of longshore transport was provided by Santa Cruz Harbor during the winter of 1978-79. It is believed that this is the first trap experiment of this duration in which accurate, continuous measurements of wave direction and energy were obtained. It provides another valuable data point confirming the efficiency of the presently accepted formulation for longshore transport.

WAVE FORCING OF BEACH GROUNDWATER

Evans Waddell
Science Applications, Inc.
Raleigh, NC

ABSTRACT

A field project was conducted to measure swash and surf characteristics and related processes on a beach with a high tide range and very low slope. Variables measured were beach waterlevels in the surf and swash zones, beach groundwater levels, and on-offshore and alongshore currents. A variety of deployment patterns and instrument combinations were used. Results show a nonlinear transfer of wave energy from high to low frequencies. This appears to have occurred because finite amplitude waves and bores caused an onshore mass flux which produced an increased local waterlevel. Periodically, this impounded water was released. Groundwater records indicate that low frequency waterlevel oscillations on the beach face were the dominant forcing function for oscillations of the beach watertable. A model is generated which adequately predicts some of the response characteristics of the groundwater table.

INTRODUCTION

As one of a series of studies conducted to examine in detail the physical mechanisms which are active in a dynamic beach system, the field project discussed in this paper was designed to examine the relationship between waves, swash, and groundwater on a very low sloping beach. The specific process to be examined in this paper is the response of the beach groundwater and water table to forcing mechanisms occurring at frequencies ranging from input wave frequencies to several minutes. It is apparent from these results that on such a low sloping beach the understanding of the groundwater flow exceeds the understanding of the complexly coupled forcing mechanisms.

METHODOLOGY

This experiment was conducted on Little Talbot Island, Florida in May 1973. Little Talbot Island is a barrier island in the St. Johns River estuary. A typical cross beach profile at the experimental site is given in Figure 1. The slope is very shallow with an average of approximately 1:70. This site was chosen because of its low slope, high tide range, and medium sand-sized sediment.

Figure 1. Beach profile, typical instrument deployment pattern, and representative tide curve. The plan view shows the cross beach locations of instruments where GW = groundwater well, SW = swash or beach waterlevel depth, input = input wave sensor. MCM and CM refer to current meters which are not discussed in this paper.

At the study site, the dominant semidiurnal tide was slightly tropic with a range of approximately 1.3 meters. This amplitude and period produced a beach face which rapidly migrated 120-150 meters during half a tidal period. For this discussion, beach is any region which is affected by swash at some time during a tidal cycle. During high tide, most of the beach was inundated and waves shoaled from the seaward or outer limit of the beach at approximately $x = 150$ meters. Waves and bores moved directly onshore, i.e., wave orthogonals were perpendicular to the shoreline and no complex refraction patterns occurred.

The beach cross section shown in Figure 1 remained rather static and exhibited no fundamental changes during the several day experiment. Small scale sedimentary features such as ripples and low amplitude sand waves would appear and disappear during a tidal cycle.

The general cross beach profile was composed of five zones distinguished on the basis of local slope. These zones correspond closely to processes active on the beach during particular portions of a tidal cycle. Zone 1, which extends seaward of $x = 140$ is the nearshore, which is continually inundated during all tidal phases except under exceptional conditions. Zone 2 ($110 < x < 140$) is a low tide terrace which is occasionally exposed or has only very shallow water during low tide. Zone 3 ($75 < x < 110$) is the low tide swash slope and a region over which swash migrates rapidly during rising or falling tide. Zone 4 ($50 < x < 75$) is a high tide terrace. This is a region of very shallow water during high tide. It is in this zone that most instruments were deployed. Zone 5 ($20 < x < 50$) is the high tide swash slope. The exact location of Zone 5 varies with a result of diurnal and fortnightly variability of high tide level.

Measurements were made between $x = 40$ and $x = 70$ m with most water-level measurements being made between $x = 50$ meters and $x = 70$ meters. In this region the beach slope was approximately 1:70. Measurements of input parameters were made between 80 m and 90 m, usually at approximately 90 m. Thus, input statistics reflect wave phenomena just prior to their transiting the very shallow Zone 4. It is in this region, Zone 3, in which waves make a transition to solitary waves and bores. Just seaward of the input wave sensor, water depth decreases from over a meter to less than .3 m.

Instrumentation and Data Runs

Three types of instruments were deployed on the beach face. Due to limitations in the number of analog recorders, all instruments were not used during all data runs. The three instruments were: (1) capacitance type waterlevel sensors which were used to measure waterlevel on the beach and in groundwater wells; (2) bidirectional, ducted impellor, current meters; and (3) a pressure transducer used to measure input surf conditions. These instruments are described and discussed by Sonu and Pittigrew (1974).

Instruments were deployed in different locations and combinations during various data runs. An example of the instruments and their deployments are given in Figure 1. Included on this figure is a representative vertically exaggerated cross beach profile and a tide level record plotted

relative to the profile datum. With this presentation water depths at any time and location can be readily determined.

Most data acquisition occurred during or near high tide. Conducting experiments during this period tended to minimize variations in local conditions that could cause a lack of stationarity in the processes active on the beach face.

Data was taken on several different days. For this discussion, primary instruments were swash probes and groundwater probes. Generally, a single instrument array was used each day. During a day, different data runs were conducted and these are referred to as Part 1, 2, or 3. A given data set is indexed by day and part. Thus "24-3" is part 3 on May 24th.

Analysis

Results of the measurement program were synchronous time series which represented variations in magnitude of the various phenomena measured. These records which have durations ranging from 10 minutes to over an hour were analyzed to give a frequency decomposition of the variance of each signal. In addition, physically related phenomena were analyzed for a frequency decomposition of the covariance of these processes. This technique permits isolation of major periodicities and associations which characterize the random processes being analyzed.

A standard method of spectral density analysis was used. In addition to spectral densities of individual time series, cross spectral densities were computed and the second order characteristics of coherence, transfer functions, and phase angle calculated. All data were demeaned and detrended during analysis to leave only periodic components of variability. Caution must be exercised when interpreting results of higher order spectral analysis. Many physical processes were related nonlinearly which can cause parameters such as coherence to be misleading.

RESULTS

Waterlevels

Design of this experiment required measurement of waterlevels in the region of the swash and surf zone. However, because of: (1) the desire to measure waterlevels during or immediately following high tide, (2) the diurnal variation in the elevation of high tide, (3) the necessity of putting instruments in place well in advance of high tide, and (4) the very low beach slope and hence very wide beach, it was not possible to have instruments in the same relative position during each data run. Therefore, during all data gathering periods, a given instrument or location does not measure or represent the same general environment. In fact, due to a lack of stationarity of still waterlevel, a given instrument may be sampling distinctly different environments in successive data runs; e.g., surf measurements in one run and swash measurements in the subsequent data run. As a

result, specific values of variance density can not be examined; however, patterns can be examined and these should reflect the processes occurring on the beach.

In almost all data runs, a critical, although at times minor, spectral peak occurred between .0667 Hz and .0769 Hz. This peak was observed at all across beach stations and was the lowest frequency peak which was uniform and consistently observed at each measurement station. The frequency of this spectral peak separates what will be referred to as high frequencies from low frequencies.

In these waterlevel spectra, Figure 2, two major features occurred: (1) higher frequency peaks apparently associated with input waves and bores, and (2) one or more low frequency peaks which are believed to have been locally generated by complex interaction of waves and topography. By local generation, it is meant that the process which produced this peak was not input to the beach system but rather was the result of local processes.

If time series of waterlevel at one location are considered as input and time series from a station further upslope are considered as output, then the relationship of the associated spectra can indicate whether spatial processes can be represented by a linear function in the frequency domain. If the spatial process is linear, then at any given frequency, the output is a linear multiple of the input; i.e.,

$$X_{out}(x_{out}, f) = |H(f)|^2_{x_1, x_2} X_{input}(x_{in}, f) \quad (1)$$

where $X(f, x)$ is the magnitude of the variance density at $x = X_{out}$ or x_{in} at frequency f , x = location on the beach relative to the arbitrary baseline in Figure 1 and $H(f)$ = frequency response function.

If the spatial processes are linear, then variance can not be redistributed in the frequency domain as the waves move from x_{in} to x_{out} . In the present beach system, it is anticipated that the linear multiple should be less than or equal to unity since energy is being dissipated as waves move upslope.

These data, Figure 2, suggest that the systems function for the entire spatial shoaling process is nonlinear. This must be concluded because of the apparent local generation and behavior of the low frequency spectral peak. The upslope increase in low frequency peaks and simultaneous upslope decrease in high frequency peaks, strongly suggests that some nonlinear process is causing variance to be redistributed in the frequency domain (Waddell, 1976).

If high and low frequency variance are viewed independently, then high frequency processes appear to be well behaved and quasi linear since there is a gradual upslope variance attenuation. This is what might occur if there was no spatial gradient in mass flux and there was simple upslope energy dissipation resulting in a continual decrease of wave or bore height. Such a situation may occur if Airy waves are gradually dissipated.

Figure 2. Contour plot of spectral density of beach waterlevels at each across beach location. The actual spectra at any location can be determined holding "distance from baseline" constant and examining changes in magnitude with frequency.

However, in the present situation, waves have definite nonlinear shape and there is most probably a spatial gradient in horizontal mass flux.

As indicated previously, for the environment being examined, local bore height depends on: (1) location, (2) initial wave energy, i.e., height, (3) rate of energy concentration, and (4) rate of energy dissipation. Therefore, it is expected that at some point on the beach face, total variance associated with the input bore spectral peaks will begin to decrease and will continue to decrease until completely attenuated. This complete attenuation may occur at the maximum limit of uprush or it may occur seaward of that point such that no wave induced uprush results (Le Mehaute, 1968).

An explanation of the cause and behavior of low frequency variance is much less straightforward. Possible sources for this variance are: (1) orderly variations in bore height causing variance at subharmonics of the input wave frequency; (2) a combined influence of radiation stress induced set-up in conjunction with arrival of wave groups, and (3) periodic impoundment and release of water moved onshore by shoaling waves and bores. One or more of these could occur simultaneously; however, in the present situation the last possibility seems the most probable.

If these low frequency peaks were the result of some orderly variation of the height of incident waves, then the low frequency peaks should occur at subharmonics of the dominant input periods. Additionally, since the dominant input spectral peak had a rather narrow bandwidth, such subharmonics should also be rather well defined. In the present data, there were no consistent patterns of low frequency variance at subharmonics of the input wave periods.

If orderly height variations caused the low frequency variance, then the magnitude of the low frequency peaks should be relatively small unless there were large differences between successive bore heights. If such were the case, there should be spatial changes in the period between successive bores because of the dependence of celerity on bore height, i.e.,

$$C = (g(h_0 + H_B))^{1/2} \quad (2)$$

where C = rate of change of location of bore front relative to the local water velocity, h_0 = initial water depth and H_B = change in water level across the bore front. If there were large sequential variations in bore height in water where H_B was the same order of magnitude as h ; i.e.,

$$O(H_B) \geq O(h) \quad (3)$$

then the band width of the input wave spectral peak should increase up-slope. No such pattern can be seen, in fact, the opposite generally occurs. As a result, it must be assumed that successive input waves did not display large sequential and orderly variations in height.

In these data some low frequency spectral peaks occurred at sub-harmonics of input wave spectral peaks, however, there was no consistent pattern and the magnitude of these spectral peaks was generally small.

It is expected that due to energy dissipation, a subharmonic peak should decrease in magnitude upslope unless secondary bores consistently rejuvenated primary bores. Even if this occurred, it is unlikely that such rejuvenation could account for low frequency spectral peaks having the magnitude of those observed.

If low frequency variance is associated with periodic set-up due to the arrival of wave groups, then the amplitude of the low frequency oscillation can be rather large. Examination of the original time series did not reveal clearly defined and repetitive wave groups, although there was some indication that small periodic variations of wave height might have been present at times. If such wave groups were the result of superposition of two deep water wave trains moving into shallow water, then it should be possible to identify the component waves in the input spectra and from these predict the approximate frequency of the low frequency oscillation. If there are two wave trains having similar amplitudes and angular frequencies ω_1 and ω_2 , then amplitude of the carrier wave will vary at a frequency of $\frac{(\omega_1 - \omega_2)}{2}$ and the variation in wave set-up will occur at $\omega_2 - \omega_1$.

All possible pairs of high frequency spectral peaks were evaluated for the frequency of the envelope wave which would be produced if they were superimposed. In all these data runs only a few high frequency peaks could be combined to produce the observed low frequency peaks. There is serious doubt as to whether this association was any more than random chance. This doubt arises because the peaks were not consistently observed across the beach face.

By elimination, impoundment and release of water from the beach appears to be the most likely explanation for the low frequency waterlevel oscillations. Since the component highly nonlinear waves caused a shoreward mass flux, a mechanism for onshore flux is readily available; however, an adequate explanation for the periodicity of impoundment and release is difficult to provide. It is possible that due to the low beach slope, wide beach zone and existence of multiple random waves in the shallow portion of the surf zone, some natural periodicity is established.

Groundwater

Spectra of groundwater indicate that low frequency oscillations of waterlevel on the beach dominated the forced groundwater oscillations (Figure 3). This is to be expected and has been documented previously (Waddell, 1973). These low frequency oscillations dominate for two major reasons: (1) the beach matrix and well point are low pass filters, and (2) groundwater was usually measured on the shoreward side of the experimental site where lower frequencies generally dominated the waterlevel spectra.

Figure 3. Groundwater oscillations at three beach stations 10 meters apart ($x = 50, 60,$ and 70 meters from baseline). The zero level or origin is shifted for each trace. Note the sequential upslope dominance of low frequency fluctuations. Also note the very slow fluctuation with a period of approximately 200 seconds.

As seen in Figure 4, examination of time-synchronized traces of beach waterlevel and well waterlevel shows that they correspond quite closely. This similarity suggests that possibly the local pressure gradient across the well wall may be the forcing function for the well waterlevel oscillations. Since velocities within the well are very small, especially at lower frequencies, pressure should be approximately hydrostatic. Also, pressure within a solitary wave is very close to hydrostatic (Ippen, 1962). Consequently, the time dependent hydrostatic spatial pressure gradient is probably the responsible forcing mechanism

A simplified model can be generated to explain the response of the beach waterlevel-well waterlevel system (Figure 5). Mass continuity dictates that flow through the well point is equal to the time rate of change of water within the well. Thus,

$$\rho Au = \frac{dQ}{dt} \quad (4)$$

where A = area of openings in the well point, u = spatial mean velocity of flow across the well point, ρ = density of water, Q = storage of water within the well. Storage within the well is given by

$$Q = \rho \pi r^2 h_w \quad (5)$$

where h_w = height of the waterlevel in the well and r = radius of the well and constant. Therefore,

$$Au = \pi r^2 \frac{dh_w}{dt} = \pi r^2 \frac{dh_1}{dt} \quad (6)$$

where h_1 is waterlevel relative to an arbitrary datum since only the time rate of change is being considered and this is independent of datum level. Let

$$u \propto (h_0 - h_1) \quad (7)$$

where h_0 = beach waterlevel and h_1 = well waterlevel, both being measured relative to the same arbitrary datum. Assuming a constant of proportionality K, then Eq. 7 is

$$u = K(h_0 - h_1) \quad (8)$$

Figure 4. Synchronized beach waterlevel and ground waterlevel traces. The well waterlevels are attenuated relative to the swash fluctuations.

Figure 5. Schematic of groundwater well configuration and associated waterlevels.

Physically, $(h_0 - h_1)$ is the forcing function for the system and is a measure of the hydrostatic pressure gradient across the well point and can be expressed as

$$AK(h_0 - h_1) = \pi r^2 \frac{dh_1}{dt} \quad (9)$$

Let $F = AK$, $D = r$, and let $h_0 = H_b \cos(\omega t)$ where $\omega =$ angular frequency of beach waterlevel changes. Assigning values to h_0 establishes a datum level for h_1 and h_0 . Eq. 9 can be rewritten as

$$\frac{dh_1}{dt} - \frac{F}{D} h_1 = \frac{F}{D} H_b \cos(\omega t) \quad (10)$$

The solution to this equation is

$$h_1(t) = h_1(0) \exp\left(-\frac{F}{D}t\right) + \frac{F^2 H_b}{D^2 \omega^2 + F^2} \cos(\omega t) + \frac{F D \omega H_b}{D^2 \omega^2 + F^2} \sin(\omega t) \quad (11)$$

where $h_1(0) =$ waterlevel in the well at $t = 0$. The first term on the right side of the above equation represents the initial response to excitation of the beach-well system. To examine a well waterlevel response relatively unaffected by the initial well waterlevel, assume $t = t_1$ where t_1 is large so that $h_1(0) \exp\left(-\frac{F}{D} t_1\right) \rightarrow 0$. In the time domain where $t \geq t_1$, Eq. 11 reduces to

$$h_1(t) \doteq \frac{F^2 H_b}{D^2 \omega^2 + F^2} \cos(\omega t) + \frac{F D \omega H_b}{D^2 \omega^2 + F^2} \sin(\omega t) \quad (12)$$

The time derivative of Eq. 12 is evaluated for the first maxima, of $h_1(t)$, following a maximum in $h_0(t)$. This occurs at

$$t = \frac{1}{\omega} \tan^{-1} \left(\frac{D\omega}{F} \right) \quad (13)$$

where $t = \tau =$ lag of the well waterlevel maximum relative to the beach waterlevel maximum.

Given environmental parameters D and F , τ is frequency dependent. In this experiment $D = 45.6$. It remains to determine K , which can be viewed as incorporating a variety of effects generally associated with flow attenuation. For illustration it is assumed that K is a linear function of A , the surface area of the openings in the well point. Obviously, such a relationship would be dependent upon the geometry of the openings, but generally, given a geometry, as surface area increases for a given pressure gradient, the mean velocity would increase. This would be true for small openings where retarding forces due to boundaries of the openings and due to grain boundaries are significant.

$$\begin{array}{ll} \text{If} & K = mA \\ \text{then} & F = mA^2 \end{array} \quad (14)$$

For the present example we assume $F = 4$. Then,

$$\tau = \text{lag} = \frac{1}{w} \tan^{-1} (11.4w) \quad (15)$$

This argument can be reversed to use measured values of τ to calculate an estimate of K which relates velocity to the pressure differential.

Since the driving force for changes in these two waterlevels appears to be a hydrostatic pressure gradient which is a linear operator, it is expected that the systems function (filter function relating these two) will be linear. This means there should be a high coherence between the two signals. This was generally observed, e.g. Figure 6.

Phase lags of surf depth and well waterlevel are anticipated (Figure 4). As seen above, these occur as a direct result of the frequency response function $H(f)$, associated with the porous media and the well point, where

$$H(f) = |H(f)| e^{j\theta(f)} \quad (16)$$

and $\theta(f)$ is the frequency response phase angle and is numerically identical to the cross spectral phase angle, $\alpha(f)$. Thus, for a linear system, τ is a direct result of the amplitude attenuation of the signal by the system.

Figure 7 contains a plot of " τf " as determined from Eq. 15. Additionally, on Figure 7 are plotted some observed values of $\tau(f)$, suggesting that for sinusoidal input signal, Eq. 15 provides a rather accurate prediction of well waterlevel oscillations. Considering: (1) that the observed values of $\alpha(f)$ represent cumulative influence of all input signals at a given frequency and (2) that the input signal in Eq. 10 was strictly sinusoidal, the agreement in Figure 7 is very good.

In some data runs the lack of close agreement between predicted and observed values at higher frequencies may in part result because the

Figure 6. Coherence between waterlevels on the beach surface and in the groundwater wells. Note the coherence remains high at low frequencies ($f < .07$ hz) and decreases at higher frequencies.

Figure 7. Phase angle or phase lag between the input signal (beach waterlevel) and the output signal (well waterlevel). Plotted are observed values and two examples of predicted phase lags from Eq. 15.

higher frequency signals were not sinusoidal but were more asymmetrical with a steep faced front and a more gradually sloping seaward side.

Specific frequency response functions between beach waterlevel and well waterlevel are, in part, dependent upon the depth of the well point below the beach surface. As suggested by the low pass characteristics of these functions, for a given beach, the deeper the well point, the lower the cut-off frequency of the filter function. Thus, in these experiments, if the well point had been closer to the surface, then the observed well waterlevels would have responded more vigorously to the input waves (i.e., 0.1 hertz).

Figures 8 and 9 are examples of the predicted response of well waterlevel to forcing functions of constant amplitude but having different frequencies. However, two identical wells placed in different locations can have different response characteristics as a result of differences in local sedimentary characteristics. Thus, to be useful in a predictive sense, each well must be "calibrated"; i.e., determine F in Eq. 13. If such a calibration is completed, nearshore wells could be used to identify slopes of oscillating nearshore waterlevels.

Since the flow parameter K is in reality dependent on the character and quantity of sediment above the well point, local changes in nearshore morphology can alter the frequency response function relating input and output signals.

High and low frequency pumping action may have very significant effects on local sediments. The pumping induced by the pressure gradient associated with the migrating bore front could cause dilation of surficial sediments. The depth of this layer would be limited by the frequency dependent amplitude attenuation which results from viscous flow through a porous media. However, low frequency pressure differentials could be transmitted to a much greater depth in the sediment deposit, thus causing flow and possible grain dilation to a much greater depth.

If spatial pressure gradients occur at high and low frequencies, it is possible that a rather thick sedimentary deposit could become fluidized. If this occurred, then such things as local shear strength of sediments could exhibit strong periodic components.

CONCLUSIONS

Waterlevel fluctuations on this low sloping, high tidal range beach exhibited a nonlinear transfer of energy from high to low frequencies. This spatial process appears to have resulted from the impoundment of water which was transferred onshore by bores and finite amplitude waves. Periodically this impounded water mass was released, resulting in low frequency waterlevel oscillations. These low frequency oscillations became increasingly dominant at the more shoreward stations. In some data runs near the mean shoreline these low frequency oscillations completely dominate almost to the exclusion of high frequency fluctuations. Thus, on the

Figure 8. Input and output signals for high frequency ($f=.1$ hz) forcing. Note the low amplitude response to a 10 cm input amplitude.

Figure 9. Low frequency response. Compare to Figure 8. Input signal has 10 cm amplitude but response is attenuated much less.

swash slope run-up due to individual bores may not even occur and periodic uprush and backwash may be associated with the low frequency waterlevel oscillations.

Watertable variance was dominated by lower frequency oscillations. This resulted because the beach acted as a low pass filter and the configuration of wells was such that high frequency fluctuations were almost completely attenuated at the depth of the well point. By assuming a form for the groundwater forcing function, it was possible to predict the lag of the groundwater maximum behind the beach waterlevel maximum. The influence of well placement and local sediment permeability and porosity are incorporated in parameters, F, D, which must be empirically determined.

ACKNOWLEDGMENTS

Field data used in this report was taken by personnel from the Coastal Studies Institute of Louisiana State University under the direction of Dr. C. J. Sonu, who is presently with Tekmarine, Inc. Use of these data are gratefully acknowledged as is the financial support of Science Applications, Inc.

CHAPTER 88

LONGSHORE TRANSPORT EVALUATIONS AT A DETACHED BREAKWATER

by

R. O. Bruno¹, R. G. Dean², and C. G. Gable³

ABSTRACT

A field experiment was conducted by the Coastal Engineering Research Center (CERC) to develop correlations between wave characteristics and longshore sediment transport. The waves were measured by two near-bottom mounted pressure transducers and the average longshore sediment transport rates were determined from sequential volumetric surveys behind an offshore breakwater which was regarded as a total trap. The data analyzed herein encompass a period of nine months during which a total accumulation of 675,000 m³ occurred as documented by eight surveys. Spectral analyses of the wave data were conducted and yielded one direction per frequency. The correlations include immersed weight sediment transport rate, I , versus (1) longshore component of wave energy flux at breaking, $P_{\ell S}$, and (2) the onshore flux of the longshore component of wave-induced momentum, S_{xy} . The most widely used correlation constant, K , in the relationship $I = KP_{\ell S}$ is 0.77. The best-fit values found from the data were $K = 0.65$ and 0.92 for linear and log best-fits, respectively, as based on the $P_{\ell S}$ values directed toward the trap. The corresponding values of K_* (dimensional) relating I and S_{xy} are 4.98 m/s and 6.37 m/s, respectively. One feature of this type of trap is the potential for overtrapping if the waves are directed nearly normal to shore.

INTRODUCTION

The need for a quantitative relationship for longshore sediment transport is common to practically all coastal engineering projects. Examples include: channel deepening, design of coastal structures and beach nourishment programs. The most widely used predictor relates longshore sediment transport rate to longshore energy flux at breaking or to some measure of wave-induced momentum flux; these relationships require calibration with field and/or laboratory data. A survey of the available field data demonstrates that of the approximately 56 data points, none are based on both measured wave direction and volumetric accumulations in a total trap. Some are based on visually observed wave directions at a location quite distant from the measured wave heights. In addition, much of the sediment data is based on tracer studies with the attendant uncertainties in estimating depth of effective motion.

The present paper describes the analysis of a subset of the measurements carried out at Channel Islands Harbor by the Coastal Engineering Research Center (CERC) during the period 1974 to 1977. The data analyzed herein include wave height and direction measurements as determined from a pair of near-bottom mounted pressure gages located in a water depth of approximately 6 meters. The sediment "trap" is an off-shore breakwater in approximately 9 meters of water and the west jetty to the entrance to Channel Islands Harbor, see Figure 1. This "trap" is believed to be nearly complete. The volumetric accumulations over a period of nine months are documented by eight surveys, during which a total sediment volume deposition of 675,000 m³ occurred. Correlations are presented of longshore sediment transport as inferred from accumulation in the trap with $P_{\ell S}$, the longshore component of energy flux at breaking and S_{xy} , the flux in the onshore direction of the longshore component of momentum.

BACKGROUND

The relationship between immersed weight transport rate of sediment, I , and longshore energy flux at breaking, $P_{\ell S}$, is generally presented in terms of a non-dimensional constant, K

$$I = KP_{\ell S} \quad (1)$$

where for a single wave train of breaking height, H_b , and breaking direction, θ_b , relative to a normal to the beach, $P_{\ell S}$ can be expressed as

$$P_{\ell S} = \frac{\gamma H_b^2}{8} C_{G_b} \sin \theta_b \cos \theta_b \quad (2)$$

in which γ = specific weight of water and C_{G_b} is the wave group speed at breaking. A more useful form of Eq. (1) is obtained by noting that the immersed weight transport rate, I , and bulk longshore sediment transport, Q_s , are related by

$$Q_s = \frac{I}{\rho \left(\frac{\rho_s}{\rho} - 1 \right) g (1 - p)} \quad (3)$$

in which ρ and ρ_s are the mass densities of water and sediment respectively, g is the gravitational constant and p is the in-place porosity of the sediment. Combining Eqs. (1) and (3)

$$Q_s = \frac{K}{\rho \left(\frac{\rho_s}{\rho} - 1 \right) g (1 - p)} P_{\ell S} \quad (4)$$

It is noted that the above equations for longshore sediment transport do not account for sediment size, beach slope, porosity, etc. and thus it is very unlikely that "K" is a true constant; however, the tests conducted to date have not provided the ranges of independent

Figure 1. Location Map and Orientation of Field Area.

variables (e.g. sediment size) or accuracy necessary to distinguish the effects of these variables.

A brief review of previous field data is helpful in assessing the currently used relationship. In this review, the laboratory data will be omitted as they do not represent a properly scaled version of the prototype since the scaled sediment size is significantly larger than is usually present with sand-sized particles. The following review is presented in chronological order of the various investigations which have yielded the data. Other reviews have been presented by Das (1971, 1972) and Greer and Madsen (1978).

South Lake Worth Inlet, FL (Watts, 1953)

Longshore transport rates were based on quantities of sand transferred by a permanent sand bypassing plant on the north jetty of South Lake Worth Inlet. The pressure drop of the bypassing pump was correlated with sand discharge by a series of pumping events into a diked disposal area on the downdrift (south) side of the inlet and subsequent surveys of the associated volumes. Thereafter transport rates were inferred from the (calibrated) pressure drop of the pump. The wave characteristics were based on: (a) wave height measurements from a staff gage mounted on the South Lake Worth pier some 16 km north of the inlet, and (b) visual observations of wave direction at the surf line as obtained from a vantage point approximately 6 km north of the inlet. This study yielded four data points with a sediment diameter of approximately 0.4 mm. The average K value is 0.90 with a standard deviation of 0.11.

Anaheim Bay, CA (Caldwell, 1956)

Dredge material from the entrance to Anaheim Bay was placed on the downdrift (southeast) shore and repeated surveys of this area were conducted as the material was transported in a southerly direction. The changes in volume were interpreted as longshore transport rates and the estimates of longshore component of wave energy flux were based on (a) wave staff measurements from the Huntington Beach Pier, some 9 km to the south, and (b) wave directions based on hindcasts and recognition of the sheltering by the offshore islands for waves originating from certain directions. This study provided a total of five data points with a sediment diameter of approximately 0.40 mm. The average K value is 0.76 and the standard deviation is 0.38.

Cape Thompson, AK (Moore and Cole, 1960)

The growth of a spit and the associated waves were observed over a three-hour period. The spit volumes were measured by plane table survey and wave characteristics were based on visual estimates. Only one data point was obtained with a K value of 0.25 for a sediment size of 1.00 mm.

Santa Barbara, CA (Johnson, 1952 and Galvin, 1969)

These data are based on two separate sources. The volumetric data were developed by Johnson (1952) from spit accumulations in the shelter

of the terminus of the Santa Barbara breakwater. The longshore energy values were developed by Galvin (1969) and represent a combination of hindcast wave heights and wave directions selected to result in the maximum longshore energy flux and still be realistic. This data set includes a total of five points with average and standard deviation values for K of 1.60 and 0.70. The sediment size was approximately 0.20 mm.

Silver Strand, CA and El Moreno, Baja California (Komar and Inman, 1970)

These data represent transport over fairly short time intervals as determined from sand tracer measurements and wave energy fluxes derived from an array of wave sensors. Sand transport volumes were usually determined over a fraction of a tidal cycle as the product of the width of the surf zone, the longshore displacement of the center of gravity of the tracer and the thickness of tracer movement. The latter quantity was based on observations of the depth to which a cylindrical "plug" of tracer had been eroded over the observational period and depth of tracer in cores. Values of this depth ranged between 2 and 10.5 cm. These measurements yielded a total of 14 data points and the average and standard deviation values of K for Silver Strand (four data points) where the average sediment size was 0.18 mm are 0.77 and 0.18, respectively. These quantities for El Moreno (10 data points) where the average sediment size was 0.60 mm are 0.82 and 0.27, respectively.

Fernandina Beach, FL (Thornton, 1969)

Mechanical sand traps were placed at discrete locations across the surf zone and used to trap the lower 20 cm of the water column down to and including material in transit on the sand bed. The traps, which were operated from a pier, could be closed and the trapped material pumped up to the pier for measurement. Wave data (height and direction) were based on two wave gages located at the end of the pier. These studies yielded a total of 14 data points with average and standard deviation values for K of 0.048 and 0.027, respectively. The sediment diameter was approximately 0.20 mm.

Channel Islands Harbor, CA (Bruno and Gable, 1976)

These data were based on the same general field program that is the subject of the present paper. The sediment transport rates were inferred from volumetric accumulations behind the Channel Islands Harbor offshore breakwater and the longshore energy flux values were based on Littoral Environmental Observations (LEO). A total of 13 data points resulted with average and standard deviation K values of 1.61 and 1.19, respectively. The sediment size at this site is approximately 0.2 mm.

Discussion

The results presented above comprise a total of 56 data points which are summarized in Table I and presented in Figure 2. It is noted that the Thornton data are significantly lower than the rest and presumably the traps were not effective in collecting the entire sediment transport. Figure 3 represents an attempt to discern any effect of sediment size, D , on the quantity K . If the Thornton data are not con-

TABLE I
SUMMARY OF FIELD DATA AVAILABLE FOR LONGSHORE TRANSPORT CORRELATION AND CHARACTERISTICS OF RESULTING "K" FACTOR

Investigator	Location	Sediment Diameter (mm)	No. of Points	Methods			Characteristics of K

KEY

1. M = Measured, O = Observed, H = Hindcast, Max. = Direction Selected to be Realistic and Yield Maximum Possible Transport.
2. I = K_{I_5} , I = Immersed Weight Transport Rate, I_{I_5} = Longshore Energy Flux of Waves.

Figure 2, Summary of Field Data I vs. P_{ls} , Including Results of This Study.

Figure 3. Plot of \bar{K} Versus Diameter, D . Initials and Numbers, N , Refer to Investigators and Number of Data Points Comprising K .

sidered, there is a fairly reasonable relationship of increasing K with decreasing sediment size, although there is only one data point for a sediment size exceeding 0.6 mm.

None of the studies of longshore sediment transport have attempted to present an error analysis of the results. Based on the normalized standard deviations (Table I), the results appear reasonably consistent within each data set, yet there is an enormous difference between the average K values of the various data sets, ranging from 0.05 for the Thornton data to 1.61 for the Bruno and Gable data. This would appear to be indicative of large biases in some of the measurements.

In general, it appears that none of the data sets were developed such that high confidence should be associated with both the wave and sediment volume data. In those studies for which the volumetric data were well-established, the wave data usually included one or more visually estimated wave parameters (height and/or direction). In the reported tracer studies, it is believed that the inferred sediment transport rates represent an overestimate of the actual transport. This expected bias is due to the estimate of the shore-parallel displacement of the center of gravity of tracer displacement being obtained from the upper 5 cm of the sediment column since a shear transport must exist within the sand bed with the upper layers moving most rapidly. Additionally, the use of a single value of thickness of transport based on the depth of erosion of a tracer plug should lead to an upward bias as the maximum erosion depth is expected to increase with time. Finally,

the longshore sediment transport in the surf zone is expected to be both spatially and temporally variable although these scales are presently unknown. Since the tracer studies represent longshore sediment transport over only a portion of a tidal cycle, it is surprising that they do not exhibit greater scatter, i.e. percentage standard deviations of 23% and 33% for the Silver Strand and El Moreno K values respectively. One of the advantages of a relatively long-term, complete sediment trap is that it integrates the temporal and spatial variability, thereby providing a good basis for investigating the mean structure of the transport phenomenon before attempting to measure and understand the fine structure.

The complexity of longshore sediment transport, the uncertainties and differences exhibited in the available data and the economic and functional impact of a valid quantitative predictor of transport certainly justify substantial future field and laboratory investigations.

SITE CHARACTERISTICS

Channel Islands Harbor (CIH) is located some 80 km northwest of Los Angeles, CA. The sediment trap is formed by an offshore breakwater parallel to the shoreline and the western jetty of the entrance to Channel Islands Harbor, see Figure 1. The offshore breakwater is some 700 m in length, is approximately 400 m offshore and is in a water depth of 9 m. The entrance to CIH was dredged in 1960-1961 and since that time the material impounded in the sediment trap has averaged approximately 1,000,000 m³/year. The capacity of the trap is approximately 2,000,000 m³ and usually the material is pumped (on a biennial basis) a distance of some two kilometers to the downdrift side of the entrance to Port Hueneme, CA, although material is occasionally placed in the "pocket beach" formed by the eastern jetty to CIH and the western jetty to the Port Hueneme entrance approximately 1.6 km to the east. An excellent description of the general characteristics of the site is presented by Herron and Harris (1966).

Although the net sediment transport is from northwest to southeast, periods of reversal do occur. The average sediment size at the site is approximately 0.20 mm; the textural characteristics of the material deposited in the trap have been reported by Bruno, Watts and Gable (1977).

One feature of an offshore breakwater is that it will tend to cause an "overtrapping" of material especially during times when the waves approach in a direction nearly perpendicular to the shoreline. This effect can be demonstrated by noting that even for waves propagating directly toward shore, the effects of diffraction will cause deposition in the form of a salient or tombolo behind the breakwater. If this deposited material is removed such that it no longer represents an equilibrium topography, more material will be transported behind the breakwater, etc. Unfortunately, the degree of overtrapping for different wave characteristics is, at present, unknown. A related question arises whether the impounded volumes should be correlated with the net or downdrift component of longshore energy flux. This will be discussed further in the "Analysis" section.

MEASUREMENT PROGRAM

The entire measurement program extended from April 17, 1974 to August 30, 1977. The portion of this program which will be presented in this paper corresponds to the period when two submerged pressure gages were operational and spans the period July 30, 1974 to May 6, 1975.

Wave Measurements

Two total pressure sensors were located near the bottom in a water depth of approximately 6 m. The gages were separated by approximately 23 meters; the geometric characteristics of the gage installations are presented in Figure 4. Pressure records were recorded in digital form approximately every two hours. The records contained 4096 data points at 0.25 sec. each resulting in a record length of 17.07 minutes. The procedure utilized in analyzing the wave records will be presented in a later section.

Figure 4. Characteristics of Two-Gage Array at Channel Islands Harbor, CA.

Sediment Volumes

A total of eight surveys were carried out during the period encompassed in this paper. Precision range-range equipment provided horizontal positioning and a standard fathometer was used to establish depths greater than could be obtained by shore-based leveling. The surveys were carried out using a LARC amphibious vehicle, thereby allowing a continuous profile to be obtained from the seaward limit of interest up onto the dry beach. When in water too shallow for the fathometer, a standard surveying rod was held over the side of the LARC and sighted on by a level from shore. This procedure ensured continuity over the entire profile.

The trap extended from the west jetty of the entrance to Channel Islands Harbor to a location 90 meters updrift of the western tip of the

offshore breakwater. In a shore perpendicular direction, the trap extended from the baseline landward of any wave activity, offshore to a distance of 425 meters. Within the trap area, the spacing of survey lines was 30.5 m and further updrift than 250 m from the updrift end of the offshore breakwater, the spacing was increased to 122 m.

ANALYSIS

As noted previously, the wave data consisted of simultaneous records of digitized pressure data from the two sensors located in approximately 6 m of water. In order to calculate $P_{\ell S}$ and S_{xy} at breaking, the following steps were carried out: (1) Calculation of the frequency-by-frequency wave direction and energy at the location of the wave gages; (2) Transformation of the wave spectrum to the breaker line, including shoaling and refraction effects, and (3) Computation of $P_{\ell S}$ and S_{xy} at the surf line. Each of these is described below.

Calculation of Wave Characteristics at Wave Gages

Each of the pressure records consisted of 4096 data points with a time increment of 0.25 sec. The time series were analyzed using a standard Fast Fourier Transform (FFT) program to determine the coefficients. For example, for the pressure time series from Gage 1

$$p_1(t_j) = \sum_{n=0}^{N-1} [a_1(n) - ib_1(n)] e^{-\frac{i2\pi nj}{N}} \quad (5)$$

in which $i = \sqrt{-1}$, and N is the total number of data points (= 4096) for each gage.

The FFT coefficients are defined in terms of the pressure time series as

$$a_1(n) - ib_1(n) = \frac{1}{N} \sum_{j=1}^N p_1(t_j) e^{-\frac{i2\pi nj}{N}} \quad (6)$$

and the $a_1(0)$ term represents the mean of the record. In calculating the FFT coefficients, there is a large number of "windows" or "tapers" that may be employed in an attempt to reduce the adverse effects of spectral leakage which arises due to representing an aperiodic time series by a periodic series (Harris, 1976). These tapers all have the form

$$p'(t_j) = w(j)p(t_j) \quad (7)$$

in which $p(t_j)$ is the measured pressure and $w(j)$ is a weighting factor. A characteristic of these tapers is that they are unity at the midpoint of the time series and decrease to a lesser value near the two ends. In the present analysis, through a number of test calculations, it was determined that although the effect of tapering at an individual frequency could be substantial, the overall effect on $P_{\ell S}$ and S_{xy} was quite small, generally less than 4%. Thus in the present analysis, no taper was employed.

The depth of water, Δh , overlying the pressure sensors is obtained from $a_1(0)$ and $a_2(0)$ as

$$\Delta h = \frac{0.5}{\gamma} [a_1(0) + a_2(0)] \quad (8)$$

in which γ is the specific weight of seawater. The total water depth, h , is the sum of Δh and the distance, S_G , of the pressure sensors above the bottom (0.3 m).

Each FFT pressure coefficient is transformed to a water surface displacement coefficient by the following linear wave theory relationship

$$\{a_n(n), b_n(n)\} = \frac{1}{\gamma K_p(n)} \{a_p(n), b_p(n)\} \quad (9)$$

in which $K_p(n)$ is

$$K_p(n) = \frac{\cosh k_n(S_G)}{\cosh k_n h} \quad (10)$$

In Eq. (10) k_n is the wave number associated with the angular frequency, σ_n as obtained from the linear wave theory dispersion relationship

$$\sigma_n^2 = gk_n \tanh k_n h \quad (11)$$

One of the disadvantages of measuring waves with near-bottom pressure sensors is evident by examining Eqs. (9) and (10). For the higher frequencies (shorter wave periods) K_p is very small resulting in very small pressure fluctuations near the seafloor for the higher frequency waves. Thus, to avoid contaminating the calculated water surface displacement, η , it is usually necessary to apply a high frequency cutoff, above which the pressure contributions are discarded. The proper selection of this high frequency cutoff depends on the signal to noise characteristics of the pressure sensor and signal conditioning system. For purposes of the present analysis, the high frequency cutoff was established at a wave period of 3.1 seconds. For a nominal water depth of 6 meters, and a height of the pressure sensor above the bottom of 0.3 m, the pressure signal is attenuated to approximately 16% of its surface value. In the area of interest, where reasonably long Pacific swell occur, it is probably justified to neglect wave energy for periods shorter than approximately 3 seconds.

Denoting hereafter the FFT coefficients for the water surface displacement as $a(n)$ and $b(n)$, it is noted that the coefficients have the following properties

$$\overline{\eta^2} = \sum_{n=1}^{N-1} [a^2(n) + b^2(n)] \quad (12)$$

$$\left. \begin{aligned} \frac{a_N}{2} + k &= \frac{a_N}{2} - k \\ \frac{b_N}{2} + k &= -\frac{b_N}{2} - k \end{aligned} \right\} \quad (13)$$

and thus

$$\overline{\eta^2} = 2 \sum_{n=1}^{N/2} [a^2(n) + b^2(n)] \quad (14)$$

Thus the total (kinetic plus potential) energy, $E(n)$, associated with a particular frequency component, n , is

$$E(n) = 2\gamma[a^2(n) + b^2(n)] \quad (15)$$

Wave Direction - Consider the definition sketch in Figure 5 and the following representation for $\eta(x,y,t_j)$

$$\begin{aligned} \eta(x,y,t_j) &= \sum_{n=1}^N d(n) e^{\frac{i2\pi nj}{N}} e^{-i(k_x(n) \cos \theta(n) + k_y(n) \sin \theta(n) - \epsilon(n))} \\ &= \sum_{n=1}^N [a(n) - ib(n)] e^{\frac{i2\pi nj}{N}} \end{aligned} \quad (16)$$

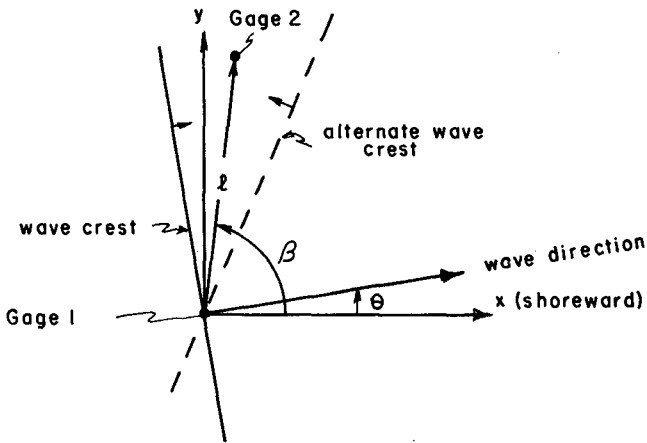

Figure 5. Showing Two-Gage Array Notation and Directional Ambiguity.

Denoting the water surface displacements at the two gage locations as $\eta(x_1, y_1, t)$ and $\eta(x_2, y_2, t)$ and calculating the cross-spectrum, $S_{12}(n)$,

$$S_{12}(n) = \overline{[a_1(n) - ib_1(n)]} [a_2(n) - ib_2(n)] \quad (17)$$

where the overbar denotes the complex conjugate,

$$\begin{aligned} S_{12}(n) &= [a_1(n)a_2(n) + b_1(n)b_2(n)] - i[a_2(n)b_1(n) - a_1(n)b_2(n)] \\ &= c_{12}(n) - iq_{12}(n) \end{aligned} \quad (18)$$

and $c_{12}(n)$ and $q_{12}(n)$ are the "co-spectrum" and "quad-spectrum", respectively of η_1 and η_2 . $S_{12}(n)$ can also be expressed as

$$S_{12}(n) = d^2(n) e^{-i[k(x_2 - x_1)\cos\theta(n) + k(y_2 - y_1)\sin\theta(n)]} \quad (19)$$

and noting from Figure 5 that the separation distance and orientation of a line joining the two gages are denoted by ℓ and β , respectively, $S_{12}(n)$ can be written as

$$\begin{aligned} S_{12}(n) &= d^2(n) e^{-ik_n \ell \cos(\theta(n) - \beta)} \\ &= d^2(n) \cos[k_n \ell \cos(\theta(n) - \beta)] - id^2(n) \sin[k_n \ell \cos(\theta(n) - \beta)] \end{aligned} \quad (20)$$

Comparing Eqs. (18) and (20), it is apparent that the wave direction, $\theta(n)$, relative to the x-axis can be expressed as

$$\theta(n) = \beta \pm \cos^{-1} \left\{ \frac{1}{k_n \ell} \tan^{-1} \left[\frac{q_{12}(n)}{c_{12}(n)} \right] \right\} \quad (21)$$

where the \pm is the result of a directional ambiguity associated with a two-gage array (Figure 5) and is avoided by choosing the minus sign which selects the wave arriving from the seaward half-plane adjacent to a line joining the two gages.

There are two conditions for which it was not possible to calculate the wave directions $\theta(n)$. These include poorly conditioned wave data, presumably due to spectral leakage, and spatial aliasing due to the fairly large separation distance (≈ 23 m) between the two gages. If the data are poorly conditioned for determining wave direction, the absolute value of the quantity within the brackets $\{ \}$ in Eq. (21) may exceed unity, clearly a physically impossible condition since the extreme values of the cosine function are ± 1 . This tended to occur for very long waves for which the energy was small and the value of k_n was also small. The percentage of energy within an individual record for which this condition occurred was relatively small, averaging 2% to 3% with a maximum of approximately 10%. The second condition is related to spatial aliasing

and requires that the wavelength be equal to or greater than twice the projection of the wave gage separation distance in the direction of wave propagation. Referring to Figure 5

$$L > 2\lambda [\cos(\theta - \beta)]_{\max} \quad (22)$$

which indicates that for the least adverse effects of spatial aliasing, the gages should be on an alignment parallel to the dominant orientation of the wave crests. In our case $\beta = 86.8^\circ$ and in general, the waves approach within approximately 40° of the shoreline. For purposes here, a variable aliasing frequency limit was developed for each record depending on the wave directions for the lower frequencies. Three frequency limits were considered, corresponding to $|\theta - \beta|$ values of 45° , 60° and 75° , with the 75° value associated with the highest frequency limit. Selection of the frequency limit required that 90% of the wave energy in a frequency range $\sigma_A/2$ to σ_A lie within the associated wave direction range, where σ_A is the frequency corresponding to the particular aliasing wave direction (Eq. (22)). For the water depth at the site, the three directional limits of 45° , 60° and 75° are associated with approximate wave periods of 5.3, 4.2 and 3.1 seconds, respectively. The percentage of energy associated with periods shorter than 5.3 s. was substantial in our data, amounting to 25-30%. In later calculations of P_{ℓ_S} and S_{xy} , an attempt was made to account for the energy above the aliasing frequency by augmenting the calculated values, illustrated for P_{ℓ_S} as follows, by

$$\left\{ P_{\ell_S} \right\}_{cm} = \left\{ P_{\ell_S} \right\}_c \frac{E_{TOT}}{E} \quad (23)$$

in which the subscripts "c" and "cm" indicate calculated and calculated modified respectively. E_{TOT} and E represent the total wave energy values and the energy below the spatial aliasing frequency. In a sense, this modification is equivalent to associating the effective direction as determined from the frequencies not affected by the aliasing consideration or poorly conditioned data to all the wave energy.

Transformation of Wave Spectrum to Breaker Line

Determination of Breaking Depth - At this stage, the wave energy and wave direction in the vicinity of the gages are determined. These values are then transformed to the breaker line accounting for shoaling and refraction.

To determine a breaking depth, a method suggested by T. L. Walton was employed in which the total onshore flux of wave energy was equated at the gages and at the breaker line with the requirement that the root-mean-square breaking wave height H_{rms} be related to the water depth by

$$\left(H_{rms} \right)_b = \kappa h_b \quad (24)$$

in which κ was taken as the usual spilling breaker value of 0.78. The total onshore energy flux, F_R , at the reference (gage) location is

$$F_R = 2\gamma \sum_{n=1}^{N/2} [a^2(n) + b^2(n)] C_{G_n} \cos \theta_n \quad (25)$$

in which the subscript "R" denotes the reference location. Considering shallow water conditions for breaking $C_{G_n} = C_G = \sqrt{gh_b}$ and $\cos \theta_b \approx 1.0$, the onshore energy flux at breaking is

$$F_b = \frac{\gamma H_b^2}{8} \sqrt{gh_b} = \frac{\gamma \kappa^2}{8} \sqrt{g} h_b^{2.5} \quad (26)$$

Equating F_R and F_b

$$h_b = \left[\frac{16 \sum_{n=1}^{N/2} [a^2(n) + b^2(n)] C_{G_n} \cos \theta_n}{\kappa^2 \sqrt{g}} \right]^{0.4} \quad (27)$$

It is worthwhile to note that neglecting wave refraction in the breaking depth determination does not result in very large errors. For example for a wave direction at the gages of 30° , the error in breaking depth would be less than 6%. For a more realistic overall wave direction of 20° , the associated error in breaking depth is less than 3%.

Transformation of Wave Components to Shore - With the breaking depth known, each wave component is transformed to shore accounting for both wave refraction and shoaling based on linear wave theory.

Wave refraction was computed in accordance with Snell's Law and the assumption that straight and parallel contours existed between the gage and breaking locations,

$$\theta_b(n) = \sin^{-1} \left[\frac{C_b(n)}{C_R(n)} \sin \theta_R(n) \right] \quad (28)$$

Shoaling was based on linear theory, resulting in the value of the sums of the squared FFT coefficients at the breaker line of

$$[a^2(n) + b^2(n)]_b = \frac{\cos \theta_R(n)}{\cos \theta_b(n)} \frac{(C_G(n))_R}{(C_G(n))_b} [a^2(n) + b^2(n)]_R \quad (29)$$

in which the first and second ratios on the right-hand side of the equation represent the effects of refraction and shoaling, respectively.

Computation of $P_{\ell S}$ and S_{xy} at the Surf Line

With the wave energy and direction known at the breaker line, the values of longshore component of wave energy flux, $P_{\ell S}$, and flux in the onshore direction of the longshore component of momentum, S_{xy} , are readily determined.

$$P_{\ell S} = G \left\{ 2\gamma \sum_{n=1}^{N/2} [a^2(n) + b^2(n)]_b \left(\frac{C_G(n)}{C(n)} \right)_b (\cos \theta(n) \sin \theta(n))_b \right\} \quad (30)$$

$$S_{XY} = G \left\{ 2\gamma \sum_{n=1}^{N/2} [a^2(n) + b^2(n)]_b \left(\frac{C_G(n)}{C(n)} \right)_b (\cos \theta(n) \sin \theta(n))_b \right\} \quad (31)$$

where the factor G is given by the ratio

$$G = \frac{E_{TOT}}{E} \quad (32)$$

as defined in and discussed in relation to Eq. (23).

It is worthwhile to comment on possible errors due to determination of the breaking depth, h_b . Under the condition of straight and parallel bottom contours as considered here, the value of S_{XY} at the gage and breaker line locations are identical. Since S_{XY} is independent of depth there is no associated error in this estimate and comparison of Eqs. (30) and (31) shows that $P_{\ell S}$ and S_{XY} differ only by the celerity, C_b , at the breaking depth. It follows that if breaking occurs under shallow water conditions (generally a good assumption), the associated error in $P_{\ell S}$ is proportional to the square root of the ratio of the respective water depths. For example, if the breaking water depth is overestimated by 20%, then the associated $P_{\ell S}$ value would be too large by 9.5%.

Determination of Gage and Shoreline Orientations

In the calculation of directional wave properties relative to the shoreline, it is extremely important to establish the orientation of the wave gage array and a representative shoreline orientation.

Orientation of Wave Gages - During the original study, the locations of the wave gages had been established by measuring angles with transits from two known shore stations on the project baseline. These angles were then translated into gage locations through standard geometric procedures. Two sets of such measurements had been carried out on June 24 and 26, 1974. The resulting gage characteristics are presented in Table II.

Although the gage separation distances as obtained from the two surveys differ somewhat more than desired, it is the gage orientations differing by 3.6° that is of particular concern. Thus on June 7, 1980, these variables were reestablished using range-range microwave equipment. Measurements were obtained from three combinations of shore-based locations, thus allowing a much better determination of gage orientation. These results are also presented in Table II and the averages of all values were adopted for purposes of this study.

TABLE II
GEOMETRIC CHARACTERISTICS OF TWO-GAGE ARRAY

Date	Gage Separation Distance	Gage Orientation With Respect to Baseline
June 24, 1974	23.55 m	10.81°
June 26, 1974	22.71 m	14.44°
June 7, 1980		
Trial 1	23.8 m	15.81°
Trial 2	23.2 m	12.74°
Trial 3	22.6 m	12.36°
Values Adopted For This Study	23.2 m	13.23°

Effective Shoreline Orientation - The determination of effective shoreline orientation proved to be a somewhat more difficult problem at this site than originally anticipated. One difficulty is that dredging and subsequent filling by longshore sediment transport in the impoundment area caused local anomalies in the bottom contours such that they were not quite straight and parallel. In particular, following a dredging event, the nearshore contours move landward more than the seaward contours. It is believed that this is an expression of the concentration of the longshore sediment transport in the nearshore zone.

The shoreline orientation was established by plotting and overlaying profiles located in the vicinity of the wave gages. The relative landward-seaward locations of the profiles were adjusted in the overlays to obtain best agreement by eye and the associated orientation determined. A range of orientations was obtained by matching the nearshore and offshore portions of the profiles. These ranges were qualitatively consistent with those determined from aerial photography, with the larger angles associated with the more seaward portions of the profiles.

TABLE III
SHORELINE ORIENTATION AS DETERMINED FROM BEACH AND OFFSHORE PROFILES

Date of Survey	Range of Effective Shoreline Orientation Relative to Baseline
May 8, 1974	9.95° to 11.33°
June 18, 1974	8.83° to 10.78°
Value Adopted In This Study	10.07°

Correlation of I with $P_{\ell S}$ and S_{xy}

In the correlation of $P_{\ell S}$ and S_{xy} with I, only the values directed toward the trap were used. The rationale is that during all periods when waves were directed toward the trap, there was sediment available for transport and therefore this variable provides the best basis for correlation.

The volumetric accumulations were interpreted as I values by Eq. (3) using $p = 0.35$ and by dividing by the time (in seconds) between surveys. The wave data were available nominally every two hours. The value of $P_{\ell S}$ (and S_{xy}) for a survey period was obtained by summing all $P_{\ell S}$ values directed toward the trap and dividing by the total number of wave recordings.

RESULTS

Table IV presents a summary of the analyzed data. A number of correlations were carried out to determine best fits of the transport data, I, with $P_{\ell S}$ and S_{xy} . These results are summarized in Table V.

TABLE IV
SUMMARY OF ANALYZED DATA

Survey Period	I (N/s)	$P_{\ell S_-}$ (N/s)	$P_{\ell S_+}$ (N/s)	S_{xy_-} (N/m)	S_{xy_+} (N/m)
July 30, 1974 to Aug. 20, 1974	182.1	120.3	49.9	22.3	10.3
Aug. 20, 1974 to Sept. 24, 1974	144.6	153.5	46.2	26.4	8.6
Sept. 24, 1974 to Nov. 6, 1974	171.2	295.8	158.2	39.2	25.6
Nov. 6, 1974 to Jan. 7, 1975	439.3	426.8	80.9	57.7	10.7
Jan. 7, 1975 to Feb. 11, 1975	401.4	446.6	0.0	57.0	0.2
Feb. 11, 1975 to March 4, 1975	245.8	330.9	144.5	45.7	17.5
March 4, 1975 to April 14, 1975	326.2	783.8	30.0	100.0	6.9

Note: $P_{\ell S_-}$ and S_{xy_-} represent fluxes toward the trap and

$P_{\ell S_+}$ and S_{xy_+} represent fluxes away from the trap.

TABLE V
 SUMMARY OF CORRELATIONS OF I WITH $P_{\ell S}$ AND S_{xy}
 ($P_{\ell S}$ and S_{xy} Are Values Directed Toward Trap)

Basis for Correlation	Coefficient	Percentage Standard Deviation in K or K_*
Least Squares Fit, Arithmetic Basis, $I = KP_{\ell S}$	$K = 0.65$	
Least Squares Fit, Logarithmic Basis, $I = KP_{\ell S}$	$K = 0.92$	
Individual Points $I = KP_{\ell S}$	$\bar{K} = 0.87$	39.6%
Least Squares Fit, Arithmetic Basis, $I = K_* S_{xy}$	$K_* = 4.98 \text{ (m/s)}$	
Least Squares Fit, Logarithmic Basis, $I = K_* S_{xy}$	$K_* = 6.37 \text{ (m/s)}$	
Individual Points $I = K_* S_{xy}$	$\bar{K}_* = 5.90 \text{ (m/s)}$	33.3%

Figure 6 presents a plot of the seven data points in the form of I vs. $P_{\ell S}$ where the energy flux value is directed toward the trap. In addition, a sensitivity analysis has been performed in which the horizontal bars represent the variation in $P_{\ell S}$ due to a $\pm 0.5^\circ$ variation in orientation of the offshore pressure gages. The vertical bars represent the variation in I due to a uniform variation in sand elevation of ± 5 cm over the area surveyed. The different bar lengths occur in $P_{\ell S}$ due to various effective wave approach angles and in I due to various volumes accumulated between surveys. It appears from Figure 6 that there is a low energy flux upward bias due to the tendency of the trap to collect material even for waves propagating directly toward shore.

SUMMARY AND CONCLUSIONS

Measurements of immersed sediment transport rate, I, as inferred from sediment accumulation in a near-total trap were correlated with longshore energy flux at breaking, $P_{\ell S}$, and the onshore flux of the longshore component of momentum, S_{xy} , as calculated from two pressure sensors mounted near the bottom.

Figure 6. Plot of I vs. P_{ℓ_S} Results From Present Study. Horizontal Bars Represent $\pm 0.5^\circ$ in Offshore Gage Orientation. Vertical Bars Represent ± 5 cm Uniform Thickness of Sand. The Numbers Denote the Sequence of Intersurvey Periods.

Based on the analysis of seven volumetric accumulation periods, it is concluded that:

- (1) On an overall basis, the results agree reasonably well with some of the previous studies. Depending on the method of analysis, the best fit dimensionless constant K in the relationship $I = KP_{\ell_S}$ ranges from 0.65 to 0.92,
- (2) For the same seven intersurvey periods, the K values obtained here are substantially lower than those obtained by Bruno and Gable (1976) as based on visual wave estimates. Their average K value is 1.40 as compared to 0.87 obtained here.
- (3) A pair of wave gages appears to perform reasonably well to determine overall directional characteristics such as P_{ℓ_S} ; however, the quality of the detailed directional results could be improved substantially by a greater number of gages.
- (4) In calculating wave direction from an array of gages, it is extremely important to determine accurately the relative locations of the gages and the shoreline orientation. For

the present data, an angular misalignment of $\pm 0.5^\circ$ can cause an associated change in P_{gS} ranging from 8% to 18%. This effect is accentuated for small obliquity of the incident waves.

- (5) An offshore breakwater, if dredged below the equilibrium topography is expected to cause an upward bias in the volumes trapped. This effect appears present in the data; the points associated with small longshore energy flux values lie above the usual relationship. Moreover, there is a tendency for the individual K values to decrease as the trap fills (Figure 6). Unfortunately, at present, the magnitude of the bias exerted by an offshore breakwater on trapped quantities and the variation of this bias following a dredging event is unquantified. The best approach in the present case may be through the use of a detailed numerical model. It is expected that the K results developed in the present study contain an upward bias.
- (6) There are variations in the K values that cannot be explained through appeal to any evident mechanisms or processes. For example, the K value associated with the last (seventh) intersurvey period is approximately one-half the average of the values for the fourth and fifth intersurvey periods.
- (7) The environmental and economic significance of an improved quantitative predictor for longshore sediment transport justifies substantial future field programs to discern the effects of individual variables (e.g. grain size, beach slope, etc.) and in general, to develop a more accurate predictor.

ACKNOWLEDGEMENTS

The approval of the Coastal Engineering Research Center (CERC) to utilize the data forming the basis for this paper is appreciated. Dr. T. L. Walton of CERC offered helpful discussions and encouragement throughout the study. The Computing Center of the University of Delaware provided support for the required computer time.

MIGRATION OF LONGSHORE BARS

by

Hans H. DETTE

1)

ABSTRACT

It is known that nearshore areas occupied by longshore bars constitute a zone of active migration of bottom deposit due to agitation by breaking waves and wave-induced on-/offshore currents and longshore currents. So far there is still a lack of actual data from the field itself concerning the magnitude and variability of single parameters involved in the stability and migration of longshore bar features.

This paper summarizes data collected from a comprehensive field study in the years from 1976 to 1979 when grain size distributions were obtained from a narrow grid of core samples and repeated soundings and continuous measurements of waves and wave-induced currents were carried out. With regard to the characteristics of different longshore bar feature relationships e. g. in between bottom gradients and mean grain sizes are analyzed. Furthermore distinct types of topographic response within the submarine belt occupied by longshore bars depending upon the variable intensity and position of breaking waves and the resulting magnitude and variability of wave-induced currents are pointed out and presented for discussion as a contribution towards a general understanding of longshore bar characteristics and changes.

1. Introduction

Sand bars extending mostly parallel to the shoreline are generally known as longshore bars. They are characteristic features of sandy beaches all over the world. Although varying considerably in size and form longshore bars belong to one of two general types; one type is predominant on non-tidal beaches and the other on beaches with a considerable tidal range.

1) Dr.-Ing. Div. of Hydrodyn. and Coastal Eng., Technical Univ. of Braunschweig, Germany

Longshore bars common to tidal seas are mostly fully developed and mainly located several hundred meters distant from the shoreline at the breaking position of large plunging breakers (see e. g. DETTE, 1980). Earlier it was proposed by KING and WILLIAMS, 1949) that this type of longshore bar might be referred to as "ridge and runnel" beach in order to distinguish this feature from that type of longshore bars predominant in non-tidal seas which should be referred to as "barred beaches".

Longshore bars in non-tidal seas occupy a definite belt on the submarine slope which KING and WILLIAMS (1949) defined as the nearshore area lying in between the waterline and the two-fathom line (approx. MSL - 3.5 m). Beach gradient figures since then mostly refer to that zone.

The belt covered by longshore bars usually extends over a third to a half of the total width of the submarine slope. ZENKOVICH (1967) concluded from extensive field observations in the Anapa region of the Black Sea that the lateral movement of material is fairly intensive in the bar zone. In regions in which longshore bars are well developed there may be up to four, five, or even six of them. Most frequently, however, there will be two, or even only one, which will be fairly close to the shore in relation to the total width of the nearshore area.

So far very few quantitative data are available on the relationships between wave action and topographic response of longshore bars. This study carried out in the non-tidal western part of the Baltic Sea (Kiel Bight) is an analysis of:

1. Grain size distribution obtained from core samples taken in a narrow grid within the area of investigation (12 kilometers in length and more than 1 kilometer distant from the shoreline)
2. Repeated soundings and beach levellings in the area of investigation
3. Longterm measurements of waves and wave-induced on-offshore and longshore currents at different points

within a selected submarine profile which is considered to be characteristic for the area of investigation

The data revealed two distinct types of topographic response within the belt occupied by longshore bars.

1. Changes that involve only shifting of the bed material in on-/offshore direction because, due to normal water levels, the breaker position of the highest breakers is located at the seaward slope of the outer bar. Only small waves ($H < 1.0$ m) pass over the bars and cause only weak longshore currents which in relation to the present grain size are not able to displace considerable amounts of material alongshore.
2. Changes that involve besides on-/offshore shifting major alongshore displacement of material. This process is connected with storm surge conditions occurring with a return period of approx. 5 years. During such events due to wind set-up, the still water level is increased by more than 1.5 m. Lasting sometimes for more than 100 hours the breaking position of the large breakers is shifted landward into the longshore bar belt. According to the water level increase higher waves pass over the bars and bring higher wave energy loads to corresponding points in the submarine profile compared to wave energy loads occurring with normal water levels. Due to the higher "breaking loose forces" (BRUUN, 1966) the longshore currents in response are increased considerably above the boundary values known for the initiation of sediment motion alongshore.

2. Presentation of data

2.1 About the study site

The field studies concerning the wave energy dissipation and magnitude of wave-induced currents as the impact forces and the topographical con-

figuration of the submarine slope as the response factor were carried out in the Kiel Bight (Fig. 1) located in the western part of the Baltic Sea which can be regarded as an enclosed sea in which waves are generated locally and have only little space in which to disperse before reaching a shoreline. The result of intermittent storm wave action typical for enclosed seas is a more or less distinct system of longshore bars because swell does not occur in order to sweep the bars back to shore. The longshore transport is almost completely confined to the surf zone which necessarily is wider than the surf zone on an oceanographic coast averaged throughout the year (SILVESTER, 1974).

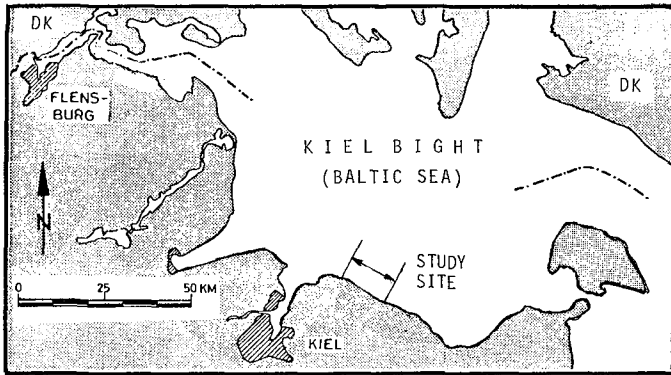

Figure 1: Location of the study site

Like in other enclosed seas, storm waves within the Baltic Sea are occurring mostly from a fairly narrow sector (DETTE and STEPHAN, 1979) so that a resultant vector applicable to any point on the coast can be derived and a predominant uni-directional alongshore transport can be assumed.

Figure 2 shows in more details the area of investigation which can be regarded as a physiographic unit consisting of an eroding feeder cliff which lies approx. 5 kilometers south-east of point 11 marked on the shoreline and an area of accretion located south-west of point 3. The zone between point 11 and point 3 can be considered as the transition area concerning alongshore transport.

Figure 2: Plan view of the study site with indication of selected study sections (Area 1 to 3) and points of wave and current measurements in the nearshore zone (Position 75 m, 125 m, and 950 m)

In the study area storm waves approach from the sector North-East causing a predominant longshore transport in Western direction.

2.2 Characteristics of longshore bar features in relation to the grain size distribution

Within the study site, which can be considered as a physiographical unit of beach section, a system of different longshore bar features exists, lying generally upon silty clay and sometimes above troughs filled up in recent times. The bars consist of ridges with heights up to more than 1.0 m, widths of several meters and in length they sometimes extend over miles.

The topography of the submarine zone within the study site can be described by mean profiles which are found in Area 1, 2, and 3 (Fig. 2) and correlated with grain size distributions which have been analyzed by KÜSTER, 1979. In Figure 3 three different longshore bar features typical for this area are shown.

Within the eastern part of the study site represented by the mean profiles found in Area 1 and Area 2 (Fig. 2) where the sand transported alongshore is originating from a nearby cliff, mainly one or two bars can be detected. They are located fairly close to the shore in relation to the total width of the nearshore zone.

The inner bar here predominately consists of sand with maximum grain sizes between 0.18 mm to 0.25 mm (fine sand). The outer bar in this area, however, has maximum grain sizes below 0.18 mm (very fine to fine sand). In the troughs, however, coarser sediments are found.

In Area 2 (Fig. 2) a 'geological boundary' is obvious. This was detected by KÜSTER (1979) after plotting the band of sediment distribution containing more than 80 percent of grain sizes between 0.06 mm and 0.20 mm (Fig. 2). This band is connected with that part of the study site where one or two bars have been found to be the typical features.

Figure 3: Mean longshore bar configurations within the study site
(Area 1, 2, 3 - see Fig. 2)

Towards the west from this boundary, that is in the direction of predominant longshore transport, a splitting-up of the longshore bar system into a multiple bar system takes place as is shown by the representative mean submarine profile for Area 3 (Fig. 2) in Fig. 3.

The bar pattern in the total study site furthermore can be evaluated from Fig. 2 by considering the areas representing contents of fine sand (0.06 mm to 0.20 mm) between 20 to 50 percent.

A typical phenomenon of the western study site is a considerable increase of the longshore bar belt in width compared with that in the Eastern part. This feature is directly related to an increase in grain size within the longshore bar belt up to a maximum between 0.25 mm and 0.35 mm which means medium sand without fine particles whereas grain sizes below 0.18 mm can be considered to be representative for the bar belt in the Eastern site.

Additionally to the investigations of fine and very fine contents of sand ($d \leq 0.20$ mm), KÜSTER (1979) analyzed the distribution of mean grain sizes (d_{50}) in different classes between $d < 0.18$ mm und $d > 0.5$ mm. Fig. 4 shows part of the results for the areas 2 and 3 which are representative of the two different longshore bar features; the crest positions of the single bars in Area 2 and 3 are marked for the purpose of orientation.

Figure 4: Distribution of mean grain sizes (d_{50}) summarized in five classes by KÜSTER (1979)

With regard to relations between longshore bar characteristics and grain size distributions within the study, the most important parameters are compiled in Table 1. From the results it can be concluded that a longshore bar system is characterized by a narrow range of materials and bottom gradients.

Table 1: Compilation of longshore bar characteristics and grain size distribution within the study site

		Area (see Fig. 2 and 3)		
		1	2	3
Bottom	A **)	1 : 75	1 : 90	1 : 150
Gradient	B ***)	1 : 110	1 : 125	1 : 220
Distance of outer bar from MSL		110 m	220 m	370 m
Crest height of outer below MSL		- 1.0 m	- 1.4 m	- 1.7 m
Mean grain size at outer bar		< 0.18 mm	< 0.18 mm	0.25 - 0.35 mm

**) Bottom gradient between MSL and MSL - 3 m

***) Bottom gradient between MSL and crest of the outer bar

The bottom gradients can be expected in the range between 1 to 50 and 1 to 200 (between MSL and the seaward boundary of the nearshore belt). When the gradient is slight, the number of bars increases. The bottom gradients are in turn connected with the nature of material. Longshore bars rarely will be found in areas where the mean size of the sand particles is greater than $d_{50} = 0.5$ mm and hardly ever found when particle sizes are smaller than $d_{50} = 0.1$ mm.

These findings are in good agreement with the investigations carried out in the Black Sea (ZENKOVICH, 1967).

2.3 Incoming waves and wave-induced currents in the nearshore zone

For the western part of the Baltic Sea within the Kiel Bight (Fig. 1) two typical storm conditions occurring intermittently were found out during the longterm field measurements:

1. Storm winds without causing considerable wind set-up (below + 1.0 m MSL)
 - Wind speeds: 20 to 30 knots
 - Wind direction: E to NE
 - Wind duration: Hours up to several days
 - Wave heights: $H_{\max} < 3.0$ m
 - Wave periods: $T_m = 3.0$ to 5.0 secs
 - Return period: 5 to 10 times per year

2. Storm winds causing storm surge conditions with considerable wind set-up (above + 1.5 m MSL)
 - Wind speeds: 30 to 50 knots
 - Wind direction: E to NE
 - Wind duration: Up to several days
 - Wave heights: $H_{\max} = 3.0$ m to 4.0 m
 - Wave periods: $T_m = 4.0$ to 5.5 secs
 - Return period: Once in 5 to 10 years

The time history of a storm surge event which lasted for more than 100 hours from December 28th, 1978 up to January 1st, 1979 is plotted as an example (Fig. 5). Measurements of wind and wave conditions were carried out during that event at intervals of 2 hours.

Storm events lasting for more than 100 hours but blowing with minor wind speeds and thus causing only negligible wave set-up also occurred during the period of measurements and were recorded.

For the two distinct events mentioned above, two representative records of wave heights and wave-induced on-/offshore currents and longshore currents measured at two locations within the surf zone are presented.

Figure 5: Time history of a storm surge event with wave set-up to +1.5 m MSL with regard to water level, wind, and wave conditions

Figure 6 is an example of storm winds causing negligible wave set-up and Figure 7 is an example of a storm surge event with wave set-up of 1.5 m above MSL.

By comparing Fig. 6 and 7, the location and width of the surf during both events appear to be more or less identical. The incoming waves break at identical locations of the submarine profile, but, are very much different because the water level increases up to 1.5 m above MSL and approx. 1.0 m higher breakers occur during storm surge conditions in comparison to the normal storm conditions.

The consequences of the large breakers and set-up are demonstrated by the rapid increase in the mean longshore velocities as well as the peak velocity components during a 10 minute record. During normal conditions (Fig. 6), the mean longshore current velocities are below $\bar{V}_L = 0.3$ m/sec which can be considered as the boundary value for the initiation alongshore transport of sediments found within the study site. Due to the higher breakers during storm surge conditions (Fig. 7) the mean longshore current velocities are increased considerably and reach mean velocities up to $\bar{V}_L = 0.8$ m/sec; accordingly a large alongshore flux of sediments can be assumed.

The changing and shifting of the longshore bar characteristics during periods without wave set-up (= normal conditions) and after a storm surge event with a return period of 5 to 10 years is demonstrated by comparing echo-sounded submarine profiles at distances of 100 m within Area 3 (Fig. 2). The erosions and accretions are plotted in Figure 8 (left side for a period without wave set-up and right side for a period with wave set-up over + 1.0 m MSL at a total of more than 100 hours).

3. Discussion

It is obvious that there exists a close relationship between the special longshore features, which may consist of one bar or multiple bars, and the grain size distribution.

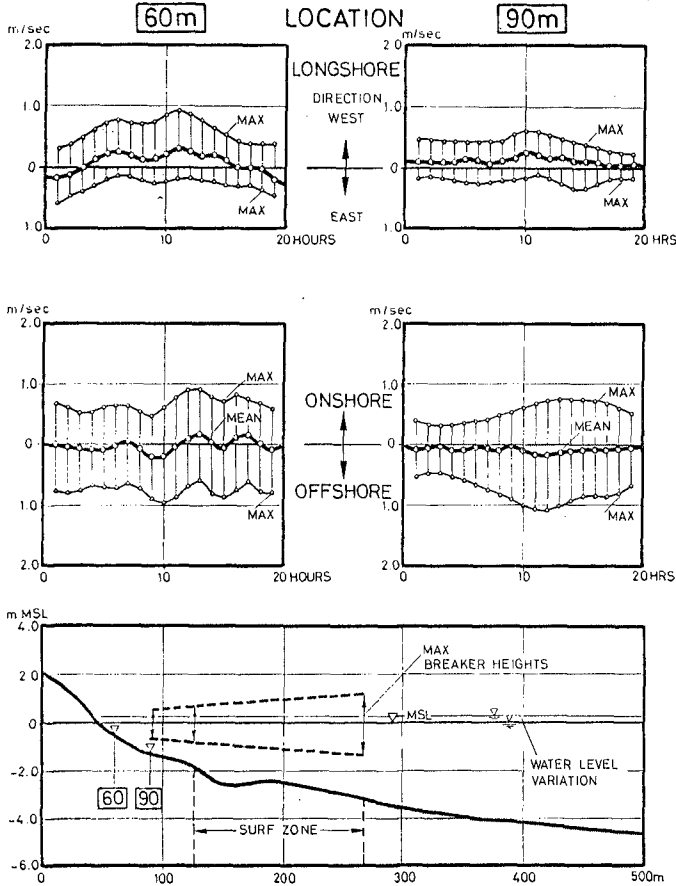

Figure 6: Location of the surf zone, envelope of max. breaker heights and wave-induced currents during normal storm winds causing negligible wave set-up

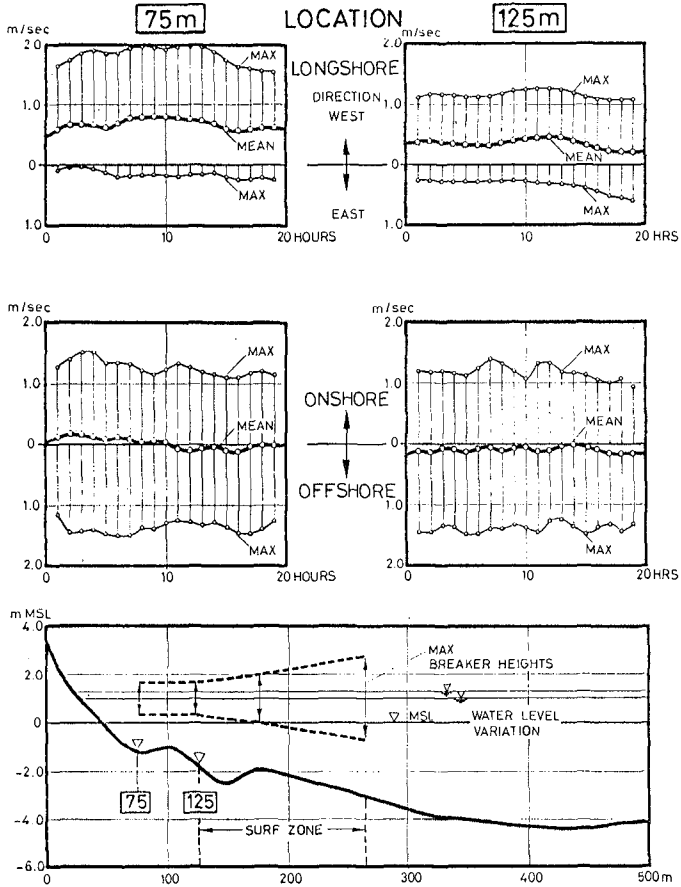

Figure 7: Location of the surf zone, envelope of max. breaker heights and wave-induced currents during storm surge conditions with a wave set-up of 1.5 m above MSL (see Fig. 5, measurements starting at 08.00 HOURS DEC. 29, 1978)

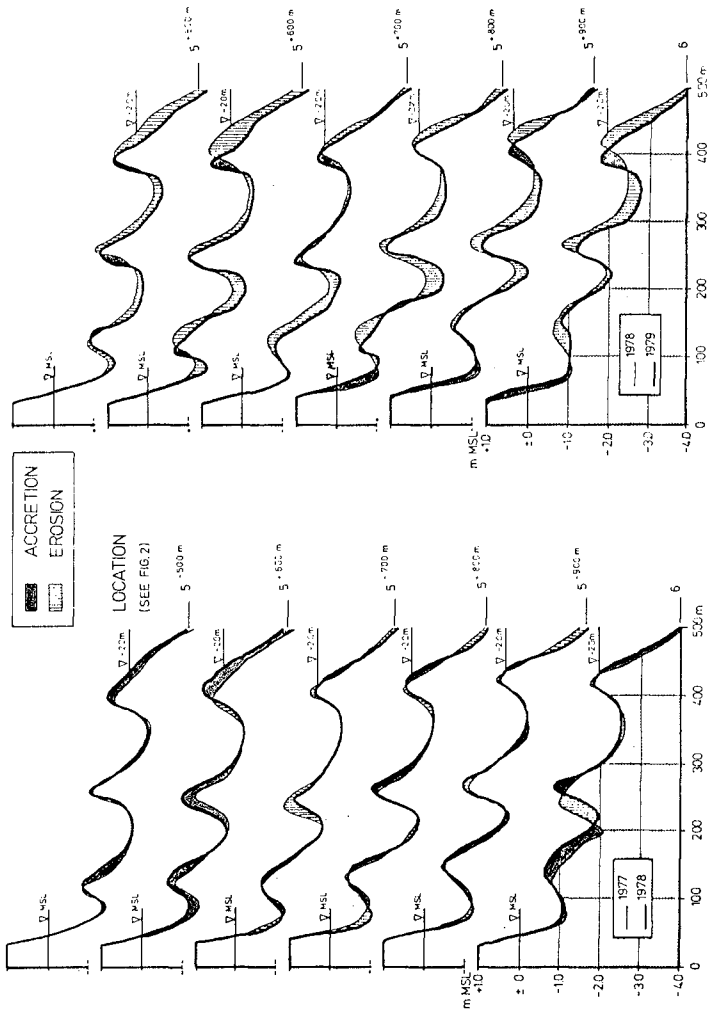

Figure 8: Changes and shiftings of the longshore bar characteristics after periods with normal storm conditions only (left side) and with storm surge conditions (right side)

With regard to the interactions of breaking waves and wave-induced currents, it can be concluded from the field study that the primary, or initial, effect on longshore bar formation and deformation is the breaking wave energy which causes the more intense on-/offshore oscillatory currents and greater magnitude and variability of longshore currents. Further investigations are necessary in order to study in more detail for example the different wave-induced currents in the vicinity of a bar trough or the bar crest. The present paper is thought as a contribution towards the collection of reliable data from the field itself as input data for further theoretical treatment of the problems.

4. Acknowledgements

The author wishes to express his thanks to the "AMT FÜR LANO- UND WASSERWIRTSCHAFT KIEL" which enabled the comprehensive field investigation programme and to Professor Köster from Kiel University who kindly placed at disposal his investigations concerning the sediment distribution within the study site.

CHAPTER 90

A PHASED-DREDGING PROGRAM FOR SANTA CRUZ HARBOR

By James R. Walker¹ and Peter J. Williams²

SUMMARY

This project was undertaken to define the littoral processes and resultant shoaling mechanisms at the Santa Cruz Harbor California, entrance channel and to develop and evaluate alternative methods of mitigating the shoaling effects. Since November 1963, when the construction of the entrance channel was finished, the channel has shoaled such that it was almost completely closed during the winter months. The study involved analysis of shoaling mechanisms and contour changes and review of past dredging procedures. Sixteen structural and non-structural alternatives for mitigation of shoaling were analyzed. A phased-dredging procedure was developed and tested over 3 winter seasons. The concept was to dredge the channel periodically each winter while shoaling occurs, thereby keeping the Harbor open to navigation most of the time. The experience gained at this site may be of benefit to others in solving a shoaling problem or in designing a new small-craft harbor.

INTRODUCTION

History

Santa Cruz Harbor, shown in figures 1 and 2, is located on the northern coast of Monterey Bay, about 65 miles south of San Francisco and 14 miles north of Moss Landing. Construction of the Harbor was authorized in 1958³. The authorized improvements included two rubble mound jetties, an entrance (outer) channel, an inner channel, a turning basin, and a sand-bypassing plant. The Harbor, figure 3, was created by dredging a 20-foot-deep channel, connecting a lagoon to the Ocean. The channel and Harbor are protected by two jetties that extend about 900 feet seaward of the beach that existed prior to the project. The jetties are 400 feet apart and the updrift (west) jetty is doglegged. The Harbor provides berthing facilities for 1,000 boats. Construction of the Harbor was initiated in February 1962 and the project was completed in November 1963, with the exception of the sand-bypassing plant which was deferred until the littoral-transport rate could be more accurately determined.

FIGURE 3: PROJECT FEATURES

PHOTO 1: SANTA CRUZ HARBOR IN SHOALED CONDITION

The entrance channel began to shoal in 1965 and navigation was severely impaired by a dangerous shoal, shown in photograph 1, for 4 months during each winter. Annual maintenance dredging on the order of 100,000 cubic yards per year had been required in the spring of each year from 1965 until 1977, when a multiyear, dredging program was implemented to maintain the channel during the winter season. In addition to the maintenance dredging, an experimental jet-pump bypassing system was installed in 1976 by the Waterways Experiment Station (WES) to field-test this new equipment. This eductor field test was terminated in March 1978.

Purpose and Scope

This study was conducted in 1977 to develop both short-term and long-term solutions to the shoaling problem with the short-term solution to suffice for the next few years. The objective was to define the littoral transport and shoaling mechanisms, with the view of developing a reliable engineering solution from existing data. This approach differs considerably from that of Seymour, et al. (1980), who were concerned with correlating potential littoral transport rates (predicted by analysis of results of a wave-gage array) with quantities of material dredged.

Physiography

The shoreline region lying northwest of Santa Cruz comprises sea cliffs and small pocket beaches, which occur mostly at the mouths of small creeks. Wave-induced erosion of the sea cliffs is a possible source of littoral drift at Santa Cruz. Near the Ocean, the steep-gradient streams originating in the Santa Cruz Mountain Range have small drainage areas and their flows are characterized by flash floods. The San Lorenzo River, 0.5 miles west of Santa Cruz Harbor, has a relatively small drainage basin of 137 square miles and an annual runoff of 125,000 acre-feet. The heaviest runoff occurs during the winter months, October through April. Estimates U.S. Army Corps of Engineers (1974) indicate that the annual sediment discharge of the San Lorenzo River is between 88,000 and 133,000 cubic yards. Of this total, 20 percent, or 18,000 to 27,000 cubic yards had sand sizes similar to those found on beaches in the study area. Yancey (1968) also determined, by studying minerals of the River basin and beaches, that the San Lorenzo River is not a primary contributor of beach sand.

Grain-size distributions for beach sediments indicate a medium-to-fine sand with sediments shoaled in the navigation channel being slightly finer than the sand found in the splash zone. The beach slope is 1 on 15 flattening to 1 on 20 toward the 20-foot depth contour, where it flattens to a very gentle slope. Most beach erosion and accretion has occurred shoreward of the 20-foot contour.

LITTORAL-TRANSPORT ANALYSIS

Wave-energy-flux calculations were made to estimate the potential for wave-induced littoral transport. Data from the wave gages described by Seymour (1980) were not available. Furthermore, a longer period of record was required to estimate long-term averages. Therefore, several sources of wave hindcasting and observation data were analyzed to compose a composite description of the wave climate.

The waves arriving at Santa Cruz can be divided into three categories according to origin: Northern Hemisphere swell, Southern Hemisphere swell, and seas generated by local winds. The landmass geometry of Monterey Bay and the bathymetry off Santa Cruz allow swell to approach from the east clockwise through west-northwest.

Most of the wave energy reaching Santa Cruz is from Northern Hemisphere swell generated primarily by extratropical cyclones in the Northern Pacific. These cyclones are most prevalent and intense during the winter and spring seasons, generating waves from the northwest that refract around Point Santa Cruz and have heights of up to 20 feet and periods ranging from 8 to 16 seconds. The National Marine Consultants (1960) 3 year hindcasts, modified by refraction and shoaling, were used for description of Northern Hemisphere swell.

Swells generated by storms in the Southern Hemisphere occurs from May through October, but are most common during August and September. Typical Southern Hemisphere swell has wave heights between 1 and 3 feet and wave periods ranging from 13 to 21 seconds. These waves approach Santa Cruz from the south through southwest. The Marine Advisors (1960) description of the Southern Hemisphere swell was used.

Locally generated seas at Santa Cruz are most severe from December through February. Predominant winds are from the northwest and north. Locally generated seas were described using the National Marine Consultants (1960) data set for waves from the south-southeast to west and were hindcast using the Summary of Synoptic Meteorological Observations (1976) (SSMO) wind rose for fetches exposed to the east and southeast.

Monthly variations of the longshore energy flux plotted in figure 4 were calculated for shoreline of various alignments by transforming the waves to their breaking position. The local seas and the Northern Hemisphere swell are the dominant factors during the winter between December and May. February has the most active contribution of wave-energy flux and the greatest longshore component of energy flux.

The longshore littoral-transport rate was estimated by applying an empirical factor to the longshore component of energy flux (P_{1s}):

$$Q = 7.5 \times 10^3 P_{1s}$$

where Q is the longshore transport rate in cubic yards per year and P_{1s} is the longshore component of energy flux in foot-pounds per second per foot.

FIGURE 4: DISTRIBUTION OF MONTHLY POTENTIAL ENERGY-FLUX FACTOR

The variation of the potential longshore transport rate by month is also presented in figure 4. The potential net littoral-transport rate was estimated to be 488,000 cubic yards per year to the east. Approximately 80 percent of this transport occurs during the winter, between December and April. The Northern Hemisphere swell causes primarily an unidirectional eastward transport. During January, February, and March the local seas tend to cause a mild westward transport an order of magnitude less than the eastward transport.

CHANNEL SHOALING

The shoaling patterns of the entrance channel have been documented by monthly hydrographic surveys. Figure 5 shows a typical monthly progression of the 10-foot depth contour into the navigation channel during the winter season. Figure 6 shows a section of the channel between the heads of the two jetties. The patterns developed in similar fashion each year, with a tip shoal developing and then extending from the head of the west jetty across the channel toward the head of the east jetty. By January, the 10-foot depth contour had closed across the channel and the beach on the east side had receded. The influx of material into the channel during the winter appears to result primarily from sand bypassing the head of the sand-saturated west jetty. This is discussed in the following paragraph.

A fillet accreted west of the west jetty after the jetty was constructed in 1962. Figure 7, shows the advance of the shoreline at two range lines west of the west jetty. By 1965, the west jetty had trapped a fillet which extended the shoreline to 400 feet seaward of the preproject beach. The jetty was not long enough to trap additional material; therefore, in 1965, significant quantities of material bypassed the west jetty.

FIGURE 5: EVOLUTION OF CHANNEL SHOALING, 10 FT. CONTOUR

FIGURE 6: CROSS-SECTION BETWEEN HEADS OF JETTIES SHOWING SHOALING

FIGURE 7: WEST BEACH SHORELINE CHANGES

FIGURE 8: IMPOUNDMENT WEST OF WEST JETTY

Primary criteria for evaluation of the alternatives were cost effectiveness, engineering-feasibility, and minimization of adverse environmental effects. Bypassing was considered a satisfactory solution; however, material would still shoal the Harbor during storms unless the west beach were cut back to pre-1965 conditions. Citizens and homeowners who have become accustomed to a wide beach would object. Furthermore, some material would enter the Harbor by wind transport, leakage through the voids in jetty arm or units, and by reversals in littoral transport. A dredge would have to be mobilized for maintenance of the 20-foot project depth. Structural solutions would require considerable first costs; further, they would require bypassing of the net littoral transport into the area. Sealing the west jetty with a diaphragm would eliminate one of the shoaling mechanisms and reduce shoaling by about 10 percent of the total. The material would then bypass the head of the jetty, after which some material would bypass the channel and some would enter the channel. This is not considered a primary solution but could be implemented at a later date in conjunction with another system, such as an offshore breakwater. Maintenance dredging is the most direct method, wherein existing equipment and technology could be used. Therefore, a maintenance-dredging program was determined to be the most cost-effective, feasible, and reliable solution.

Figure 8 plots sand volumes impounded in the fillet west of the west jetty. Within the first 2 years of the project, 500,000 cubic yards were impounded; less than 200,000 more were impounded over the next 14 years. During this period of initial fillet-formation, the downdrift beaches experienced erosion, (Griggs 1975). The initial high rate of fillet impoundment may be partially be attributed to a relatively severe flood in 1963, which caused the San Lorenzo River to have a peak discharge rate of 13,400 cubic feet per second as compared to the long-term average of the annual maximum discharge rates of 7,961 cubic feet per second.

The shoreline east of the east jetty to Black Point had a more complex and variable evolution than that of the west beach. The jetties apparently shadow the predominantly westerly waves in the winter and cause a crescent-shaped beach to form near the east jetty. Comparison of the summer and winter shoreline configurations shows that the summer shoreline tends to rotate about 6 degrees clockwise relative to the winter shoreline.

MAINTENANCE-DREDGING RECORDS

The quantity of littoral drift that has shoaled in the entrance channel was determined through analyses of hydrographic surveys and maintenance-dredging records. Figure 9 shows the volume of littoral drift that accumulated between June 1972 and April 1978 within the control area shown in figure 10. The accumulation of material in the control area increased during each winter and was dredged in the late winter or in the spring. This dredging program was modified in 1977, when a series of multiyear, phased-dredging programs were implemented.

FIGURE 9: COMPARISON OF ACCRETION AND DREDGING QUANTITIES BY MONTH (1972-1977)

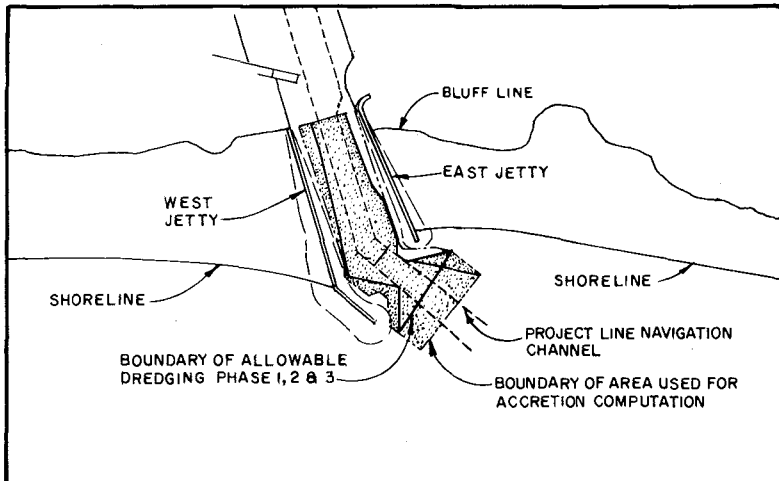

FIGURE 10: SHOALING BOUNDARIES

Maintenance-dredging records are plotted in figure 11. "Pay yardage" represents the quantity of material for which the Government agreed to pay the contractor. Pay yardage is not necessarily equal to the quantity of material actually removed. The dredgerman estimated that they actually removed as much as twice the pay yardage prior to 1977, when pay quantities were determined by comparing pre-dredging and postdredging surveys. This gave erroneous results when the dredging occurred simultaneously during the late winter and in the spring when shoaling also occurred.

The Waterways Experiment Station (WES) experimental jet-pump sand-bypassing system started operating on 26 June 1976. The bypassing system comprised three movable jet pumps operating in the channel off the west jetty, a movable jet pump at the head of the west jetty, and a stationary jet pump on the west side of the west jetty. The system was capable of bypassing about 100 cubic yards of sand per hour. The discharge area was 1,000 feet downdrift of the channel entrance, on the east beach. During the period July 1977 to June 1978, the WES plant dredged an additional 57,000 cubic yards.

FIGURE 11: ANNUAL MAINTENANCE DREDGING HISTORY

SHOALING PROCESSES

Shoaling of the Santa Cruz Harbor entrance channel can be attributed to a number of disparate littoral processes, including: bypassing a saturated jetty (acting as a groin), leakage through voids in armor units on the jetties, wind transport, onshore transport, tidal-current transport, and updrift movement. This section describes each process and analyzes the history of shoaling to estimate the relative importance of each process. The nature of the available data and the state-of-the-art of defining littoral processes render it difficult to assign a definitive percentage of quantity of littoral transport to each process. However, for design purposes, it is often necessary to make certain assumptions in areas where precise quantification is not possible. Therefore, in order to prepare a plan to mitigate shoaling, estimates of the quantity of littoral transport attributable to each of the processes were made for design purposes.

Bypassing Saturated Jetty

Sand bypassing the head of the west jetty is the primary source of channel shoaling. Within 3 years after construction of the jetties, the west fillet had grown such that it reached the angle-point of the doglegged west jetty. As the west beach moved seaward during this period, maintenance-dredging pay yardage increased to quantities of more than 100,000 cubic yards per year.

Leakage Through Voids In Jetties

The west jetty is a rubble mound, armored with quarystone and quadripods. The seaward portion of the west jetty has a concrete cap, but the jetty is not impermeable and sand can be pumped through the voids in the large armor and underlayer stones of the structure. An estimated 20,000 cubic yards of sand leaks through the voids of the west jetty into the channel annually. The east jetty has a better seal and is exposed to less wave energy. The transport into the Harbor through the east jetty is estimated to be less than 1,000 cubic yards per year.

Wind Transport

The fine sand on the beaches is susceptible to windblown transport. An estimated 5,000 cubic yards are transported eastward over the west jetty annually while 2,000 cubic yards are transported westward over the east jetty.

Onshore Transport

Onshore transport of sediments near the Harbor entrance can be a source of shoaling; however, it is difficult to estimate the quantity involved. Long-term and seasonal bathymetric measurements of the offshore area indicate very little change in the bottom at depths of greater than 20 to 25 feet. This is consistent with a limit depth calculated by methods described by Hallermecier (1978). The contribution of offshore sources is therefore estimated to be relatively minor compared with that of longshore transport because the jetty 20 feet of water.

Tidal-Current Transport

The maximum tidal currents in the navigation channel are estimated to be less than 0.15 feet per second; therefore, the contribution of tidal-current transport to shoaling is minimal. The tidal prism of the Harbor is 9.8×10^6 cubic feet or 42 acres of water-surface area with a 5.3-foot mean tidal range. The cross-sectional area of the channel maintained a 400 square foot area as predicted from the O'Brien (1968) equation.

Updrift Movement

The total potential westward component of the littoral-transport rate is about 40 percent of the eastward component; however, conditions are appropriate for westward transport primarily during times of short-duration, local storm winds, at which time the east beach is well shoreward from the head of the east jetty. Thus, the actual updrift contribution to channel shoaling is smaller than the potential updrift contribution and is estimated to be 20,000 cubic yards per year.

Natural Bypassing

Some of the littoral drift that reaches the Harbor area is believed to bypass the Harbor entrance by natural processes. The sediment budget indicates that approximately 50,000 cubic yards of littoral drift shoals in the entrance each year. Some fraction of this is accumulating on the sides of the channel. Nearly twice as much drift as that which shoals in the channel may naturally bypass the Harbor via the bar that forms across the entrance during the winter. Removal of the bar during the winter by maintenance dredging would tend to increase the amount of material trapped in the Harbor and decrease natural bypassing. The long-term solution had to be designed with this large potential bypass taken into account.

ALTERNATIVE SOLUTIONS

The 16 preliminary alternative solutions for mitigating the shoaling of Santa Cruz Harbor were developed and evaluated. Alternatives were classified in three categories: maintenance, bypassing, and structural (table 1). Maintenance pertains to the removal of material from the project channel and disposal of the material on the downdrift beach. Bypassing is a preventive procedure wherein sand is trapped or intercepted outside of the project channel and transported to the downdrift beach. A structural alternative either provides protection for a dredge or prevents material from entering the Harbor. Structural solutions must be supplemented by some form of maintenance or bypassing. In all cases, sand was to be deposited on the downdrift beach.

PHASED-DREDGING PROGRAM

Description

The philosophy of phased dredging is to maintain the entrance channel for a greater length of time each year by periodically in phases removing the shoaled material during the year rather than once annually. A phased-dredging contract would be awarded late in the calendar year to mobilize a dredge onto the site by November 15. The dredge would be activated several times between November 15 and April at times when the channel has shoaled to a minimum depth of 10 feet. A final dredging episode in April would bring the channel to over-depth and over-width project dimensions in order to create as large a storage capacity as feasible with the present entrance configuration and thus to maintain a navigable entrance channel until the following winter season.

A review of the dredging and accretion histories of Santa Cruz Harbor for the period between 1972-1977 indicates that the shoaling rate decreases between April and November and that dredging of the navigation entrance to the full project width and depth in April results in a navigable channel through the busy summer boating season. Periodic maintenance dredging would be required between November and April to keep the channel open to navigation. A total sand bypassing program with the existing Harbor entrance configuration would not be feasible because there is neither adequate protection to keep a dredge operating during storms nor sufficient storage capacity to create an effective sediment trap.

Two conflicting problems evolve. The channel should be wide and deep enough for safe navigation, yet narrow and shallow enough to maximize the natural bypassing of littoral drift during the winter. A compromise between these conflicting problems would be to reduce the project depth, at least during the winter. For example, if the navigation

channel could be maintained at a depth varying between 10 and 15 feet MLLW over a width of 100 feet, it should be reasonably safe for navigation (except during storm wave episodes) and yet not completely interfere with the movement of littoral drift that naturally bypasses the Harbor entrance seaward of the 10-foot depth contour.

Figure 12 shows the shoaling quantities and figure 13 shows the idealized phased-dredging program. Figure 13 also shows variation in shoaling quantities that have occurred and how the variation affects the program. Note a final dredge episode at the end of the winter season to clear the channel to project depth.

Results of Phased-Dredging Program

The phased-dredging program was initiated in the winter of 1977. The first contract was awarded for 2 years to Shellmaker, Inc. and the second 2 year contract was awarded to Watson, Inc. The purpose of a multiyear contract was to spread the cost of mobilization and demobilization of the dredge over more than 1 year. A longer contract period was considered; however, the experience gained during the first 2 years would benefit both contractors and the Government.

3	35,000	30,000	
FINAL (estimated)	50,000	40,000	
TOTAL	213,000	166,000	

*Includes mobilization and demobilization

Contractual and permit problems have delayed implementation of the project. The basic concept was to mobilize the dredge by 15 November each year; however, starting dates have been 19 December 1977, 19 January 1979, and 12 December 1979. The first and last delays were for legal reasons and resulted in several months of a partially closed harbor. The 1978 to 1979 winter was very mild and dredging was not required until mid-January.

The results of the first 3 years of the program are summarized in table 2. Two estimates of the quantities of material reportedly dredged during each episode and the total cost, including mobilization and demobilization for each dredging season are included. The Government pay yardage was estimated by taking leadline soundings from the back of the dredge as it operates and comparing them with predredging soundings. This method minimized the amount of material that can shoal during the dredging operation as was the case in measuring procedures prior to 1977; however, comparison of the contractor estimate compared with the government estimate reveals some large inconsistencies. In the cases revealing large inconsistencies, such as for phase 2 of the 1979-1980 winter, the contractor claimed that he dredged nearly twice the amount of material for which he was paid. The differential in estimates represents the amount of material that shoals from the time of predredge survey are taken until the time soundings were made. The dredging episodes typically last for 2 weeks. The average shoaling rate during a 2-week period is about 10,000 cubic yards. A severe storm over a 2-3-day period can deposit three times that amount. The dredgerman estimated a 26 percent greater total quantity than the Government allowed. The improved method of estimating dredged quantities has improved the differential between the amount the Government pays for and the amount the contractor claims he removes.

CONCLUSIONS

The phased-dredging program solved the shoaling problem at Santa Cruz during the first 3 years to the satisfaction of Harbor users. A large part of the success of the program is attributable to having an experienced and reliable dredgerman in charge of the operations. The system requires no initial capital expenditure for permanent structures and can be modified or adjusted to account for differences in littoral transport regimes seasonally. If at some future date, an efficient eductor system is developed and proven reliable, it can be installed at such a time.

The phased-dredging program has doubled the quantity of pay yardage compared with the previous system of dredging once in the spring. This is attributed to three factors:

1. unusually severe winters;
2. improved method of calculating pay yardage by taking soundings from the dredge; and
3. interruption of natural bypassing that occurs, when a shoal exists in the entrance channel.

RECOMMENDATIONS

1. The phased-dredging program should be considered as a viable nonstructural alternative to harbors with shoaling problems similar to those of Santa Cruz Harbor.
2. If in the future a structural solution is sought for Santa Cruz, careful consideration should be given to designing the capacity of the equipment to trap or handle an even greater quantity of material than the phased-dredging program has had to handle. For example, if a fixed eductor system is to be installed to maintain the channel to project depth, it should be prepared to remove at least 400,000 cubic yards per year.

ACKNOWLEDGEMENTS

The authors wish to thank Mr. Doug Pirie for his assistance on this project and to thank Col. J. Adsit, District Engineer, San Francisco District, Corps of Engineers, for permission to publish this summary. Mr. William Herron and Mr. Ogden Beeman participated in developing the phased-dredging procedure and Mr. James Dunham provided valuable comments.

CHAPTER 91

DESIGN OF ENCLOSED HARBORS TO REDUCE SEDIMENTATION

Craig H. Everts, M, ASCE¹

ABSTRACT

Sedimentation may be an important problem when quantities of suspended material are carried into an enclosed harbor on a flooding tide. In order to forecast future maintenance costs, two methods for predicting the sedimentation rate prior to harbor construction are proposed: 1) a sedimentation tank to be placed at the proposed harbor site, and 2) a mathematical model which uses sediment and hydraulic data collected at the harbor site.

Certain considerations in the design phase of a project may effect a reduction in harbor sedimentation. If feasible, the harbor may be sited in a region where suspended sediment concentrations are low and sediment sizes (settling velocities) are small. Proximity to river sediment sources may be a factor. Conversely, a harbor site in a clear-water river adjacent to a sediment-laden estuary may be desirable if bedload transport during freshets would not be a problem. Settlement of suspended material may occur in the channel which connects an enclosed harbor basin with navigable waters. This material may subsequently be resuspended and carried into the basin thereby increasing the sedimentation rate. To reduce that rate the channel should be designed as short as possible. A sill in the channel may also be used to reduce initial excavation costs and the sedimentation rate. Flotation for vessels in the basin will be provided at all times, but movement into and out of the harbor will be reduced to times of higher water. In high latitude areas where harbor use is limited to periods when ice cover is absent, the sedimentation rate may be reduced using a channel closure structure during non-use periods. Winter sedimentation rates can be predicted using the mathematical model for summer conditions, and when ice thickness is known.

INTRODUCTION

Special attention to sedimentation problems is warranted in the design of an enclosed harbor sited in a high tidal range, sediment-laden coastal area. Large quantities of suspended material will likely be carried into the harbor each floodtide. Because of the relatively quiescent conditions in the harbor when compared to outside waters, a part of the suspended sediment will probably settle out of suspension before being carried out on the ebb tide. Two important considerations are to predict the sedimentation rate prior to harbor construction in order to forecast future maintenance costs, and to site and design the harbor

¹Chief, Engineering Geology Branch, Coastal Engineering Research Center, Kingman Building, Fort Belvoir, VA 22060

to minimize sedimentation. These considerations are the subject of this summary paper. Deposition from suspension is assumed to be the only mechanism by which sediment infilling occurs. The only design criterion considered is that of minimizing the sedimentation rate.

In 1970, the Coastal Engineering Research Center (CERC) began a study for the U.S. Army Engineer District, Alaska, to address the problem of sedimentation in Alaskan small-craft harbors. Because of extremely high sedimentation rates and the attendant high dredging costs involved, the Alaska District requested that a means be developed to predict those costs before construction. It was noted that the feasibility of new harbor projects would, in some cases, hinge on maintenance dredging costs. The CERC study continued for 9 years. In that period, summer and winter monitoring of a prototype harbor at Dillingham, (Everts, 1976a) and measurements in Cook Inlet, Kenai River, and especially Knik Arm, Alaska, were made to identify and quantify the sediment and hydraulic mechanisms responsible for the harbor shoaling problem. A mathematical model (Everts, 1980) and a field measuring device (Everts, 1975) were developed to predict the sedimentation rate. Through the conduct of the study it also became apparent that certain considerations in the design of an enclosed harbor could effect a reduction in the sedimentation rate.

HARBOR CHARACTERISTICS AND SEDIMENTATION PROCESSES

For application of the results described in this paper, harbor conditions should conform to those described in this section. An enclosed harbor connected to coastal waters by a navigation channel is considered (Fig. 1). Because of high-velocity, tide-driven currents, and severe ice conditions, the protection offered by enclosed harbors is a special requirement in some of coastal Alaska. A sill in the navigation channel is a possible added design feature. It may be at any elevation. A sill, usually sited at the basin opening (Fig. 1), is used in high tidal range areas to reduce basin excavation costs. While providing flotation for vessels at low tidal stages, a sill restricts navigation in and out of the basin to times of higher tidal elevations. Harbors in Alaska with such sills are called "half-tide" harbors.

The harbor basin and channel may be of any size and shape as long as the rise and fall of the water surface inside the basin is nearly in phase with and of the same amplitude at that outside the basin (Everts, 1980). This means the volume of water that enters the basin as the water surface rises is equal to the volume of the basin above the sill. Basin and channel sidewalls may be sloping or vertical. If a sill is present, the basin is assumed stagnant below sill elevation. Therefore, when a suspended-sediment particle settles below that elevation it is considered deposited, even though it has not yet reached the bottom. Horizontal circulation within the basin is of such magnitude that sediment, once deposited or once it has settled below the sill elevation, it is not re-suspended.

Sedimentation results when suspended material settles from suspension. Bedload transport into the basin is assumed to be negligible. Sedimentation rates are assumed to be nearly equal throughout the basin; i.e., back eddies or other preferred depositional areas do not exist.

Figure 1. Definition sketch of an enclosed "half-tide" harbor illustrating major components: navigation channel, sill, and basin.

PREDICTION OF SEDIMENTATION RATE

To plan maintenance expenses before harbor construction in areas where sediment is carried in suspension, it is necessary to forecast future sedimentation rates. Two means for doing this were developed in the study: (1) a sedimentation tank, and (2) a mathematical model.

Prototype Harbor.

Dillingham Harbor, Alaska, was selected as the prototype on which to scale the tank and to test the model. Dillingham is located 500 km southwest of Anchorage, in the upper reaches of Nushagak Bay (Fig. 2). The local tidal range is 6 m and suspended-sediment concentrations vary from 50 to 1,500 mg/l of fine-grained material (1 to 100 micrometers). Local and transient fishing boats and commercial barges to 15-m long use the harbor. The harbor basin area is 21,500 m² at a project elevation of +0.6 m mean lower low water (MLLW). The sill elevation is +1.8 m MLLW and basin sidewall slopes are 1:5. Moorage is provided for 140 boats. Sedimentation has averaged almost 2 m/yr since the harbor was constructed in 1961. This requires nearly continuous dredging during the ice-free season.

June through September mean shoaling rates (5,400 m³/mo) are almost twice the mean October through May rate of 3,100 m³/mo (Fig. 3). Sediment infilling is nearly uniform throughout the basin when the basin bottom is below the elevation of the sill. An exception is a small

region near the sill that is scoured during the lower stages of a flood-tide. The channel has been stable in plan view and cross section since slightly after construction.

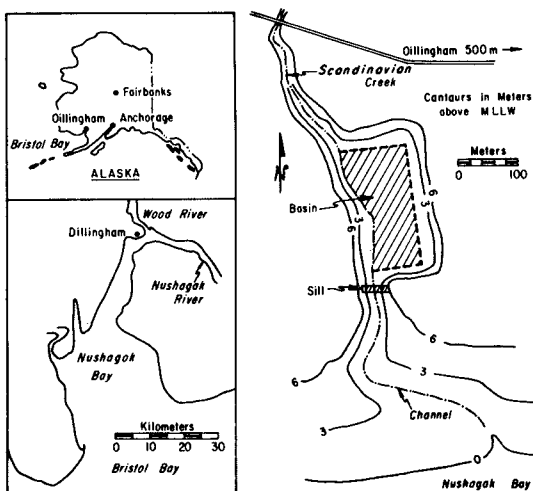

Figure 2. Location map of Dillingham Harbor, Alaska (Everts, 1976a). Discharge from Scandinavian Creek is negligible.

All sediment is transported into the harbor in suspension. At the sill, suspended concentrations are greatest as the rising tide initially passes over the sill (Fig. 4). More than 50 percent of the suspended material brought into Dillingham Harbor enters during the first hour of the 3-hour-long flood-tide cycle in the basin. The concentration at any given time is nearly uniform from the sill to the water surface. At any specific time the concentration is also nearly uniform throughout the basin at the water surface (samples within the water column in the basin were not taken). The bulk density of deposited material in the basin is about 1.5 gm/cm^3 .

Water velocities over the sill in the basin at any specific time are generally uniform from the water surface to the elevation of the sill. In the basin, the region below sill elevation appears to be near stagnant and a particle which settles below that elevation is not removed on an ebb-tide. Velocities above sill elevation are low enough in most of the basin that resuspension after deposition on the sidewalls does not occur. The basin appears to be turbulence-free and movements of fluid into and out of it are directed in line with the navigation channel.

Figure 3. Shoaling rate in Dillingham Harbor, Alaska, as a function of bottom elevation in the basin (Everts, 1976a). Note the decrease in the shoaling rate as the bottom shoals above the sill elevation. This occurs because as the bottom elevation rises, less water and suspended sediment are carried into the harbor basin each floodtide, and consequently less sediment is deposited.

Sedimentation Tank.

A sedimentation tank was developed as an in situ instrument to obtain the shoaling rate as would be expected in an enclosed harbor (Everts, 1975). It was a hollow, upright cylinder fabricated of 5-mm steel, 9.1 m high and 3.7 m in diameter (Fig. 5). A narrow, vertical slot, 3 cm wide, 1.2 m long and of height sufficient to extend from the sediment-water interface to above the mean higher high water (MHHW) surface, was used to simulate the entrance channel. The tank was set in an excavated hole near the site of a proposed harbor in a tidal flat bordering Knik Arm, near Anchorage. The shoaling rate was obtained by monitoring the buildup of sediment within the tank during summer months of 1971 and 1972 (Fig. 6).

An important aspect of the study was to evaluate the tank. In most respects, depositional conditions within the tank were found to be similar to those at Dillingham Harbor. The study indicated the design could be modified to reduce fabrication, placement, and removal costs. The tank can not be scaled in its vertical dimension. However, it can be any plan shape or size, and a smaller plan area would serve the design purpose. Below the entrance slot the tank depth must be great enough to accommodate sedimentation expected during each field test. A critical aspect of the design is to provide an entrance which permits free exchange of water to or from the tank when the water surface rises or falls, but which inhibits in-tank circulation. The slot design (Fig. 5) worked well where waves were <0.6 m. In areas of higher waves the slot might be oriented away from the prevailing wave direction. The orientation, however, should be normal to the direction of the tidal current to inhibit

direct current access. The slot simulated a harbor entrance channel, but did not account for channel deposition and resuspension that could affect the amount of material that would be expected to enter a half-tide harbor. The result could be an underprediction of the actual shoaling rate if the proposed harbor is to have a navigation channel.

Figure 4. Suspended-sediment concentrations at the Dillingham Harbor, Alaska, sill over a harbor basin tidal cycle (Everts, 1976a). Concentrations are averaged through the water column and are based on sampling at the sill over five tidal cycles. Note the rapid decrease in concentration from the time the water level reached the sill until the time of high water.

Sedimentation Model.

Everts (1980) developed a model, posed in the Lagrangian representation, to simulate sediment shoaling. A mass of suspended particles is followed from the time and elevation at which it enters the basin in suspension until it is deposited or possibly removed from the basin during the outflow phase. The one-dimensional formulation has the essentials of the problem because the depositional process is assumed to be nearly uniform throughout the basin. The dependent variable is the mass of deposited sediment. Independent variables are the elevation and time - dependent mass of sediment discharged to the basin, the settling velocity distribution of that mass, and the harbor geometry. Data from the sedimentation tank and Dillingham Harbor were used to evaluate the model. In both cases the model results were between 10 and 12 percent less than the measured shoaling rate. Because of field sampling difficulties it is difficult to determine whether the errors are a result of an inadequacy in the model or are caused by sampling errors or omissions.

Figure 5. Side and plan view of sedimentation tank which was placed at half-tide elevation in a 500-m-wide tidal flat adjacent to Knik Arm near Anchorage, Alaska (from Everts, 1975). The median tidal range is 8.7 m. The entrance slot was oriented away from shore and normal to floodtide and ebb-tide currents.

The shoaling rate may be obtained in three steps: (1) Predict the total mass of sediment that will enter the harbor, (2) predict the part of that mass that will be deposited, and (3) predict the shoaling rate (bottom elevation increase).

(a) Step 1. During a rising tide the mass of sediment carried into a harbor is a function of the time-dependent concentration of entering suspended sediment, $c(t)$ time rate of water surface elevation, $\frac{dh}{dt}$ and the elevation-dependent plan area of the harbor basin at the water surface which is a function of time in the tidal cycle, $A(t)$. The total sediment mass which enters a harbor during a rising cycle, M_e , is

$$M_e = \int_{t_s}^{t_m} c A \frac{dh}{dt} dt \quad (1)$$

in which t_s = time floodtide reaches elevation of sill, and t_m = time floodtide reaches maximum elevation.

Figure 6. Sediment accretion in sedimentation tank in 1971 and 1972. Values are averages based on six measurement locations in tank. Note near-constant accretion throughout the summer and the 20 percent larger accretion rate in 1971.

(b) Step 2. That part of M_e deposited in the harbor is primarily dependent upon the settling characteristics of the sediment, the distance the sediment has to settle to be deposited, the time during which the suspended material settles, and the sill elevation. Figure 7 shows the part of the suspended material, P , that will be deposited as a function of tidal range and particle size. For diurnal and semidiurnal tides, the settling characteristics of disaggregated material less than 1 micrometer in diameter are such that little will be deposited in the harbor. Most particles larger than 32 micrometers will be deposited. Figure 7 is based on the mathematical model discussed by Everts (1980). Because all natural systems contain a range of sediment sizes, it is necessary to obtain M_e and P for each size grouping, then sum the individual masses to obtain the total deposited mass, M . In integral form this is

$$M = \int_{d_s=0}^{d_s=\infty} M_e P \, dd_s \quad (2)$$

in which d_s = suspended-sediment particle size. Figure 8, obtained using the model, shows the mass of sediment deposited per tidal cycle when sill

elevation, tidal amplitude, and particle size (fall velocity) are varied at the Anchorage sedimentation tank site.

Figure 7. Part of sediment mass entering harbor basin which is deposited as a function of sediment particle size (based on sphere fall velocity in freshwater at 20°C) and tidal amplitude (from Everts, 1980). Solid lines are for a 12.4-hr. tidal period; dash lines are for a 24.8-hr. tidal period. Sill elevation is zero.

Sill elevation is not considered in Figure 7. At most, the increase in P will be 10 percent when the sill is at an elevation $A_0/2$ (half-tide elevation) and $P = 0.7$, where A_0 = tidal amplitude. When sill elevation = $A_0/4$ and $P = 0.7$ the increase is only 5 percent. In using Figure 7, the concentration of suspended sediment entering the harbor is not assumed to vary with time. If concentrations are highest early in the tide cycle, P will be larger than shown in Fig. 7. Suspended-sediment fall characteristics are assumed to be constant through time.

Particle aggregation may be an important factor in increasing the settling velocity of suspended material, especially in a saline estuary environment. In south-central Alaska, clay minerals constitute less than 2 percent of the total suspended-sediment load. Even there, however aggregation plays an important role which must be considered in harbor sedimentation (Fig. 9). Unless the settling velocities are obtained in the fluid in which they are collected (versus distilled

water used in some laboratory analyses) large errors in predicted sedimentation rates may result.

Figure 8. Sensitivity analysis of equations (1) and (2) using a mathematical model to predict sedimentation in a half-tide harbor (Everts, 1980). The model test basin was the sedimentation tank located in Knik Arm, Alaska. Predicted sediment mass entering and deposited in the tank is based on actual average values of all parameters except that shown.

The part of the sediment which enters the harbor and is subsequently deposited will probably be near constant from one tidal cycle to another, even though the total quantity which enters may vary widely (Everts and Moore, 1976; Everts, 1976a). Everts (1976a), for example, reported that the quantity carried into the basin at Dillingham Harbor varied by a factor of three between tidal cycles, but that the part deposited was near constant at 81 percent (range: 76 to 84.2 percent for five tidal cycles). Thus, to accurately predict M_e , a number of tidal cycles must be sampled to obtain representative concentration values.

(c) Step 3. If it is desirable to predict the rate of bottom elevation rise caused by sediment deposition, sediment mass deposited must be converted to sediment volume deposited. The part of a unit volume of deposited material with a density, ρ_d , which is composed of sediment of density, ρ_s , is V_s , given as

$$V_s = \frac{\rho_d - \rho_f}{\rho_s - \rho_f} \quad (3)$$

in which $0 \leq V_s \leq 1.0$, ρ_f = water density. Then the mass of sediment per unit volume of deposited material, m_v , is

$$m_v = \rho_s V_s \quad (4)$$

and the shoaling rate (per tidal cycle), S_r , in the basin is

$$S_r = \frac{M}{F m_v} \quad (5)$$

in which f = plan view area of the basin bottom.

Figure 9. Comparison of median grain size, based on fall velocity, for duplicate samples of glacier-source sediment from Knik Arm using the hydrometer method with distilled water and with Knik Arm water (from Everts, 1976b). Sediment with a median grain size less than 0.075 mm settled at a faster rate in saltwater even though the clay mineral percentage was less than 2 percent.

HARBOR DESIGN TO REDUCE SEDIMENTATION

In the course of the study, a number of possible means to reduce the shoaling rate became apparent. These are summarized in the following sections.

Harbor Siting.

If a number of harbor sites are considered, the site where sediment concentrations are lowest and sediment sizes are smallest, all other conditions being equal, will experience the lowest sedimentation rate (see eq. 1 and Fig. 7). The size and concentration of sediments suspended in the water column may vary throughout an estuary and this may be a consideration in where a harbor is sited. Temporal variations in size and concentration may also be a factor. For example, a decision to close a harbor during certain nonuse times of the year may hinge on the predicted sedimentation rate during the closure period versus that of the remainder of the year.

In estuaries such as Knik Arm, most of the suspended sediment is contributed by glacier-fed rivers. High concentrations in the estuary are clearly related to the summer influx of river-borne sediments, although a phase lag appears in the estuary where autumn concentrations remain high (Fig. 10). Everts (1976b) found suspended-sediment concentration to be related to water discharge for the two largest contributors (Knik and Matanuska Rivers), but size was a function of water discharge only in the Knik River. A single year's water and sediment discharge record is not enough to predict average yearly suspended-sediment concentrations in a river-dominated estuary because yearly variations of 50 percent about the yearly mean may be expected. In addition, sediment discharge cannot be extrapolated from one river basin to another in glacial areas, even where the basins are adjacent. In south-central Alaska, river sampling during the 3 summer months (June, July, and August) is sufficient to determine the total yearly sediment load within 10 to 15 percent.

Floods may move a significant quantity of suspended material. In off-river harbors and harbors located near river mouths, the impact of flood discharge must be considered. A 2- to 5- day flood may discharge more than 50 percent of the yearly sediment contributed by a river. Sediment sizes carried by floodflows are considerably larger than the size carried during normal flow times.

Off-River Harbor Sites.

Siting a harbor beside or adjacent to a clearwater river may substantially reduce the sedimentation problem caused by fine-grained material. The reduction results because sediment-laden, landward-moving estuary waters are diluted by seaward-flowing, clear river waters. The decrease in suspended-sediment concentration, and in the predicted shoaling rate (eq. 5) can be obtained using data from a sediment sampling program during the time of floottide incursion near the proposed enclosed harbor site. Temporal variations in river-borne sediment concentration and size must be considered.

Potential problems exist in using an off-river harbor. Caution is advised to ensure that deposition of river-carried bedload sediments, and the river sediment load during flood times, will not mitigate the savings.

Figure 10. Average suspended-sediment concentrations in Knik Arm, an estuary in which much of the suspended material enters directly from glacier-fed rivers; and Nushagak Bay, an estuary where the material is continuously resuspended from the estuary bottom.

Channel Length.

Suspended sediment enters an enclosed harbor from two sources. The primary source is the adjacent estuary. An important secondary source may be the navigation channel between the harbor basin and estuary. At Dillingham Harbor, for example, current velocities in the channel are low when the tidal elevation is below the sill; consequently, suspended material settles in the channel during these times. As the next flood-tide rises over the sill, channel currents increase rapidly to accommodate the increased water discharge required to fill the basin. At that time, when the submerged channel cross-sectional area is smallest, the velocities are greatest and material previously deposited in the channel is resuspended. The amount of sediment entering Dillingham Harbor from the channel source is 40 percent of the total amount brought in.

Economies can be achieved when an entrance channel is designed to reduce the accumulation of channel sediment. Usually, this will require that the channel length be designed as short as possible.

Sill Design.

Sedimentation within a harbor may be reduced if the mass of sediment carried in each floodtide is reduced. One way to effect this is by placing a permanent sill in the entrance channel at an elevation above the harbor basin bottom and MLLW (Fig. 8). This reduces the tidal prism.

The design consideration, therefore, becomes one in which initial harbor cost plus future maintenance expense is balanced against the percent of time navigation is restricted into and out of the basin.

The period of restricted navigation can be easily calculated using the tidal hydrograph and sill elevation based on a consistent datum, and the draft and clearance required of the vessels using the basin. The mass of sediment carried into the harbor versus sill elevation can then be established (eq. 1).

Changes in suspended-sediment concentration with time differ greatly from one location to another. Everts and Moore (1976) measured an increasing concentration toward high water at the sedimentation tank site in Knik Arm, while Everts (1976a) found the concentration to decrease through the tide cycle in the estuary at Dillingham Harbor. Concentrations in Knik Arm seemed to be related to current speed and direction; the highest concentrations were measured on an ebbtide, i.e., sediment was moving away from a major riverine source. At Dillingham the concentration is greatest near midtide in Nushagak Bay where the fine-grained sediment source is the bay bottom and tidal flats. The channel resuspension mechanism greatly increases the early high concentrations.

Basin Closure.

When harbor use is seasonal, a channel closure structure may be warranted during nonuse periods. The cost-effectiveness of the structure and its emplacement and removal is determined by calculating the sediment volume that would be deposited during the nonuse period and the attendant maintenance cost for its removal.

Ice and winter conditions restrict the use of many harbors in Alaska to 6 months or less. Summer sedimentation rates do not prevail during ice-cover conditions. The submerged ice volume reduces the discharge volume of water and suspended sediment to the basin. That reduction can be estimated. A reduction in the amount of water and suspended sediment in an ice-covered channel will reduce the sediment mass inflow from that source. The mass of sediment which enters a harbor may also vary seasonally, especially where river discharge is an important source, as it is in Knik Arm. Wide seasonal variations, however, are not always the case. In Nushagak Bay the average monthly concentration of suspended sediment is near constant year round (Fig. 10). Sediment in Nushagak Bay comes from the suspension and resuspension of bottom sediment, not river discharge.

Because sediment size, water viscosity, and particle aggregation affect the settling velocity of suspended material in the basin, these factors must be considered on at least a seasonal basis. At Dillingham, median particle size varied from 0.014 mm in the summer to 0.005 mm in winter. Temperature affects water viscosity, and hence the fall velocity of the sediment particles. For example, at 0°C winter water temperature, the fall velocity of a particle 0.008 mm in diameter is about 70 percent the velocity it would be at 10°C. This must be considered. The effect of salt on the settling rate of clay minerals becomes distinguishable at seawater concentrations of about 1 to 2 parts per thousand (ppt).

Aggregation and hence the settling rate of the aggregated mass increase to seawater concentrations of 10 to 15 ppt. Suspended sediment in water samples with salt content of 0.5 ppt at Dillingham during the summer did not appear to aggregate. However, when the winter salinities reached 3 ppt, aggregation might have occurred.

At Dillingham, the winter shoaling rate (about 50 percent of the summer rate) was correctly estimated using these considerations. The major effects were decreased water and sediment discharge to the harbor because of the ice volume within the basin, and the reduction in sediment resuspended in the channel for which the ice cover was also responsible.

SUMMARY

This paper results from a 9-year study of enclosed harbors in Alaska. Two methods to predict harbor sedimentation rates prior to construction are presented and a number of design considerations to reduce sedimentation are suggested.

ACKNOWLEDGEMENTS

The analysis and results presented in this paper were based on research conducted at the Coastal Engineering Research Center under the Coastal Engineering Research Program of the U.S. Army Corps of Engineers. Much of the field work was done by the U.S. Army Engineer District, Alaska. Permission to publish this information is appreciated.

NOTATION

- P = deposited part of total suspended mass carried into harbor basin on floodtide
- c = suspended-sediment concentration
- h = water surface elevation
- A = plan area of harbor basin at water surface
- M_e = total sediment mass carried into harbor basin on floodtide
- t_s = time after low water that floodtide reaches sill elevation
- t_m = time after low water that floodtide reaches maximum elevation
- d_s = suspended-sediment particle size
- M = total mass deposited in harbor
- A_0 = tidal amplitude
- V_s = sediment part of unit volume of deposited material
- ρ_d = density of deposited material

ρ_s = sediment particle density

ρ_f = water density

m_v = mass of sediment per unit volume of deposited material

S_r = harbor shoaling rate per tidal cycle

F = plan area of harbor at basin bottom elevation

1. INTRODUCTION

Sedimentation in tidal lagoons and estuaries has become an acute problem, particularly where there has been over-dredging to accommodate today's deep draft vessels, 0(15m). The rise in mean sea level, which created natural estuaries, has not kept pace with the demand for greater draft ships. The limited number of navigable lagoons confronting a growing demand for more inland waterways has encouraged reconstruction dredging of some closed or partially filled lagoons.

Man's efforts to deepen existing or relict estuarine systems have disturbed the steady state equilibrium of the systems. Sedimentation acts continuously to restore this equilibrium by either of two processes. One is flocculation of fine-grained fluvial born sediments, a process accelerated when an estuary is deepened thereby allowing greater salt wedge intrusion. The other is the interception of the longshore transport of coarse grained beach sediments by the lagoon inlet. The larger tidal prism of an enlarged lagoon draws a greater percentage of the longshore transport into the lagoon from the adjacent surf zone. In the absence of wave suspension within the lagoon, very little of this sediment is carried back out of the lagoon on ebbing tides.

These sedimentation processes confront the coastal engineer with several distinct problems. A particular set of counter-measures are needed against accumulations of cohesive fines from the rivers, another set against accretion of cohesionless coarse grained sediments from the beaches. Still other methods are needed to reopen a closed lagoon.

Dredging has been the most widely practiced solution to all of these problems for the past 150 years. It is a solution we may not be able to afford indefinitely. In addition to intrinsic high rates of energy consumption and equipment breakdown, there are ever-growing costs associated with dredge spoils disposal. Ninety percent of the material annually dredged is contaminated by heavy metals, concentrated in the flocs from either natural erosion of country rock or industrial sources (Malloy, 1980). Further contamination results from chemical

and oil spills, sand blasting, paint removers and other shipyard and harbor activities. Sand is rarely contaminated because it is chemically inert. The contaminated sediments pollute the disposal sights, imposing additional costs to measure the pollution and minimize its effect. Recent climatic cycles and real estate developments have accelerated erosion and sediment runoff, ultimately bringing many spoils ponds to full capacity before their expected lifetime (N.E.S.O., 1976). Ocean dumping of poisoned spoils is environmentally unsound and strictly limited by environmental protection laws. Alternative spoils ponds are generally available only at great distance from the lagoon, requiring expensive booster stations and additional pumping capacity to transport the dredge spoils (Little, 1975).

This paper reports on five separate prototype scale field experiments that test alternative measures to dredging. Two of these experiments evaluate techniques of resuspension and exclusion for reducing fine sediment accumulations in quiet water, cul-de-sac berths, where the observed shoaling rates are greatest and dredging most difficult. These berths are essentially sediment settling basins where currents are insufficient to resuspend new deposits. The fine sediment control studies were performed in and around berths at Mare Island Naval Shipyard. Another two experiments involved by-passing sand around the inlet of Agua Hedionda Lagoon, California using fluidized trenches funnelling into a crater sink. The final experiment used open trench fluidization to reopen Penasquitos Lagoon, California.

2. SEASONAL AND EPISODIC MUD ACCUMULATION IN BERTHS

There is abundant data showing that the deposition rates of settled flocs in berthing areas and around structures within a tidal estuary exceed those in unobstructed navigation channels (NESO, 1978; Van Dorn, Inman, McElmury, 1977; 1978). This was dramatically shown in Mare Island Straits, California, during the record flood winter and spring of 1978 that brought an end to the California drought that began in 1945. Figure 1 compares the average bottom shoaling rates along a line extending across the navigation channel with the shoaling rates at two stations within the finger pier complex at Mare Island Naval Shipyard, pictured in Figure 2. Mare Island Straits are over-dredged to 13 m and situated at the confluence of the Napa and Sacramento Rivers on the eastern side of San Pablo Bay in the San Francisco Estuary. The shoaling at both stations within the finger pier berths at Mare Island were found to be three times the mean sedimentation rates across the navigation channel. Mud was found to accumulate at nearly uniform rates in both the channel and berthing areas through the wettest months of February and March, when the combined fresh water discharge of the Napa and Sacramento Rivers ran as high as $2.12 \times 10^3 \text{ m}^3/\text{sec}$, about 1/2 the tidal flux in Mare Island Strait. When the river discharge dropped to $1.13 \times 10^3 \text{ m}^3/\text{sec}$ by the end of April with subsidence of Pacific storms, the sedimentation rate in the finger pier berths abruptly increased. By this time 2 meters of new deposition occurred, 4 times the shoaling during the previous drought year of 1977 (Van Dorn, Inman, and McElmury, 1978).

Figure 1 Shoaling history within a berth and across a navigation channel.

Figure 2 Mare Island Strait, ebb current and river flow to the left.

Initially new deposits of mud are fairly mobile, fluid mud, with a low threshold of motion of typically 15 cm/sec depending upon the time of immobility of the mud (Le Mer, 1962, and Van Dorn et al, 1977). In the navigation channels these threshold stress levels, $\approx (1 \text{ dyne/cm}^2)$ are exceeded more frequently, particularly if not over-dredged. Some fraction of the newly deposited fluid mud is resuspended and flushed out by tidal circulation. The remaining fraction of resuspended floc settles again next slack water, eventually reaching quiet water. The quiet water of the berthing areas allow for much less resuspension of fluid mud and greatly restrict circulation that might remove the resuspended material. Low density fluid mud (10-15 gm/l) which is not resuspended within 24-72 hours begins to compact under gravity, driving out interstitial water. After a week it becomes a high density (1.22 gm/cm³) anoxic mud, (Krone 1962) which can only then be moved by mechanical means. Eddies from pier piles, ship hulls and other vertical structures in and around the berth increase particle collisions and mix the higher salinity bottom water into the remainder of the water column,

further promoting flocculation. These factors all play a role in contributing to the higher siltation rates of berthing areas, although the relative importance of each may vary from place to place.

The seasonal variations of runoff in turn cause seasonal variation in sediment abundance and water properties. Figure 3 shows the vertical distributions of suspended sediment concentration, C, salinity, S, and temperature, T, from mid winter through summer 1978 at Station 3 inside the berth at Pier 23. Salinity and temperature are scaled on the horizontal axis in ‰ and °C along with concentration in gm/l. These data were collected during spring tides at four phases of tidal elevation labeled H, L, F and E for high, low, flood and ebb respectively. The salinity profiles show that the river discharge during the maximal rainfall months, from February until mid April, produced a thick lens of fresh water on the surface and rather low bottom salinities of 1-7 ‰. The salinity was uniform over depth at low tide indicating total retreat of the salt wedge from the berths by the end of ebbing tide. By mid June most of the Sierra snow pack had melted and the discharge of the Sacramento and Napa had fallen to $1.7 \times 10^4 \text{ m}^3/\text{sec}$. The fresh water surface lens then grew thinner into summer until finally an isohaline vertical distribution of 20 ‰ results from the tidal flux. The temperature distribution remains isothermal since thermal diffusivities $\approx (10^{-3} \text{ cm}^2/\text{sec})$ are large compared with diffusivities of salts, $\approx (10^{-5} \text{ cm}^2/\text{sec})$.

With the declining river discharge in late March, the salt wedge intrudes more freely into the berthing areas and bottom salinities reach the flocculation threshold of 7-10 ‰ (see Krone 1962). From this time on through summer, suspended sediment profiles show a high concentration toe, $\approx (100 \text{ mg/l})$ in the lower meter of the water column. The toe is due to the settling of flocs toward the bottom boundary and the re-suspension of those flocs by the tidal and eddy motion over pier piles, dredge banks and other bottom obstructions. However during periods of subthreshold salinities, e.g., following a train of local storms, 9 March 1978, the sediment remains uniformly distributed through the water column in spite of high sediment abundance.

The bi-weekly profiles of discrete properties in Figure 3 give a good resolution of the seasonal trends but may be somewhat aliased by weekly or daily variations. These short term fluctuations are most prevalent during the wet months as river discharge fluctuates daily in response to local storms passing over the water shed. As a result of these fluctuations, fine sediment deposition will exhibit episodes of extremely rapid build up, or "mud storms" when bottom salinities are near the flocculation threshold (7-10 ‰) while rivers remain laden with charged clay particles from recent runoff. Under these conditions four such mud storms, each depositing 0.6 m or more of new fluid mud at a time, were observed in the entrance to Pier 21 N at Mare Island during a near record flood winter in 1980 (see Figure 4). This echogram was taken using a 40 kHz echo transceiver. Each dated horizon is a veneer of loose floc trapped between thick layers of denser more consolidated fluid or anaerobic mud. The trapping of these floc layers implies that the subsequent build-up of mud occurred so rapidly that insufficient

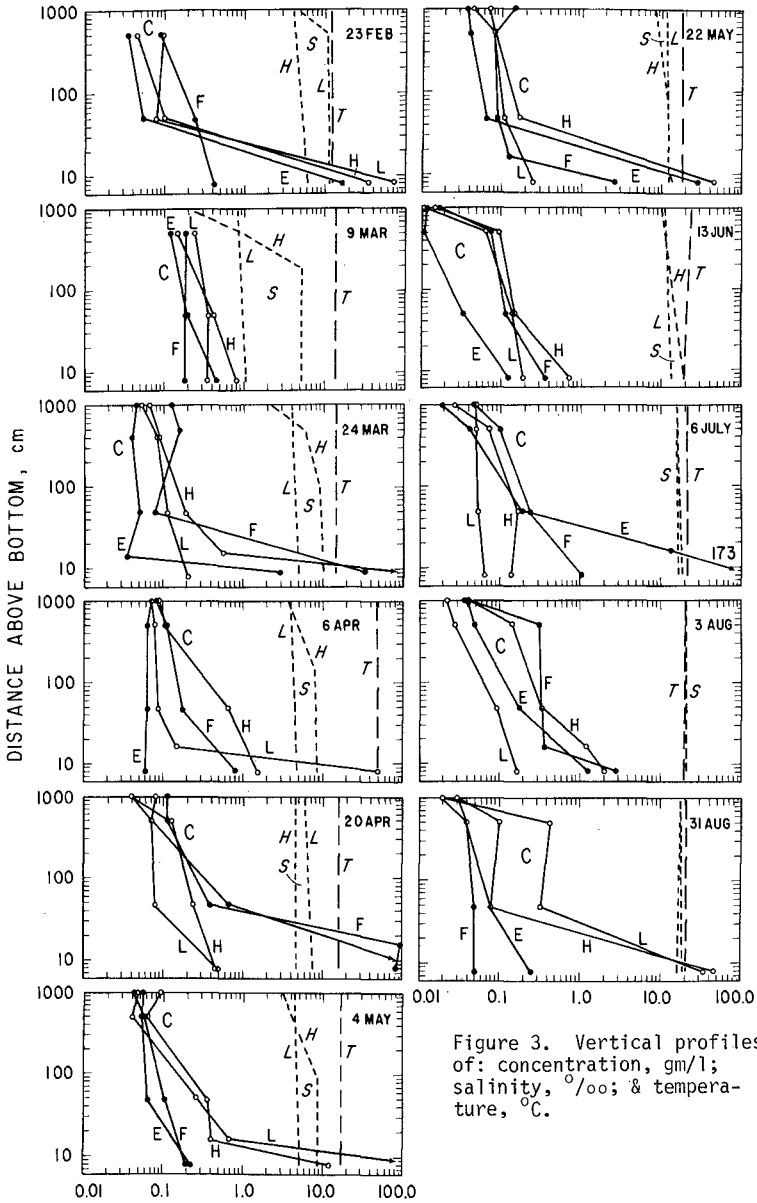

Figure 3. Vertical profiles of: concentration, gm/l; salinity, ‰; & temperature, °C.

time had lapsed for the water content of the floc layer to diminish. The accumulations of these mud storms are found between the dates of the horizons following the initial pulse of runoff from series of Pacific storms. The rise in bottom salinity in between these pulses triggers flocculation and a subsequent abrupt build-up in fluid mud. The flocs themselves appear as a speckled pattern in the water column between the surface reflection and the first bottom horizon on the echogram.

Figure 4

Figure 5

To a lesser degree the river discharge fluctuates during drier summer months, principally in response to manipulation of containment reservoirs and dam diversions. These fluctuations do not produce the episodes of rapid sediment accumulation found during the wet winter months. Shoaling in the summer months is characterized by a nearly steady state build up of about 0.25 cm/day. Whereas the controlling variable for shoaling in the winter is a bottom salinity of sufficient magnitude to induce flocculation in the presence of high sediment abundance, the summer shoaling rate in the presence of higher salinities appears strictly limited by the small amounts of suspended sediment brought in by the rivers. Krone (1959, 1960) has shown by tracer studies that suspended loads in the lower 80% of the water during the summer are in fact resuspended by wind waves over permanent shoals elsewhere in the estuary and carried subsequently into berthing areas by the density-stratified tidal flows.

Although these seasonal and episodic variations of water properties and fine sedimentation were observed at a single place, the mechanisms

of flocculation and resuspension are at work in most every tidal lagoon and estuary. The fact that these observations were made during an extreme in the weather cycle and covered maximum ranges of temperature, salinity, suspended sediment, and shoaling rate, should make them a useful design guide for sediment control measures anywhere.

3. CONTROL OF MUD ACCUMULATION BY RESUSPENSION

The first attempt to control mud accumulation by resuspending newly deposited layers of fluid mud date back to the Chinese in the 5th century A.D. Figure 5 shows a rolling suspensifier, the hun Chiang lung, first illustrated in the Ho Kung Chhi Chii Thu Shuo and reproduced here from Needham, 1974. This device was drawn along the bottom by a vessel or team of horses proceeding upstream. The teeth on the roller raised clouds of silt which were carried away on the ebbing tide.

The modern equivalent of the Chinese suspensifier is the tide actuated water jet array shown in Figures 6 and 7 tested on the water front of Mare Island at Berth 7 shown in Figure 1. The fundamental environmental constraint in the successful application of any such resuspending device is the presence of unidirectional currents for a sufficient period to advect away the material which has been resuspended. Berth 7 at Mare Island is ideal in this respect. This berth rests along the streamlined western shore of Mare Island Strait where 1200 m of unobstructed concrete quaywall stabilizes the bank against over-dredging to a depth of 10 m. Here bottom ebb current commences about 2.5 hours before high tide and persists for about 5 hours giving a rather long window to transport resuspended material. The weakest ebb current amplitudes at low river discharge, $10^2 \text{ m}^3/\text{sec}$, still produce near threshold stresses for newly deposited fluid mud, rising from 20 cm/sec at 0.5 meters above the bottom to 80 cm/sec on the surface. The tide actuated switching circuit entered in Figure 7 was synchronized for a 4 hour duty cycle through the period of maximum ebbing bottom currents.

The water jet array itself, Figure 6, was designed to operate from a fixed mounting on the quay wall where vulnerability to damage from dragging anchors and channel dredging activities is minimized. The most protruding components, the jet nozzles themselves, are secured to the discharge manifold by a quick-release Camlock clamp for easy diver replacement in the event of damage or malfunction. Ten equally spaced 7.3 cm diameter jet nozzles comprise the linear array 63 meters in length at a depth of 8.2 meters below MLL sea level. The jet array was driven by a 1910 gpm water pump at 92 psi powered by a 140 hp, 220 v electric motor. The automatic switching circuit, Figure 7, sequences the entire pump discharge through each individual nozzle one at a time beginning from the upstream side of the array. This was accomplished through an arrangement of pneumatically operated pinch valves operating on an inlet pressure of 67 psi. In this way each jet is able to produce a discharge velocity of 760 cm/sec, or nearly 1.65×10^7 dynes of static thrust. Wall jet experiments by Poreh, et al (1967) and Sforza and Herbst (1969) indicate that the bottom stress on an immobile boundary will decay with distance, r , from the jet as $r^{-2.3}$. These data suggest, that each jet will exert a super-critical bottom stress of 4.6 dynes/cm^2

Figure 6: Quay wall Installation of Water Jet Array

Figure 7 Tide Actuated Duty Cycle Control System for Jet Array

out to the design scour radius of 15.24 m, while not decaying to the threshold stress of fluid mud, 1 dyne/cm², until 30 m out from the quaywall. These ranges of coverages are sufficient to protect draft to beam ratios of most modern vessels.

The jet nozzles were inclined downward to allow the jet flow to be directed around the bottom of the hull of a moored ship, given the constraint of mounting the array above the over-dredged depth. A number of deflection angles were tested ranging from 20° to 45° of downward inclination. Figure 8 shows three time staggered bottom profiles along

three separate range lines measured out from the concrete quaywall. Those for the control were taken downstream in Berth 8 (see Figure 1). Another control area was monitored on the upstream side of the area in Berth 6. Curves for Jet 3 and Jet 8 compare the effects of different degrees of downward deflection. Jet 3 used 29° of downward deflection while Jet 8 was inclined 35° downward from horizontal. Bottom profiles labeled 30 March were taken just after the completion of dredging in Berth 7. Curves labeled 17 May show the build up of mud over 1 1/2 months while the jet remained inoperative pending Coastal Commission permits. The jet array became operational on 30 May. Therefore the curves labeled 9 August indicate the scour and protection provided by the array over a 2 1/3 month period. The most nearly optimum coverage

SURVEY ON TEN ELEMENT SWEEPING JET ARRAY

Figure 8

MUD ACCUMULATION NEAR QUAYWALL

Figure 9

appears to have resulted from the 29° downward deflection provided by Jet 3. The larger downward deflection of Jet 8 is shown in Fig 8 to have excavated a 1.2 m deep impact crater extending from 3.05 to 12.19 m out from the quaywall, but depositing a mound beyond 12.19 out to 21.33 m. The lower curve of Fig 9 plots the net change due to Jet 3, showing scour out to 21.33 m and little new accumulation out to 30 m during the 2 month operational period. Integrating over all survey contours for the entire array, and comparing with the accumulations at the upstream control in Berth 6, it was determined that the jet array prevented or scoured 1200 cubic m of deposition in Berth 7 from 30 May to 9 August.

There was also an additional downstream influence from the jet array that can be found in the control contours from Berth B in Fig 8. Here only about 15 cm of new deposition was observed over the 2 1/3 month operational period as compared to an average of 45 cm during the same period at the upstream control in Berth 6. Factors which may have contributed to this apparent downstream influence were the presence of a 13 m diameter submarine and a highly stratified and stable water column with a Richardson's number, $R_i = g(d\rho/dz)/(du/dz)^2 \approx 10^5$ through May and June. Both these factors inhibit vertical mixing and keep the turbulent jet effluent confined near the bottom where it resuspends sediment while being advected downstream with the ebb flow.

The jet array resuspension technique is an attractive alternative to bucket and scow dredging presently used near structures. The jet array was also found to effectively prevent the new accumulations of mud along channel-side quaywalls during hopper dredging of the navigation channel.

4. CONTROL OF MUD ACCUMULATION BY EXCLUSION

Finding that the preponderance of suspended sediment is in the lower portions of the water column (Figure 3) led to the hypothesis that a flexible barrier, or curtain, could block these sediments from continuously circulating and settling into a berth by either tidal density-stratified currents or eddy motions. The finger pier complex notched out of the banks of Mare Island Strait (Figure 2) is well suited for this application. The entrance to the berth in between Pier 20 and

Figure 10

21 was partitioned off from the main channel by a 82.9 m long Hypalon curtain that extended from the bottom up to MLL sea level (see Figure 10). The lateral seal on the berth was provided by an undredged mud bank extending up to MLL water under Pier 21, and by a concrete quay-wall on the Pier 20 side. The 1.2-2.1 m gap over the curtain and mud bank between MLL and MHH water allows Berth 20-21 to equilibrate any sea surface inequality with the channel or neighboring berths during a tidal cycle. The lens of water overtopping the curtain and mud bank would be expected to transport a negligible amount of suspended sediment, even for the nearly isotropic conditions of peak rainfall periods, as during the 9 March extreme shown in Figure 3.

The curtain was constructed in 13 sections, each 6.4 m in length. The Hypalon curtain material on each section was anchored to the bottom by an 18 inch storm drain conduit filled with concrete aggregate weighing 8000 lbs. The 9.14 m high curtain sections were supported vertically in the water by curtain buoys constructed from 18 inch storm drain conduit filled with poly-urethane foam. A pair of air filled 10 inch diameter PVC pipes were retrofitted to the curtain buoys, seen in Figure 11, to trim the buoyancy against additional water absorption by the foam and concrete aggregate.

Figure 11 Rigging a curtain section for proper buoyancy

To raise the curtain as shown schematically in Figure 12, a second set of buoys at the surface are connected by a length of chain sufficient to extend down to the submerged buoy floats at a higher high water during spring tides. At the low tide preceding curtain opening, the surface floats and buoy floats are at nearly the same level, and the slack chain is drawn up and secured by a stopper arrangement. With the ensuing flooding tide, the additional buoyancy of the 24 inch diameter foam filled surface buoys are sufficient to gradually overcome the bearing stress of the fluid mud, about 20 dyne/cm², seen in progress in Figure 13. At high tide the curtain floats free of the bottom illustrated in Figure 11, whence it can be swung open into the berth by towing behind a small tug boat as shown in Figure 14. The end about which the curtain pivots was anchored to Pier 21 by cutting a notch in the slope of the mud bank and allowing the first curtain sections to become buried. The curtain rotates

about tongue and pin joints between the second and third sections. Consequently it was not necessary to raise the first two sections allowing surface floats adjacent to Pier 21 to be removed. This gave access to the berth by shallow draft barges while the curtain still remains closed and anchored (Figure 15).

Figure 12 Curtain cross section in raised configuration

Figure 13 Surface buoys while raising anchored sections from the mud during a rising tide

Figure 14 The curtain being opened by the Sea Mule yard tug

Figure 15 The curtain in the closed and anchored configuration as seen looking into the Pier 20-21 berth

The shoaling with time averaged across the Pier 20-21 berth appears in Figure 16, comparing mean shoaling on two survey ranges inside the curtain with another two outside. The range lines were taken across the berth perpendicular to Pier 21 at positions measured from the shoreward end of the 228.6 m length Pier. The shoaling along these range lines is shown in Figure 17 to have been fairly uniform. Four months of

Figure 16 Shoaling history averaged across the berth

Figure 17 Mud accumulation across the berth beginning from 12 December 79

operational testing with six curtain opening cycles showed that only 0.46-0.76 m of new deposition occurred inside the curtain while 1.52-2.59 m accumulated in the unprotected waters outside the curtain. This represents a 70% effectiveness during high depositional conditions with several protracted periods in the open configuration necessitated by ship movements. An apparent dredging savings of between 18,000 to 30,000 cubic meters was achieved. This 4 month savings payed for the material costs of the curtain considering dredging costs at the present local value of \$2.50/yds³. Comparing the dates in Figures 16 and 17 with the mud storm events in Figure 4 it is concluded that most of the deposition behind the curtain occurred during February when the curtain was open for only one 3 day period. Only about 6" of deposition inside the curtain occurred in the months of December, January and March when there were 5 opening cycles adding up to 36 open days. Therefore the timing between mud storm events and curtain opening seems critical in achieving maximum protection of a berth by exclusion techniques. It was fortunate in this experiment that the curtain happened to be closed during the mud storms in December and early March when the large mud accumulations are shown in Figure 16 to have occurred outside the curtain.

5. CONTROL OF SAND ACCUMULATION BY CRATER-SINK/FLUIDIZATION

The crater-sink sand by-passing concept, which uses a crater shaped depression in the channel bed to capture sand, was first proposed by Inman and Harris (1970). Several systems based on this concept have been tested in both the laboratory and the field (Harris et al, 1976; McNair, 1976), and full scale systems are currently operating at Mexico Beach, Florida (Pekor, 1977), and at Rudee Inlet, Virginia.

One of the limitations of the crater-sink concept has been the relatively small trapping radius as compared with depositional patterns. Harris et al (1976) found that the trapping radius of a crater could be enlarged by feeding the crater with a fluidized trench cut across the depositional area. These trenches are themselves sinks to the sediment flux. The trench is both cut and maintained by a fluidizer pipe having a line of downward axially slanted water jets along its length. The jets fluidize the neighboring sand and impart momentum to the resulting slurry in the direction of the jet effluent. A momentum survey of the process in closed duct configurations is discussed in Bailard and Inman (1975).

The Agua Hedionda Lagoon selected for these experiments is located 30 miles north of San Diego, California. The lagoon consists of an outer, middle and inner section with a total area of $1.04 \times 10^6 \text{ m}^2$. The tidal prism is approximately $1.68 \times 10^9 \text{ m}^3$, passing through a stabilized inlet channel with a cross sectional area of 33.4 m^2 . One third of the tidal prism is removed from the lagoon each tide cycle and diverted through the cooling condensers of a power plant and discharged into the sea. The corresponding reduction in ebbing currents through the inlet which intercepts the longshore transport of sand results in an average influx of beach sands of about $11,000 \text{ m}^3/\text{month}$. This influx is deposited entirely in the outer lagoon where the utility company operates a

suction dredge on a yearly or bi-yearly basis.

A crater-sink/fluidization sand by-passing system was designed to intercept the inflow of sand and return it to the downdrift (south) beach face (Figure 18). The system was sited at two different locations between

Figure 18

1978 and 1979 near the outer bank of the curved inlet where the centrifugal accelerations on a flooding tide direct the influx, depositing a sand bar. The latest of several system designs for Agua Hedionda Lagoon consisted of a 1-4 m deep crater excavated by a 6"x6", 150 hp centrifugal dredge pump connected to a 270 m long, 6 inch diameter discharge pipeline. A 50 m long fluidizer trench cut across the primary depositional bar powered by a 6 inch 100 hp water pump discharging into the crater on the interior downslope side of the bar. The fluidizer pipe was 4 inches in diameter with 0.282 cm diameter jets drilled at 45° angles and spaced 6.25 cm apart. The flow rate from the fluidizer drive water pump was 784 gpm at 100 ft total head pressure. One third of this discharge was diverted to a 2 inch diameter liquifier jet in the bottom of the crater, dropping the pressure to the fluidizer pipe down to 22 psi. The liquifier jet fluidized the sand at the crater suction inlet to minimize suction losses on the dredge pump. The flow rate through the dredge pump and sand discharge pipeline varied between 890 and 1000 gpm at 180 ft of total head, depending upon the amount of vertical lift required to remove the sand. To minimize the required suction lift, which varied between 2-6 m depending upon crater depth, tidal phase, and sand bar level, the pumping systems were operated from a moored barge.

To evaluate the ability of the system to capture and by-pass sand, the flow rate and sand concentration in the discharge line was monitored through the period of maximum flooding tide. Figure 19 shows the by-passing history during the 1978 experiment using a 60 cm deep fluidizing trench. The mean capture rate of 2.75 l/sec accounts for about 1/2 of the average sand influx rate, 4-6 l/sec. Flood currents during

this period peaked at 130 cm/sec on the surface above the fluidizer trench. If the sediment transport rate is taken to vary as the cube of

the velocity according to Bagnold (1966) then 1/2 the sand influx would be suspended load at these current speeds. Hence the capture efficiency of the system is in proportion to the bed load. Suspended load is transported over a shallow fluidizer trench. Furthermore underwater observations discovered that the initially sharp lip of the trench became rounded (Figure 20) after about 55 minutes of operation under currents in excess of 1 m/sec. With this round-off the flow no longer separated at the top of the trench, allowing the flood current to sweep into the

trench and carry away sand, as indicated in Figure 19 by the decline in sand capture with the onset of trench breakdown.

To avoid trench breakdown the 1979 experiment was moved further into the lagoon where flooding current amplitudes and suspended load were less. The fluidizer trench was deepened to 3 m to create a flow divergence over the trench that would drop the suspended load. Figure 21 shows by-passing time histories in which the average total sand influx (5-6 1/sec) was exceeded for extended durations without trench breakdown at current speeds as high as 110 cm/sec. However, these experiments were plagued by extra-normal amounts of kelp and bottom debris broken loose offshore by unseasonably high waves and subsequently swept into the lagoon on flooding tide. When captured by the system and mixed into the fluidized sand, the kelp would conglomerate in masses as large as 10 m in diameter which the system had insufficient power to move. A porous screen lid over the trench and crater successfully shielded the system for a two week period but required frequent diver maintenance. Another approach tested was to simply allow a kelp fouled system to become buried. Under the added pressure of the sand overburden kelp decays anerobically to a

SAND BY-PASS RATES FROM AQUA HEDIONDA LAGOON

Figure 21

less fibrous black mulch which the system can move again in several days to a week. With a single fluidizer trench this procedure restricts the number of by-passing cycles. To circumvent that in future by-passing schemes, multiple fluidizing trenches extending out from a single crater in a fan arrangement could be alternately cycled and allowed to bury once fouled.

6. OPENING A TIDAL INLET BY OPEN TRENCH FLUIDIZATION

Pepasquitos Lagoon is a relatively small lagoon encompassing about $1.29 \times 10^6 m^2$ and is located approximately 10 miles north of San Diego. Past studies have shown that the normally closed lagoon inlet channel is periodically opened during times of high precipitation in which the lagoon

Figure 22

Figure 23

is filled to overflowing. The lagoon then remains open until it is closed by the longshore transport of sand. Closure is enhanced when high waves coincide with neap tides. This condition results in a large influx of sand into the lagoon and causes a sand plug to form in the seaward end of the inlet channel. An overwash fan then forms behind the sand plug, filling the channel with sand.

A crater-sink/fluidization system was designed to cut a new channel across the sand plug. The system consisted of a 6 inch, 100 hp dredge pump connected to a short discharge pipeline, and a 43 m long spiral wound fiberglass fluidizer pipe powered by a 4 inch, 30 hp water pump (Figure 22). The design of the pipe was based on a modified form of the analytic model developed by Bailard and Inman, (1975). The fluidizer pipe was 4 inches in diameter with 0.145 cm diameter jets angled at 45° and spaced 6.3 cm apart. The water flow rate to the pipe was 520 gpm at a pressure of 3.85×10^6 dynes/cm², (55 psi).

The procedure for cutting the channel consisted of starting at the lagoon and "leap-frogging" the system across the overwash fan. The system successfully cut a 210 m long channel in 5 steps (Figure 23) removing 600 m³ of sand. In fine sand the fluidizer moves sand at a rate of 100 m³ per hour; however due to the presence of extensive cobble beds, the maximum cutting rate of the system was 30 cubic meters per hour, cutting a 1.5 m deep, 3.7 m wide, 43 m long channel segment in approximately 3.5 hours.

8. ACKNOWLEDGEMENTS

The Fine Sediment deposition control studies in this paper were funded by the Naval Facilities Engineering Command through the Geography branch of the Office of Naval Research, Contract No. N00014-76-C-0631. The 1977-78 Agua Hedionda and Penosquitos Lagoon experiments were sponsored by NOAA, Office of Sea Grant, U. S. Department of Commerce under grant number UCSD-R/CZ-33D.

The authors are grateful for the efforts of Dr. William Van Oorn, who was our colleague in the fine sediment studies prior to his retirement in August 1979. We have appreciated assistance and logistical support from Mr. James Oillard, technical assistant to the public works officer at Mare Island Naval Shipyard. We are further indebted to Marion Horna, plant manager, San Diego Gas and Electric Co. for the support of cable, barges, and electric power in the Agua Hedionda by-passing experiments.

RESEARCH IN SOUTHERN QUEENSLAND INTO
THE MANAGEMENT OF COASTAL SAND DUNES

James B. McKenzie¹ and David A. Barr²

1. INTRODUCTION

Queensland's Beach Protection Act (1968-1974) resulted, inter alia in the formation of the Beach Protection Authority, which is responsible for investigating coastal erosion, planning remedial works, recording and evaluating results of investigations, and various other functions.

Control of windblown sand and retention of vegetated and naturally stable coastal sand dunes are valuable means of decreasing coastal erosion and because of this the Authority implements a broad research program into the management of coastal dunes in Queensland. Field trials are carried out at the Authority's Dune Management Research Station on South Stradbroke Island to determine methods of repairing, stabilizing and managing coastal dunes.

The research program conducted so far consists of fifteen separate field trials within four general areas of investigation:-

(a) Dune Forming Fences

Two trials were installed in blown-out sections of the frontal dune to compare different types of semi-permeable fences (eg. wooden slats) and brush matting (a surface mulch of tree branches) on the basis of their ability to accumulate windblown sand and initiate dune formation.

(b) Dune Stabilization Techniques

Three trials were installed on bare dunal areas to evaluate methods of temporary sand surface stabilization (organic mulches and spray-on materials) as an aid in establishing dune vegetation.

(c) Dune Vegetation

Two trials were conducted to produce and compile information on the performance of important or potentially useful dune plants.

(d) Plant Nutrition

Eight trials using different combinations and rates of fertilizer were used to study methods of improvement of establishment and early growth of dune stabilizing plants, particularly sand spinifex grass (*Spinifex hirsutus*). Good establishment and rapid early growth is required in order to accelerate, improve, and decrease the costs of, the stabilization process.

 2. Principal Dune Conservationist, Department of Harbours and Marine, Queensland, Australia.

The trials carried out in each area of investigation are described below.

2. DUNE FORMING FENCES

Where there is a significant width of sand of suitable median grain size between high water mark and the seaward toe of the dune strong on-shore winds will transport large quantities of sand landwards.

In the absence of dune vegetation which traps and holds windblown sand, semi-permeable dune forming fences can be used for the same purpose. The fences function by lowering wind velocities adjacent to the fence below the critical threshold velocity required to keep sand moving. This results in sand accumulating on both sides of the fence, eventually burying it, and an artificial sand dune is formed.

Semi-permeable dune forming fences can be used to repair dune "blow-outs" or to initiate rebuilding of a new dune line. The most satisfactory types of dune forming fence in use are those constructed of spaced timber slats, brush material and moulded plastic or nylon materials.

(a) Trial 1

In 1971, a trial was installed in blown-out sections of frontal dune to measure and compare the rate of accumulation of windblown sand against three types of semi-permeable material attached to wooden post and wire fences. The semi-permeable materials used were spaced hardwood timber slats, 'Trical' (moulded polyethylene mesh) and 'Raschel' (woven polyethylene netting). Each fence material had a solid to space ratio of about 1:1. The fences were erected across each of three dune "blow-outs" and placed above, and parallel to high water mark. The fence treatments were replicated to enable statistical analysis.

Cross sections at each fence were surveyed to calculate volumes of accumulated sand. The cross section lines extended 6 m on both the seaward and landward side of the fence. Each fence was about 1 m high.

The volume of sand accumulated by each type of fence treatment, and the results of statistical analysis are presented in Table 1.

The slat fence initially accumulated windblown sand at a faster rate than the 'Trical' or 'Raschel' fence. During the 6 week period following installation the sand surface beneath the 'Raschel' fence suffered wind erosion (indicated by the negative value in Table 1). However, after 23 weeks the 'Raschel' fence was effectively trapping windblown sand. At 66 weeks after trial installation all fence treatments had completely filled with windblown sand.

(b) Trial 2

Another trial was installed in 1972 across a large blown-out section of frontal dune to compare the sand trapping ability of 6 types of semi-permeable material when attached to two parallel fences 6 m apart. The treatments used were: brush fence (pieces of brush attached to the fence wires), brush matting (successive layers of brush placed on the sand

surface), wooden slats, 'Trical', 'Easy Fencing' (plastic impregnated netting) and 'Sarlon' (loose woven polypropylene ribbon fabric). The parallel fences were placed above and parallel to high water mark. The experimental design used was that for a Randomised Complete Block:- 6 fence treatments randomly allocated within each of 3 replicates.

Cross sections at each fence treatment were surveyed to calculate volumes of accumulated sand, and the results are presented in Table 2.

Initial rates of sand accumulation were similar in all treatments but later in the trial brush matting showed a superior ability to accumulate windblown sand. The brush fence and wooden slats were similar in terms of rate and volume of sand accumulation and superior to the plastic materials ('Trical', 'Sarlon', 'Easy Fencing') which were the less effective sand accumulators. All fence treatments had completely filled with windblown sand after 128 days. The parallel fences in this trial accumulated sand more rapidly than the single fences in the first trial.

A wider dune having a more uniform profile of accumulated sand can be formed using two fences parallel to each other. Provided there is a sufficient quantity of sand blown landward from the beach both fences will fill quite rapidly with the seaward fence filling first.

To provide more permanently stability to the re-formed dune it is advisable to apply brush matting to prevent wind erosion and to plant the dune with suitable dune colonising vegetation.

3. DUNE STABILIZATION TECHNIQUES

Initial sand surface stabilization using organic mulches and spray-on materials and rapid establishment of vegetation are integral parts of any program designed to stabilize exposed wind eroded coastal dunes. Surface stabilizing agents prevent wind erosion for a sufficient period of time to allow establishment of dune colonising vegetation which stabilizes the sand surface more permanently.

(a) Field Stabilization Trial

In 1971 a bare unstable dune area (4.6 ha) was selected to test the normally recommended method of frontal dune stabilization. Stabilization was to be a step-wise procedure utilizing the growing seasons and growth habits of annual and perennial plant species. The area was planted with sand spinifex grass (*Spinifex hirsutus*), marram grass (*Ammophila arenaria*) and cover crops consisting of cereal rye (*Secale cereale*), sand plain lupin (*Lupinus cosentii*), Zulu sorghum (*Sorghum vulgare*), Tamworth pearl millet (*Pennisetum typhoideum*) and Rhodes grass (*Chloris gayana*). Fertilizer containing nitrogen, phosphorus and potassium was applied at planting and throughout the trial period. The planted area was brush matted (about 10 tonne brush material per hectare) to prevent wind erosion. Tree seedlings of horsetail she-oak (*Casuarina equisetifolia* var. *incana*) and coastal wattle (*Acacia sophorae*) were also planted.

Ground cover estimates were used to assess development of a stabilizing vegetative cover. Brush matting provided initial sand surface stabilization, prevented wind erosion and allowed establishment of vegetation. Ground cover of vegetation averaged 60-65% within 30 months from planting and the trial area was completely stabilized by sand spinifex grass, Rhodes grass and the tree species. The annual plant species (cereal rye, sorghum) were dominant ground cover components early in the trial and were gradually replaced by the perennial species (sand spinifex grass, Rhodes grass) which stabilized the sand surface more permanently. The application of fertilizer (over 1 tonne ha⁻¹) throughout the trial period assisted establishment and growth of vegetation.

(b) Mulch Trial 1

In the winter of 1971 a plot trial was installed on a bare area of wind eroded dune to compare the effectiveness of various surface stabilizing agents in initially stabilizing sand and allowing establishment of vegetation. The trial area (0.4 ha) was planted with sand spinifex grass (28 kg ha⁻¹), marram grass (4 kg ha⁻¹), cereal rye (44 kg ha⁻¹), Zulu sorghum (11 kg ha⁻¹), Rhodes grass (11 kg ha⁻¹) and sand plain lupin (11 kg ha⁻¹). A mixed (N,P,K) fertilizer was applied at planting and the following treatments were applied to plots (9 m x 4.5 m) randomly allocated within each of four replicates: brush matting (2.5 kg brush m⁻²), straw mulch (0.62 kg straw m⁻²), 'Terolas' (bitumen emulsion mixed with 5 volumes of water and sprayed at 0.28 l emulsion m⁻²), 'Curasol' (poly vinyl acetate emulsion mixed with 30 volumes of water and sprayed at 0.05 l emulsion m⁻²), straw plus 'Terolas' and straw plus 'Curasol'. Fertilizer to promote plant growth was broadcast over the treatment plots during the 90 week trial period.

Measurements of plant establishment, ground cover and resistance to wind erosion were used to assess treatment effect. Each treatment gave sufficient surface protection to allow vegetation to establish and stabilize the sand. The brush matting treatment provided better conditions for plant establishment and growth than did most of the other treatments. In all treatments annual plants (particularly cereal rye) were dominant early in the trial but after 7 months the perennial plants, Rhodes grass and sand spinifex grass, were dominant. Ground cover in all treatments improved generally over the term of the trial (Fig. 1). Early ground cover was provided mainly by cereal rye and was slightly better in the treatment plots where this species established best i.e. in the treatments where straw was used. At the end of the trial (after 90 weeks) ground cover on the brush matting treatment was not significantly different from that on those treatments containing straw but it was significantly greater ($P = 0.95$) than ground cover on the 'Terolas' and 'Curasol' treatments. Rhodes grass was the dominant ground cover component in the brush matting treatment at the end of the trial. Visual ratings showed that brush matting had the greatest resistance to wind erosion. The surface seal provided by straw mulch was the first to deteriorate. The 'Terolas' and straw plus 'Terolas' treatments lasted slightly longer than the 'Curasol' and straw plus 'Curasol' treatments. The 'Curasol' and 'Terolas' treatments showed signs of deterioration at 10 months after application.

(c) Mulch Trial 2

A similar trial to the one above was installed in the summer of 1974. The trial area (1.2 ha) was sown (broadcast) with spikelets of sand spinifex grass at the rate of 67 kg ha⁻¹ and seed of Tamworth pearl millet at the rate of 11 kg ha⁻¹. A mixed (N, P, K) fertilizer was applied at planting and harrowed in with the seed.

Figure 1. Ground cover on surface stabilization treatments.

Nine treatments were randomly allocated to plots (10 m x 5 m) within each of 4 replicates at 2 sites (each site 0.6 ha). The treatments applied were:-

Brush matting: 2.5 kg brush m⁻².

Straw mulch: 0.45 kg straw m⁻².

'Terolas': bitumen emulsion mixed with 4 volumes of water and sprayed at 0.36 l emulsion m⁻².

'Curasol': poly vinyl acetate emulsion mixed with 18 volumes of water and sprayed at 0.1 l emulsion m⁻².

'Unisol': synthetic latex and mineral oil emulsion mixed with 15 volumes of water and sprayed at 0.1 l emulsion m⁻².

Straw plus 'Terolas'.

Straw plus 'Curasol'.

Straw plus 'Unisol'.

Nil: bare sand without surface treatment.

The buffer strips between plots and all bare surrounding areas were brush matted to prevent wind erosion and sand encroachment onto treatment plots. Additional fertilizer was applied as required during the trial. Measurements of plant establishment, ground cover and resistance to wind erosion (longevity of surface seal) were used to assess treatment effect.

The nil treatment was completely ineffective and was brush matted to prevent sand blowing onto adjacent plots. All other treatments were initially effective in stabilizing bare wind-blown sand. Brush matting was again the most effective stabilizing agent and favoured establishment and growth of sand spinifex grass and Tamworth pearl millet. These plants also grew well in those treatments containing straw but establishment and growth were very poor in the 'Unisol' and 'Terolas' treatments.

Figure 2. Spinifex ground cover on surface stabilization treatments.

The millet cover crop was the main ground cover component early in the trial and provided protection for establishing sand spinifex grass which was then the dominant ground cover for most of the trial. Development of spinifex ground cover during the trial period is shown in Fig. 2 and indicates that spinifex ground cover developed best in the brush matting treatment. Spinifex growth was also favoured by the 'Curasol' treatment and those treatments containing straw. There was poor development of spinifex ground cover in the 'Unisol' and 'Terolas' treatments.

All mulch treatments (except nil) initially stabilized the sand surface but as the trial progressed the surface seal provided by the treatments either rapidly or gradually deteriorated. Visual observations of the treatments indicated that the surface seals deteriorated in the following order:

nil (after 2 weeks); 'Unisol' (after 3 months); straw plus 'Unisol', straw, 'Curasol', straw plus 'Curasol' (after 7 months); straw plus 'Terolas', 'Terolas' and brush matting (seal still effective at trial completion).

4. DUNE VEGETATION

As coastal sand dune stabilization is usually based on the use of vegetation, it is necessary to make the best use of available species if the stabilization program is to be most effective.

(a) Spinifex Growth Pattern Trial

Sand spinifex grass is the most widespread and important primary coloniser of coastal dunes in southern Queensland and in the winter of 1971 a trial was installed on a bare section of frontal dune primarily to obtain information on the growth pattern of this perennial species.

The grass was planted in plots (about 14 m x 5 m) either by seed or by stolon tip cuttings, with nil, medium (500 kg ha⁻¹), or high (1000 kg ha⁻¹) rates of a mixed (N,P) fertilizer. The trial design was that of a 3 x 2 factorial in a randomised tri-replicated complete block. After planting brush matting was spread over the plots and surrounds to prevent wind erosion. When the grass had established, at about 6 months after planting, regular ground cover measurements were used to assess treatment effect. Observations were also made on the requirements for good seed set of spinifex plants grown from seed and stolon tip cuttings. Additional fertilizer applications were made as required to maintain growth during the trial.

Good establishment occurred both from seed and stolon tip cuttings. Vegetatively established plants grew faster than the seedlings. However the two methods of plant establishment produced similar ground covers. The higher plant numbers produced in plots established from seed compensated for the slower seedling growth. The development of spinifex ground cover over a 3 year period is shown in Fig. 3. Growth was best during the summer months with gradual die-back in winter. Ground cover was similar on plots receiving medium and high rates of fertilizer and ground cover on the fertilized plots was much higher than on unfertilized plots. The fall-off in ground cover after June 1973 was caused by the plots being inundated with windblown sand which occurred during a storm in July 1973. While fertilizer increases growth, climatic factors largely govern the plants growth pattern. The dramatic increase in ground cover after October 1972 is associated with increasing temperature and also the fact that 460 mm of rainfall occurred in late October 1972. Maximum ground cover was initially achieved in the fertilized and unfertilized plots at about 20 months after planting. The results indicate that where rapid stabilization is required fertilizer should be added. Plants raised from stolon tip cuttings produced more inflorescences than plants raised from seed in the first few years after planting. The addition of fertilizer markedly increased seed yield from both types of plant. To obtain maximum seed yield in the shortest possible time stolon tip cuttings should be planted and heavily fertilized.

Figure 3. Development of spinifex ground cover over a 3 year period.

(b) Species Evaluation Trial

In 1974 a trial was installed to produce and compile information on the performance of important or potentially useful dune plants. Selected native and exotic species planted at 3 dunal sites of varying exposure are compared with sand spinifex grass (control species). Selected species are planted in duplicate 6 m long single rows at each site, either as seed or seedlings. Mixed (N, P, K) fertilizer is applied at 3 monthly intervals to all species except legumes (or other N-fixing species) which receive (P, K) fertilizer at 3 monthly intervals. Ground cover and vigour and persistence ratings appear to be the most useful measurements for comparing different plants.

The plants being studied include sea oats (*Uniola paniculata*), shoredune panicum (*Panicum amarulum*), beach grass (*Thuarea involuta*), green panic (*Panicum maximum* var. *trichoglume*), beach bean (*Canavalia maritima*), vigna (*Vigna marina*), vitex (*Vitex ovata*) and marram grass (*Ammophila arenaria*).

Ground cover, vigour and persistence of sand spinifex grass are generally superior to that recorded for all plants studied at each site. However sea oats, green panic, beach grass, vitex and beach bean may be suitable species for planting with sand spinifex grass on exposed frontal dunes. Sea oats, shoredune panicum, beach grass, green panic, vigna, vitex and marram grass have shown good growth at the less exposed sites but their vigour and persistence depends on season.

5. PLANT NUTRITION

Good establishment and rapid early growth of vegetation is required in order to improve the effectiveness of dune stabilization and to decrease costs by minimising the need for brush matting and repair work. Different combinations and rates of fertilizer were used in trials to improve establishment and early growth of dune stabilizing plants.

(a) Spinifex/Lupin/Nitrogenous Fertilizer Trial

In 1972 a trial was installed on the exposed seaward slope of the frontal dune to determine the effect of nitrogenous fertilizer on the growth of sand spinifex grass and sand plain lupin. Five rates of ammonium nitrate (34% N) fertilizer were applied to plots (9 m x 5 m) sown with spinifex and lupin seed. The rates used were 11.7, 23.4, 46.7, 93.4 and 186.8 kg N ha⁻¹ applied at planting and then at intervals of 3 months for 2 years. All plots received a basal dressing of all other essential plant nutrients at planting and the plots and surrounds were brush matted to prevent wind erosion. Treatments were randomly allocated within each of four replicates. Ground cover and dry matter yield were used to assess treatment effect.

The development of spinifex ground cover at 3 rates of nitrogen application is shown in Fig. 4. Accelerated growth and ground cover of sand spinifex grass occurred at 5 months after planting continuing until maximum ground cover was achieved at 15 months after planting. Increased spinifex growth was obtained by increasing the rate of application of nitrogenous fertilizer up to 934 kg N ha⁻¹ in 5 equal split applications over 15 months. Differences in spinifex ground cover in fertilizer treatments at 18 months after planting are shown in Table 3.

TABLE 3: SPINIFEX GROUND COVER IN TREATMENTS AT 18 MONTHS

Treatment ($\text{kg N ha}^{-1} \text{ 3 months}^{-1}$)	186.8	93.4	46.7	11.7	23.4
Ground Cover (%)	74.1	65.8	61.9	48.6	44.3

Note: 1. Values underlined are not significantly different ($P = 0.95$).

The application of increasing amounts of nitrogenous fertilizer increased dry matter yield of spinifex from about 1000 kg ha^{-1} to over 4300 kg ha^{-1} after 15 months. More frequent applications of nitrogenous fertilizer during the growing season are likely to improve growth, ground cover and yield of this grass. Heavy and frequent applications of nitrogenous fertilizer may be detrimental to lupin growth. No short term beneficial effect of using lupin as a nitrogen source for sand spinifex grass could be detected in this trial.

Figure 4. Effect of rate of application of nitrogenous fertilizer on spinifex ground cover.

(b) Spinifex/Superphosphate Trial

A trial was installed in 1972 on a bare section of frontal dune to determine the effect of superphosphate (9.2%P) on the growth of sand spinifex grass. Plots (9 m x 5 m) were sown with seed of sand spinifex grass at the rate of 112 kg ha⁻¹ and the plots and surrounds were brush matted to prevent wind erosion. Superphosphate was applied at the following rates: 126, 251, 502, 1004 and 2009 kg ha⁻¹. Each treatment was replicated 4 times in a randomised complete block design. Each plot was split and at planting each half of each plot received the appropriate fertilizer rate. Repeated applications of superphosphate were made at 6 monthly intervals for 2 years to the same half of each plot. All plots received adequate nitrogenous fertilizer during the trial. Dry matter yield was the main measurement used to assess treatment effect and the grass was harvested at 9 and 15 months after planting. The results obtained for each harvest are shown in Fig. 5. Establishment and growth of sand spinifex grass seedlings was unaffected by applications of superphosphate ranging from 126 to 2009 kg ha⁻¹ but the highest rate depressed early seedling growth. A yield increase at the 15 month harvest resulted from the application of superphosphate at moderate rates (502 kg ha⁻¹) when compared with the lowest rate (126 kg ha⁻¹). At each harvest date repeated applications of super produced marginally higher yields than the single application. An apparent yield suppression at the highest rate could not be confirmed statistically.

Figure 5. Effect of rate and timing of applications of superphosphate on spinifex dry matter yield.

(c) Millet Cover Crop/Fertilizer Trial

In 1973 a trial was installed in a semi-exposed bare area on the main dune to investigate the growth response of a cover crop of Tamworth pearl millet to different levels and combinations of potassium, sulphur and calcium fertilizers. Treatment plots (7 m x 7 m) were sown (broadcast) with millet seed at a rate of about 11 kg ha⁻¹. All plots received a basal dressing of nitrogen (40 kg ha⁻¹), phosphorus (30 kg P ha⁻¹), copper (10 kg ha⁻¹ of copper sulphate) and zinc (10 kg ha⁻¹ of zinc sulphate). The following rates (or levels) of nutrient elements were applied in factorial combinations: 0 and 26 kg K ha⁻¹; 4, 16, and 56 kg S ha⁻¹; 0 and 28 kg Ca ha⁻¹. Twelve nutrient element combinations were randomly allocated within each of 3 replicates. Statistical analysis of millet establishment counts indicated that there were significant differences between treatments in terms of plant establishment. The treatment plots were harvested 10 weeks after planting and dry matter yield was used to assess treatment effect. The effect of levels of K, S and Ca on millet dry matter yield is shown in Fig. 6. The application of potassium at 26 kg ha⁻¹ together with basal nitrogen and phosphorus increased dry matter production of Tamworth pearl millet. The application of calcium or sulphur had no significant effect on dry matter yield and there were no significant yield interactions between any of the levels of the 3 nutrient elements applied.

Figure 6. Effect of potassium, calcium and sulphur on millet dry matter yield.

(d) She-oak Nutrient Requirement Trial

In February 1975 a trial was installed at 2 sites on the main dune to investigate the nutrient requirements of horsetail she-oak seedlings. One site was exposed and the other was protected from onshore winds. The trial was an "omission" type with a randomised complete block design. Each site consisted of 24 plots (7 m x 7 m) in 3 replications of 8 plots. The plots and surrounds were brush matted to prevent wind erosion and planted with she-oak seedlings (about 20 cm high) on 1 m centres. The following fertilizer treatments were randomly allocated within each replicate at both sites: nil; complete (containing N, P, K, Ca, Mg, S and trace elements); complete minus N; complete minus P; complete minus K; complete minus Ca and Mg; complete minus S; and complete minus trace elements (Cu, Zn, Mo, B, Fe, Mn). The nutrients N, P and S were applied as split applications every 6 months and the remaining nutrients were applied annually. Tree height and basal diameter were the most useful measurements for assessing treatment effect. At the exposed site 15 months after planting there was no significant difference in height of trees in the following treatments: complete, -P, -K, -Ca/Mg, -S and -T.E (trace elements).

Trees in the nil and -N plots were significantly smaller in height than trees in other treatment plots. This marked difference in height was evident throughout the trial and is shown in Fig. 7. The -K, -Ca/Mg, -S and -T.E treatments are not shown as they are not significantly different from the complete and -P treatments.

Figure 7. Effect of fertilizer treatments on the height of horsetail she-oak tree seedlings.

Similar trends for tree height within treatment plots were evident at the protected site. Results for basal diameter of trees within treatment plots at both sites showed similar trends to those for tree height. The trial has shown that nitrogen was the most important plant nutrient required for establishment and rapid early growth of horsetail she-oak seedlings.

(e) She-oak/Nitrogenous Fertilizer Trial

The she-oak nutrient requirement trial showed that nitrogen was the most important nutrient for growth of horsetail she-oak seedlings. Because of this a trial was installed in August 1975 on an exposed section of frontal dune to investigate the effect of different forms and rates of nitrogenous fertilizer on establishment and growth of she-oak seedlings. A randomised complete block design (with split plots) was used and consisted of 15 plots (18 m x 6 m) in 3 replicates of 5 plots. The plots and surrounds were brush matted to prevent wind erosion and planted with she-oak seedlings (about 20 cm high) on 1 m centres. The following fertilizer treatments were randomly allocated within each replicate: urea (46%N) plus basal P, K and T.E; blood and bone (4%N) plus basal K; di-ammonium phosphate (19%N) plus basal K and T.E; urea formaldehyde (38%N) plus basal P, K and T.E; and sulphur coated urea (36%N) plus basal P, K and T.E. Each nitrogenous fertilizer treatment was applied to split plots at rates equivalent to 100, 200 and 400 kg N ha⁻¹ yr⁻¹ in split applications every 6 months.

Tree height and basal diameter were used to assess treatment effect. Average height per tree in three fertilizer treatment over a period of 15 months from planting is shown in Fig. 8. At 15 months from planting the height of she-oak seedlings in the sulphur coated urea treat-

Figure 8. Effect of different forms of nitrogenous fertilizer on the height of horsetail she-oak tree seedlings.

ment was significantly greater than the height of seedlings in all other treatments. There was no significant difference in height of trees growing in the urea formaldehyde, blood and bone, di-ammonium phosphate and urea treatments. Increasing the rate of application of di-ammonium phosphate, urea or blood and bone did not result in any significant increase in tree height. However, sulphur coated urea and urea formaldehyde applied at the rate of $400 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ produced trees that were significantly taller than those resulting when each fertilizer was applied at the rate of $100 \text{ kg N ha}^{-1} \text{ yr}^{-1}$.

The trends in basal diameter of she-oak trees are similar to those described for height. The application of sulphur coated urea or urea formaldehyde in split applications every 6 months at rates from 100 to $400 \text{ kg ha}^{-1} \text{ yr}^{-1}$ significantly increased growth of established she-oak seedlings. Both these fertilizers appear to be more beneficial to the nutrition of she-oak than the other forms of nitrogenous fertilizer. This is probably because forms of available nitrogen (eg. nitrate) are released from these fertilizers at a slower rate than they are from other fertilizers, and the nitrogen, which is easily leached from the root zone, is available to the trees over a longer period of time.

(f) Spinifex/Mycorrhiza Trial

In 1977 a small pilot trial was installed at a protected site on the main dune to investigate the effects that indigenous soil micro-organisms (mycorrhizas) may have on the phosphorus uptake and growth of sand spinifex grass. Data was collected but the results obtained were inconclusive.

(g) Spinifex/Superphosphate/Urea Trial

A trial to investigate the effect of various combinations and rates of superphosphate (9.2%P) and urea (46%N) on the growth of sand spinifex grass was installed on a bare section of the main dune in December 1977. The treatments consisted of 4 rates of superphosphate (0, 125.4, 250.8, and $501.7 \text{ kg ha}^{-1} \text{ yr}^{-1}$) applied in two ways, viz. "all-on" at planting and every 6 months, combined with 2 rates of urea (0 and $250.8 \text{ kg ha}^{-1} \text{ yr}^{-1}$) split into quarterly applications.

Ground cover of sand spinifex grass is being measured at intervals of 3 months. Early results clearly indicate the beneficial effect of quarterly applications of the nitrogenous fertilizer urea on growth and ground cover of sand spinifex grass. However the application of superphosphate did not seem to improve spinifex growth or ground cover.

(h) Spinifex/She-oak/Fertilizer Trial

In 1978 a trial was installed on a bare section of the main dune to determine optimum rates and timing for the application of nitrogenous and phosphatic fertilizers to horsetail she-oak tree seedlings planted into an established stand of sand spinifex grass. The trial will also determine the effect of competition between the trees and the grass on their respective growth rates. Data collection is still in progress.

6. INFORMATION GAINED FROM THE RESEARCH PROGRAM

The research program has produced quantitative and specific information on:

- (a) The rate of dune formation that can be expected using semi-permeable fences or brush matting.
- (b) The effectiveness of the recommended procedure for dune stabilization in immediately stabilizing base mobile coastal dunes and allowing rapid establishment of vegetation.
- (c) The relative effectiveness of organic mulches (eg. brush matting) and spray-on materials (eg. bitumen emulsion) in temporarily stabilizing bare coastal dunes and allowing establishment and growth of vegetation.
- (d) The likely value of a number of introduced and native sand colonising plants tested under field conditions for possible inclusion in dune management programs.
- (e) The growth patterns and nutrient requirements of sand spinifex grass and horsetail she-oak tree seedlings which are the two main species used in planting programs for dune stabilization in southern Queensland.

7. USING RESEARCH INFORMATION

Information gained from the research program is used to improve management of coastal dunes in Queensland as one means of decreasing rates of coastal recession. The information is used in the following ways:

- (a) It is progressively incorporated into a series of advisory leaflets on the vegetation and management of coastal dunes.
- (b) It is used by the Beach Protection Authority to provide free advice to coastal Local Authorities on establishment and management of dune vegetation.
- (c) It is tested and demonstrated in Field Trial Areas implemented on frontal dunes in co-operation with coastal Local Authorities.

Current and future trials in the research program will be aimed at improving all important aspects of coastal dune management in Queensland, and refining where necessary the information gained to date and presented in this paper.

8. ACKNOWLEDGEMENTS

Acknowledgement is made to the Queensland Department of Harbours and Marine and the Beach Protection Authority for supporting the research program and for giving permission to publish the results. Thanks is extended to Mr T.J. McDonald and the Queensland Department of Primary Industries for co-operation in the trial to investigate the growth pattern of sand spinifex grass, and to Dr I. Bevege and the Queensland Forestry Department for advice, assistance and co-operation in the horsetail she-oak trials. Sincere thanks is also given to Ms. E. Goward, Senior Biometrician, in the Queensland Department of Primary Industries for advice on trial design and subsequent analysis of results.

WIND AND SEDIMENT MOVEMENT IN COASTAL DUNE AREAS

JOHN R. HAILS

Director, Centre for Environmental Studies,
University of Adelaide, Adelaide, South
Australia

and

JOHN BENNETT

Flinders Institute of Atmospheric and Marine
Sciences, The Flinders University of South
Australia, Bedford Park, South Australia.

INTRODUCTION:

Little is known about how air-sediment interaction processes control the differential rates and direction of dune migration along the coast of South Australia. Information is needed on sand transport and dune formation in order to establish better guidelines for conservation and agricultural management programmes in areas that are undergoing erosion.

The writers, with financial support from the Coast Protection Board, Department for the Environment, South Australia, have commenced a pilot research project to examine dunes in the lower Coorong and adjacent areas in the southeast of the State (Figure 1). The aims of the project are -

To determine:

- (a) instantaneous surface stress values on the windward slopes of active transgressive dunes;
- (b) sand movement over the crestline as a function of surface stress on the windward slope in order to establish the life expectancy of stability of individual dunes;
- (c) the extent to which the local topography affects the wind regime in the dunal areas.

To obtain:

- (a) air trajectories over and around transgressive dunes;
- (b) information on dune geometry (slope inclinations, crest heights, base lengths, etc.).

To measure thermal energy budgets so that time histories of the change in surface cohesion can be found - cohesion depending to a degree on moisture content, evaporation rate and surface temperature.

Monitoring stations have been established within an amphitheatre and along the crest of an active transgressive dune complex at the southern end of the Coorong in order to make a comparative study of the wind flow within, over and around different morphological features in dune fields (Figures 2 and 3) So far, field work has been conducted in the summer months with visits to the experimental areas in December and February.

↓ FIG. 2: Surveyed transects across the amphitheatre (top) and active transgressive dune complex (bottom).

Φ ANEMOMETER SITE

FIG. 3: Seaward and landward margins of active transgressive dune complex

FIELD TECHNIQUES:

Miniature cup and Gill UVW propellor anemometers are used to determine the surface shear stress from profile measurements and eddy correlation techniques respectively. It is intended to relate the shear stress to the initiation, rate, and direction of sand transport at the monitoring stations. The complexity of the flow at sites where air is accelerated or decelerated by the topography makes the interpretation of data from shear stress measurements difficult. Results will be reported when further work has been completed.

The meteorological factors that control the cohesion of surface sand grains through the thermal energy and water budgets of the sand surface require the measurement of net radiant energy to it, the sensible (convective) and latent heat (water vapour) losses from it, and the conducted heat into the sand. The radiant energy is measured with a net all-wavelength pyranometer and the sensible heat flux is found from observation of the vertical profiles of air temperature and windspeed above the surface. Heat conducted into the dunes is estimated from records of temperature at two depths (2.5 and 13 cm) in the sand. The latent heat flux is to be determined from eddy correlation techniques combined with measurements of the sand moisture content.

The variations in wind speed through the active dune fields are measured with arrays of cup anemometers. In the amphitheatre, a total of twenty-four instruments were placed at regular intervals over the floor and sloping sides (Figures 4 and 5), while at the active transgressive dune, they were placed along and across the crest at three places (Figure 2, bottom). Because of the size of the dune, it was difficult to arrange

the anemometers so that a detailed wind pattern could be observed at one time. Since the direction and speed of the wind on the approach slopes were practically constant over several hours, more detail was obtained by moving part of the array to new sites on different occasions.

The cup anemometers are mounted 60-70 cm above and perpendicular to the sand surface, in order to measure the component of the wind parallel to the ground. The anemometers, manufactured after the design by Bradley (1969), have starting speeds of around 20 cm s^{-1} , and produce electrical pulses that are counted some distance away from the sensors.

← FIG. 4: Schematic diagram to show instrument layout within amphitheatre, February 13, 1980.

FIG. 5: Floor and west rim of amphitheatre

The mean wind speed is calculated from the counter readings by using the individual calibrations of the anemometers. For all the anemometers, the counting period began at almost the same time and had the same duration, so the mean speeds apply to effectively the same instant for one set of observations.

The wind direction is monitored with a portable, damped wind vane and magnetic compass.

The steadiness of the wind direction at both sites during the observation periods (generally to better than $\pm 10^\circ$) means that wind vectors, showing the speed and direction of airflow, can be constructed for each anemometer site. In addition, it is possible to construct isotach maps (showing lines of constant speed over an area) from the twenty-four average windspeeds centred at a particular time and measured at points across each site. This is done here from linear interpolations of the speed between adjacent anemometer stations.

Sand movement is measured with the aid of a 6-bin horizontal sand trap, with an effective downwind length of 1.5 metres. The mass of sand per unit time and per unit across-wind distance, in saltation and as surface creep, is calculated from the amount caught in the trap.

The textural (size distribution, shape, etc.) properties of the sand are determined by sieving and other standard sedimentological techniques.

RESULTS:

(a) Amphitheatre

The "surface" wind maps, showing the mean isotachs and wind vectors generally indicate that the velocities are higher near the floor of the amphitheatre and they progressively decrease towards the rim. The wind direction inside the depression depends strongly upon the direction of the undisturbed flow some distance from it. Two examples are illustrated in Figure 6.

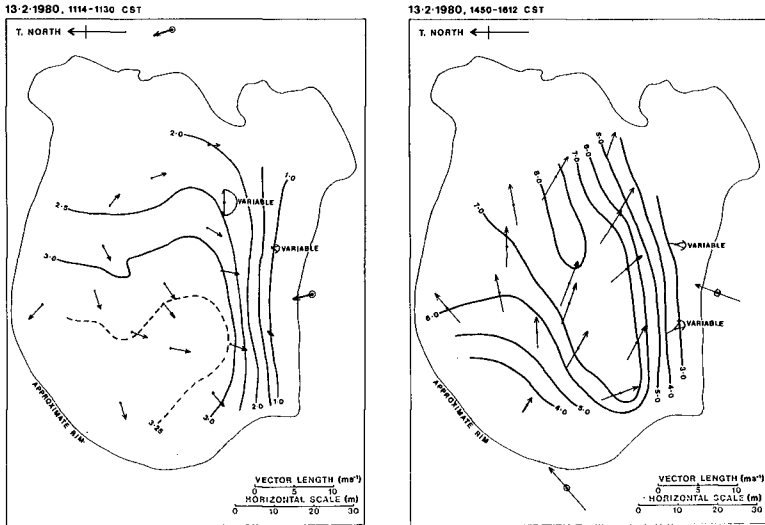

FIG. 6: Mean isotachs (ms^{-1}) and wind vectors in amphitheatre, 1114 to 1130 (left) and 1450 to 1612 (right), February 13, 1980.

The one on the left shows the isotachs for mid-morning, February 13, 1980, when the wind direction measured at the eastern rim was about 150° . At the time, the wind strength was insufficient to transport dry sand within the amphitheatre. On the same day, the wind veered to the southwest and freshened partly because of a change in the synoptic situation which reinforced a local sea-breeze. The one on the right applies to the later afternoon, by which time the wind speed was high enough to move sand on the north and south walls of

the amphitheatre. The isotachs show that the maximum speed was still confined to the floor, which was damp because of a shallow water table. No sand was moved from this relatively cohesive area.

Operation of a Gill UVW anemometer set erected on the east rim, when a strong and steady wind was blowing from the west in the amphitheatre, showed that the flow there was also quite steady. In addition, there was practically no evidence for any updraught from the amphitheatre.

It was observed that unobstructed airflow off the sea, as measured on the beach, had a more southerly component than at the western rim of the amphitheatre. Flow inside the depression had a decidedly westerly component, but the speeds on the beach and at the west rim were nearly identical.

The sand in the amphitheatre is predominantly medium to fine-grained, with mean values within the range 1.75ϕ to 2.10ϕ ($\phi = -\log_2$ diameter in mm). Standard deviation (sorting) values, in the range 0.35ϕ to 0.55ϕ , show that the sand is well to moderately-well sorted. The values for skewness, or the third moment measure, vary from $-.32$ to $+.52$. Coarser sand grains occur at the western (seaward) and eastern flanks of the amphitheatre, while poorer sorting has been identified along its west-east axis. The sign of skewness varies from site to site, and there is no clearly-defined trend with height above the floor of the depression. The skewness vs sorting is shown in Figure 7.

(b) Active Transgressive Dune

So far, observations indicate that the wind flow over one of a number of parallel, elongated active transgressive dunes and originating in an extensive deflation hollow, appears to be quite smooth and regular. Both the wind direction and strength were almost constant over an averaging period, although there was a freshening in the afternoons from the same cause as reported for the amphitheatre. When wind directions were around 190° (off the sea and at roughly 50° to the dune ridge) the isotachs were parallel and uniformly spaced down the windward and leeward sides of the ridge. The pattern was slightly displaced to windward of the crest. The highest speeds occurred along the crest rather than on the exposed upwind slopes with their long fetch across the relatively flat deflation hollow. The wind always slackened towards the snout of the dune while on the lee side, the lowest speeds occurred on the floor of the valley between neighbouring dunes. The speed there was 42-47% below the value on the crest.

The wind direction veered slightly from the windward side to the crest and backed a similar amount to the lee. An example of the wind distribution is given in Figure 8.

FIG. 7: Plot of the skewness versus standard deviation (sorting) for sand samples collected from the amphitheatre and active transgressive dune complex.

FIG. 8: *Isotachs and wind vectors for active transgressive dune, February 15, 1980,*

The windspeeds were sufficiently high to move a considerable volume of dry sand across the crest of the dune, and to carry fine dust high into the air. The amount of dry sand removed from some areas was sufficiently large to expose a moist, stable surface.

Analysis of the active transgressive dune sand shows that it is mainly medium-grained, with mean values between 1.65ϕ and 2.27ϕ . Overall, the dune sands are not so well sorted as those in the amphitheatre, with values in the range 0.43ϕ to 0.74ϕ . Except for one sample, the skewness values are positive and fall within the range $+0.05$ to $+0.86$ (see Figure 7). Such positive values are indicative of sands deposited under uni-directional flow conditions.

DISCUSSION:

The wind maps for each site show that, for the particular wind conditions recorded, the flow within the amphitheatre is much more complex than across the active transgressive dune. The wind vectors are the more informative parameters. At the amphitheatre, Figure 6 (left) shows that when the wind blows from 150° (as indicated by the two vectors at the eastern and southern sides outside the rim) there is pronounced reversal in the flow direction across the entire floor of the depression. This strongly suggests that a rotor forms in the lee of the southern rim for that particular wind direction. The nature of the circulation in both horizontal and vertical sections as deduced from Figure 6 (left) is sketched in Figure 9.

When the wind veered 50° from a direction along the crest of the main dune within which is the amphitheatre, the dominant contrary flow contracted to a small region high up on the southern wall, and was

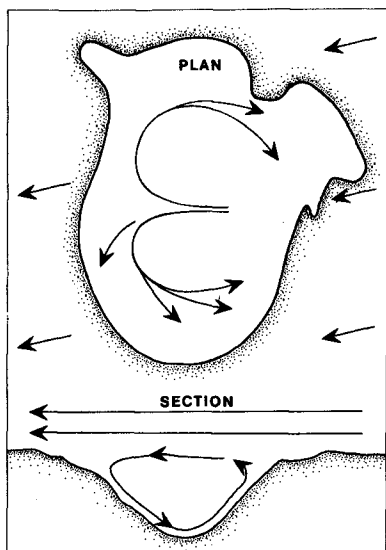

FIG. 9: Schematic diagram of wind circulation in amphitheatre (inferred from Figure 6, left)

replaced by a strongly-channelled flow through the amphitheatre from the west (Figure 6, right). The diminution in reversed flow is partly explained by the relatively low entrance to the amphitheatre from the west compared with the south (see sections in Figure 2, top). However, the main flow direction still differs appreciably from that of the unobstructed wind off the sea. Hence it is apparent that the foredune and main dune steer the flow to some degree, with the break in the main dune formed by the west rim, acting as a point of convergence for that flow. At the east rim, the flow was still from the west rather than the south-southwest, so the horizontal scale of any modification to the wind was of the same order as the length of the amphitheatre at least.

The wind observations in the amphitheatre suggest that the history of sand movement might be quite complicated in depressions. The sand could be moved from an area that is apparently sheltered from the unobstructed wind (but is

actually exposed to a reversed flow) to a new location that becomes exposed subsequently to winds from other directions. The observations also suggest that sand should be preferentially removed from the bottom and transported outside, or deposited on the walls of the depression. Here, however, because the floor was continually damp, even during the height of a hot and dry summer, it is unlikely that significant amounts will be transported from this part of the amphitheatre. The observations to date suggest that the driest sand on the walls moves first. There is active deposition on the east and south walls, while some sand moves through a small col on the northeast rim to add to a small dune behind it. The source of the mobile sand appears to be within the amphitheatre itself because a fresh supply of beach sand must cross a barrier of about 50 metres of thick vegetation before it reaches the depression. Old soil horizons are exposed on those parts of the north and west walls which are depleted of sand.

The distribution of windspeed across the amphitheatre might be expected to produce a corresponding variation in such statistical parameters as the first moment (mean), standard deviation (sorting), the third moment (skewness) and the fourth moment (kurtosis). Although the samples collected at different sites within the amphitheatre are generally well sorted, there is no marked trend in the degree of sorting from site to site, apart from poorer grain sorting along the west-east axis of the depression.

Figure 7 shows that 50% of the sand samples from the amphitheatre are negatively skewed, thus indicating a coarse-grained tail in the distribution. It is possible that the skewness values partly reflect the history of the sands, as well as the subtleties of air-sediment interaction, if the material in the amphitheatre has been reworked repeatedly over geologic time and can be described as both *polygenetic* and *polyeyelic*. However, higher moments are extremely sensitive to small changes and/or inaccuracies in the grain size distribution data, and therefore the values of these moments must be treated with caution (Hails, 1972). Obviously more analyses are needed to see if a relationship exists between environment-sensitive parameters and airflow within the amphitheatre.

Surprisingly, the airflow over the transgressive dune was comparatively simple. There was no reversal and only very slight steering of the wind by the dune itself. The absence of any lee eddy when the wind was blowing diagonally across the crest is presumably related to the smooth profile presented by that dune. The approximately 45% decrease in speed from the crest to the valley floor between adjacent dunes means that sand in transport on the crest would be dumped in the lee if the critical velocity for sand transport was higher than the actual velocity there. This feature would cause the dune crest to move downwind over an extended period of time, rather like a barchan dune.

In contrast to the amphitheatre sands, those comprising the active transgressive dune complex are positively skewed, except for one sample. This trend is characteristic of both modern and fossil dune sands and, in this instance, reflects the relatively simple uni-directional airflow over the dune system.

Figure 7 shows that, overall, the dune sands are less well sorted than those in the amphitheatre. The elongated shell fragments and sand comprising ripple crests are coarser than those in the troughs.

SAND TRANSPORT UNDER THE ACTION OF WIND

by

Ulrich ZANKE¹⁾

1) Dr.-Ing., Head of a research group on Sediment-transport at SFB 79, Universität of Hannover, West-Germany

ABSTRACT

Field investigations on sand-transport by wind were carried out at German North-Sea coast. A special trap was constructed, which allows to measure bed load and suspended load seperated. In addition wind speed was measured up to 10 m over the bottom. The results of the field investigations were used to calibrate a transport-equation for sand-transport by wind.

1. INTRODUCTION

In coastal areas much sand is transported by the flow of wind. Hence wind generated sand movement on coasts can be a major factor in some areas, but very little is known about the basic meachnisms of the transport by wind yet. With growing use of artificial placement of sand for restoration and protection of beaches, wind generated sand movement shoreward of the waterline has become more and more a matter of interest.

In 1978 (4) the author presented a new transport equation which is valid for the calculation of bed load as well as suspended load in water flow, as it was demonstrated by many examples. Based on some results on the quantity of wind-generated sand transport given by KADIB (1964), O'BRIEN (1936) and EXNER (1928), the author demonstrated that the above mentioned equation is, in principle, also valid for wind generated sand transport. Either most of the earlier experimental results on wind transport were taken from tests in small wind tunnels and were carried out with sand-traps that did not separate the bed load and the suspended load, or the particular results for the two types of transport have not been published.

Hence, field measurements on sand transport under the action of wind were carried out at the German North Sea coast (Island of Spiekerog). Based on the results of these measurements, the transport equation was calibrated for the sediment transport by wind.

2. THEORY

The transport equation given by the author (4) is

$$q_b = a_1 \left(\frac{v_1^2 - v_{C1}^2}{w^2} \right)^2 D^{*4} v \frac{1}{p} \text{ for bed load} \quad (1a)$$

$$q_s = a_2 f(h) \frac{(v_1 - v_{C1}^2) (v_1^2 - v_{\ell 1}^2)}{w^4} D^{*4} v \frac{1}{p} f(\text{visc}) \quad (1b)$$

for suspended load.

Herein is

- q = transported volume per unit width and unit time
 v_1 = actual bottom velocity in the reference level
 $y_1 = 1$ cm over the bottom
 v_{C1} = critical velocity for start of bed load movement
(in $y_1 = 1$ cm)
 $v_{\ell 1}$ = critical velocity for start of suspension
 w = terminal settling velocity
 D^* = $(\rho'g/v^2)l/3d$
 d = grain-size
 g = coefficient of acceleration
 h = flow depth
 ρ' = $(\rho_s - \rho_f)/\rho_f$
 ρ_s = density of sediment
 ρ_f = density of fluid
 ν = kinematic viscosity
 p = 0,7; factor regarding the degree of compaction
of natural sands
 $f(h)$ = $\begin{cases} (h/h_1 \text{ with } h_1 = \text{reference level } y_1 = 1 \text{ cm,} \\ \text{for water flow;} \\ 1 \text{ for flow} \end{cases}$
 $f(\text{visc}) = \begin{cases} (\nu/\nu_0 - \nu)^{1/4} \text{ for water flow } (\nu_0 = \nu \text{ at } 0^\circ\text{C}) \\ 1 \text{ for air flow} \end{cases}$

The values of a_1 and a_2 are also different in the case of water or air flow probably because the turbulence structure, which is not directly included in Equ. (1), is different in both cases. (For water flow $a_1 = 10^{-7}$ and $a_2 = 10^{-8}$ (for air flow see 4. RESULTS)).

The critical velocity v_{C1} in Equ. (1) is

$$v_{C1} = A + B - \sqrt{AB} \quad (2)$$

$$A = C_1 \cdot 2,4 \cdot (\rho_s' g d)^{1/2} \quad (2a)$$

$$B = C_1 \cdot 7,78 \cdot (\rho_s' g \nu)^{1/3} \quad (2b)$$

$$C_1 = 1 \text{ for water flow} \quad / \quad 0.5 \text{ for air flow}$$

$$\rho_s^i = \rho' + \rho_a / \rho_F \quad (3)$$

where ρ_a is an "additional weight" effected by adhesion forces

$$\rho_a = \begin{cases} 9 \cdot 10^{-5} \text{ (cm}^2\text{)}/d^2 \text{ for natural sand in water;} \\ \text{function of moisture content for sand in air} \\ \text{(see 4. RESULTS)} \end{cases}$$

The critical velocity $v_{\ell 1}$ in Equ. (1b) is given by the author (4)

$$v_{\ell 1} = C_1 \cdot 3,14 w \quad (4)$$

where

$$w = \frac{11v}{d} (\sqrt{1 + 0,01 D^{*3}} - 1) \quad (5)$$

3. EXPERIMENTAL TECHNICS

For the calibration and test of the equation for wind flow, field measurements were carried out at the German North Sea coast over a duration of altogether 15 weeks in 1978 and 1979. During this time, wind-velocity profiles were measured up to 10 m over the bottom and sand-transport was measured seperately as bed-load and suspended load in two large traps. The inlets of the traps moved automatically into the direction of wind. The results were registrated continuously. In addition, air humidity, air temperature, air pressure and moisture content of the sand in the traps were measured. The following figures give an overview of the sand traps used during the field measurements. (The pictures were taken after heavy rainfall. Therefore the sand is wet).

Figure 1 is an overview of the test field: On a mast 5 wind-velocity-meters (variable hight) were installed. The apparatus in front of the mast is the suspended-load-trap.

Figure 2 is a view to the front inlet of the trap. Sand and air enter the trap and are seperated inside the trap. The wind-outlet is on the upper backside. The velocity-profile is not disturbed in front of the inlet. The sand is sampled inside the trap. The weight of the sampled sand is measured automatically and is plotted continuously.

Next, Figure 3, shows the entry of the bed-load trap. The sand moving near the bottom falls into an underground-trap. The axis of the inlet for the bed-load-material is always directed to the wind by the suspended-load-trap. Thus the area of the inlet is well defined every time. The weight of sand sampled in the bed-load-trap is also plotted continuously.

Fig. 1

Fig. 2

Fig. 3

4. RESULTS

Based on the measurements the following results were obtained:

1. ρ_a in Equation (3) can be approximated by

$$\rho_a = \frac{0,116 \ln (W^{1/2} + 1)}{d^2} \frac{(\text{cm}^2)}{(\text{cm}^2)} \text{ for } W > 0,0025 \quad (5a)$$

or

$$\rho_a = \frac{2,28 \ln (W + 1)}{d^2} \frac{(\text{cm}^2)}{(\text{cm}^2)} \text{ for } W < 0,0025 \quad (5b)$$

or

$$\rho_a = \frac{8 \cdot 10^{-3} \ln (H + 1)}{d^2} \frac{(\text{cm}^2)}{(\text{cm}^2)} \quad (5c)$$

where $W = \frac{\text{weight of wet sample} - \text{weight of dry sample}}{\text{weight of dry sample}}$
 $H = \text{relative humidity of air}$

Fig. 4
Threshold velocities under wind action

Fig. 4 illustrated the dependence of threshold velocity on moisture content. Equations (5a) and (5b) are only valid for a short time after a rainfall. Then the sand is dried by the flow of wind and the critical velocity decreases. Nevertheless it is still impossible to set up a formula to calculate this decrease for each practical case, because in the nature sunshine, rainfall and wind speed can change rapidly. Moreover, some time after a rainfall, a layer of comparatively dry sand moves over a layer of more wet sand.

Equation (5c) is only valid, if there is no sunshine and if the moisture content is only effected by air humidity.

As a result of the measurements, calculations for practical use should at present therefore be carried out taking

$$\rho_a \approx 0 \text{ to } 5 \cdot 10^{-4} / d^2 \text{ for comparatively dry sand}$$

$$\rho_a \approx 2 \cdot 10^{-3} \text{ to } 4 \cdot 10^{-3} / d^2 \text{ for moved wet sand}$$

(din cm)

2. The values of a_1 and a_2 in Equations (1a, 1b) could be determined to be $a_1 \approx a_2 \approx 1.5 \cdot 10^{-6}$ in the case of sand-transport by wind.
3. For calculations of the quantity of wind generated sand transport in the nature the wind speed is, in general, only given for one level. Thus, to set the actual velocity in this given level in relation to the reference level of $y_1 = 1$ cm in Equs. (1), (2), (4), the velocity profile must be known. The investigations on the velocity profile gave the result that the velocity profile in the nature can be calculated by the Prandtl - Equation for rough boundary conditions with good agreement.

$$\frac{v_{y1}}{v_{y2}} = \frac{\ln \frac{30 \cdot y_1}{d}}{\ln \frac{30 \cdot y_2}{d}} \quad (6)$$

Equation (6) could be shown to be valid up to 10 m over the bottom for a velocity range between threshold and 20 ms^{-1} although the sand in the test field was comparatively fine ($d = 0.24 \text{ mm}$) (see Fig. 5). Effected by the irregularities of a natural sand bed in opposite to laboratory tests, a velocity distribution according to smooth conditions was never registered.

Fig. 5
Some examples of observed velocity profiles

5. SUMMARY AND CONCLUSIONS

A method for the calculation of the rate of wind generated sand-transport was developed in a half-empirical way. It could be demonstrated, that the critical velocity, v_C , increases rapidly if the sand becomes wet. Subsequently, depending on the duration and strength of wind, air humidity and rate of sunshine the layer of sand becomes drier and v_C decreases. On the functional coherences of these effects further research is needed.

For practical purpose an approximation for the calculation of v_C is given in this paper based on a great number of field investigations.

6. ACKNOWLEDGEMENTS

The investigations this paper is based on were financially supported by the SFB 79 (governmental found) and the Fran-

zius-Institut of the University of Hannover. Field investigations were carried out by friendly permission of the Bauamt für Küstenschutz, Norden, the Bezirksregierung Weser-Ems, Oldenburg, and the Gemeinde Spiekeroog. The author expresses his thanks to the Hermann-Lietz-Schule, Spiekeroog, for kindly supporting the field investigations.

versität Hannover

Summary

A numerical sediment transport model is formulated that serves especially for the simulation of bedform mechanics. The model is based on the idea that sediment transport is determined by the erosion rate and the path length of bed material. Formulas for the erosion rate and the path length are derived from physical considerations and from measurements; they depend mainly on the local values of the shear velocity and the mean flow velocity near the bed. The behaviour of detached sediment is simulated by a Monte Carlo procedure, which is based on the mean flow velocities and the eddy viscosity. All flow properties that are needed for the sediment transport model are computed by a numerical flow model that includes two turbulence equations. Results of the flow model and the sediment transport model are compared with measured data.

NOTATION

A	eddy viscosity	$[\text{cm}^2 \text{s}^{-1}]$
D	mean grain diameter	$[\text{cm}]$
g	acceleration of gravity	$[\text{cm s}^{-2}]$
h	bed height	$[\text{cm}]$
H	mean water depth	$[\text{cm}]$
k	$= 0,5 (u'^2 + v'^2 + w'^2)$, turbulent kinetic energy (per unit mass)	$[\text{cm}^2 \text{s}^{-2}]$
p	pressure	$[\text{g cm}^{-1} \text{s}^{-2}]$
q_s	sediment transport rate	$[\text{cm}^3 \text{cm}^{-1} \text{s}^{-1}]$
u, w	local mean flow velocities in x- and z-direction	$[\text{cm s}^{-1}]$
u', v', w'	turbulent flow fluctuations in x-, y- and z-direction	$[\text{cm s}^{-1}]$
$u_{\text{bed}}, w_{\text{bed}}$	mean flow velocities 1 cm above the bed	$[\text{cm s}^{-1}]$
u_m	mean (depth integrated) flow velocity	$[\text{cm s}^{-1}]$
$-\overline{u' w'}$	Reynolds shear stress	$[\text{cm}^2 \text{s}^{-2}]$
$v_{cr,e}$	critical shear velocity for the end of grain movement	$[\text{cm s}^{-1}]$

v_*	effective shear velocity	[cm s ⁻¹]
v_*^k	shear velocity calculated from k	[cm s ⁻¹]
v_*^{cr}	critical shear velocity for material entrainment	[cm s ⁻¹]
x	horizontal coordinate in flow direction	[cm]
y	lateral horizontal coordinate	[cm]
z	vertical coordinate	[cm]
η	erosion rate of sediment	[cm ³ cm ⁻² s ⁻¹]
σ	path length of moving grains	[cm]

1 INTRODUCTION

Ripples and dunes develop in the lower regime of alluvial flows. Dunes are large-scaled bed structures which can have a height of about 0.25 of the water depth and which influence appreciably the transport of bed material.

Experimental research about bedforms has achieved a good deal of progress; most efforts were directed to laboratory experiments. On the other hand, theoretical knowledge about bedforms is meager. One reason for the lack of knowledge on this field is the complexity of the interdependencies between flow, sediment transport and bed deformation. An important point among this set of problems is the impact of turbulent flow fluctuations on the bed material.

2 FLOW COMPUTATION

We only consider two-dimensional (horizontal (x) - vertical (z)) flows. The flow model uses the Reynolds equations and the continuity equation in order to compute the pressure p and the mean flow velocities u and w (see Sündermann and Puls /1/), and it uses the equations derived by Launder and Spalding /2/ to compute the turbulent kinetic energy k and its dissipation rate ϵ . From k and ϵ we obtain the eddy viscosity A .

The flow equations are solved by a finite difference procedure. We only compute stationary flows. The flow model is the basis for the calculation of sediment transport. Therefore we must take care that especially the near bed flow is simulated as well as possible. Fig. 1 gives an idea of the grid being used both for the computation of the flow and the sediment transport.

Fig. 4 shows a comparison of measured and calculated flow quantities. It must be emphasized that discrepancies are not only caused by the shortcomings of the flow model, but also by shortcomings of the measurements (which is especially valid for turbulence measurements). But we don't want to find excuses if the measured and the computed data do not coincide: in some respects the model is really imperfect. This is especially valid for the simulation of large-scale turbulence structures. In addition, problems arise due to the numerical solution procedure: the transformation of differential terms of the flow equations into finite difference terms always causes a loss of physical information.

Fig. 1 : Computational Grid

The comparison of measured and computed data is performed by means of two flow examples: a flow above a negative step (Fig. 2) and a flow above a schematized dune (or to be more precise, a range of dunes, Fig. 3).

Fig. 2 : Negative Step Geometry

Fig. 3 : Dune Geometry

The experiment with the negative step was performed in a wind tunnel by Moss et al. /3/. The height of the wind tunnel is 84 cm, the step height H_s is 7.6 cm, the mean air velocity is about $u_m = 1000 \text{ cm s}^{-1}$, the kinematic viscosity is $15 \text{ cm}^2 \text{ s}^{-1}$. Fig. 4 shows vertical profiles

Fig. 4 : Vertical profiles of u , k and $-u'w'$; flow above a negative step, data from Moss et al. /3/

of measured and calculated values of the mean horizontal velocity u , the shear stress $-\overline{u'w'}$ (which is expressed in the model by $A \frac{\partial u}{\partial z}$) and the turbulent kinetic energy at the positions $x H_s^{-1} = 3, 5$ and 7 (compare Fig. 2). The length of the separation zone in the lee of the step is calculated to be $5.7 H_s$, while the measured value is $5 H_s$. This can be seen in Fig. 4 by the disagreement of measured and calculated u at $x H_s^{-1} = 5$ and 7 . Fig. 5 shows a comparison of the measured and the computed bottom pressure.

Fig. 5 : Bottom pressure; flow above a negative step, data from Moss et al. /3/

Rifai and Smith /4/ measured the water flow above dune-shaped bedforms in a flume. The water depth at $x = 0$ (see Fig. 3) is $H_0 = 30.5$ cm, the mean flow velocity at $x = 0$ is 57.65 cm s^{-1} . The measured quantities are $\overline{u'^2}$ and u . For the comparison of k and $\overline{u'^2}$, we assume $\overline{v'^2} + \overline{w'^2} = \overline{u'^2}$. Fig. 6 shows the comparison of measured and calculated vertical profiles of u and k . As well as in the case of the negative step, the agreement is satisfactory. The greatest differences appear at $x = 7.6$ cm (see Fig. 3), where at $z H_0^{-1} \approx 0.15$, the measured k is much larger than the calculated k . The reattachment point was measured at $x = 15$ cm; the same result is given by the model.

In addition to the two bed examples shown above, the model was also applied to other bed configurations.

On the whole, the flow model of course would need some corrections. However, being compared with the flow conceptions that are used till today for tackling sediment transport, our flow model is a real improvement, both concerning the structure of the mean flow and the turbulence.

3 SEDIMENT TRANSPORT MODEL

3.1 Formulation of the model

The sediment transport model serves for the small-scale simulation of sediment transport. The computation is based on a division of the bed into horizontal intervals. For any of these intervals, the flow model

Fig. 6 : Vertical profiles of u and k ; flow above dunes, data from Rifai and Smith /4/

yields the near bed values for u , w , k and A .

One of the main faults of earlier works on bedform mechanics is the direct relation between the flow forces (usually in the form of the shear velocity v_*) inducing the sediment transport and the rate of sediment transport q_s . That this is wrong is easily shown by a simple example. Imagine a plane bed with a flow running above it; v_* is constant all over the bed. The upstream part of the bed is rigid, the downstream part is movable. Of course, q_s is zero on the rigid bed and develops from zero to an asymptotic value on the movable bed. Thus q_s varies over the movable bed though v_* is constant. A similar situation is found on bedforms downflow of the reattachment point. Therefore, in order to investigate bedform mechanics, the assumption of a direct relationship between v_* and q_s must be dropped.

Our device for the calculation of sediment transport is expressed by

$$(1) \quad \frac{\partial |q_s| (x)}{\partial x} + \frac{|q_s| (x)}{\sigma(x)} = \eta(x)$$

with σ being the path length a grain travels under homogeneous conditions from entrainment to deposition; η is the rate of material (measured by the total volume of bed material) being entrained from the bed per square unit and unit time. Equation (1) is valid for the absolute values of q_s only, because σ is positive definite. The sign of q_s is determined from the direction of the local mean flow near the bed. If η and σ are constant with respect to x , the differential term in (1) can be omitted, yielding

$$q_s = \eta \cdot \sigma$$

The next task is to get information about η and σ . There exist only a few experiments that have been concerned with direct measurements of η or σ . The erosion rate of non-consolidated mud was measured at HRS /5/. Takahashi, whose data is given by Nakagawa and Tsujimoto /6/, measured the probability of grains to be entrained on a flat bed. The information of both works can be expressed by ($v_* > v_*^{cr}$):

$$(2) \quad \eta = \text{const}_\eta \cdot D \cdot \frac{v_*^2 - (v_*^{cr})^2}{(v_*^{cr})^2}$$

with $\text{const}_\eta = 0.018 \text{ s}^{-1}$ from Takahashi's data and $\text{const}_\eta \approx 0.05 \text{ s}^{-1}$ from the HRS-data.

The path length σ was measured by Wulzinger and Liebig /7/ and by Nakagawa and Tsujimoto /6/. The quintessence of these measurements is a formula for the grain path length of bed load (for $v_* > v_*^{cr,e}$)

$$(3) \quad \sigma_{\text{bed}} = 820 \frac{\rho}{(\rho_s - \rho)_g} |u_{\text{bed}}| (v_* - v_*^{cr,e})$$

The values for $v_*^{cr,e}$ are taken from the Hjulstroem diagram (in Graf /8/).

The path length of suspended load cannot be deduced from direct measurements. The behaviour of suspended material is controlled by the settling velocity w_s and the eddy viscosity A . Our formula reads (for a derivation see Puls /9/)

$$\sigma_{\text{sus}} = \sigma_{\text{bed}} \left(1 + c_s \frac{A^S v_*^A}{w_s^3} \right)$$

A^S is an eddy viscosity being representative for the near bed zone, v_*^A is a shear velocity that is determined from A^S . c_s is a constant with the value $c_s = 30 \text{ s}^{-1}$.

The path length σ of total load (= suspended load + bed load) is determined by

$$\frac{1}{\sigma} = \frac{R_{\text{sb}}}{1 + R_{\text{sb}}} \frac{1}{\sigma_{\text{sus}}} + \frac{1}{1 + R_{\text{sb}}} \frac{1}{\sigma_{\text{bed}}}$$

with R_{sb} being the ratio of suspended load and bed load. Using the data of Guy et al. /10/, a rough formula for R_{sb} is

$$R_{\text{sb}} = 5 \frac{e^{-w_s z_s} (A^S)^{-1}}{1 - e^{-w_s z_s} (A^S)^{-1}}$$

with $z_s = 0.5 \text{ cm}$.

3.2 CALCULATION OF THE SHEAR VELOCITY

An essential point for calculating q_s is the choice of the shear velocity v_* . Because turbulence is the predominant factor for the capability of the flow to erode a grain and to prevent its deposition, v_* should be derived from the intensity of turbulence at the bed.

Using k_{bed} as the turbulent kinetic energy at the bed level, we obtain a shear velocity v_* from the equation

$$v_*^k = 0.51 (k_{\text{bed}})^{0.5}$$

Using v_*^k instead of v_* in (2) and (3), however, there is usually too much erosion in the reattaching zone of bedforms. Better results are achieved with

$$(4) \quad v_* = 0.7 v_*^k + 0.3 \cdot 0.07 (u_{\text{bed}}^2 + w_{\text{bed}}^2)^{0.5}$$

which uses the near bed mean flow velocities 1 cm above the bed. The weights 0.7 and 0.3 are found empirically in order to achieve acceptable agreement of the bed profile and the curve of q_s in Fig. 10.

3.3 BEHAVIOUR OF DETACHED SEDIMENT

The transport equation (1) is based on the assumption that σ is evaluated from v_* and u_{bed} being specific for the near bed region. This assumption is not fulfilled for particles being transported over a bedform's crest and which get caught in the separation zone in the lee of the bedform. In this case the particles are exposed to the local flow conditions which have nothing in common with the near bed values for the same x-coordinate. This is generally true if flow detachment occurs.

In such a case the transport of sediment is not calculated by (1) but by a Monte Carlo procedure (e.g. Maier - Reimer /11/). During this procedure, single (fictitious) particles are exposed to the direct influence of the local mean velocities and the local turbulence. The particles describe random walks like that plotted in Fig. 7.

Fig. 7 : Random walk of a particle

The Monte Carlo procedure is tested by comparing its results with measurements of Allen /12/. Allen's experimental setup is shown in Fig. 8, simulating the lee slope of a bedform. Above the upper end of the slope,

Fig. 8 : Experimental setup

sand grains are injected into the flow having a velocity u_g that equals that of the surrounding fluid. Touching the lee slope, the grains are arrested by a coat of glue. Measured and computed distributions of grains having settled down on the lee slope are shown in Fig. 9. On the

Fig. 9 : Distribution of settled particles

whole, the agreement is satisfactory; the centres of mass as well as the width of the distributions are reproduced quite well by the model.

4 SEDIMENT TRANSPORT OVER BEDFORMS

The transport model outlined above is applied to bedforms in unidirectional flow. For a bedform migrating with the velocity U_w without bed deformation, the relation

$$(5) \quad \frac{\partial q_s}{\partial x} = U_w \frac{\partial h}{\partial x}$$

is valid. The integration of (5) yields qualitatively

$$(6) \quad q_s(x) - q_{s,\min} \sim h(x) - h_{\min}$$

with $q_{s,\min}$ and h_{\min} being the minimum values of q_s and h respectively. The relation (6) fulfills the condition $q_s = q_{s,\min}$ at $h = h_{\min}$. For our comparison we consider three widely different bedforms: a laboratory ripple, a laboratory dune and a dune in the Elbe river. The Figures 10, 11 and 12 show the comparison of the measured bed profiles

Fig. 10 : Comparison of h and q_s ; ripple profile taken from /13/,
 $u_m = 30 \text{ cm s}^{-1}$, $H = 13 \text{ cm}$, $D = 0,042 \text{ cm}$

$h(x)$ and the transport rates $q_s(x)$ that are calculated by the transport model. The values of h_{\min} and of $q_{s,\min}$ are placed on the same level. Further, the scale of q_s is chosen in order to obtain identical maxima for h and q_s . Thus if the relation (6) is really fulfilled, the curves of h and q_s must coincide irrespective whether U_w is simulated by the model or not. As we see from Figures 10, 11 and 12, the curves of q_s and h agree quite well. Of course, we must not forget that the model was drafted just in order to achieve the agreement of h and q_s . But nevertheless, we obtain the confirmation that our conception of sediment transport, i.e. the calculation of q_s with the help of η and σ , is able to yield good results.

Fig. 11 : Comparison of h and q_s ; dune profile taken from /14/,
 $u_m = 62 \text{ cm s}^{-1}$, $H = 73 \text{ cm}$, $D = 0.026 \text{ cm}$

Fig. 12 : Comparison of h and q_s ; dune profile taken from /15/,
 $u_m = 120 \text{ cm s}^{-1}$, $H = 700 \text{ cm}$, $D = 0.04 \text{ cm}$

As stated above, the agreement of h and q_s is qualitative only. An additional quantitative comparison means to compare the absolute values of measured and calculated q_s .

No data is available for the dune in the Elbe river.

The transport rate over the ripple was measured to be $q_s = 6 \cdot 10^{-4} \text{ cm}^2 \text{ s}^{-1}$ whereas the calculated value is $q_s = 8 \cdot 10^{-3} \text{ cm}^2 \text{ s}^{-1}$ (using $\text{const. } \eta = 0.036 \text{ s}^{-1}$). The discrepancy could be caused by a "firmness" of the skin of the laboratory sand ripple (see also Guy et al. /10/): because of the low transport rate, a moving grain has a good chance to find a refuge in the bed, where it can easily resist to further flow attacks. Such a bed firmness decreases the erosion rate η appreciably.

For the laboratory dune, the qualitative comparison yields a better result: the measured migration velocity of the dune is $U_w = 0.049 \text{ cm s}^{-1}$,

while the calculated value is $U_w = 0.045 \text{ cm s}^{-1}$ (with $\text{const}_\eta = 0.036 \text{ s}^{-1}$).

The computed values of v_*^k , v_* , u_{bed} and σ over the three bedforms are shown in Figures 13, 14 and 15. The curves of v_*^k always have their

Fig. 13 : Computed values of v_*^k , v_* , u_{bed} and σ over the ripple taken from /13/

maximum in the reattaching zone. According to the influence of u_{bed} (see equation (4)), the curve of the effective shear velocity v_* is more smooth than that of v_*^k . The values of u_{bed} are negative in the recirculation zones. The most important point in Figures 13, 14 and 15 is the fact that σ is always in the order of the bedform length.

Fig. 14 : Computed values of v_*^k , v_* , u_{bed} and σ over the dune taken from /14/

Fig. 15 : Computed values of v_*^k , v_* , u_{bed} and σ over the dune taken from /15/

CONCLUSION

Up to now, theoretical attempts to simulate in detail the sediment transport over bedforms and to explain the characteristics of bedforms have suffered from the following shortcomings:

- the flow was simulated in a simplified way only (e.g by using potential flow theory)
- turbulence was not included in the considerations
- a direct relationship between the flow parameters and the transport rate was assumed

The numerical model outlined in this paper avoids these shortcomings and is thus able to simulate in a physically adequate way the sediment transport over bedforms.

ACKNOWLEDGEMENT

The work reported in this paper was performed within the investigation program of the Sonderforschungsbereich 79, Hannover.

ESTUARINE RESPONSE TO DREDGING
IN THE TWEED RIVER, AUSTRALIA

Bruce M. Druery
Supervising Engineer, Estuary Process Investigations
Department Public Works, State Office Block,
Phillip Street, Sydney. AUSTRALIA.. 2000.

ABSTRACT

Between mid 1974 and mid 1975, 760,000 m³ of sand was dredged from the bed of the Tweed River for the purpose of nourishing cyclone damaged beaches of the Gold Coast (Queensland). A comprehensive field data programme was established in 1976 to record the changes in the hydraulic processes of the Tweed River brought about by the dredging. The field measurements demonstrated that the dredged area was being infilled with sediments of both marine and estuarine origin. The dredging increased tidal ranges throughout the lower estuary, the effect being more pronounced at low water.

Sediment bedload rates were estimated from detailed measurements of bedforms and used to calibrate a sediment transport formula. The formula was used in conjunction with a 1 Dim. numerical model of tidal hydraulics to simulate estuarine shoal dynamics by means of a simple sediment routing technique. The results showed that the dredging had altered the tidal hydrodynamics so as to enhance the ebb transport of sediment towards the dredged hole. In the long term it was found that the sediment transport switched to a weak net upstream movement of sediment. The detailed hydraulic mechanisms involved are discussed. The study demonstrates that the impact of dredging can be minimised by location upstream of the entrance plug of marine sand.

1. INTRODUCTION

The coastal margins of a large number of estuaries in New South Wales (N.S.W.) have developed near regime channels in marine sands which were pushed against the coastline during the sea level transgressions of the late Pleistocene and Holocene epochs (Thom 1978). Typically the beds of these estuaries are composed of moderate to well sorted sands (D50 approx. 0.3 mm) and small scale sand extraction has been common place.

Areas of large scale sand extraction are associated generally with the building industry and are located well upstream of the estuary mouths. These upriver operations tend to have very little effect on the tidal hydrodynamics (N.B. fluvial hydrodynamics can be certainly affected though). Past dredging activities in the entrance reaches have been generally small scale, involving maintenance of navigation channels only.

There is strong evidence to indicate that substantial portions of the N.S.W. coastline are receding (Gordon et al 1978, Roy 1980). Increased public acceptance of the realities of a receding coastline

LOCALITY MAP

creates more demand for coastal management techniques, such as beach nourishment, by which the amenity of the coast can be maintained. The lower reaches of estuaries are convenient sources of sand for beach nourishment but the quantities of sand required are no longer small and significant alteration of tidal hydrodynamics is possible. Consequently large scale sand extraction in estuaries should be examined closely so that all the environmental contraindications are identified.

FIELD DATA PROGRAMME

- DREDGE AREA (760,000m³) AND SURVEY CONTROL AREA
- Cross-sections at 30 metre intervals
- AUTOMATIC STAGE RECORDERS
- 1 Entrance
- 2 Letitia 1
- 3 Letitia 2
- 4 Dry Dock
- 5 Terranora
- 6 Cobaki
- 7 Barney's Pt.
- GAUGING LOCATIONS

2. SAND EXTRACTION FROM THE TWEED RIVER

The Tweed River is the most northern river of N.S.W., located in part along the boundary between N.S.W. and Queensland - see fig. 1. Mean Spring Range at the estuary mouth is 1.3 m and is associated with a peak tidal discharge of 600 cumecs. The river catchment is relatively short and steep producing floods which are characteristically fast flowing but short lived. Fluvial flow is flashy with floods punctuating lengthy periods of low freshwater runoff.

Early in 1974 cyclones caused extensive damage to the Queensland resort of Kirra Beach - see fig. 2. The beach was restored by nourishment with 760,000 cubic metres of sand extracted from the Tweed River and pumped overland between July 1974 and October 1975. Once the dredging had been completed, however, there were reports of a number of marked changes in tidal levels, flows and phasing within the estuary, for instance:

Navigational difficulties were encountered by some of the larger craft operating from Boyd's Bay fishing harbour as a result of a reduction in low water levels.

Oyster farmers in Terranora Broadwater reported an increase in the range of the tide about their oyster racks.

Oyster farmers also reported a significant reduction in the tidal lag between Terranora Broadwater and the river entrance.

Whilst these reports would have involved some element of exaggeration and most of the reported consequences were of minor concern only, there was an overall concern that the effects could be "the tip of the iceberg" if further sand removal was carried out before the estuary had fully recovered. This concern was underlined by the Queensland authorities' desire to dredge similar quantities of sand from the river in the future.

3. FIELD MONITORING PROGRAMME

A comprehensive field monitoring programme was set up progressively from the end of 1976 - see fig. 2. The objective of the programme was to record the gradual recovery of the estuary and in so doing identify and quantify the real effects of the dredging. It incorporated the following:

- * A network of 7 automatic recorders.
- * Repetitive hydrosurveys of dredging area (in detail) and upper reaches (broad control).
- * Stream gauging of tides and floods.
- * Underwater photography of bedforms.
- * Measurement of bedform movement.
- * Sidescan and conventional sonar profiles.

3.1 Hydrographic Surveys

Seven hydrographic surveys were completed between December 1976 and March 1979, providing coverage of the dredged area at 30 metre intervals. Contour plans of each survey and isopach plots between successive surveys were prepared to illustrate the mode of shoaling. The surveys showed that the dredged area was undergoing both marine and estuarine infilling. The overall trend is summarised in fig. 3 which shows the total erosion and accretion over the period of the surveys (i.e. 2 1/4 years). Marine sand appears as a broad continuous shoal up to 3 m thick extending from the entrance. The estuarine sand appears as a 2-5 metre thick localised accumulation on the upstream edges of the dredged area. In the vicinity of chainage 1895 the two sands mix.

Fig 4. demonstrates the bathymetric impact of the April 1978 flood which had a probability of occurrence of 20%. The flood scoured the bed of the main arm upstream of the dredged area and the sharp reduction in sediment transport capacity, as the flood flow entered the deeper dredged area, caused deposition up to 1.5 metres in the confluence area. Deposition up to 2.5 metres occurred at the entrance to Terranora Inlet probably due to redistribution of flood deposits from the main arm. The entrance shoal of marine sand had restricted flood flow and considerable scouring of the surface had taken place.

The results of volumetric analyses of survey cross sections are presented in Table 1. Generally the estuarine infilling has been 10-20% of the total. The increasing trend of the estuarine infilling rate is probably indicative of the effect of mixing at the leading edge of the marine sand.

Hydrographic Surveys - Isopach Plots

Figure 3

TABLE 1 SEDIMENT INFILL RATES OF DREDGED AREA

SURVEY PERIOD DATES / DURATION (months)	TOTAL INFILL (m ³)	MARINE INFILL (m ³)	ESTUARINE INFILL (m ³)	MARINE INFILLING RATE (m ³ /yr)	ESTUARINE INFILLING RATE (m ³ /yr)
DEC '76 - JUL '77 (8.0)	68,300	62,200	6,100	93,300	9,100
JUL '77 - APR '78 (8.6)	28,000	66,900*	6,500*	93,300*	9,100*
APR '78 - OCT '78 (6.3)	48,700	38,000	10,700	72,300	20,400
OCT '78 - MAR '79 (5.4)	44,500	37,100	7,500	82,400	16,600

* Estimated from Dec. '76 - Jul. '77 survey period implying a flood scour of 45,400m³.

3.2 Tidal Gradients

Fig. 5 demonstrates the modification of the tidal wave which can take place due to shallow water effects.

Figure 5 Comparison of Tidal Reference Planes

In 1977 the lower estuary was free of shoals because of the nourishment dredging and this contrasted with the heavily shoaled conditions of 1960. The constricted tidal ranges and the raising of half tide level are characteristics of the 1960 gradients (fig. 5) which signify the presence of pronounced shoaling. Considerable damping of the tidal wave, leading to high head losses, occurred within the first one to two kilometers from the entrance.

The determination of the tidal planes was based on the Range Ratio Method as developed by the Royal Navy Hydrographer (1969), using observations of high and low water over a period of one month in 1960 and 4 months in 1977. Druery and Curedale (1979) examined the inherent variability of local half tide levels and tidal amplitudes and concluded that for these short period observations the values of M.H.W.S. and M.L.W.S. could only be defined to ± 0.059 m and ± 0.032 m respectively

at Letitia 1 (95% Confidence Interval). Whilst this means that considerable caution must be exercised when making quantitative comparisons between different sets of tidal gradients, nonetheless, the behavioural trends described previously are well in excess of these confidence limits.

3.3 Bedform Dynamics

Suspended sediment sampling and underwater observation, during peak flows, indicated that away from the immediate entrance area the movement of the bed sediment ($D_{50} = 0.3$ to 0.35 mm) was restricted primarily to bedload. Individual sand grains either scudded across the surface or moved in discrete jumps which rarely extended more than 150 mm into the water column. During peak velocities (viz: 0.64 m/sec, 0.4 m above the bed) the majority of the dune surface was moving as either sheet flow, a few grains thick, or as short crested ripples of height 1-2 cm. Occasional boils of sediment occurred when one of the ripples disintegrated but the momentarily suspended sediment rapidly settled back to the bed and the ripple reformed a short distance downstream.

Detailed measurements of dune profiles were carried out at Letitia 1 (see fig. 2 for location) using an underwater frame to provide a fixed reference - see fig. 6. Bedform profiles were measured at slack water for a range of Spring and Neap conditions. Vertical and horizontal accuracy was $\pm 1-2$ cm.

Figure 6 Underwater Bedframe

Typical profiles taken during Spring tide conditions are shown in fig. 7. Gross transport took place in the form of migrating dunes of typical amplitude 30-40 cm and 6 m wavelength in water depths varying from 2 m to 5 m across the estuary. During ebb tide the surface ripples migrated along the flat slope of the much larger dunes, passed over the crest and sand was deposited on the steep forward advancing face of the dune. In this manner the overall dune progressed downstream.

Figure 7 Dune Profiles at Letitia 1, Spring Tides

During the succeeding flood tide the ripples reversed and erosion of the downstream face of the dune occurred. The eroded sediment then proceeded to move upstream on the back face of the dune as a much smaller depositional face - see fig. 7. The dunes always preserved their downstream orientation due to the dominance of the ebb tide at Letitia 1 but the small reverse flood tide dune face was always eliminated by the following ebb tide. Nasner (1976) observed similar behaviour with large ebb oriented dunes on the bed of the Weser River, Germany, (D50 0.3 to 0.7 mm). He attributed a decrease in dune height during flood tide to a flattening of the steep lee slope and deposition of the eroded material on the luff slope. Allen (1974) also refers to a re-activation face during tidal flows counter to the orientation of the bedforms.

3.4 Determination of Estuarine Sediment Transport Rates

The gross sediment bedload per ebb or flood half tide was calculated as the volume of accretion or erosion, respectively, which occurred on the front face of the dune between successive slackwater profiles. This transport rate represents the gross bedload flux across the dune crest, expressed in m^3/m crest width.

Initially the gross bedload (Q_s) was calculated from profile measurements of a single dune using the bed frame (viz. 1.5 m x 6 m with 200 mm grid) and the results are shown in fig. 8A. However it was found that the bed frame could be replaced with a single line profile without significant loss of accuracy. The single line profile enabled accurate bed measurements over 20 m of river bed thereby allowing 3-4 consecutive dune profiles to be obtained. The gross bedload averaged over the multiple number of dunes is shown in fig. 8B. In addition the profiling was carried out simultaneously at three locations across the river width (viz. A, B. & C in fig. 8B).

The tendency for lower values of Q_s in fig. 8A stems from the single dune measurement. It was recognised on each occasion that the dune was not the largest in the dune field and hence the calculated transport rates were less than the later and more representative rates of fig. 9B. It was concluded that fig. 8B was a more realistic measure of the bedload rate, however the general trends of fig. 8A would still be applicable.

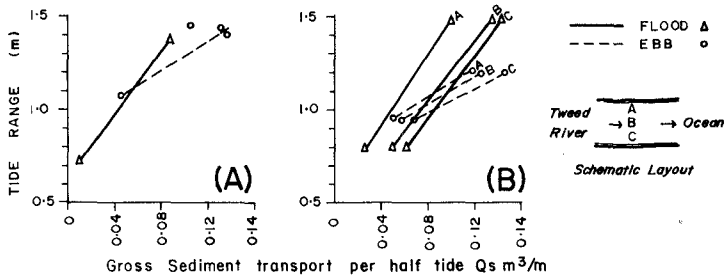

Figure 6 Results of Bedform Measurements at Letitia 1

4. DISCUSSION OF MEASURED BEDLOAD RATES

The peak gross bedload during Spring tides was measured to be 0.15 cubic metres/m/half tide which was approximately five times that for Neaps. Peak net transport was measured at approx. 0.1 cubic metres/m/day at Letitia 1 which is comparable to the bedload estimates obtained by Heathershaw and Carr (1974) from sand tracer studies in Swansea Bay, U.K., where sand transport took place primarily in response to strong tidal streams. Their studies indicated transport rates of 0.11 and 0.21 cubic metres/m/day in the deep and shallow areas of the bay respectively involving fine sands ($D_{50} = 0.21$ mm).

During Spring tides the difference between ebb and flood sediment transport was at its greatest leading to dune migration of up to 0.4 m per tide cycle. However during Neaps, conditions were near threshold and there was no substantial net transport of sediment and negligible dune migration.

Allen and Friend (1976) carried out continuous monitoring of dunes at Lifeboat Station Bank, Norfolk, U.K., over two consecutive Spring/Neap cycles and concluded that the largest "mature" dunes in a tidal dune field are tuned to the peak flow conditions at higher Spring Tides. Lesser tides had insufficient energy to significantly alter the dimensions of the mature dunes. If it is assumed that a fully developed tidal dune is functionally related to peak Spring Tide flow conditions, the work of Fredsoe (1979) can be applied. Fredsoe (1979) relates the ratio of dune height to wave length in alluvial conditions by the following expression:

$$h/L = 0.12 (1 - 0.06/\theta - 0.4\theta)^2$$

where θ is Shields shear stress parameter viz:

$$\theta = \tau_b / ((\gamma_s - \gamma) d) = RSf / (S-1) d$$

where R is the hydraulic radius, Sf is the friction slope, s is the relative density of sediment and d is the mean grain diameter.

Using typical Spring values at Letitia 1 of $R = 2.0$ m at the dune crest during ebb flow, $S_f = 38 \times 10^{-6}$, $S = 1.65$; $d = 0.0003$ m implies:

$$\theta = 0.21 \text{ and } h/L = 0.048$$

The actual values of h/L for all dunes ranged from 0.037 to 0.05 with an average of 0.044. Furthermore it can be shown from Fredsoe's transport formula viz:

$$q = [(S-1)g d^3]^{0.5} \left\{ 1 + \left(\frac{0.267}{\theta - 0.05} \right)^4 \right\}^{0.25} (0.5 - 0.7\theta^{0.5})$$

that the theoretical unit transport rate of a dune with $\theta = .21$ is 0.19 cubic metres/m/hour i.e. approx. 0.38 cubic metres/m/half tide which compares with the peak values, inferred from field measurements, of 0.2 - 0.25. It appears that the work of Fredsoe shows promise for possible quantified interpretation of tidal bedforms.

5. MODELLING OF TIDAL HYDRAULICS

5.1 Model Development

Tidal stage and discharge were modelled using a one-dimensional numerical model based on the specified time version of the method of characteristics as developed by Fischer (1970). The model was calibrated using stage and discharge data from a full Spring tide cycle and verified against two sets of neap data. Even though the estuary possessed some complex branching it was found that the one-dimensional schematisation adequately represented the bulk flow characteristics. The Spring tide calibration and a neap tide verification are shown in fig. 9.

5.2 Impact of Dredging on Tidal Hydraulics

The calibrated model was used to hindcast the changes in tidal levels caused by the sand extraction. The propagation of a Summer Solstice Tide using 1977 bed geometry is shown in fig. 10. The propagation of the same tide based on the bed geometry of the most recent comprehensive survey prior to the dredging (i.e. 1971) is also shown.

Fig. 11 portrays the same behavioural trends as fig. 5 however it is valid to draw quantitative conclusions from fig. 10. The numerical hindcasting demonstrated that the dredging produced a pronounced increase in the tidal range throughout the lower estuary, the effect being more pronounced at low water. The increase in range of 7 cm on Terranora Broadwater and the lowering of low water by 25 cm inside Terranora Inlet are substantial changes and are consistent with the observations reported in Section 2. Harten (1980) describes similar effects arising from channel deepening associated with port development in a number of German estuaries. The dredging produced an increase in tidal range roughly apportioned as one third due to an increase in high water and two thirds due to lowering of low water.

Figure 9 Numerical Model Calibration and Verification

Figure 10 Predicted Tidal Propagation

6. MODELLING OF ESTUARINE SEDIMENT TRANSPORT

The foregoing numerical model of tidal hydraulics was incapable of assessing the recovery rates of the estuarine shoals or the long term impact of dredging on the estuarine sediment regime. Hence a sediment routing procedure was developed.

6.1 Selection of Transport Formula

Yalin (1976) undertook a fundamental examination of the transport of coarse bed material under conditions of oscillatory tidal flow and indicated that ebb and flood sediment transports can be viewed as separate unidirectional events. The result is a pattern of alternating, but intermittent, sediment motion. It was proposed that unidirectional theories could apply except near slack water where inertial effects become significant. Hence conventional formulae may be applicable during the bulk of the tidal cycle.

Based on a review of eight major transport equations by White, Milli and Crabbe (1975) the method of Ackers and White (1973) was adopted.

6.2 Sediment Transport Parameters

Friction Gradient (Sf)

The Ackers and White formula was developed from laboratory and field data under steady, uniform flow conditions in which the surface slope (Sw) and the friction slope (Sf) were identical. In order to facilitate the general application of the formula to tidal flows it was desirable to adopt Sw as the friction slope. Mehta et. al. (1976) concluded inertial effects were negligible except at slack water on the basis of field studies carried out on two tidal inlets of Florida. It was therefore considered that Sw was a reliable estimate of Sf for the majority of the tide during which sediment transport took place. When calculating the instantaneous sediment transport rate at any particular cross section the convention adopted was to set Sw equal to the water surface slope of the model element immediately upflow of the cross section.

Section Averaged Velocity

Initial predictions of sediment transport using the predicted cross section average velocity indicated no transport during low flow conditions such as Neaps. Even though net sediment transport approached zero during a full Neap tidal cycle, significant gross sediment transport occurred during each ebb and flood half tide - see fig. 8. This discrepancy occurred because the cross section average velocity in a 1 Dim. model will always be substantially less than the depth averaged velocity at any particular point. Hence an empirical correlation was established between the field values of depth averaged velocities and the predicted cross section average velocity. It was found that a single linear regression was sufficient to satisfy both Spring and Neap flow conditions at each gauging station.

6.3 Calibration of Gross Sediment Transport Rates

The individual bedload measurements at each Station A, B and C (see fig. 8B) were integrated across the river width and divided by the total cross section width to yield an average section transport rate per unit width. The result is shown in fig. 11. The general trend of fig. 8A was used to extrapolate fig. 11 at the higher tide ranges.

Figure 11 Integrated Bedload Transport Rates (Letitia 1)

A variety of tides of varying range were run through the numerical model to predict values of water surface slope and scaled velocities (at Letitia 1) at twenty minute intervals during each tide. Instantaneous sediment transport rates were calculated and a sediment flux curve was produced which was integrated with respect to time to determine the theoretical gross sediment transport for each half tide.

The theoretical gross transport rate per half tide was compared to the rate interpolated from the curves of field results for the same tidal range (i.e. fig. 11) - see fig. 12. It was found that the Ackers and White formula, using S_w and scaled velocities, gave reasonable results (\pm factor of 50%) for Spring conditions. However the greatest deviation occurred as the threshold condition was approached and hence sediment transport was still significantly underestimated under conditions of marginal velocity or gradient.

The general trend of fig. 12 was used to adjust the procedure for calculating sediment transport rates viz.:

- (a) If $.011 \leq p^1 \leq .15$
- $$P = 0.36 p^1 + 0.096$$
- (b) If $p^1 > 0.15$ then
- $$P = p^1$$

where:

p^1 = initial prediction of gross transport rate using Ackers and White with scaled model velocity, average depth and water surface gradient: cubic metres/m/half tide

P = Corrected prediction of gross transport rate: cubic metres/m/half tide

For values of $p^1 < .011$ a simple correlation with the peak velocity was developed. This corrected procedure for the calculation of sediment transport was used for all locations throughout the estuary.

Figure 12 Comparison of Calculated and Measured Transport

6.4 Verification of Calibrated Transport Formula

Infilling of the dredged area during 1977, by the downstream transport of sediment, was predicted by the following procedure:

- (i) The Spring-Neap cycle at the River mouth was divided into six representative, symmetrical tide cycles of varying tidal ranges R_i - see fig. 13.

Figure 13 Annual Occurrence of Tides at Tweed Entrance

- (ii) The net sediment transport of each tide, q_i , was calculated at a number of locations throughout the estuary.
- (iii) Each representative tide cycle was assigned a size band within the 1977 tidal frequency curve. The relative percentage occurrence of each band, P_i , was determined as the proportional area under the curve.
- (iv) The annual transport of sediment at each particular location was calculated as:

$$700 \sum_{i=1}^{i=6} q_i P_i$$

where 700 is the number of tide cycles in one year.

The predicted total estuarine transport of sediment moving downstream in the Tweed main arm and Terranora Creek was $8,300 \text{ m}^3$ which is in reasonable agreement with the quantities of estuarine infill determined from hydrographic surveys (see Section 3.1). In addition the directions of net transport throughout the estuary agreed with all direct and indirect lines of evidence. This will be discussed further in the next section.

7. PREDICTED ESTUARINE SHOALING RATES

The impact of the nourishment dredging on the broad pattern of shoaling in the estuary by tides alone (i.e. ignoring the short term effects of floods and cyclones) was investigated with a sediment routing technique. The sediment routing incorporated interaction of bed levels with flow.

Except at the estuary mouth the predicted annual sediment transport values were increased by a factor of five to produce a coarse five year routing step. Because of the complexity of wave and current interaction at the entrance and the presence of strong secondary currents on the entrance bend, the predicted peak velocity and gradient were used to calculate an index of net sediment transport potential at the estuary mouth. When applying the first sediment routing step this index was assumed to represent the measured entrance sediment infeed rate of $93,000 \text{ m}^3 \text{ p.a.}$ (see Table 1). The entrance sediment infeed for all subsequent routing steps was reduced proportionately according to the predicted reduction in this index.

At the end of each five year routing step the channel geometry was reschematised according to the volumes of net accretion or erosion in each sediment routing compartment. Throughout the sediment routing it was necessary to assume that the empirical velocity scaling factors did not vary in time. The results are shown in fig. 14. While the results are not good for strict accuracy they do provide insight into the broad behavioural patterns of sediment movement and shoaling under pure tidal influence.

Figure 14 Results of Sediment Routing

7.1 Discussion of Predictions

Immediately after dredging (1977) there is a strong infeed of sand through the entrance. Immediately upstream of the dredged area the net sediment transport is downstream in both arms of the River.

By 1982 the dredged area is approx. 60% infilled and the impact on estuary flows is substantially reduced. Sediment reversal in Terranora Creek has occurred because the dredged area no longer has a significant influence on tidal flow patterns. Similarly in the main arm, at Letitia 2, the effect of the dredging on the sediment transport has diminished.

By 1987 the dredged area is completely restored and complete sediment transport reversal has taken place in the main area.

By 1992 the estuary is very shoaled due to continued sand feed (at a greatly reduced rate) from the entrance. The shoaling is causing considerable head losses in the lower estuary leading to a damping of velocities and gradients in the upper estuary where the net sediment transport is weakly directed upstream. The presence of the broadwaters in Terranora Creek helps to maintain relatively steeper gradients and higher sediment transport rates.

An interesting feature of these behavioural predictions is that the dredging produced a temporary reversal in the direction of net sediment transport immediately upstream of the dredged area. In the main arm this effect was predicted to extend upstream to some region between Letitia 2 and Barneys Point. Although no bedform survey was carried out prior to the dredging, partial verification of the predicted reversal point is shown in fig. 15. Further verification came from a careful study of all available aerial photography by Druery and Curedale (1979) which demonstrated that shoaling in Terranora Creek, near the Boyd's Bay fishing harbour, was due to the downstream movement of a shoal which had been stable for twenty years prior to any dredging of the lower estuary.

8. ESTUARINE SHOALING MECHANISMS

A detailed breakdown of the quantitative results of the numerical simulation of estuarine sediment dynamics is given in fig. 16 for a Summer Solstice tide. These will be discussed in order to obtain a better understanding of the hydraulic mechanisms involved.

8.1 Detailed Discussion Letitia 2

In Section 5.2 it was demonstrated that the immediate impact of the dredging was manifest as a drop in low water level and an increase in high water, the effect being more pronounced at low water. So, as the dredged area infills with time a progressive decrease in high water and a progressive increase in the level low water would take place. This is indicated by the decrease in the depth at peak flood tide velocity and the increase in depth at peak ebb tide velocity.

In terms of peak velocity at Letitia 2 there would be a tendency for the peak ebb velocity to decrease due to the increased depths and the opposite for the flood tide where velocities would tend to increase because of the decreasing depth. However there must also be an overall trend for reduction in velocities due to the decreasing peak discharge. Hence the depth effect results in the flood velocity decreasing to a much lesser extent than the ebb velocities.

Peak surface gradients show a decline with shoaling due to damping of the tidal wave but the peak flood gradient always remains higher than the peak ebb gradient.

The gross sediment transport per half tide is greatest on the ebb, initially, due to the depth effect providing greater enhancement of the ebb velocities. Hence there is net ebb oriented sediment transport. As the dredge area shoals, ebb velocities decrease due to the depth effect, both gradients diminish and the flood tide transport begins to dominate. So as shoaling takes place the net sediment movement reverts to the long term trend which is a weak net upstream movement of sediment.

Figure 15 Longitudinal Echosounding Plot of Main Arm Showing orientation of bedforms. Note reversal between Letitia 2 and Barney's Point.

8.2 Terranora Broadwater

Looking quickly at Terranora Creek it is apparent that the presence of the broadwater suppresses any potential change in water levels and hence there is no significant depth effect. Velocities diminish at an equal rate in proportion to the decreasing discharge. The flood velocities and gradients are always greater than the ebb due to the different shapes of the discharge curves. Hence the overall trend is a net transport into the broadwaters.

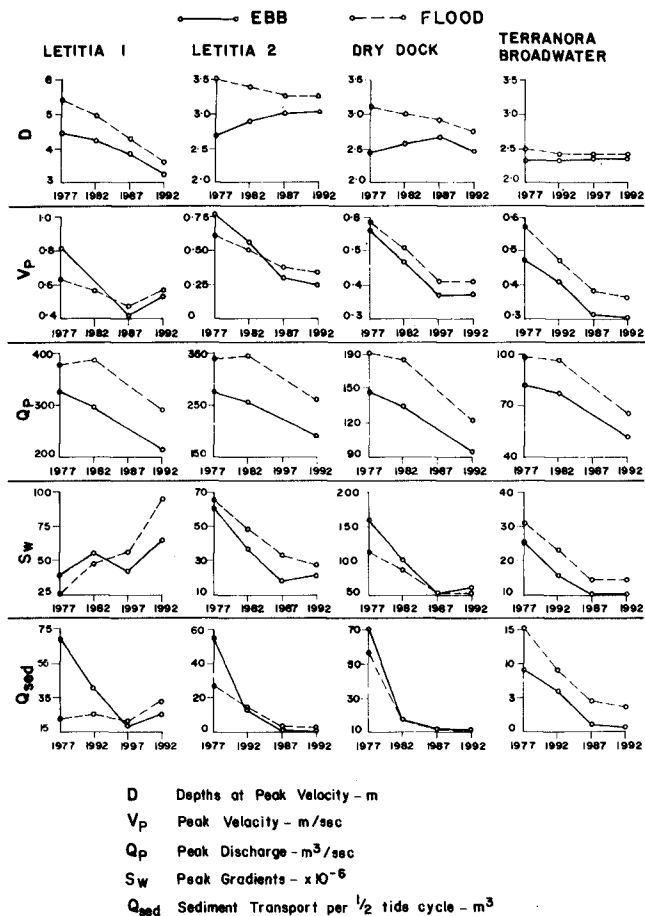

Figure 16 Variation of Hydraulic Parameters Due to Shoaling

8.3 Letitia 1

The picture is more complex at Letitia 1 because it is situated in the area of shoaling and this is reflected in the decreasing depths at both peak flows. Nonetheless a subtle enhancement of the peak flood velocities is discernable. Peak gradients increase due to the increasing head losses in the lower estuary, the flood gradient more so than the ebb. Ultimately the net transport reverts to the long term trend i.e. weak upstream movement of sediment.

9. CONCLUSIONS

- (1) Tidal propagation in a shallow estuary is very sensitive to the ruling channel depth within the initial 2-3 kilometres of the estuary. The extraction of 760,000 m³ of sand from the initial 2 km of the Tweed River had a significant effect on tidal levels and sediment dynamics throughout the estuary.
- (2) The dredging affected sediment movement for a distance of 3 km upstream in the main arm and 6 kms upstream in Terranora Creek.
- (3) Infilling of the dredged area initially took place at 100,000 m³ p.a. of which 85% was marine sand brought in through the entrance and 15% was derived from reworking of upstream estuarine sands.
- (4) In the long term the sediment transport throughout the estuary should trend towards a weak upstream movement of sediment.
- (5) The detailed monitoring of large scale bedforms can provide practical values of gross sediment transport rates provided the bed material is sandy and the transport mode is entirely bedload.
- (6) Sediment transport rates under Spring tides were five times that of Neap tide.
- (7) Points of reversal of net sediment transport were predicted and observed in the Tweed River. These are considered to be indicative of non regime conditions.
- (8) The hydraulic and environmental impact of large scale dredging in estuaries can be significantly reduced by location well upstream of the entrance.
- (9) Further field studies are needed to verify the broad behavioural trends predicted in this study and to evaluate the effect of floods and cyclones on estuary shoal regime.

10. ACKNOWLEDGEMENTS

The author acknowledges the tremendous effort and dedication of the late John Curedale to all phases of the investigation, particularly the preparation of the primary study report.

The author is grateful to Jan Iwaszkiewicz for his untiring assistance and initiatives in the field and Alan Dyson for his assistance and discussion in the computing side of the work.

NOOSA BEACH RESTORATION SCHEME

**R.J. Lloyd, B.E. (Civil), Executive Engineer, Beach Protection Branch,
Department of Harbours and Marine, Queensland, Australia.**

1. SUMMARY

A significant beach restoration scheme has been implemented at the coastal resort of Noosa in South-East Queensland. The scheme which cost \$1,400,000 involved sand nourishment, dune stabilisation works and the relocation of the entrance to the Noosa River using sand pumping techniques.

The effect of the scheme has been to greatly improve the quality of the main surfing beach at Noosa as a recreational facility and to provide much needed protection to a canal estate development which had been constructed within the Noosa River estuary close to the river entrance.

The successful implementation of this scheme also demonstrates that practical solutions to beach erosion problems are available and that sand pumping techniques may be used to economic advantage where relocation or closure of a river entrance is required and where local conditions and analysis indicate that such techniques can be applied.

Photograph 1 shows the completed restoration scheme.

2. SITE DESCRIPTION

Noosa Beach is located immediately south of the entrance to the Noosa River and seaward of the barrier dunes which separate the Noosa River estuary from the Pacific Ocean. The beach extends south east to the rocky headlands of Noosa Heads and is well known for producing excellent, safe surfing conditions.

The main commercial centre of Noosa is located precariously on the barrier dune landward of the surfing beach. Further landward is the Noosa River estuary and Hays Island - an area which was recently developed as a canal estate. Figure 1 shows the site of the restoration scheme.

The catchment area of the Noosa River comprises an area of approximately 87,000 ha. Most of this area is low lying with only two percent above 150 m above Mean Sea Level. The area is drained by a complex series of lakes and streams which finally join together to form the Noosa River which in turn meets with the ocean in the form of a wide unstable tidal estuary. Lake Cootharaba (3750 ha) and Lake Weyba (990 ha) are the major lakes of the drainage system and both are only slightly tidal with tidal ranges being less than 5 percent of the corresponding ocean tide ranges. Figure 2 shows the catchment area.

3. GEOLOGICAL DESCRIPTION

In terms of geological units the Noosa River estuary is defined as a Holocene Tidal Delta - an area of developed intertidal banks which represent successively abandoned channels.

PHOTOGRAPH 1 - The completed scheme (August 1979)

FIGURE 1 - Noosa River estuary showing the scheme of works

FIGURE 2 - Noosa River catchment area

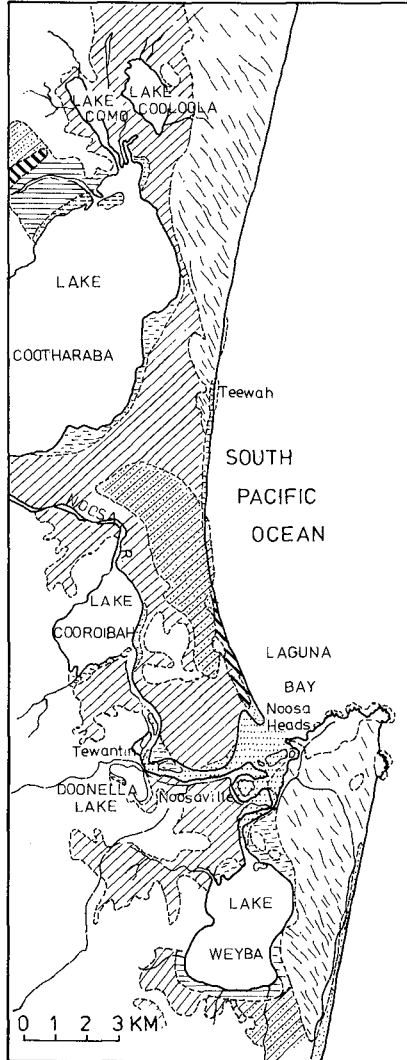

FIGURE 3 - Noosa area, geological units

The sand forming the delta has been shown to have been trapped from the beach system and to have its origins in the coastal rivers of Northern New South Wales to the south. The trapping mechanism could have been favoured by early increases in sea level.

The barrier dune which separates the estuary from the ocean is also of the Holocene epoch (probably formed in the past 10,000 years) and comprises well sorted quartz sands with minor heavy mineral deposits. Soil development on the fore dunes is minimal.

Reference 1 draws attention to alternating trends in dunal growth at Noosa and also to short term accretion trends within the estuary. Figure 3 shows the Noosa area subdivided into geological units.

4. EROSION PROBLEMS AT NOOSA

The main surfing beach at Noosa had suffered severely from erosion prior to implementation of the restoration scheme and following severe cyclonic storms in 1968 it had been necessary to construct a boulder wall full length along the beach to provide adequate protection to the development located on the barrier dune. The boulder wall was located in the swash zone and by partially dissipating wave energy in the form of turbulence and partially reflecting the waves established a process which further lowered the beach immediately seaward of the wall.

The canal estate developed on Hays Island within the Noosa River estuary had also been threatened as unforeseen movements of the main channel of the Noosa River had given rise to high velocity currents adjacent to the development. These had caused undercutting and partial collapse of some of the revetments to the development. Effectively the old channel on the northern side of the estuary which for many years had carried the main body of flow of the Noosa River was progressively abandoned in favour of a newer developing southern channel which in turn was in conflict with the canal estate development. Photographic records of the estuary indicate that the process of abandoning the older northern channel was quite natural and that the new southern channel adjacent to Hays Island was well established before any construction work at Hays Island commenced. Figure 4 shows the progressive changes which recently occurred in the estuary.

With the development of the new southern channel it was possible for waves entering the estuary through the river entrance to impinge on the works at Hays Island and the revetments had not been designed for such a contingency.

The development of the southern channel also had a direct impact on Noosa Beach. Coupled with the strengthening flow in the southern channel the river entrance moved south cutting into a camping reserve at Noosa Woods at the northern extremity of the commercial centre and at the same time reducing the length of the main surfing beach.

The overall effect was that by the time a decision was made to proceed with restoration works in 1977 Noosa Beach was virtually nonexistent.

FIGURE 4 - Photographs showing progressive changes to the main channel within the Noosa River estuary

5. THE RESTORATION SCHEME

In seeking solutions to the erosion problems at Noosa model studies at the University of Queensland were initiated and several investigations commissioned (References 2 and 3). The findings of these investigations indicated that the Noosa River would have to be diverted away from Hays Island if the threat to the canal estate was to be removed.

The final scheme which was prepared in September 1977 after consideration of various alternatives was designed to provide a complete solution to all the problems previously outlined. It included the following works:-

- (a) Redevelopment of flow in the old northern channel of the river by opening a new entrance approximately 500 metres north of the existing river entrance.
- (b) The blocking of flow in the southern channel by means of sand pumping to form a closure bund across the original river entrance.
- (c) Development of a new beach system including a large dunal area north of the Noosa Woods camping area thereby reinforcing the closure of the southern channel and protecting the development at Hays Island from wave attack.
- (d) Sand nourishment of the original beach at Noosa at the rate of 250 cubic metres of sand per metre length of beach which would permit the establishment of a beach seaward of the existing rock wall.
- (e) The construction of a rock groyne and revetment on the southern side of the new river entrance to retain sand on the newly developed beach and also to prevent further southward migration of the new entrance.
- (f) The stabilisation and vegetation of all newly formed dunal areas (approximately 20 ha) to prevent damage by wind erosion.
- (g) The implementation of an effective monitoring program to record changes to Noosa Beach and within the Noosa River system.

Sand required for implementation of the works would be taken from borrow areas within the estuary. Figure 1 shows the location of the works including the designated borrow areas.

6. LIMITATIONS OF THE RESTORATION SCHEME

At the time the scheme was prepared its limitations were recognised. The more important of these were as follows:-

- (a) Undercutting of the rock groyne and revetment on the southern side of entrance might occur and maintenance could be required.
- (b) Erosion of freehold properties to the north of the new entrance could occur as northward movement or development of the new entrance would not be constrained by the scheme.

- (c) The new beach alignment would depend on the natural action of the sea and the supply of sand to the newly formed and restored beach.
- (d) A continuing maintenance commitment would be required to retain the newly vegetated dunal areas in satisfactory condition.
- (e) Maintenance of the beach in the form of additional sand nourishment following periods of severe storm wave attack might be required.
- (f) The scheme was not designed to control the behaviour and movements of channels within the Noosa River estuary.

7. CRITICAL PHASE OF THE SCHEME

The most critical phase of the restoration scheme was the closure of the original entrance to the Noosa River. While initially it had been expected that earthmoving plant might be required to effect final closure detailed examination showed that closure could be effected by sand pumping alone. Furthermore alternative techniques involving the use of earthmoving plant were found to be more costly.

Design calculations indicated the following:-

- * A continuous sand pumping rate of approximately 500 cubic metres per hour was required to construct a sand bund across the southern channel following the opening of a new entrance to the old northern channel.
- * The nett loss of sand from the works area during the closure operation would be minimal even though sand transport in the region of the closure bund would be high.

On this basis it was decided to adopt the sand pumping technique for the closure operation and the more costly techniques involving earthmoving plant were discarded.

In preparation of contract documents for implementation of the restoration scheme a sand pumping rate of 800 cubic metres per hour was specified for the entrance closure operation. This rate which was 300 cubic metres per hour in excess of the theoretically required sand pumping rate was considered necessary because of possible dredging plant failure.

8. CONSTRUCTION

Implementation of the restoration scheme comprised two distinct phases - the civil engineering works involving sand pumping and groyne construction and the dune stabilisation works.

Tenders for the civil engineering works were invited and five tenders ranging from \$1,263,435 to \$2,299,702 were received. The lowest tender was accepted and sand pumping works commenced on site on June 12, 1978 under the supervision of Departmental engineers. The specified sand pumping capacity was provided by these dredgers fitted with 250 mm diameter suction and delivery lines connected to pumps powered by diesel engines of 200 Kw rating.

Dredging commenced at the site of the new entrance with spoil being directed to the closure bund which was being developed from the northern side of the existing entrance. By June 20 the new entrance to the northern channel had been opened and by June 27 closure of the original entrance had been effected.

During the closure operation sand was pumped to the head of the closure bund to discharge points located well above water level. This resulted in much of the sand being deposited on the head of the closure bund above water level and rapid forward progress of the toe of the bund was made when slumping of this deposited material occurred.

While no technical problems were encountered with the entrance closure operation, the decision to specify a sand pumping rate of 800 cubic metres per hour was justified as actual records of dredging plant indicate that the average pumping rate achieved during the period June 12 to June 27 was only of the order of 600 cubic metres per hour because of dredging plant failures and the need to shift and maintain the associated equipment and dredge lines.

Following completion of the entrance closure operation, vehicular access to the site of the rock groyne became available and groyne construction was able to proceed. At the same time the final phases of sand pumping works were able to commence and all such works including the development of the beach and dunal areas north of the Noosa Woods camping area as well as sand nourishment of the original beach were completed by September 13, 1978.

During the progress of the works sand pumping rates being achieved by individual dredgers were measured. The rates varied between 280 and 370 cubic metres of sand per hour with only one test showing a result of less than 300 cubic metres per hour. Based on these measurements it is estimated that in excess of 1,000,000 cubic metres of sand were incorporated in the works. Of this approximately 150,000 cubic metres of sand were required for the entrance closure operation.

Progress of the civil engineering works is shown on Figure 5, a sequence of aerial photographs of the works.

After the completion of sand pumping works dune stabilisation works were able to proceed. These works proceeded on a day labour basis under the control and supervision of Departmental staff well experienced in dune stabilisation techniques.

Approximately 20 ha of the newly created dunal areas were initially stabilised against wind erosion by the establishment of a vegetative cover of grass. The speed with which this operation was carried out was greatly assisted by the balanced application of fertilizer.

In addition to establishing grasses, in excess of 20,000 creepers, shrubs and tree seedlings were planted and are now well established. Fencing and access paths were also constructed to control both vehicle and pedestrian movements in the stabilised areas.

FIGURE 5 - Photographs showing progress of the works

9. MONITORING

The restoration scheme included an extensive monitoring program as an integral part of the scheme. The major activities included in the program were as follows:-

- . Water level monitoring at four locations - three stations upstream of the development site on the Noosa River and a single station at Boreen Point on Lake Cootharaba.
- . Aerial photography at regular intervals.
- . Regular measurements of the tidal compartment.
- . Sand sampling.
- . Daily recording of wave and beach conditions at Noosa by a trained volunteer observer.

This monitoring program many aspects of which have remained in operation is providing valuable information on erosion and accretion trends of the restored beach and also on behavioural patterns of water level movements within the Noosa River and Lake Cootharaba.

10. BEHAVIOUR OF NOOSA BEACH SINCE IMPLEMENTATION OF THE RESTORATION SCHEME

The nett longshore transport at Noosa Beach is to the north. This conclusion is based on longshore transport calculations using observed and derived wave climates for Noosa Beach. It is also supported by the fact that available photographs of an old groyne which was constructed on Noosa Beach show sand build up on the southern side only. The nett longshore transport rates which have been derived are of the order of 140,000 cubic metres of sand per year to the north.

Since implementation of the restoration scheme the southern portion of Noosa Beach has receded visibly and successive surveys carried out along fixed lines spaced at 80 m intervals along the beach indicate that in excess of 100,000 cubic metres of sand has been lost in the 12 month period following implementation of the scheme. The bulk of these losses have been concentrated in the area above the -5 metre contour (relative to Mean Sea Level) and there has been no observable loss to offshore areas. The beach lines extend several kilometres offshore. The likely explanation of this behaviour is that the supply of sand to the southern portion of Noosa Beach has not been sufficient to make good sand losses from the area due to longshore transport to the north.

In the mid region of Noosa Beach adjacent to and to the immediate north of the Noosa Woods camping area surveys indicate that there has been little or no change in the quantity of sand on the beach in the 12 month period following implementation of the restoration scheme. While there have been some beach profile changes above the -7 metre contour (relative to Mean Sea Level) seaward of this contour the shape of the seabed profile appears to have remained relatively constant and any variations in level between surveys are considered to be caused primarily by the accuracy limitations of the survey techniques adopted. Based on the above it is considered that in the mid region of Noosa Beach there has been a balance between supply and loss of sand.

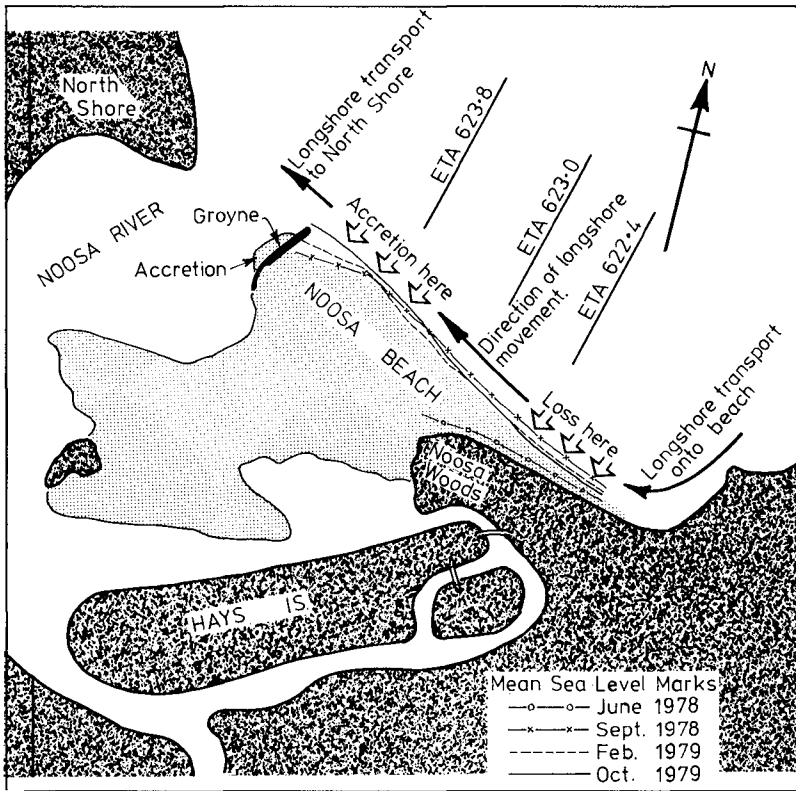

FIGURE 6 - Movements of the 0.0 contour (Mean Sea Level) as determined by beach surveys at Noosa

In the northern portion of the beach in the region of the rock groyne in the same period there has been obvious visible accretion and a substantial beach berm has developed. Beach surveys confirm this accretion and indicate that there has been accretion of sand of the same order of magnitude as the sand losses which occurred in the southern region of the beach. Virtually all profile changes were limited to the area landward of the -7 metre contour (relative to Mean Sea Level).

The nett result has been an overall change in beach alignment. Figure 6 gives an indication of this change in alignment and shows the 0.0 metre contours as determined from successive surveys carried out in June and September of 1978 and also in February and October 1979. The June 1978 survey was carried out prior to implementation of the restoration scheme. Figure 7 shows typical beach profiles obtained by survey.

FIGURE 7 - Typical beach profiles at Noosa as determined by beach surveys. Location of beach lines is shown on Figure 6.

The accretion of sand in the northern region of Noosa Beach is attributed mainly to groyne action. However, sand bypassing has not been prevented by groyne construction as a large sandy spit has developed on the northern side of the groyne as a result of sand bypassing and the new entrance to the Noosa River has been displaced to the north.

The grain size of sand obtained from the estuary for beach nourishment purposes was generally coarser than the native beach material and it is not considered that sand losses at the southern extremity of the beach have been significantly increased by the loss of fine material. Figure 8 shows the results of sand sampling within the estuary and also on Noosa Beach.

It is postulated that the beach recession which has occurred along the southern portion of Noosa Beach has been caused by an intermittent sand supply from around Noosa Headlands. This argument is supported by photographic evidence which shows that the condition of Noosa Beach and the small pocket beaches between the headlands fluctuates with time. It is considered that the fluctuating condition exhibited by these beaches is the result of a fluctuating sand supply to these beaches and that the condition of the southern portion of Noosa Beach where restoration work has been carried out will continue to fluctuate under the influence of natural processes. The small pocket beaches between the headlands have not been in good condition since the restoration scheme was implemented. Thus it could be expected that the southern portion of Noosa Beach would currently be experiencing a period of recession.

FIGURE 8 - Photographs showing the fluctuating condition of beaches around Noosa Heads. Immediately south of Noosa Beach. The January 1978 photograph is typical of the condition which has existed since implementation of the restoration scheme.

11. BEHAVIOUR OF WATER LEVELS WITHIN THE NOOSA RIVER AND LAKE COOTHARABA

Monitoring of water levels within the Noosa River and further upstream in Lake Cootharaba has not shown that current water level behaviour differs greatly from that which was previously recorded prior to the restoration scheme being implemented.

Spring tide ranges at Munna Point (refer Figure 1) are as follows:-

- * Prior to Restoration Scheme being implemented -
 - 1974 - 0.77 m
 - 1975 - 0.70 m
 - May 1968 - 0.48 m
- * Following implementation of restoration scheme -
 - November 1978 - 0.73 m
 - July 1979 - 0.62 m
 - December 1979 - 0.62 m.

The above figures indicate that fluctuating spring tide ranges were a feature of water level behaviour within the Noosa River prior to the restoration scheme being implemented. Spring tide ranges based on data recorded since implementation of the scheme lie within the limits of previously recorded ranges.

12. MONITORING OF THE ENTRANCE CLOSURE OPERATION

During the entrance closure operation a sand bund with a crest level of approximately RL +4 metres (relative to Mean Sea Level) and a base width of approximately 150 metres at RL -2 metres was constructed across the entrance to the southern channel over a period of approximately 16 days. During this period regular surveys of the closure gap were carried out. The results of selected surveys are shown on Figure 10. Each of the surveys shows the presence of a deep channel located hard against the head of the closure bund. This channel was effectively pushed ahead of the closure bund as the closure operation proceeded.

The cross-sectional area of natural material eroded from the entrance is represented by the difference in cross-sectional area between the original channel profile and a line traced by the lower limit of the previously described channel as it was pushed ahead of the closure bund. This area which has been estimated to be 330 square metres is shown on Figure 9 as a cross-hachured area marked below the plot of the first survey of the entrance which was carried out on June 16, 1968.

Based on this survey information and aerial photography it was estimated that of the order of 30,000 cubic metres of sand was eroded from the natural bed of the entrance channel during the closure operation.

FIGURE 9 - Sand sampling results

FIGURE 10 - Surveys of Noosa River entrance during closure operation

13. BEHAVIOUR OF NEW ENTRANCE

In the 18 month period following opening of the new entrance to the old northern channel of the Noosa River estuary on June 20, 1978 the entrance has continued to develop with the pattern of flow changing continuously. A new bar across the entrance has formed and surveys carried out in February 1980 show that this is continuing to extend seaward.

The cross-sectional area of the new entrance measured below Mean Sea Level as determined by survey in October 1979 was approximately 300 square metres. This is similar to the area which existed in 1896 when the entrance was first surveyed. It is also similar to that which existed when the restoration scheme was first investigated in September 1977.

As the cross-sectional area of an untrained entrance may be related to the tidal prism (Reference 4), the behaviour of the entrance would indicate that implementation of the restoration scheme has not had a significant impact on the tidal compartment of the Noosa River.

14. CONCLUSIONS

From a beach protection viewpoint the Noosa restoration scheme has been successful. The aerial photograph of the restoration scheme site which was taken after the artificially formed beach profiles had time to adjust to prevailing wave and current conditions shows that large areas of new beach are now available for a wide variety of recreational purposes whereas previously no such beach areas existed. Although there have been several periods of rough seas and high tides there is no evidence of a significant nett loss of sand from the beach system. In addition the new beach north of the Noosa Woods camping area has successfully withstood the attack of two cyclones without any damage to the artificially created frontal dune.

From the viewpoint of the development within the Noosa River estuary the threat of damage to revetments and property through undercutting and wave action has been removed.

From a technical viewpoint the success of the entrance relocation operation using sand pumping techniques has demonstrated for the first time in Queensland that both suitable plant and the necessary expertise are available locally to enable full use of this specialised low cost technique of entrance closure.

In view of the above, it is considered that the scheme has provided an effective solution to the erosion problems at Noosa and demonstrates clearly the benefits which can be derived from a well conceived beach restoration scheme.

BEACH NOURISHMENT AS A MANAGEMENT TECHNIQUE

David M. Chapman,
Coastal Studies Unit,
University of Sydney, Australia

1) INTRODUCTION

Beach nourishment is considered an environmentally safe management technique, since an unsuccessful nourishment project would simply result in the redistribution of borrow material by wave action into environments more in keeping with a state of equilibrium. No permanent modifications of the beach and nearshore environment need result, and since no permanent structures are required for beach nourishment, the management commitment allows rapid project abortion if necessary. Beach nourishment monitoring has usually been concerned with evaluating changes in the extent of subaerial beach and/or retention of fill volume. These parameters are important, but it is also necessary to consider the way in which nourishment sand is taken up by the beach system since relationships between volume change, change in extent of subaerial beach, and changes in beach morphology are complex. This paper is concerned with evaluating beach nourishment on the Gold Coast (Figure 1), Australia's major resort, where 2.4 million cubic metres of fill were applied in the largest beach nourishment project attempted in this country at the time of writing.

Methodology, reported in Chapman & Smith (1977) and Chapman (1978a) included repetitive profile survey from backshore to point of zero change in inshore zone (over 400 profiles) using highly accurate techniques, and use of 38 tonnes of tracer, which was injected into the dredge line at a controlled rate.

2) BEACH BEHAVIOUR

2.1 Width/Volume Relationships

Analysis of Gold Coast survey data showed that subaerial (or "dry") beach width, taken alone, is a poor indicator of the volume of sand present in the active zone, or swept prism (Chapman & Smith, 1980), and is therefore not a reliable index of resistance to erosion. Correlation of subaerial beach width, per se, and sand prism volume is poor, and comparisons only become meaningful if beach morphologic states are taken into consideration.

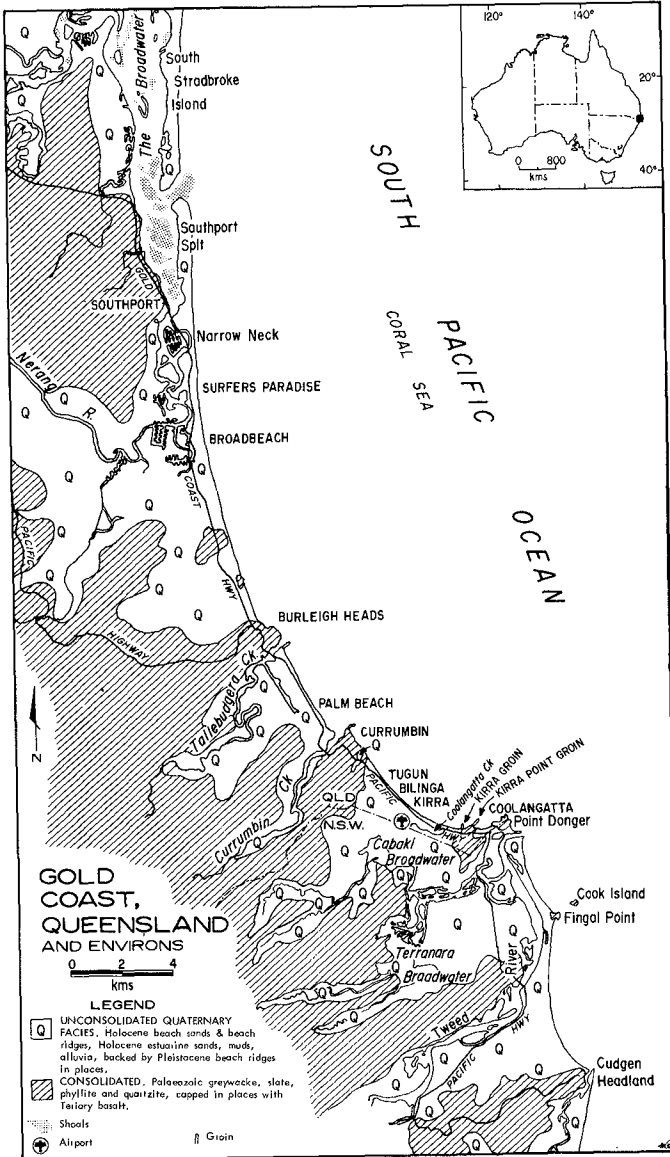

FIGURE 1

Net change in volume of the Lower Gold Coast beaches following nourishment is shown in Figure 2, with change in width of the sub-aerial beach shown in Figure 3. Datum in both cases is the beach state at commencement of survey. Although a net gain of volume occurred, Fig. 2 demonstrates that distribution of change at end of survey was very uneven, with the bulk of the fill remaining close to the delivery point in the form of two large "slugs", or parcels of sand. Comparison of Figures 2 and 3 also shows the importance of the subaqueous profile (or in-shore zone). Shoreline changes do not reflect the true state of erosion or accretion following beach nourishment. The total sand volume contained in the nourished area is critically dependent on the subaqueous profile. Shoreline recessions may be accompanied by accretion of the subaqueous profile. The lack of correlation between Figs. 2 & 3 is significant, showing as it does that width of subaerial beach is not a good indication of sand storage in the total beach system.

The large slug of sand centred on 2500 metres is almost wholly contained in the subaqueous part of the profile, being poorly reflected in added beach width, whilst small gains in beach width at 2000 metres and 3,500 metres do not reflect added volume in the beach prism at these points, but rather the reverse is true.

Most of the active zone of the beach is subaqueous (Chapman & Smith, 1980); a wide subaerial beach may give a deceptive appearance of security to resource managers, since the widest subaerial beach for a given fixed volume of sediment in the active zone, is associated with fully accreted, highly reflective beach states (cf. Short, 1978; Wright, *et al.*, 1979). Beaches in this condition are very sensitive to sudden increase in wave power, which causes rapid transfer of sediment to the subaqueous beach, and corresponding loss of subaerial beach width.

Re-distribution of beach sand by high energy waves was observed on the Lower Gold Coast seven months after project completion, when tropical cyclone "David" crossed the shoreline at about Lat 24°S. A reduction in dry beach width of over 20m occurred over the study area, with overall gradient being reduced from approx. 1:40 to approx. 1:80. The volume of the swept prism (Chapman & Smith, 1980) remained unchanged.

2.2 Manner of Sand Movement

It was found that the phenomenon of slugs of sand discussed above was not restricted to the nourishment project. Slugs of sand have been observed at three scales: (a) small-scale irregularities in beach volume revealed by survey as in Fig. 2; (b) medium-scale parcels of several hundred thousand cubic metres, usually associated with the flushing of flood-tidal deltas from estuarine inlets, and their subsequent accession to adjacent beaches; and (c) large-scale slugs of a million cubic metres or more, which appear as somewhat

CHANGE IN BEACH AND NEARSHORE SAND VOLUME
 FIGURE 2

CHANGE IN BEACH WIDTHS, KIRRA - CURRUMBIN
 FIGURE 3

subtle, low amplitude variations in subaerial and subaqueous sand storage over beach lengths of several kilometres.

Longshore transport, both in the short term of the nourishment monitoring study, and the longer term of some years, was effected by the alongshore migration of these slugs rather than as a continuous longshore flow of sand. Small and medium scale slugs tended to retain their identity whilst moving alongshore (drift direction is south-to-north, or left to right in Figs. 2 & 3) for distances of one or two kilometres, but then to diminish in amplitude and to coalesce into large-scale slugs.

Observations of large-scale slug movement, made over a period of 10 years, have revealed the slow longshore progression of forms illustrated schematically in Figure 4. Drift direction is from left to right; longshore movement of identifiable forms is indicated by the oblique arrows. The alongshore movement of the slugs of fill material from Kirra ($1.0 \times 10^6 \text{ m}^3$) and Surfers' Paradise ($1.4 \times 10^6 \text{ m}^3$) was particularly evident, since, although diffused with native sand, the fill slugs still exhibited a slightly different hue compared with the native sand in 1980. Calculations of volumes present in the slugs and rates of movement of their centroids indicated that longshore transport volume effected thereby was of the order of $2.0 - 2.5 \times 10^7 \text{ m}^3 \text{ yr}^{-1}$, a result remarkably similar to the figures of 2.84 and $2.52 \times 10^7 \text{ m}^3 \text{ yr}^{-1}$ derived for the Lower Gold Coast by intensive volumetric survey and tracer analysis (Chapman, 1978b).

The phenomenon of shore-parallel sediment movement in the form of discrete slugs has also been reported from the New Jersey coast of the U.S., where slugs of wavelength 4000-5000m were observed by Everts (pers. comm.)

2.3 Nourishment and Beach Topography

Fill application to the Lower Gold Coast resulted in a beach and inshore morphologic response similar to that observed on the beach sections adjacent to estuarine inlets following flushing by floods of flood-tidal deltas of marine sand contained in them, viz., amorphous inshore shoals, expansion of surf zone width, highly dissipative (as defined by Wright, *et al.*, 1979) conditions, and considerable wave setup.

As the slugs of fill moved alongshore, intensified and persistent rips developed ahead of them, leading to loss of beach width and volume as revealed in Figures 2 & 3. It is thought that a longshore gradient of radiation stress associated with wave setup over the fill slugs may have contributed to scour at the downdrift toe. The intensified rip at 3600 metres from the origin locally modified wave behaviour in the course of a short and relatively minor storm such that wave attack caused sea-wall collapse and property erosion behind the cell.

FIGURE 4

The phenomenon of scour at the downdrift end of fill on the Lower Gold Coast did not occur at the site of the contemporaneous nourishment project at nearby Surfer's Paradise. At Surfer's Paradise, it was more convenient for the contractor to place the fill by extending the delivery pipe incrementally in the opposite direction to the longshore transport system. No perturbations at the downdrift end of the nourished beach were observed.

3) FILL SELECTION & PLACEMENT

3.1 Fill Evaluation Criteria

A priori, one might expect that nourishment sand should be texturally matched to native sand if the "artificial" beach is to be successful. It may be anticipated that erosive forces would be less competent to remove sand of a coarser texture, hence use of nourishment sand substantially coarser than native might be expected to produce a more durable beach. Newman (1976) for example, considered that nourishment sand should have a median diameter $1\frac{1}{2}$ - 2 times that of native sand, and the well-known critical ratio concept has been developed around the foregoing assumption (Krumbein and James, 1965) to define the ratio of volume of nourishment sand required to be placed to the volume retained on the beach in equilibrium with shore processes. In most cases critical ratios considerably exceed unity, predicting that the proposed borrow material is less than ideal and that winnowing will selectively remove unsuitable fractions of the fill until it becomes compatible with the existing beach regime.

An alternative approach to evaluating the modification of nourishment sand by beach processes was proposed by James (1975), in the form of the re-nourishment factor which attempts to predict frequency of re-nourishment and to evaluate the long-term performance of proposed fill materials with regard to suitability, maintenance, and expense. The active beach system is considered a compartment which gains sediment through longshore transport and from gradual erosion of the store of sediments forming the backshore, and loses sediment by longshore and offshore transport beyond its boundaries. Fill is viewed as an increase to the backshore store. Sediment particle residence time in the compartment is longer for coarse grained material than for fine; thus a comparison between composite size distributions of native and borrow sediments is used to predict the "lifetime" of fill. A renourishment factor of $\frac{1}{2}$ means that borrow material would be expected to erode at half the rate of native material; renourishment with such borrow material should be required half as often as renourishment with sediment of identical composition to native material. Conversely a renourishment factor of 2 indicates that renourishment would be required twice as often as would be the case if native type sediment were used. The renourishment factor increases with an increasing difference between native and borrow means; the finer the borrow material compared with native, the higher the predicted retreat rate. Poorly sorted borrow material results lower predicted retreat rate since it contains a larger fraction of coarser material which is considered to provide a stable armour.

As the textural correspondence between native and borrow materials used in the Lower Gold Coast project was almost perfect, both the critical ratio and renourishment factor formulae gave values close to unity. However, using data derived from sediments actually present within the dynamic swept prism (Chapman & Smith, 1980) of the Lower Gold Coast, sensitivity analyses made on the formulae cast doubt on their validity. Aggregated samples varied between the limits (mean = 2.0ϕ , $s=0.4\phi$) and (mean = 2.5ϕ , $s=0.5\phi$), a remarkably homogeneous sand body; nevertheless both the critical ratio and renourishment formulae predicted that one or the other of these materials would generate quite marked changes in beach behaviour* in an environment where both were demonstrably in equilibrium.

Losses of beach nourishment material have often been ascribed to supposed winnowing of the finer fraction of such material, with the assumption that the fine sediment is lost to the system. Such is not necessarily the case, for, if a beach is moved into a different state by fill application, and redistribution of material to the inshore and inner nearshore takes place as a result, introduced material is not lost, but merely distributed in a different way to native material. In many cases the "lost" material will still be found within the dynamic swept prism (Chapman & Smith, 1980); absolute loss presupposes the existence of a sink. Accession of fill to the subaqueous part of the swept prism may produce a beach of lower overall gradient, with but slight increase in width, but one in which the swept prism has the capacity to absorb a great deal of wave energy without substantial withdrawal of sand from the subaerial part of the prism.

Introduction of finer-than-native material may well shift the beach regime into a more dissipative regime (cf. Wright, et al., 1979) with wider inshore zone, which could, by causing greater frictional dissipation of wave energy at greater distance from the backshore than in the pre-fill state, enhance erosion resistance. The fine sand, highly dissipative beach also requires more wave energy, compared to other beach states, to produce substantial erosion (Wright, 1980).

Use of coarser-than-native material, on the other hand, could conceivably cause a shift to a more reflective beach regime associated with a narrower inshore zone; this beach state is the one most delicately poised and subject to rapid collapse and removal of sand from the subaerial beach with input of increased wave energy (Wright, et al., 1979).

However, Gold Coast experience indicates that diffusion of fill into native sand may be rapid enough to warrant consideration of a new sand population formed as a mixture of fill and native materials. For the first two months after commencement of fill delivery, advection of added volume occurred principally over the first 1.5 km downdrift of the input point (Fig. 2) but diffusion of nourishment sand was very rapid, and revealed a high degree of over-turning within the sand prism.

* e.g. the renourishment factor varied between 0.41 and 1.92 in tests cited

Coring of the prism and analyses of tracer concentration (Chapman & Smith 1977) that the ratio of nourishment to native sand could be described by $r = e^{-(y/0.1)}$ where y is distance alongshore in kilometres.

Fill evaluation formulae as discussed above also presuppose the loss of the finest sand from the beach system. However, many microscopic examinations of beach sediments from a wide range of energy environments in eastern Australia have invariably revealed a significant tail of very fine sand, even in the extreme case where ϕ mean approached zero. Since Hobson & James (1978) have shown that elutriation of fines not in equilibrium with the beach environment can be very rapid, the persistent presence of very fine tails in beach sands suggests that these form part of the normal populations of the beaches concerned. Work in progress also suggests that behaviour of the sediments may be related to the frequency distribution of specific surface, as distinct from mean diameter (Smith & Gordon, 1980), in which case the fine tail achieves greater prominence.

The critical ratio and renourishment factor concepts appear to have evolved from the perception of a wide subaerial beach as the most desirable state, and assume uniform profile retreat under erosion. Rather than searching for field data for verification of the concepts, as has been suggested (e.g. Dean, 1976) it may be that criteria are required for the evaluation of fill suitability in terms of its effect on beach morphology within a given energy environment.

3.2 Fill Placement

Fill placement has usually been thought of in terms of a design profile of beach nourishment distribution (Delft, 1970; Silvester, 1974; Vallianos, 1975). Silvester suggested the calculation of an "equilibrium" profile form, whilst Vallianos used the concept of a design profile, complete with shaped dune form. Experience from the Gold Coast suggests that, whilst the design profile concept may be useful for calculation of fill quantities, it is of little value as a practical working criterion for the reconstruction of beaches by means of nourishment, since the procedure assumes both fill retention and morphology are predictable.

The concept of an artificially shaped profile, complete with formed dune, was an essential element in the scheme for the Gold Coast (B.P.A., 1973). The sand supplied to the beach was to be distributed above high water level by bulldozer and vegetation was to be established upon an artificially formed dune. The design concept envisaged that the fill would be placed as high on the beach as possible, covering any boulder walls present, and allowing the surplus only to escape to the swash zone.

However, execution of the concept proved impractical. Emplacement of fill sand in the design profile meant that the unnaturally high "berm" was scarpred at high tide. This not only gave the public the impression that fill was being lost by erosion, but made beach access

difficult for swimmers which resulted in public relations problems for the Local Authority.

The artificially formed "dune" concept also proved impractical. Immediately upon drying out, sand began to drift onto the backshore and encroach upon parking areas and esplanades. Moreover, attempts at establishment of the sand-binding grass, Spinifex hirsutus, in the pumped sand proved abortive. The tight packing characteristics and fines content of pumped sand were dissimilar to the lightly packed, free moving sand of the normal accreting foredune. It appears that the dissimilarity was great enough to inhibit Spinifex development.*

Much of the literature on beach management is imbued with static notions of beach equilibrium. The beach must be recognised as a dynamic system, and managed within its dynamic range, for management to be effective. The concept of the equilibrium inshore profile was shown by Chapman (1978b) to be a chimera. Use of an appropriate three-dimensional model allows a number of more-or-less discrete beach stages (or equilibria) to be recognized, as described by (e.g.) Short (1978) or Wright, et al., (1979). Viewed in this context, management of a beach by means of nourishment involves more than merely the addition to the active zone of sand having a suitable 'critical ratio' or 'renourishment factor'. Manipulation of the beach system could involve consideration of the characteristic morphologic states of the beach in question with their probabilities of occurrence spatially and temporally and in relation to most probable energy inputs. Given a variety of possible sediment sources it may be possible to induce beach behaviour of more dissipative or more reflective modes if these were considered desirable. Timing of application of nourishment with respect to existing or probable morphologic states and energy inputs, both from sea and wind, in order to maximise fill utility and encourage formation of backshore dunes, also may be seen as a management variable.

4) CONCLUSION

To the lay beach user, or even to the resource manager unfamiliar with inshore morphodynamics, a wide subaerial beach is interpreted as a sign of the presence of a large sediment volume. Results reported above show this perception may be quite erroneous.

A commonly applied guideline of one square foot of beach area gained per cubic yard of fill, may be seen in its general form as an attempt to relate subaerial beach area to volume of the sand prism; however it was shown above that width (or area) of subaerial beach is

* S.hirsutus is propagated by seed. Vegetative propagation is possible but not practical. The popular Ammophila spp. used in many cool temperate areas, A. Arenaria and A. breviligulata, were unsuitable for the Gold Coast as the sub-tropical location is beyond the environmental tolerance of the latter species.

poorly correlated with volume in the sand prism. Width will depend, inter alia, on beach state and on texture of added sediment.

Commonly-used renourishment factor or critical ratio concepts are unsoundly based; since both use simplistic data as basic input they can at best provide over-simplified approximations of the complex and dynamic beach regime, and no process terms are included in either. Basic to both concepts is the assumption that a coarser-than-native sediment is desirable for fill purposes, and is likely to prove more stable under the wave climate of the problem area. Whilst coarser non-cohesive sediment is less likely to be moved by any given wave than is fine sediment, it does not necessarily follow that coarser sediment will ultimately produce a more stable beach or more desirable beach state than native material.

A beach will be built, by waves, of whatever suitable material is available; high energy wave climates are not necessarily always associated with beaches of coarse sediment, or vice versa.

Sediment size is but one of a matrix of factors responsible for beach behaviour at a site under any given wave climate; varying sand grainsize may simply cause a shift into a different stage in the morphodynamic continuum rather than producing a beach of different erosion resistance.

The design profile concept is useful for computing required fill amounts by comparison with existing beach profiles; however, it assumes that both fill retention and morphology are predictable and that the design profile can be constructed. In practice, in a moderate-to-high energy environment, the concept may be operationally impractical, and establishment of vegetation by seed in pumped-sand "dunes" proved difficult. Fill redistribution by natural marine and aeolian processes proved more effective and economic than attempts to create an idealised profile. Apparent "losses" from the dry beach were accounted for by redistribution in the inshore zone.

Perturbations of the inshore system caused by fill application may affect local erosion patterns and longshore transport in ways which would be unexpected from observation of the beach in its normal state. Radiation stress gradients developed as a result of topography associated with nourishment may lead to intensified erosion adjacent to the filled beach.

If fill redistribution within the dynamic swept prism is seen as normal, and the movement of sediment to the subaqueous part of the prism as morphodynamic change rather than loss of material, it may be possible to consider a wide variety of potential nourishment sources to increase the erosion resistance of a given beach, and even to think of "tuning" to achieve desirable morphologic states.

CAPRICORN COAST BEACHES

D.C. Patterson and L.R. Ford
 Engineers, Beach Protection Branch, Department of Harbours & Marine,
 Queensland, Australia

1.0 INTRODUCTION

The Beach Protection Authority of Queensland published in December 1979 a report outlining the results of its investigation into all the factors which determine the coastal behaviour of the 90 km strip of Central Queensland's coastline known as the Capricorn Coast (Fig. 1). The purpose of the investigation was to provide a detailed explanation of beach behaviour in this area including all the data necessary for the preparation of a comprehensive program of works and management strategies for improving beach conditions and minimising present and future erosion problems. This paper represents a brief summary of the contents of the published report.

2.0 OBJECTIVES

No previous studies have been made into the nature and behaviour of the Capricorn Coast beaches. It was clear from the location and wave exposure of this stretch of Queensland's coast that the behaviour of the beaches is unique and not easily related to other previously studied areas. Hence it was necessary to initiate a full scale investigation into all aspects affecting the beaches of this coastal region. The investigation into coastal behaviour along the Capricorn Coast was commenced in 1975 and carried out in compliance with the Beach Protection Authority's stated functions which include:-

- (a) The carrying out of investigations with respect to erosion or encroachment by the sea of or upon lands of the coast;
- (b) The investigation and planning of preventative and remedial measures in respect of erosion or encroachment by the sea of or upon lands of the coast;
- (c) The recording and evaluating of the results of such investigations and plans.

The primary objective of the study was to provide a firm basis for the preparation of an overall scheme of works and management for the beaches and dunes. The Beach Protection Authority's approach involves determining the extent of foreshore which is likely to be vulnerable to erosion in the future and attempting to restore or carefully manage this land so that it remains available as a buffer zone between the ocean and nearby development. The extent of buffer zone depends on -

- The rate of long term coastal erosion (R metres per year)
- The extent of the design cyclone erosion (C metres)

$BUFFER\ ZONE\ WIDTH = [(N \times R) + C] + F$ (metres)

where N = Planning period (years)

F = Factor of safety (metres).

Hence the investigation was directed toward quantifying the values R and C for each beach in the study area. The Beach Protection Authority has adopted a planning period of 50 years and a factor of safety of 40 metres for the Capricorn Coast area.

2.1 Data Collection

Data collection was carried out over the three years 1975 to 1977 inclusive. During that time repetitive surveys, wave recording, dune vegetation studies, geological investigations and current measurements were carried out.

This program of data collection provided data on -

1. the geological history of the region;
2. beach sediment properties;
3. beach profile forms and measured modifications under varying wave attack;
4. meteorological conditions;
5. incident wave conditions;
6. dune vegetation;
7. nearshore currents;
8. sea level fluctuations resulting from tides and storm surges;
9. beach and dune conditions;
10. the nature of the coast and the erosion problems.

2.2 Data Assessment

The task of assessing all of the available data was carried out by engineers and scientists of the Beach Protection Branch of the Department of Harbours and Marine. Assistance was also provided in respect of -

- (a) the geology of the area by geologists from the Geological Survey of Queensland and
- (b) dune vegetation by botanists from the Department of Primary Industries.

The principle aim of this data assessment was to provide an understanding of the active beach processes in the Capricorn Coast area with particular regard to -

- . sediment supply and distribution along the coast
- . erosion/accretion behaviour of the beaches in both the short and long term
- . the role of dune vegetation in beach and dune stability
- . buffer zone widths within which future dune erosion is likely to occur.

3.0 LOCATION AND TOPOGRAPHY

The Capricorn Coast is uniquely placed along Queensland's coastline (Fig. 1). Its location in relation to the Great Barrier Reef, the continental shelf and the shape of the adjacent coastline exposes it to wave, current and tidal forces different from those experienced elsewhere on our coast.

The physical appearance of this 90 kilometre stretch of coast is one of great contrasts. Prominent rocky headlands separate numerous sandy pocket beaches in the central sections while to the north and south long stretches of uninterrupted beach have developed (photo 1). The beaches of the Capricorn Coast are gently sloping, consisting of relatively fine sand containing a significant proportion of muds. The 4 metre ocean tidy typically rises and falls across a beach width exceeding 150 to 200 metres.

Fig. 1a Locality Plan

Fig. 1b The Study Area

Photo 1. The Yeppoon region of the study area.

The most common coastal landform along the beaches of the area is extensive sand dune development in various forms including recent foredunes, older parallel beach ridges, and both mobile and stabilised transgressive dune formations.

The Fitzroy River is by far the largest of the streams in this coastal region. This river has a comparatively large catchment area of about 14 million hectares. However the major part of the Fitzroy's catchment receives only 600-700 mm of rainfall per year on average, and significant fresh water flows in the river are typically associated only with cyclonic activity in the region.

4.0 GEOLOGICAL HISTORY

The present day topography of the Capricorn Coast and the beach processes taking place there are more readily understood when the past behaviour of the region is known. The beaches and dunes as we see them today have formed during the last 6000 years. The reason for this relates to the rise in sea level which ended at that time. Fluctuations of the sea level reaching about one metre above and below the present level have occurred since then. During the sea level rise, the position of the coastline moved landward from its former alignment resulting in large scale submergence of the former coastal plain to form the present day Keppel Bay. In the process many former mainland hills became headlands of the present shoreline or islands such as Great Keppel Island. The present day seabed topography of Keppel Bay is shown on Figure 2a. The present coastline has developed in response to the last 6000 years of wave and current influence and the input and output of sediment from offshore, alongshore and river sources.

4.1 Fitzroy River Sediments

The Fitzroy River carries with it vast quantities of sand and silt which are discharged to the sea and settle to the bed of Keppel Bay. These sediments have been eroded from the upstream catchment areas and exhibit characteristics which identify them as less mature than the pre-existing coastal sands of Keppel Bay. For example, the Fitzroy River sediments are finer grained and contain a significant proportion of muds. They also contain relatively large amounts of certain minerals such as feldspar which can be visually identified under microscopic examination and which break down in the coastal environment with time so that they are not present in mature sands. As well, sediment deposited from the river during floods has not been sorted (a winnowing process) by wave and current action and can be differentiated from the better sorted mature sands by grain size distribution analysis.

During the investigation nearly 700 samples of sand were collected from the seabed of Keppel Bay and from the beaches and dunes for analysis to identify these characteristics. This enabled the zone of deposition and transport of sediments supplied from the Fitzroy River during the last 6000 years to be delineated. This zone is shown on Figure 2 and is unusual in that it forms a well defined nearshore belt along the entire Capricorn Coast rather than extending directly seaward from the river mouth. Seismic profiling provided information on the total depth of the nearshore sands and the thickness of the Fitzroy River derived sediments. Using this information together with data on flow in the Fitzroy River during floods, it was estimated that an average quantity of 350,000 cubic metres of sand is supplied by the river each year.

The beaches and seabed in the vicinity of the Fitzroy River exhibit a very strong trend of accretion which diminishes with distance away from the river. This indicates that the rate of distribution of the input sediment is not as great as the rate at which the river supplies it. This has resulted in the flat shallow offshore profiles which characterise the southern Keppel Bay regions and which contrast with the steeper profiles further north.

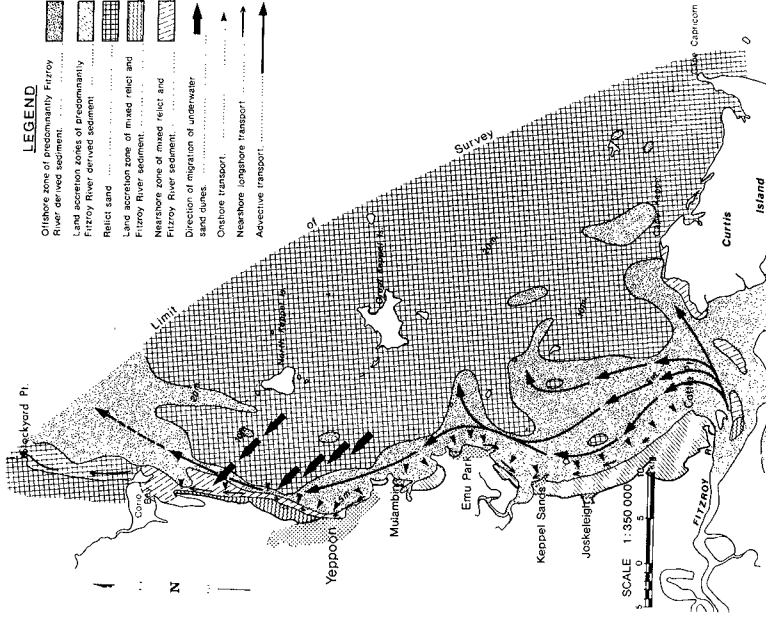

Fig. 2b Sediment Movements in Keppel Bay

Fig. 2a Keppel Bay Contours

4.2 Offshore Sediment Distribution

The seabed sediments of Keppel Bay are being gradually distributed northwards away from the Fitzroy River (Fig. 2b). The sediment in motion includes both the relatively new Fitzroy River derived muddy sands and the older mature relict sands drowned by the sea transgression prior to 6000 years B.P. The mechanisms involved in this movement of sediment are not clearly understood but are thought to result from the combined action of waves and a northerly current induced by the predominant south easterly winds producing advective transport.

There are no established techniques readily available for calculating these advective transport rates using the available wave and current data. However an estimate has been made from the quantities of Fitzroy River derived sand which has been transported northwards past various locations over the last 6000 years (Table 1).

TABLE 1
NET NORTHWARD ADVECTIVE TRANSPORT IN KEPPEL BAY

Location	Total Holocene Sedimentation North of Location (cubic metres)	Net Northward Advective Transport (m^3/yr)
Cattle Point	2160×10^6	360,000
Keppel Sands	1146×10^6	191,000
Tanby Point	990×10^6	165,000
Double Head	900×10^6	150,000
Farnborough	726×10^6	121,000
Water Park Point	588×10^6	98,000

These rates of transport are large compared with the nearshore longshore transport rates particularly in the southern and central regions. Clearly advective transport represents the primary mechanism for the northward supply of sediment along the coast from the Fitzroy River.

4.3 Holocene Coastal Accretion

At the Capricorn Coast extensive accretion has occurred during the last 6000 years as a result of a persistent onshore movement of sand from the nearshore area of Keppel Bay. Most of this sand has come from the zone of Fitzroy River sediment delineated on Figure 2, and average rates of up to 2000 cubic metres per kilometre of beach per year have been assessed.

The land developed by this Holocene accretion (the "outer barrier") often has the form of a series of dune ridges and swales that correspond to erosion/accretion cycles probably associated with major cyclone events and are clearly evident from the air (Fig. 3 and photo 2). This dune ridge system is superimposed on a broader sequence of accretion features associated with six significant fluctuations in sea level which have occurred during the last 6000 years. During phases of high sea level the accretion sequence is truncated by sustained periods of erosion. Despite this however, the general landward movement of sediment from nearshore continues so that phases of falling sea level are accompanied by accelerated accretion.

As Fig. 2b shows, the beach areas strongly exhibiting this trend of long term accretion are -

- (a) the southern region between the Fitzroy River and Emu Park, including Keppel Sands (photo 2).
- (b) the deeply embayed shoreline of Mulambin and Kinka Beach.
- (c) the Farnborough area north of Yeppoon. In this area an additional input of the older mature sand from both nearshore and alongshore can be identified in the accreted dune sands.

Fig. 3 Section of Holocene Accretion

Photo 2. Holocene accretion
Cattle Point to Keppel Sands

4.4 Persistently Eroding Beaches

In contrast to the strong accretion discussed above, those beaches where nearshore profiles are steep or where the onshore sand supply is moved away along the coast show little accretion and in some locations, general erosion.

Nine Mile Beach and the northern section of Farnborough Beach near Corio Bay show evidence of persistent erosion. This part of the Capricorn Coast is more exposed to the ocean wave conditions than the southern beaches which lie in the lee of the nearshore islands. Erosion by the rising sea level, longshore movement of sand and cyclones has led to persistently unstable foredunes and wind erosion on a large scale. Dune blows and extensive transgressive dune formations are thus the main landforms there (photo 3) and have allowed considerable vertical growth of the dunes reaching to over 150 metres above mean sea level inland of Nine Mile Beach.

Photo 3. Transgressive dunes - Nine Mile Beach

5.0 NATURAL FACTORS INFLUENCING BEACH PROCESSES

5.1 The present day behaviour of the beaches varies from year to year, seasonally and from day to day depending on the occurrence of cyclones, climatic changes throughout the year and daily weather variations. Longshore transport and onshore/offshore transfer of sand were assessed on the basis of surveyed beach properties and measured forces such as the wind, waves and currents. The growth of dune vegetation which controls the stability of the dunes against wind erosion is determined largely by the climate and the nature of the dune soils.

Some of the natural factors influencing beach processes are outlined briefly below.

5.2 Meteorological Influences

Wind strengths at the coast are consistently moderate to fresh with velocities exceeding 20 km/hr about 50% of the time and essentially no calm days. Strong winds in excess of 50 km/hr occur less than 2% of the time. South east winds predominate and persist longer than all other winds.

There is considerable variation in annual rainfall along the Capricorn Coast with a predominant trend for average rainfall to increase from south to north (Table 2). This trend coincides with a general increase in relief in the coastal topography from south to north with minimum rainfall occurring in the low coastal plains at Cattle Point and maximum rainfall occurring in the coastal ranges inland from Stockyard Point.

TABLE 2
MONTHLY & ANNUAL RAINFALL DATA YEPPOON & EMU PARK

Recording Station	Recording Period	Average Rainfall (mm)												Year
		Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	
Yeppoon	1891-1975	259	240	183	104	77	77	47	30	36	66	76	149	1344
Emu Park	1886-1976	203	201	145	78	59	60	43	24	30	46	71	123	1083

The incidence of tropical cyclones is a significant feature of the study area's climatology. On the average, the Capricorn Coast suffers the effects of tropical cyclones once every two years, although the occurrence of widespread cyclonic destruction in the study area is a much rarer occurrence.

TABLE 3
CYCLONE CENTRAL PRESSURE VS
PROBABILITY OF OCCURRENCE

Pressure Range	Representative Pressure	Probability
> 985	990	0.5
975-985	980	0.1
968-975	970	0.08
963-967	965	0.01
958-962	960	0.005
953-958	955	0.003
948-952	950	0.001
943-947	945	0.001
935-942	940	0.0002
< 935	920	0.00002

5.3 Dune Vegetation

Coastal processes would not approach or attain the dynamic equilibrium status common along many coasts without plants that tolerate salt spray, resist strong winds, trap and hold windblown sand and add organic soil components. The establishment, maintenance, and protection of vegetation within those zones affected by coastal processes, are important aspects of coastal management.

The type and distribution of coastal dune vegetation along the Capricorn Coast is highly variable and is determined by geology, landform/topography, climate and land use.

A field survey of vegetation in the Capricorn Coast study area was undertaken as a joint project by the Authority's Dune Conservation Section and the Botany Branch, Queensland Department of Primary Industries.

The survey was carried out to produce a vegetation map and report on the existing vegetation communities of the study area with special reference to beach and dunal areas.

The aggregation of plants in a coastal beach/dune system form, in general, three types of vegetative cover:-

1. a pioneer type composed mostly of herbaceous plants;
2. a heath/scrub type of woody shrubs, vines and small trees with a few associated herbs;
3. a woodland or forest type dominated by trees.

Nearly all the plants of the first two types are tolerant to salt spray, strong onshore winds and various degrees of soil salinity. The pioneer herbaceous vegetation occurs on foredunes nearest the beach. The scrub vegetation is found on the partly to fully stabilised older foredunes landward of the pioneer zone. The forest vegetation usually occurs towards the interior on the oldest and most stable dune/beach ridge systems.

Pioneer vegetation is the chief dune-forming agent. These herbaceous plants grow in a manner that enables them to help develop dunes in conjunction with wind action. Plants growing on the upper part of the beach trap windblown sand and initiate formation of a low frontal dune. Most of the pioneer plants occur on the seaward slope, crest and landward slope of the frontal dune.

Pioneer plants are the initial vegetation of the coastal succession or sequence of vegetation that finally develops into a climax community be it grassland, shrubland, heath, scrub, woodland, forest, or wetland. They increase the rate and height of dune formation and determine the pattern of vegetation development of the coastal dune system. They prepare the soil and other habitat conditions for the development of other vegetation communities (e.g. scrub) in the normal course of coastal succession.

Beach spinifex grass (Fig. 4a) is the most important pioneer sand stabilising plant occurring naturally on the frontal dune and foredunes and is usually the dominant species colonising the seaward slope of the frontal dune in exposed situations. It is tolerant to air borne salts, strong onshore winds, and has the ability to grow through accumulations of windblown sand.

Fig. 4a Beach Spinifex Grass

Fig. 4b Coastal She-Oak

Coastal she-oak (Fig. 4b) belongs to the genus: *Casuarina* which is the only non-legume genus native to Australia that can "fix" atmospheric nitrogen. Micro-organisms in the root nodules convert nitrogen from the air into a form which is more readily used by the plant. This process improves the nitrogen content of the sand/soil enable more nutrient demanding plants to establish.

Symbol	Plant	Map Unit	Commoner Designation	Vegetation Zone
	Mangroves	1	Mangroves, mudflats	Disturbed
	Mudflats	2		Littoral
	Spinifex	3	Spinifex - (former) Mt Bluff	Sand
	Scaevola	4	<i>Heterostichus scoparius</i> has been noted	
	Casuarina	5	At Mt Bluff, <i>casuarina</i> is noted	
	Casuarina	6	At Mt Bluff, <i>casuarina</i> is noted	
	Heath	7	Fringing dune heath scrub and open heath scrub	Fringing
	Scrub	8	Fringing dune scrub and open scrub	Beach Ridge

	Scrub	29	Coastal open heath and dune heath	

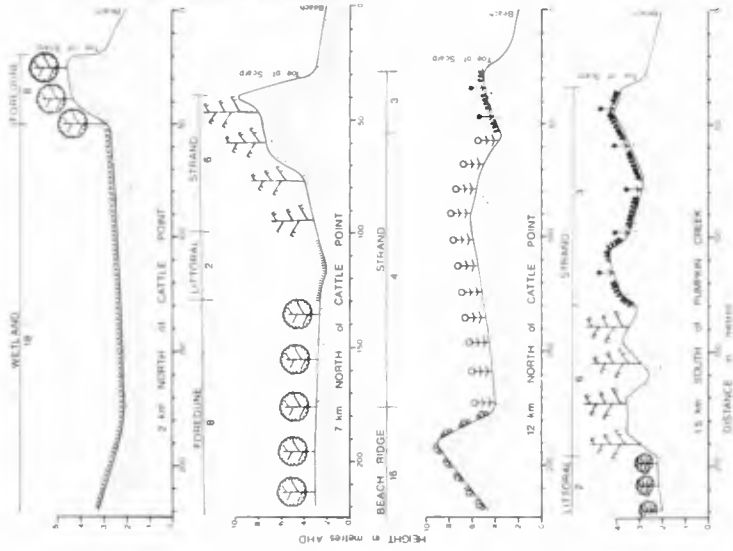

Fig. 5 Typical Vegetation on Dune Profiles

5.4 Sea Level Variations

Variations in sea level substantially influence beach behaviour through their effect on various wave phenomena such as refraction, shoaling and breaking, and the level at which the waves attack the beach. A significant change in sea level will upset a pre-existing equilibrium and result in changes to the original shoreline profile or plan form. Major sea level variations in the geological time scale are important in understanding contemporary coastal behaviour especially in relation to sediment distribution. During the Holocene period (last 10,000 years), the sea level has risen 20 metres. This rise occurred prior to 6,000 years ago and since then fluctuations in sea level of magnitude about ± 1 metre and period of almost 1,000 years have occurred.

Adopted values for the various tidal planes at the Capricorn Coast are as follows -

TABLE 4
TIDAL PLANES CAPRICORN COAST

Tidal Plane	Low Water Datum	Australian Height Datum
Mean High Water Springs:	4.0m	1.7m
Mean High Water Neaps:	3.1m	0.8m
Mean Low Water Neaps:	1.5m	-0.8m
Mean Low Water Springs:	0.6m	-1.7m

Three separate studies concerning storm surge statistics along the Capricorn Coast have been prepared over recent years. The most recent of these was carried out by the James Cook University, Townsville, for the Beach Protection Authority. It involved the numerical simulation of various cyclones in the Capricorn Coast region in terms of the cyclone intensity and direction of approach. Results from that study are outlined in Table 5.

TABLE 5
MAXIMUM SURGE AT VARIOUS LOCATIONS AS PREDICTED BY NUMERICAL MODEL

LOCATION	CYCLONE RETURN PERIOD		
	1 in 50yrs	1 in 100yrs	1 in 500yrs
Stockyard pt.	1.52	1.66	2.00
Water Park Pt.	1.67	1.83	2.19
Yeppoon	2.03	2.21	2.62
Emu Park	2.54	2.75	3.22
Fitzroy River	2.12	2.29	2.66
Cape Capricorn	1.11	1.21	1.41

5.5 Wave Climate

Waves affecting the Capricorn Coast may be generated locally within 100-500 kilometres of the study area or may arrive as decaying swell generated outside the vicinity of the region. The possible directions from which waves can arrive are confined to the seaward sector between north (0°) and south (180°), being the general alignment of the coast. Swell waves are further restricted by the shape of the coast and offshore reefs to directions between 60° and 120° , being intercepted by the Great Barrier Reef to the north-east and Fraser Island to the south-east. Recording of waves using the Dutch Waverider wave recording system was carried out at one location over the period November 1974 to April 1978. The recorder location was 33 km east of Yeppoon in 28 metres of water, being seaward of North and Great Keppel Islands and away from the sheltering effects of Cape Capricorn.

WAVEHEIGHT EXCEEDANCE

$$\text{AVE NO HOURS PER YEAR} = \frac{(pe)}{100} \times 8760$$

$$\text{AVE NO EVENTS PER YEAR} = \frac{(pe)}{Pm} \times 87.6$$

For a particular persistence _____

$$\text{AVE NO EVENTS PER YEAR} = \frac{(pe)}{Pm} \times 87.6 \times \frac{(pn)}{100}$$

$$\text{AVE RECURRENCE INTERVAL} = \frac{Pm}{0.876 (pe \cdot pn)}$$

Fig. 6 Wave Climate - Capricorn Coast

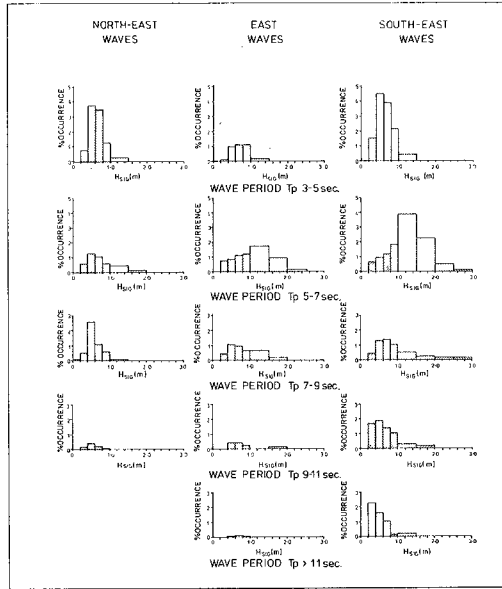

Fig. 7 Wave Height/Period/Direction Occurrence

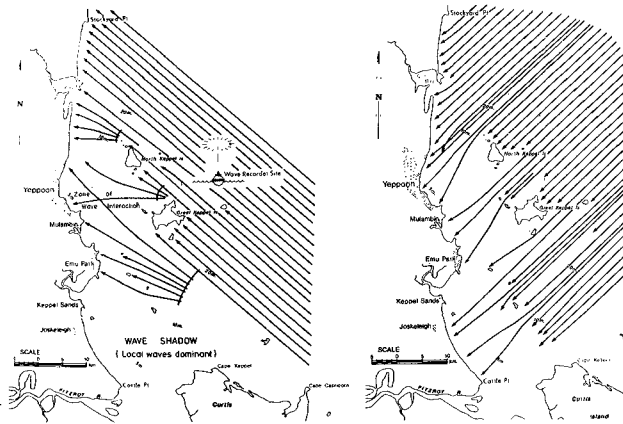

Fig. 8 Typical Wave Refraction

A wide range of basic wave parameters were analysed for each 20 minute wave record. However, the parameters considered most useful for determining beach processes were the significant wave height (H_{sig}) and the period corresponding to the peak of the energy spectrum (T_p). Hindcasting was also performed using twice daily wind data recorded at Cape Capricorn Lighthouse over a 17 year period. This involved the use of the revised S.M.B. empirical relationship for the non-deep water situation.

The reasons for hindcasting wave height data were -

- (a) to compare the results with recorded data to confirm a wave hindcasting/forecasting procedure for use in estimating wave heights during particular storm events either in the future or for past cyclones for which wind data is available.
- (b) to extend the time base of available wave data from the 3 years of recording to the period of available wind data namely 16 years in this region. This provides a better basis for statistical analysis of the less frequent high wave occurrences.

The calibrated hindcasting model provided wave height data showing good agreement with the recorded data over the three year period of recordings. Wave directions were assessed on a daily basis from synoptic charts and from wind data used in the hindcasting procedure.

Representative wave data for the Capricorn Coast determined from the wave study are outlined in Figures 6 and 7. The largest significant wave height recorded during the investigation was 4.26 metres associated with cyclone "David" in January, 1976.

Wave refraction procedures based on first order wave theory using peak energy wave periods were used to transfer the offshore wave data to the various locations along the coast (Fig. 8).

5.6 Nearshore Currents

Current measurements were undertaken both within the surf zone and nearshore outside the surf zone. Four types of currents were considered -

- Ocean Currents
- Nearshore Tidal Currents
- Nearshore Wind Drift Currents
- Wave Induced Currents

Measurement techniques involved the use of current meters outside the surf zone to provide the vertical velocity and direction profiles and float and dye tracking within the surf zone. It was found that both the wind and the tide contributed significantly with wave induced forces to the generation of longshore currents.

The data obtained was used to confirm or determine analytical expressions from the longshore current necessary as input to the calculation of the longshore transport of sand.

6.0 CYCLONE EROSION

Erosion of the beaches and dunes often accompanies the occurrence of major storms and cyclones in the region. Abnormally big waves attack the dunes during the high tides and accompanying storm surges and move sand in the offshore direction.

6.1 Measured Cyclone Erosion

The extent of erosion caused by Cyclone "David" in 1976 was monitored by surveys in terms of the quantity of sand eroded and the typical horizontal recession of the toe of the frontal dune. This is shown in Table 6 (terms defined on Fig. 9).

TABLE 6
EROSION DURING CYCLONE DAVID

Location	Quantity Eroded (m ³ /m)	Horizontal Recession (m)	Transition Level (m) (related to M.S.L.)	Offshore Limit of Deposition (m)	
				Related to M.S.L.	Below peak storm tide
Cattle Pt. to Keppel Sands	35	15	+1.0	-1.0	4.2

Yeppoon to Bangalee	70	15	+0.5	-4.5	7.7
Nine Mile Beach	65	9	-1.0	-4.5	7.7

6.2 Erosion by the "Design" Cyclone

The method of Edelman for estimation of dune erosion during storms is based on the principle that a characteristic beach profile is developed by the cyclonic waves with sand eroded from the dune (Fig. 9).

Fig. 9 Dune Erosion - Buffer Zone

Beach surveys immediately after cyclone David indicated that the Edelman profile closely approximated this characteristic profile for the Capricorn Coast beaches and could reasonably be used in the absence of more reliable information. Clearly sand grain size strongly influences the shape of this profile. For the estimation of erosion resulting from the adopted "design" cyclone conditions, the profiles actually developed during cyclone David were used for each individual beach along the study area.

The extent of cyclonic dune erosion depends also on the storm tide level and the wave height. Design wave heights were based on the recorded data as outlined in Section 5 with appropriate modification to allow for refraction. Design storm tide and wave heights for various beaches along the coast are shown in Table 7 along with the assessed dune erosion results.

TABLE 7
"DESIGN" CYCLONE DUNE EROSION

Location	Design Wave Height (m)	Design Storm Tide Level (m)	Erosion Quantity (cu m/m)	Erosion Distance (m)
Nine Mile Beach				
- High Fore-dune	5.9	3.40	50	20
- Low Fore-dune	5.9	3.50	140	35

Cattle Point	2.2	4.00	50	50-150 ⁺

*Sections of beach protected by seawalls

⁺Large horizontal erosion where overtopping of fore-dune occurs.

7.0 LONGSHORE TRANSPORT

At the Capricorn Coast where the offshore profiles are relatively flat and wind and tide induced currents are frequently large compared with wave induced currents, the transition from the offshore advective transport to the nearshore longshore transport is not a clear one.

Several methods were used to estimate the gross and net longshore transport rates for the various beaches (refer Fig. 1b). These were -

- the "CERC Method which is based on the assumption that all transport is caused by wave forces alone
- the Bijker method which allows the input of the appropriate longshore current velocity together with wave, sediment and profile parameters
- a method developed by the Authority for estimating longshore transport using observed daily wave and longshore current information from the COPE stations.

The results are summarised in Tables 8 and 9. Greater reliability is expected of the COPE data results as they incorporate longshore current directions and velocities obtained by direct measurement and include the influence of the tide and wind.

8.0 GRADUAL EROSION

Persistent gradual erosion may result from a differential in the longshore transport along a beach, the effects of a rising sea level or wind erosion. Historical information given by the geological study and successive surveys or aerial photography is available, together with the assessed longshore transport data, to quantify the gradual erosion for each beach. Rates in the range 0-4 metres per year have been obtained.

TABLE 8
SEDIMENT TRANSPORT CALCULATED FROM WAVE DATA

Site	SEDIMENT TRANSPORT						
	Refracted Offshore Waves		Wave Generated Within Keppel Bay		Total Sediment Transport		
	Upcoast	Downcoast	Upcoast	Downcoast	Upcoast	Downcoast

9.0 BUFFER ZONES AND BEACH PROTECTION SCHEMES

Using the assessed rates of gradual erosion over the adopted 50 year planning period and the extent of the design cyclone erosion for each beach, the buffer zones have been calculated as outlined in Section 2.0. Typical results are outlined in Table 10.

Existing and potential erosion problems have been identified and recommendations for protection (including restoration where necessary) of the beaches are outlined in the published Beach Protection Authority report. While several beaches require works such as beach nourishment, groynes or seawalls, most of the beaches can be protected by careful dune management and control over adjacent residential development.

Cattle Point to Keppel Sands	0-200	50	10	40	100-300

*Protected by seawall.

10.0 CONCLUSION

The provision of adequate buffer zones between development and the sea and the protection of the dunes contained within them by careful dune management is clearly the best way of protecting both the beaches and the nearby development. Every effort should be made in future town planning schemes to make such provisions. However some beaches are already experiencing erosion problems where development has been permitted too close to the sea in the past and has come under threat of erosion by cyclonic wave action. Determination of the most appropriate remedial action is not simple and depends on the individual beach behaviour. The consequences of incorrect decisions in beach protection matters can be financially severe and physically disastrous for the beach itself. To date the financial resources available for beach protection measures has been limited. It is important that available funds are directed towards the most appropriate solutions which do not create other problems. It is therefore necessary for beach protection proposals to be based on a thorough knowledge of local behaviour.

The Capricorn Coast Beaches investigation has provided an explanation of beach behaviour in that area in quantitative terms based on actual field data with the additional testing and use of empirical and theoretical predictions.

The Beach Protection Authority is convinced that such detailed investigations are necessary to determine the optimal use of the limited money resources available for the improvement of existing beach conditions and the minimising of future erosion problems.

ACKNOWLEDGEMENT

The permission of the Chairman of the Beach Protection Authority of Queensland and Director of the Department of Harbours and Marine, Mr. J. Leech to publish this paper is gratefully acknowledged.

CHAPTER 101

THE BEACH IMPROVEMENT PROGRAMME : NEW SOUTH WALES

Neale A. Philip and Philip H. Whaite¹.

1. INTRODUCTION

The Coastal Engineering Branch of the Public Works Department N.S.W administers the Beach Improvement Programme, a programme of works with an average annual expenditure of one million dollars, for the improvement of the State's public recreational beach amenities.

Priority is given to beaches with highest usage, resulting in the first two years' funds being allocated to the densely populated coastal strip between Newcastle and Wollongong.

Priority is also assigned to various types of works:-

1. Preservation, conservation or restoration of the beach itself by sand nourishment, dune stabilisation, seawall demolition;
2. Erosion control where appropriate, by seawall and revetment construction and land acquisition;
3. Provision of facilities such as car parks, access roads, dressing sheds and toilet blocks;
4. Beautification such as grassing and tree planting.

The near city beaches in Sydney, Newcastle and Wollongong have mostly been fully developed with seawalls and promenades behind the beach berm, while in outer Metropolitan areas, the beaches have been left in a more natural state, with some development such as car parks and dressing pavillions on or behind the sand dunes.

2. BACKGROUND

The New South Wales coastline experiences the highest recreational pressures on it of all Australian States. With the shortest coastline length and the highest population this pressure is overwhelming by Australian standards.

1. The Authors are Engineers in the Coastal Engineering Branch of the Public Works Department, New South Wales.

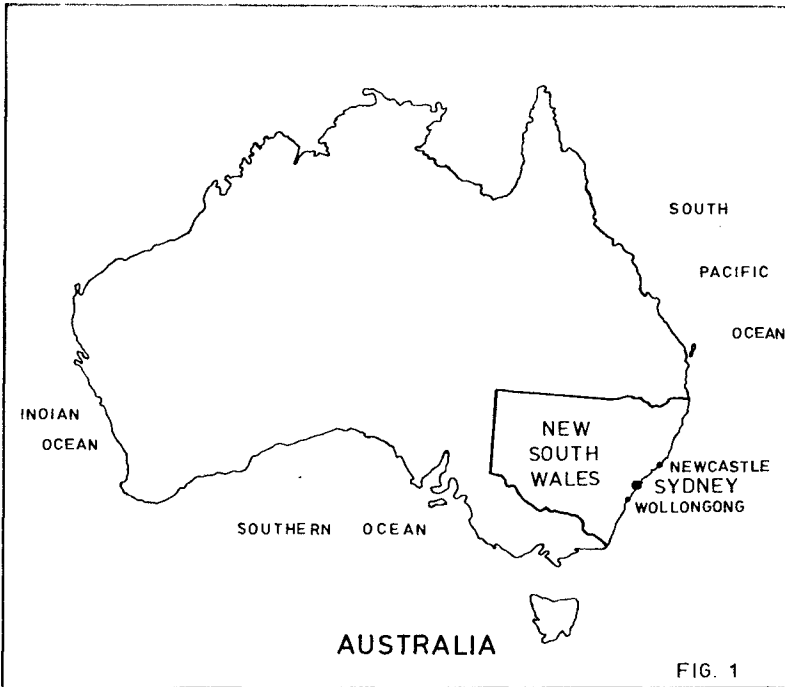

FIG. 1

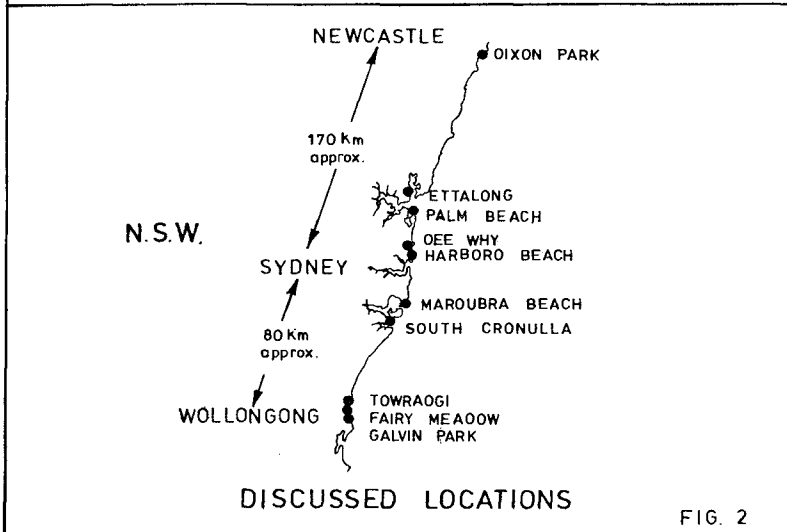

FIG. 2

Given this high potential demand on the recreational resources of the New South Wales coast and the later documented evidence confirming the suspicion that the New South Wales coastline is receding, the State Government, four years ago, introduced the Beach Improvement Programme.

3. BEACH USAGE

Although it is obvious that the population density along the New South Wales coast is low when compared to the European or U.S. situation, usage of beaches for recreation is encouraged by the climate, the availability of the free beach resource and the high mobility of the community.

A study of the accessibility of beaches to the population of the Sydney region (approximately 2.8 million in 1976) (Whaite, 1979) provides a measure of the potential customers for beach usage in that region. This study utilised travel times from the Sydney Area Transportation Study (1974) and Australian Bureau of Statistics population data (1977).

Table 1 indicates how close the regions population is to an ocean beach.

TABLE 1 : MINIMUM TRAVEL TIMES TO A SYDNEY BEACH
FOR PERCENTAGE OF REGIONS POPULATION

Travel times (mins.)	30	60	120
Percentage of population taking less than travel time	21	59	97

A more detailed study at a relatively inaccessible beach in the region (Palm Beach) reveals that 72% of all users at this beach come from local government areas which are not coastal and that only 13% of users are local residents. It is also interesting to note that 5% of users travel for more than two hours. This fact is related to the particularly scenic location of this beach.

This example illustrates how local government Councils have beaches accessible to large populations from outside their areas of responsibility. Local government is responsible for the upkeep of the beaches. The need for some State involvement in improvement work at beaches with high usage is apparent. Thus the Beach Improvement Programme, by offering grants to local government for beach works, has helped to distribute the burden of upkeep of this valued recreational resource.

4. PROGRAMME MANAGEMENT

Expert technical input to investigation and/or design of projects can come from the Department, the State Soil Conservation Service or consultants. The Department provides coastal engineering and/or landscape architectural expertise, the Soil Conservation Service provides dune stabilisation expertise, and the consultants, where used, provide coastal and structural design or architectural expertise.

Local councils initiate proposals and carry out the works. In an advisory capacity at the proposal stage, the Department has conducted a number of beach management studies in which a beach system has been examined, overall beach management strategies have been formulated and improvement works recommended.

5. MANAGEMENT STUDIES

5.1 Dee Why Study

In 1977 the Department carried out a proto-type Coastal Management Study at Dee Why, a beach situated in Sydney's northern beach region. The Dee Why area was an obvious choice for a proto-type study as a large amount of research into the local coastal system was available from studies undertaken by various government authorities and the three Universities in Sydney.

The area is interesting for study purposes as it consists of a lagoon/beach system which is relatively common along the New South Wales coast. Further, the area is surrounded by urban development and the resulting pressures of human activity highlight the need to develop appropriate management strategies.

The management study proposed a number of alternative strategies, namely:

1. 'No Nothing' Strategy
2. Minimum Management Strategy
3. Desirable Management Strategy
4. Back to Nature Strategy

The Beach Improvement Programme has funded works which are contained in the Desirable Management Strategy. The works include dune stabilisation and reno-mattress training works at the lagoon entrance designed to stabilise the lagoon breakout zone.

This is an example of how the Beach Improvement Programme by providing financial incentives, has encouraged local councils to consider various management options available for coastal areas and make decisions that will improve an area's capacity to withstand future usage and natural forces.

5.2 Maroubra Beach Management Study

The Maroubra Beach Management Study (D.P.W., 1978) employed the combined expertise of coastal engineers and landscape architects from the Department, and consultant architects.

During the study, interviews were held with all authorities having an involvement with the beach and with members of the public who use the beach. These interviews, subsequently interpreted by the varied expertise possessed by the study personnel, and combined with the latter's observations, identified a number of problems existing at the beach and works solutions were recommended where appropriate.

The major recommendations were :-

- revised landscaped parking scheme and new landscaped area linking the major beach buildings
- the reconstruction of the existing pavilion to house a kiosk; new change rooms and beach inspectors room and paved terrace areas
- stabilisation of dune system with a programme of fenced plantings and access ways over an area measuring 50 metres wide by 400 metres long.

Many aspects were examined to reach appropriate conclusions regarding management of the beach and recommendations on improvement works. Aspects studied included beach behaviour, beach management, visual character, parking and general access, vegetation and services proved to the public.

The dune stabilisation recommendation has been implemented and landscaping work will commence shortly.

6. PROJECTS

6.1 Dixon Park Project

Dixon Park Beach (D.P.W., 1978) is part of a small embayment approximately 1 kilometre long, bounded by a minor headland to the north and a headland to the south.

The objectives of the project were as follows:-

- (i) Restoration of the beach amenity in the form of a large beach area.
- (ii) Erosion control in the form of revetment construction.
- (iii) Improved access by way of steps, paths and boat ramp.
- (iv) Provision of amenities such as picnic area.
- (v) Beautification such as grassing, shrubbery and aesthetic restoration.

The design of the revetment used the basic Hudson's formula approach but the usual secondary under layer of rock was not used as the slag fill behind contained material of this size. This also reduced the number of steps required in the construction procedure. The armour stone was keyed into firm material at the toe.

6.2 Beach Nourishment Projects

The programme has been and is currently involved in a number of beach nourishment projects.

Nourishment of South Cronulla Beach, the most southerly major beach in the Sydney region (Foster, Gordon, 1978) involved the placing of some 130,000 cubic metres of sand onto the beach berm in two stages commencing in July 1977 over 3 months and again in May 1978 over a further 3 months period. The local Council undertook the work which involved trucking from the sand source, a major transgressive dune system some three kilometres north of the beach.

Another beach nourishment project currently in progress is at Ettalong Beach an estuarine beach north of Sydney. Delay of commencement to that project was necessary to avoid interference with summer holiday recreational activities. This project is a consequence of a Departmental Report (Ray, Hoffman, 1978) which proposed so called 'soft' management techniques to restore 'natural' sand circulation in the estuary. The borrow area is a shoal within the estuary and a dredge is being utilised to move some 60,000 cubic metres of sand to nourish the beach and nearshore channel.

In both the above projects monitoring programmes are being undertaken to gauge the success of the works and provide information for any future works of this nature in both ocean and estuarine environments in general and of the needs for periodic nourishment in the actual works location.

6.3 Wollongong Region Projects

A beach system where a number of works have been constructed is situated near Wollongong.

Terminal revetments have been constructed at Towradgi and Galvin Park to protect recreational amenities at each end of the embayment, and in between dune stabilisation is under construction from Fairymeadow to Towradgi.

The terminal revetment at Towradgi and Galvin Park are of Reno mattress construction, and as such are world leaders in the application of this structure in a wave climate as severe as is experienced on this section of the Australian coast.

Mattresses were selected both for economic reasons, and as a trial structure to assess their effectiveness. Aesthetic treatment of the revetment has been provided by sand cover planted with marram grass. Board and chain walkways provide access over the structure onto the beach.

Along the shoreline between these two structures, is several kilometres of dune stabilisation work. Where necessary, sand in the hind dune area has been excavated and placed in the frontal dune area to rebuild a continuous and effective frontal dune system.

To reduce costs, marram grass has been planted by mechanised methods, and the entire frontal dune area has been fenced, with access ways at appropriate locations.

6.4 Eastern Suburbs Beaches

Beaches in Sydney's eastern suburbs (the coastline from Sydney Harbour to Botany Bay), surrounded by urban developments, attract high user concentrations. The beach accessibility study (Whaite 1979), showed that these beaches are the most accessible to the greater proportion of Sydney's population.

The involvement of the Beach Improvement Programme in this region to date has been in the form of landscaping and beautification such as the financing of retaining walls, turfing, shrub plantings and irrigation systems. Landscape architecture input has been used to guarantee high aesthetic standards and to ensure selection of plant species tolerant to the harsh foreshore climate.

6.5 Harbord Project

Harbord Beach on Sydney's northern beach region provides an example of how the Beach Improvement Programme has funded a variety of works at one site. The original proposal from the local council formed the basis for discussions between council staff, the State soil conservationists and Public Works' coastal engineers and landscape architects. The resulting final design represents a major change in the previously degraded character of the beach and surrounding area.

The works have rebuilt sand dunes, re-organised parking by providing limited asphalt spaces with grassed overflow areas and have diverted drainage lines.

Although this beach was not subject to a formal Beach Management Study, the multi-disciplinary approach produced the integrated nature of the components which constituted the final design. Major schemes of this nature, or works forming part of a major scheme are proving to be the most successful projects in improving the beach amenity.

6.6 Cost of Works

Table 2 summarises the costs of a number of works discussed. A cost of works per metre of coast is included to enable some comparison between the different types of works.

TABLE 2 : BEACH IMPROVEMENT WORKS : COST COMPARISONS

Project Location	Type of Work	Total Cost A\$(x 1000)	Cost per Metre (A\$/m)
Dixon Park	Rubble revetment	275	1100
South Cronulla	Sand nourishment	250	600
Towradgi and Galvin Park	Reno-mattress revetment	350	800
Fairymeadow/ Towradgi	Dune reshaping and stabilisation	100	75
Maroubra	Dune stabilisation	60	100
Harbord	Dune re-building and stabilisation	60	200

7. CONCLUSIONS

In the four years since the commencement of the Beach Improvement Programme works at over thirty sites have been undertaken. A trend has developed towards a total scheme concept where beach preservation/restoration works, such as dune stabilisation or beach nourishment, are complemented by provision of back beach amenities, such as landscaped and car parks areas. The use of management studies to define management options, utilising knowledge of the local coastal system, has proved of great benefit by providing a basis for discussion concerning an area's possible development which ultimately results in preparation of beach improvement proposals suiting their environment and acceptable to the public.

EDDY CURRENTS AND SEDIMENT TRANSPORT OFF THE DAMIETTA NILE

S. P. Murray, J. M. Coleman, H. H. Roberts, and M. Salama*

Coastal Studies Institute, Louisiana State University

Baton Rouge, Louisiana 70803, U.S.A.

Abstract

Current meter observations indicate that a trapped eddy with a high-speed outer limb is formed downcurrent of the Damietta Nile promontory. This eddy is instrumental in the formation of the highly mobile sand body that extends seaward from the Damietta mouth, out onto the shelf, and curves back toward the coast just east of the Suez Canal entrance. Orientation of sand waves along the sand belt mirrors the direction of current flow within the eddy and indicates that the zone of reattachment of the separation streamline is located to the east of the Suez Canal. Dissipation of this sand belt will likely result in increased coastal erosion locally.

*Coastal Protection Branch, Institute of Oceanography and Fisheries, Academy of Scientific Research and Technology, Alexandria, Egypt

Introduction

Between September 1964 and October 1966 the monthly discharge from the Nile River decreased by an order of magnitude, from $1.9 \times 10^{10} \text{ m}^3/\text{month}$ to $4 \times 10^9 \text{ m}^3/\text{month}$, as a result of the closure of the High Dam at Aswan. The corresponding decrease in sediment brought to the coast resulted in the marked acceleration of an already serious coastal erosion problem and the transition of the inner shelf from one dominated by riverine processes to one dominated by marine processes, i.e., waves and currents. The resulting erosion problems along the entire coast fronting the Nile Delta have been the subject of exhaustive studies originally sponsored by the United Nations and continued under the auspices of the Academy of Scientific Research and Technology (ASRT), Cairo. For extensive summaries see UNDP (1976, 1977). These studies emphasized changes in beach morphology as an indication of coastal retreat and relied heavily on large-scale oceanographic cruises (e.g., Summerhayes and Marks, 1976) and reinterpretation of earlier shelf sediment surveys (Misdorp and Sestini, 1976) for knowledge of sedimentation on the adjacent shelf.

Because of wartime conditions, access to the shelf by the U.N. project was greatly restricted, and, according to Nielsen (1977), essentially prohibited east of the Damietta promontory. Accordingly, the start of a joint United States-Egyptian bathymetric resurvey in 1978 of the continental shelf from Damietta eastward past Port Said, at the Suez Canal entrance (Fig. 1), presented an excellent opportunity to further our understanding of the physical processes and sediment transport active in this area. A combined team from the Coastal Studies Institute and the Institute of Oceanography and Fisheries, ASRT, Cairo, was provided space and logistical support on the survey ship U.S.N.S. Harkness to carry out scientific studies of the currents and bottom sediment behavior. The most conspicuous geomorphic features along the coast of the delta are the large promontories or cusped capes at the mouths of both the Rosetta and the Damietta branches. As earlier work (e.g., Murray and Wiseman, 1976) had documented the intermittent presence of a large eddy downstream (west) of the Mississippi delta promontory, it was suspected that the Nile capes might also exert a significant influence on the local current field. A similar suspicion was voiced by Misdorp (1977) to explain the sand distribution east of the Damietta promontory. Thus current observations were concentrated immediately downcurrent or eastward of the Damietta promontory.

In this report we shall emphasize the results of the current studies and the interaction of currents with the bottom. A brief review of physical processes in the local area will be followed by a discussion of the current velocities, temperatures, and salinities obtained during our measurement program. The current velocity field will be shown to have a highly coherent spatial structure intimately related to the geometry of the Damietta promontory. A composite model of the current field constructed from theoretical, experimental, and numerical studies will then be compared to both the observed current field and the observed patterns of sediment movement. The presence of a mesoscale eddy trapped in the lee of the Damietta promontory and its strong control on bottom sediment transport is established, and its implications on the future of the coast between Damietta and Port Said are discussed.

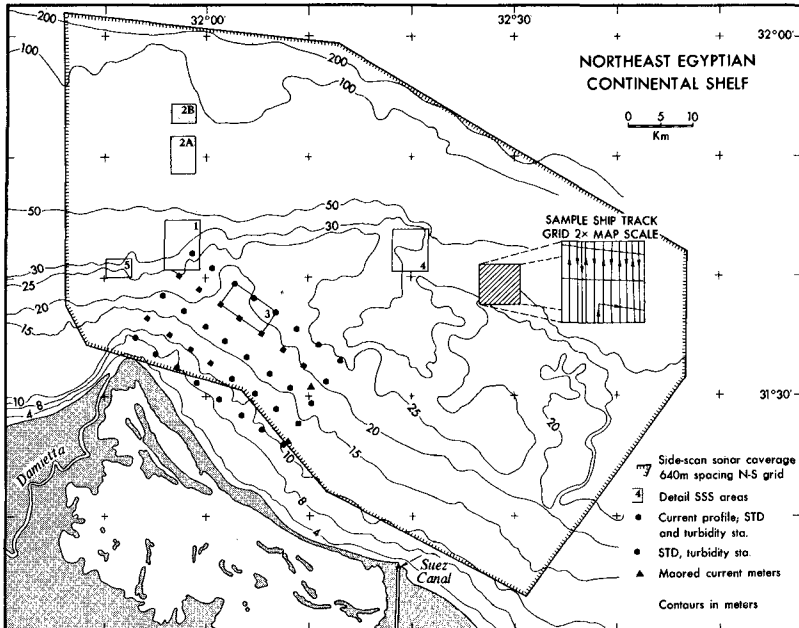

Figure 1. Location map of study area off the Damietta branch of the Nile River. The inset shows a survey grid typical of those carried out over the entire area.

Background Processes

The average properties of winds and currents are obtained from the data archived at the U.S. National Oceanographic Data Center (Fig. 2). A good correlation is clearly seen between the wind direction and the current direction. The modal wind direction is clearly to the southeast from May through October. A strong secondary peak of winds blowing toward the northeast is present from December through March. Both of these winds, with east-going components, can be seen to produce east-flowing currents in the Damietta-Port Said area. Other peaks of wind direction, to the southwest in April-May and October-November, are seen to reverse the dominant current drift to the east and drive the surface currents westerly. Representative background current speeds from this data set are seen to be 15-20 cm/sec.

Direct observations of currents along the Nile Delta coast are discussed in Manohar (1976); Manohar et al. (1977); and Tebelius (1977). Unfortunately, again for security reasons, these measurements were

Figure 2. Percentage distribution of current speed and current direction throughout the year for the Port Said 1°-square from NODC data. Percentage distribution of wind direction throughout the year at Port Said from the Sailing Directions.

restricted largely to the surf zone. Manohar (1976) did show current speeds up to 600 m from shoreline in water depths of 2-4 m to reach 30-40 cm/sec, but he noted that these data were as yet unanalyzed. Tebelius (1977) presents a discussion of a current measurement program in Abu Quir Bay, near the mouth of the Rosetta Nile, but, as with Manohar's data, these results do not apply to the inner shelf (10-30 km offshore), which is the focus of this paper.

Perhaps the best source of modern data on the background drift current along the Egyptian Mediterranean coast is Gerges (1978). Analysis of the return data from Woodhead surface drifters released monthly for 18 months in 1976 and 1977 (total of 2,664 drifters) indicated a general easterly drift of 10-15 cm/sec. The May 1977 drifter returns clearly showed the intermittent westerly setting current reversal suggested in Figure 2.

Physical Oceanographic Measurements

Data were collected through the 40-station grid along lines normal to the coast (034° M), moving west to east (Fig. 1). Current meter profiles requiring an anchor station were restricted to the outer, middle, and inner stations on each line; all stations also included a vertical profile of salinity, temperature, and turbidity. Thirty-eight of the forty stations were occupied in the 6-day interval 29 April - 4 May 1978, during which period winds always had onshore components blowing from NNW to NE at 5-10 m/sec.

The current meter profiles at the anchor stations which are of principal interest here were taken from a 12-m-long LCVP, which, while open and rough-riding, proved to be an excellent vehicle for the current studies. Even in light winds the boat swing at anchor was minimal, and good current

data were the rule. The current meter used was a Marine Advisors Q-15 ducted impeller meter with a bidirectional sensing capability designed to mechanically and electronically filter out "noisy" wave motion. A Plessey STD Model 9060 gave in situ measurements of salinity and temperature with a 20-40 ppt salinity range. Wind velocities were measured on the Harkness and LCVF, but the most reliable data were obtained from the Suez Canal Research Center at Port Said.

In addition to the spatial coverage of the current field provided by the anchor stations, two current meter moorings equipped with acoustic releases were installed at the eastern end of the grid, as shown in Figure 1. Each mooring had two Marine Advisors Q series meters in line which had the same response characteristics as the Q-15 profiling meter described above.

Station data. The complete data set on the current field obtained from the anchor stations is presented in Figure 3. Stations on the western most line (1-5) reflect the expected background easterly drift current, but note the unexpectedly strong (~30 cm/sec) surface layer currents at the outer two stations (1 and 3). Also note the sharp deceleration in current speed from station 5 to station 6, which were taken within 1 hour of each other at a time of steady northerly winds. On the following day (30 April) stations 10 and 11, only 4 km apart and taken within 90 minutes of each other, show extreme horizontal current shear. Station 11 is particularly remarkable; speeds of 40 cm/sec throughout the water column from the surface to the bottom were directed seaward essentially against a weak north-northeasterly wind of 2-3 m/sec on that day. It appears likely from the stations that this seaward-directed high-speed zone is only 1-2 grid units (4-8 km) across.

Four stations on the middle and inner lines (13, 15, 16, 18) were next occupied, on 1 May. All four showed a westerly directed current of 10-15 cm/sec against the regional drift, which cannot be accounted for by the weak winds of that day. Clearly a convergence or zone of stagnation exists in the area between stations 6-8 and 13-15. On 2 May the apparently narrow jet of seaward-directed high speeds was again penetrated by stations 21 and 23. It was extraordinary to note the entire water column moving seaward at speeds in excess of 50 cm/sec. The great difference in speed and direction between stations 20 and 21 and between 23 and 25, each taken within 90 minutes of the other, strongly indicate a relatively narrow, highly coherent local circulation system. It appears that the high-speed zone had migrated from the vicinity of station 11 on 30 April, easterly to the vicinity of station 21, 2 days later, on 2 May.

The remaining stations, all located outside the zone of strong seaward flow, must be examined carefully for wind-driven effects in the surface and mid-depth layers. For example, at the shallow nearshore stations (e.g., stations 26, 35) and at deeper stations outside the high-velocity jet, where the speeds are generally lower (e.g., stations 30, 31), the onshore surface layer currents clearly result from local wind driving. In contrast, the remarkably strong seaward motion near the bottom, directed toward the high-speed zone at stations 28 and 33 and again at 26 and 35, indicates that the forces driving the circulation pattern are barotropic, i.e., they extend throughout the water column down to the bottom, where

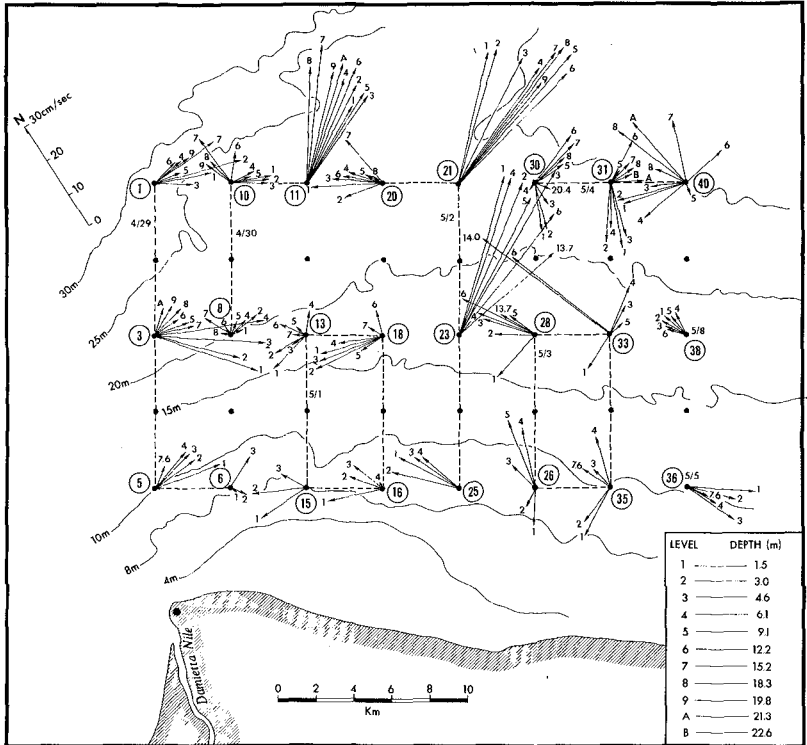

Figure 3. Vertical profiles of current velocity at each grid anchor station. Depth of observation is coded by a level number or letter except where actual depth is stated in metres. Stations occupied on same day are connected by a dashed line.

they overpower the frictional forces associated with wind driving.

Salinity, temperature, and velocity cross sections. Considerable insight into the spatial pattern of the flow field is also obtained by inspecting hydrographic sections. Two offshore lines that were completely covered in 1 day are shown in Figures 4 and 5, the westernmost section off the Damietta promontory and the central section through the core of the offshore jet, respectively. In the Damietta section (Fig. 4A) the along-shore speed component (parallel to the grid) shows a distinct offshore jet with a surface maximum of 25-30 cm/sec located 15 km offshore. Alongshore speeds decrease monotonically with depth. The cross-shore speed component is directed onshore (negative values) only in a shallow near-surface prism in the center of the section. The bulk of the section has offshore components reflecting the shunting of the background flow seaward by the curvature of the Damietta promontory. The salinity values of about 38 ppt are typical of the eastern Mediterranean but are interesting in that they still reflect coastal drainage by slight increases of a few tenths parts

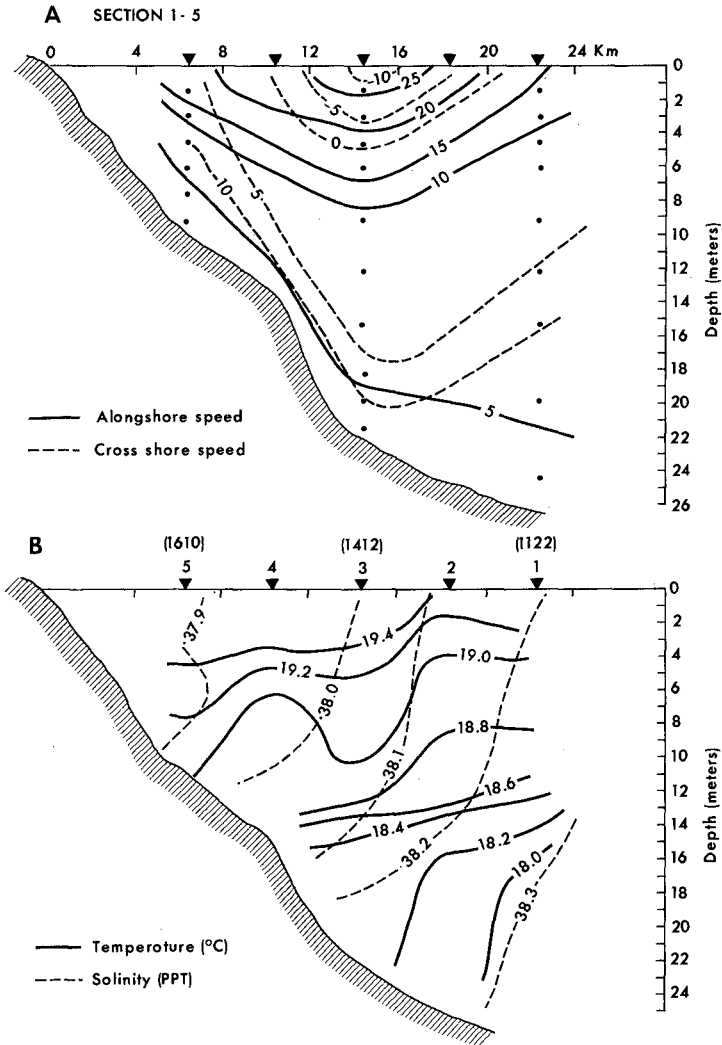

Figure 4. A, alongshore and cross-shore current speed components and, B, salinity and temperature distribution along the cross-shore line through stations 1-5 on 29 April 1978. Cross-shore speeds are positive offshore; alongshore speeds are positive downdrift or to the southeast. Time station was occupied is given above station number.

per thousand both with depth and in the offshore direction. The temperature distribution in Figure 4B shows a thermocline at the 12-14-m depth.

Only 3 days later the section through stations 21-25 (Fig. 5), taken 16 km downcurrent (southeast), is in marked contrast to the picture along the Damietta line (Fig. 4). Here the cross-shore speed is the dominant component, showing offshore (positive) values across the entire section, with a maximum of over 40 cm/sec located 16 km offshore. Continuity, of course, demands an inflow somewhere to supply the volume transported offshore in this jet. Equally instructive is the alongshore speed component. Seaward of station 24 (11 km offshore) the flow is entirely downcurrent or southeasterly, while shoreward of this mark the flow is entirely upcurrent or northwesterly. Here, then, is the inshore return flow to resupply the jet. The water temperatures here (Fig. 5B) are consistently higher, by as much as 1-2°C, than in the Damietta section, nicely reflecting the inshore origin of the jet water. The salinities, however, remain a puzzle, requiring further analysis to understand why high salinities (38.2-38.3) characterize the warm offshore jet.

Combining knowledge of the background drift current from the literature with our own current observations (Figs. 3, 4, 5), we can infer a streamline pattern for the flow field around the Damietta promontory, excluding wind effects on the surface layer, as shown in Figure 6. The easterly background longshore flow of 15-20 cm/sec is shunted seaward by

Figure 6. Streamline pattern interpreted from interior layer currents shown on Figure 3. Note narrow zone of high speed exiting seaward edge of grid.

the curvature of the Damietta promontory. Flow separation takes place several kilometres downstream (eastward) of the river mouth and induces a seaward-flowing high-speed jet as the northern limb of a topographically trapped eddy. A broad, slow northwesterly return flow forms as the southern limb of the eddy. The separation streamline must, of course, return to the coast somewhere downstream and form another stagnation zone of divergent currents flowing westward to feed the eddy and eastward to reestablish the background drift current.

A laboratory visualization (Prandtl and Tietjens, 1957) of the type of eddy we believe forms in the lee of the Damietta promontory is shown in Figure 7. The upward (seaward) shunting of the background flow, the high-speed jet, and the inshore return flow are all present, but of course we expect the natural scale eddy to be more elongate alongshore and diffuse due to the gentler angles involved.

Moored current meters. Figure 8 is an example of the current meter data obtained from the outer mooring (Fig. 1). The temporal behavior of the current velocities at these two levels are consistent with the interpretation of the current structure based on the station data. Note that between 27 April and 1 May the upper level currents are generally weaker than the deep currents, except for two short-lived events apparently asso-

ciated with wind decelerations at 0400 on 28 April and a wind acceleration at 0600 on 29 April. The deeper currents are persistently more energetic, generally showing an upcurrent or north to northwesterly motion toward the narrow zone of strong seaward flow, thus again indicating the influence of the circulation of the trapped eddy on the currents below the wind-driven surface layer. It is probable that the sudden episode of strong, persistent currents at the upper level on 1 and 2 May reflect the increased influence of the eddy as it migrated southeasterly toward the mooring on 1 and 2 May, as suggested by the station data of Figure 3.

The data from the inner current meter mooring is heavily influenced by accelerations and shifts in the wind. Further analysis will be necessary to establish any relationship between these meters and the eddy circulation system. As anticipated, the current meter records show the tidal current to be on the order of only 5-8 cm/sec, and thus the lack of synopticity of the station data does not seriously disturb the inferred flow field of Figure 6.

Bottom Morphology--Side-Scan Sonar

While performing its primary mission of a detailed bathymetric survey, the Harkness towed side-scan sonar (SSS) over the 4,450 sq km of the Egyptian shelf outlined in Figure 1. The survey grid consisted of north-south track lines spaced at 650 m with a side-scan scale of 400 m (total swath width was 800 m), giving a 150-m overlap on each adjacent line. While these SSS data were taken to assist the bathymetric survey, experienced users can interpret morphologic features, sediment type, and sediment mobility from the same data. Our results from such an interpretation are shown in Figure 9.

After mapping of bottom morphology from the SSS data taken by the Harkness was completed, several areas of special interest in differing types of shelf morphology were chosen for a more closely spaced survey grid with a higher resolution range on the side scan (detail areas 1-5, Fig. 1). In these regions the line spacing was 150 m, with a swath width of 200 m set on the side scan, giving a 50-m overlap on each line. In addition, bottom samples were collected within each area to assess the sediment type composing each morphologic unit. Thus this survey allowed coverage of a large shelf area in greater detail than any other previous survey of the eastern Nile shelf.

Perhaps the most exciting discovery from these data was the presence of a broad sand belt extending from off the mouth of the Damietta eastward and finally curving landward along the eastern boundary of the survey region in the vicinity of the Suez Canal (Fig. 9). This sand belt lies in water depths of 25 to 60 m, and the belt ranges in width from 5 to 20 km. This belt consists typically of large sand ribbons which display small migratory sand waves and fields of large-scale migratory bedforms or sand waves. These features are similar to the sand ribbons described by Kenyon (1970) in European tidal seas, Kenyon and Belderson (1973) in the Mediterranean, and Swift and Ludwick (1976) on the east coast of the U.S. While the major morphologic features forming on the sand belt are the sand ribbons, there are areas where large patches of sand waves are present. Figure 10 shows the detailed mapping of area 1 (see Fig. 1 for location)

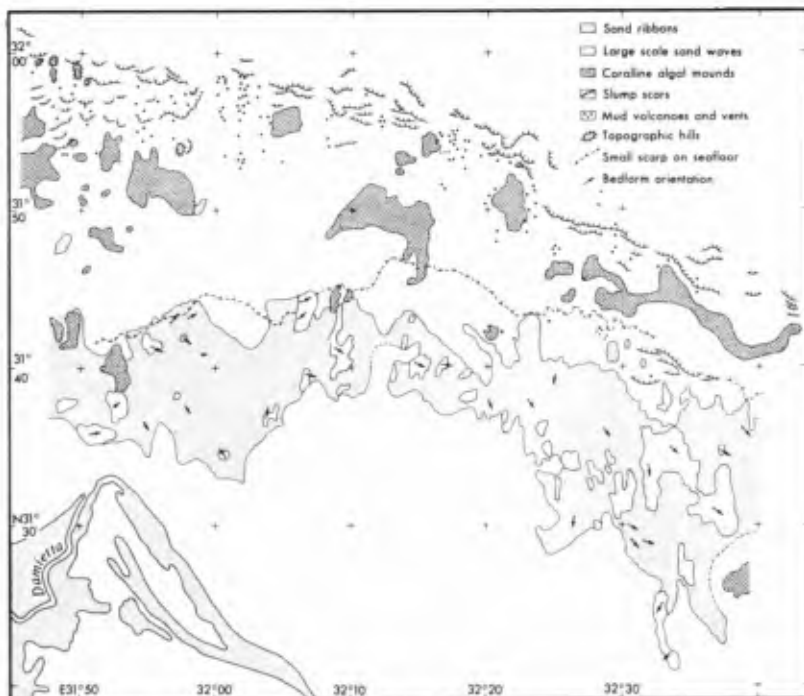

Figure 9. Bottom morphology of the Nile shelf as mapped from side-scan sonar data. Small arrows give direction of movement as determined from bedform orientation.

within the sand belt. Notice that the sand ribbons vary in size considerably, ranging from 150 m wide and 1 km long to much larger, 1-2.5 km wide and 10-18 km long. The sand ribbons display heights above the general sandy silt sea bottom that range from less than 2 m to 10 m. Small-scale sand waves are often found on the ribbons, especially on the larger features, where the ribbons obtain some elevation above the bottom. The sand waves normally display crest lines that are generally perpendicular to the long axis of the ribbons.

Figure 11 is an enlargement of actual side-scan data taken from a sand wave field on one of these ribbons. The sand waves are seen to be about 50 m long and 3-5 m high. Clearly, strong, persistent currents are necessary to mold the bottom to this condition. Utilizing the side-scan sonar data, the orientation of the various bedforms could be mapped, and these are shown on Figure 9. Near the Damietta distributary the bedforms show a general NNW orientation and near the seaward edge swing toward the

Figure 10. Detailed morphology of sand ribbons and sand waves moving over a mud bottom in area 1 (see location on Fig. 1).

east and ESE. In the central part of the sand belt the bedforms show a general east and southeast direction of sediment migration. Along the easternmost edge of the study region the bedforms display a general southern or toward-shore migration pattern. Note also in this area that there is a large accumulation of sand, and the contour map (Fig. 1) shows the presence of a large shoal just east of the Suez Canal. It is highly probable that this sand migration pattern has been responsible for the sediment accumulation in the Suez Canal region. The pattern of sand wave

movement certainly appears to be with the eddy current structure inferred from Figure 3. This will now be examined in more detail.

Model of Eddy Circulation East of Damietta

Fluid flow around obstacles is a frequent topic for laboratory experimentation in hydro- and aero-dynamics. The experimental results from flow around flat plates and blunt obstacles such as seen in Figure 7 have been used successfully in formulating models of flow separation, cavity (trapped eddy) formation, and return flow for design of nuclear reactor shells (Halitsky, 1968). Only recently have analytical and numerical techniques been successful in describing the air flow over hills. Jackson and Hunt (1975) presented an analytical treatment of the velocity field over gently sloping hills, while Mason and Sykes (1979) recently described a numerical model which treated hills steep enough to produce flow separation.

The essential results of these three approaches, experimental, analytical, and numerical models, have been synthesized in Figure 12 and applied to the Damietta promontory, considered as an obstacle to flow. According to Jackson and Hunt (1975), the background flow U_0 approaching

Figure 12. Composite model of flow field around an obstruction, synthesized from experimental, analytical, and numerical studies.

the promontory is amplified into a free jet with a magnitude 2 to 4 times U_0 , located at a position above the obstacle equal to three-tenths of its height (H). Experimental work indicates that the cavity or trapped eddy will resemble an ellipsoid of revolution with a downstream dimension of at least $2.5-3H$ and a cross-stream dimension of $1.5-2.0H$. In the center of the eddy there will be a return flow of $0.6U_0$. The zone of high speed will follow the separation streamline deflected cross-stream by the obstacle. The essential features of these models were reproduced in the elegant numerical solutions of flow over steep topography by Mason and Sykes (1979).

In Figure 13 the basic geometry of the trapped eddy is compared to the current velocity observations and the sand body mapped by side-scan sonar. The zone of high-speed currents first identified in the station data is clearly the right magnitude and location to be on the seaward limb of the trapped eddy. The return flow along the coast at the inner line of stations also fits the model rather well. There can be little question that the high-speed outer limb of the eddy is interacting strongly with the bottom as the curvature of the inner shelf sand body follows the predicted axis of the eddy quite closely except at its eastern end. Far more striking is the agreement among the direction of movement of sand waves shown on the figure, the observed current velocities, and the current speeds and directions expected from the flow separation-trapped eddy model.

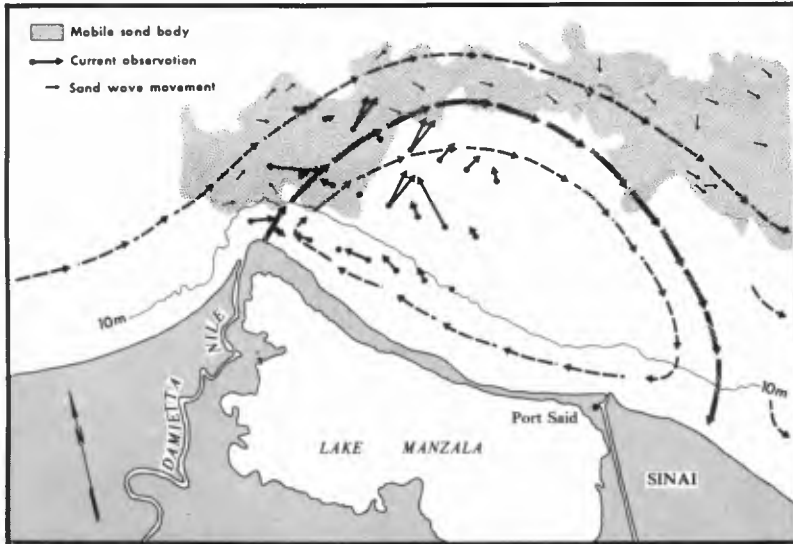

Figure 13. Observations of currents and sand wave movements compared to the composite model of a trapped eddy shown in Figure 12.

Implication to future coastal erosion. The coastline between the Damietta promontory and the Suez Canal is already undergoing severe erosion (Nielsen, 1977). As closure of the Aswan High Dam has cut off the input source of sand for the sediment transport system driven by the Damietta eddy, we expect the arcuate sand ribbon belt to gradually consume itself. The tail or western boundary of the sand belt will migrate easterly due to lack of replenishment, and the height of individual sand ribbons will gradually lessen as the arcuate sand belt dissipates, allowing increasingly higher levels of wave energy to impact the coast, accelerating the erosion rate.

Summary and Conclusions

The closure of the High Dam at Aswan on the Nile River markedly accelerated an already severe erosion problem along the Mediterranean coast of Egypt. In 1978 the U.S.N.S. Harkness, while performing a bathymetric resurvey of the shelf between Damietta and a line eastward of the Suez Canal entrance, obtained side-scan sonar coverage of the entire survey area. On the basis of these data a combined program of physical oceanographic and marine geologic measurements was made at a much finer resolution in an area immediately east of the Damietta Nile promontory and leads us to the following conclusions.

1. A seaward-directed jet of high-speed current 4-8 km across forms

off the Damietta promontory and shoots out northeasterly against the prevailing wind. Flow separation occurs a few kilometres east of the vertex of the promontory.

2. A broad, slow return flow to the northwest forms in the shallower waters along the coast. This return flow is highly influenced by the local wind.

3. These two zones are elements of a mesoscale (~50 km) eddy trapped in the lee of the promontory.

4. The spatial and velocity characteristics of the eddy are consistent with a composite model of eddies induced by flow separation based on analytical, numerical, and experimental studies. Further observations of the temporal and spatial behavior of such an important feature are clearly warranted.

5. Detailed side-scan sonar surveys of bottom morphology indicate that the eddy is underlain by a highly coherent, mobile sand belt that extends about 50 km downcurrent (east). Orientation of sand waves reflects the measured currents in the eddy and indicates that reattachment of the separation streamline occurs about 10 km to the east of the Suez Canal entrance.

6. As a principal source or input of sediment to the eddy driven sand belt was shut off by the closure of the Aswan High Dam, we expect the relief on the sand belt (up to 10 m) to diminish gradually, allowing greater wave energy to impact the coast, thus aggravating the local erosion problem.

Acknowledgments

We gratefully acknowledge the highly capable assistance of the officers and men of the U.S.N.S. Harkness during the work at sea. Captain J. R. McDonell, Dr. William E. Hart, and Mr. Dodd Ouellette of the U.S. Naval Oceanographic Office, Commander William Friskin of the Royal Navy, and Dr. James Bailey of the U.S. Office of Naval Research provided essential assistance in our utilization of the Harkness. Drs. A. R. Bayoumi and A. A. Khafagi, of the Academy of Scientific Research and Development, Cairo, arranged cooperative efforts with the Egyptian scientific community. The Port Said wind data were supplied by Dr. M. El Ghamry of the Suez Canal Research Center. This work was carried out under a contract between the Coastal Sciences Program, Office of Naval Research, Arlington, Virginia 22217, and Coastal Studies Institute, Louisiana State University.

A Comparison between Dredge Induced Sediment Resuspension and that
Produced by Natural Storm Events

W. Frank Bohlen

University of Connecticut
Avery Point
Groton, Connecticut
U.S.A.

Abstract

Field observations indicate that the effect of dredge-induced resuspension on sediment transport within small estuaries is generally negligible in comparison to the transport induced by natural storm events. Data obtained in the Thames River, near New London, Connecticut show dredge-induced resuspension to be essentially a near field phenomenon. The resultant plume of material increases total suspended load in the river by approximately 25% but extends over less than 2.5% of the total estuarine area. In contrast storms are observed to increase total suspended load by a factor of three, influencing concentration levels throughout the estuary. These factors, in combination with the lower frequency of dredging vis-a-vis significant storm events, appear to effectively limit the influence of dredge-induced resuspension.

Introduction

During the past ten years dredging operations intended to maintain the viability of navigable waterways within the northeastern United States have often been surrounded by intense environmental debate. These coastal areas typically contain sediments contaminated by a variety of organic and inorganic pollutants and concerns have centered on both the short and long-term biological impacts associated with dredge-induced resuspension and disposal related dispersion of these materials. In many cases these concerns have served to slow project completion, forcing rescheduling and, on occasion, have provided a basis for legal injunctions, completely blocking further dredging.

Unfortunately, many of the above activities have proceeded despite the absence of hard data. This has been particularly true for the case of dredge-induced resuspension where, until recently, essentially no information has been available detailing the characteristics of the downstream plume of materials or the significance of this source of suspended sediments vis-a-vis naturally occurring storm events. Within the past three years this situation has improved to some extent and several investigations have been conducted providing insights into the factors governing the distribution of dredge resuspended sediments and the spatial extent of the resultant plume (Bohlen, 1978; Bohlen, et al., 1979). In addition, the increasing amounts of field data have also served to provide a basis for the development of predictive modeling schemes applicable to both clam-shell (Cundy and Bohlen, 1979) and hydraulic (Wilson, 1979) dredging operations.

The detail provided by the above investigations is sufficient also to permit an initial evaluation of the magnitude of dredge-induced resuspension relative to that produced by natural storm events. This paper presents the results of such an evaluation.

Study Area

Since 1974 the Thames River estuary (Fig. 1) located in southeastern Connecticut, approximately 120 km east of New York City, has been the site of several major dredging projects. This stream represents a typical small New England estuary. Annual streamflow varies between 70 and 76 m³/sec while the mean tidal range equals 0.78 m at New London. The combination serves to distribute sediments supplied from both upstream terrestrial and downstream marine source areas. Typically, these materials consist of fine sands and silts with minor fractions of clay. The effect of winds on these distributions in the estuary appears to be negligible.

Sediment deposition and the resultant shoaling requires periodic dredging to maintain the assigned depth of the navigational channel. Operations usually employ floating cranes equipped with large volume (10 m³) clam-shell buckets. Spoils are placed in hopper barges for transport to an offshore disposal site. The frequency of those operations over the past six years has provided ample opportunity to study the characteristics of dredge-induced resuspension.

Survey Methods and Procedures

The characteristics of the suspended material field within the Thames River have been the subject of intensive study since 1974. During 1974-76 surveys of a network of 12 stations (selected numbers shown in Fig. 1) were conducted monthly to determine ambient concentrations and the degree of spatial and temporal variability. At each station water samples were obtained at the surface, mid-depth and near bottom, using a 5 l Van Dorn bottle. Samples were placed in pre-washed and rinsed glass bottles and returned to the laboratory. By weight concentrations of total suspended solids were determined for each sample by vacuum filtration, using dried and preweighed Nuclepore filters (0.40 μ pore size, 47 mm dia.) mounted in a standard Millipore filtration apparatus. After careful washing to remove salts each filter was dried and reweighed. Surveys were, in general, confined to the ebb tidal cycle.

In 1977-78 primary emphasis was placed on determinations of the characteristics of the dredge-induced plume of sediments. Several surveys were conducted while the dredge operated near the northern limit of the study area (Fig. 1). The methods used in the surveys have been described in detail in an earlier paper (Bohlen, et al., 1979). Very briefly, optical techniques were used to define the limits of the plume and to establish a network of stations along the defined centerline. Sampling techniques employed at each station and the procedures used to determine the suspended material concentration in each sample were the same as those used for the large scale surveys described above. Here again surveys were conducted only during the ebb phase of the tidal cycle.

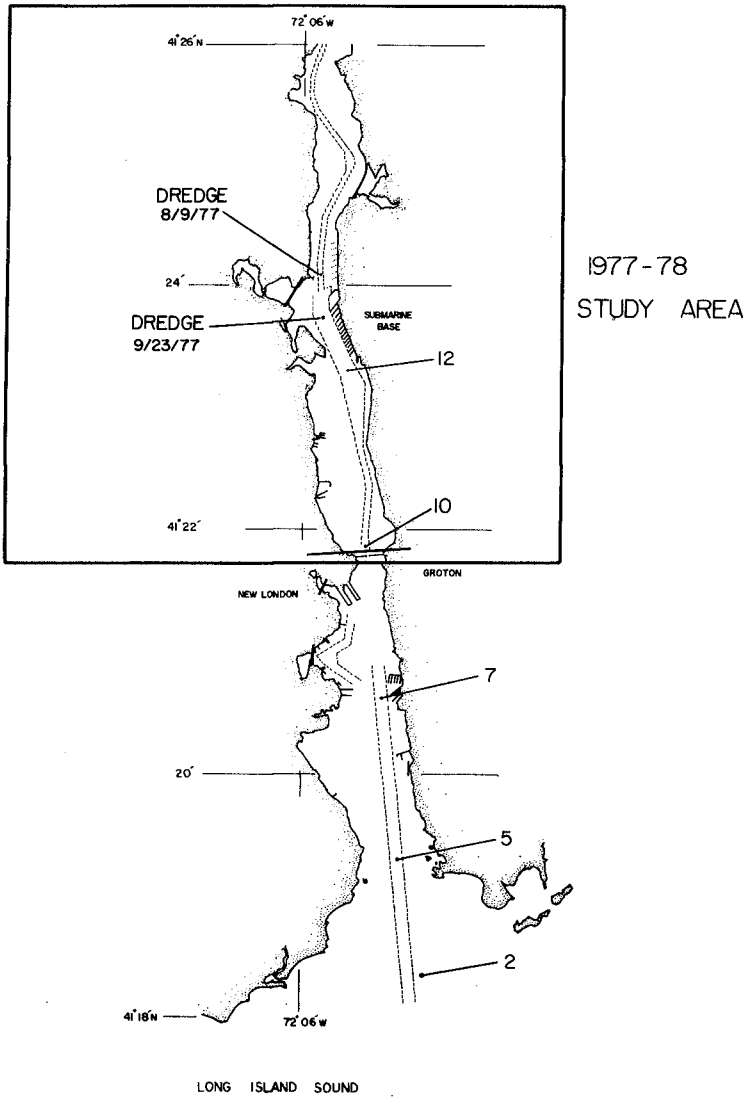

Fig. 1. Lower Thames River Estuary

Results and Conclusions

a. Storm induced resuspension: The suspended material field within the Thames River displays no well-defined seasonal variability (Fig. 2). At each of the main channel stations concentrations averaged between 4.0 and 5.0 mg/l during the major portion of the survey period and displayed only minor variations over the vertical.

The first major concentration anomaly, contrasting sharply with the otherwise persistent homogeneity, occurred on February 1, 1976 coincident with a major storm event. This storm, characterized by long periods (i.e., >24 hrs) of high wind stress and relatively minor precipitation, served to increase material concentrations within the lower river by a factor of four. Proceeding upstream, the magnitude of the increase becomes progressively less with concentrations simply doubling by Station 12. This trend implies that the observed increase is produced by an upstream transport of sediments resuspended by the storm within adjacent Long Island Sound rather than either local resuspension within the estuary or streamflow driven downstream transport. These latter factors would favor distributions differing sharply from that observed. Significant local resuspension tending to produce perturbations of similar magnitude at each station while streamflow dominated transport would favor upstream rather than the observed downstream maxima. This dominance of the offshore source area appears representative of the majority of coastal embayments in southern New England.

A second storm event occurred during March 1977. However, the resultant increase, despite similar storm intensity and duration, was substantially less than that observed during the February event and was largely confined to near bottom waters. Again concentrations decreased progressively with distance upstream further supporting the dominance of the offshore source area.

The response of the suspended material field in the Thames River to the events of February and March, 1976 indicates that storms have the potential to significantly increase the mass of sediments in suspension throughout much of the estuary. At concentrations of 5 mg/l, a reasonable background value (see Fig. 2), approximately 25×10^7 gr of sediment would be suspended in the estuary. The storm event of February 1, 1976 increased this load by approximately a factor of three to 75×10^7 gr. This was an estuary-wide increase and persisted for nearly two days, the duration of the storm. It is against this response that the effects of dredge-induced resuspension should be evaluated.

b. Dredge-induced resuspension: In contrast to the large scale effects of storms, dredge-induced resuspension appears to be essentially a near field phenomenon. Although the field surveys (Figs. 3 and 4) show that concentrations in the area immediately adjacent to the dredge exceed background by more than a factor of 40, values tend to decrease rapidly with distance downstream. Surface concentrations decay most rapidly and appear to reach background within 200 m downstream of the dredge. Mid-depth and near-bottom values are persistently higher than surface values and approach background within approximately 700 m downstream of the dredge. Under those conditions the surface area impacted by the dredge resuspended plume equals less than 2.5% of the total area of the estuary.

Fig. 2. Suspended Material Concentrations Thames River 1975-1976

Fig. 3. Suspended material concentrations along the centerline of the plume downstream of the operating dredge, August 9, 1977. (from Bohlen, et al., 1979).

Fig. 4. Suspended material concentrations along the centerline of the plume downstream of the operating dredge, September 23, 1977. (from Bohlen et. al., 1979).

Estimates of the mass of sediment contained in the dredge-induced plume cannot be simply realized since the field measurements were confined to the longstream axis and provide no indication of the cross-stream distributions and concentration levels. Using the optical data to define the plume width, a "worst-case" estimate can be developed assuming that the suspended material concentrations are constant across each lateral section. Using the observed centerline values to define the concentrations at each section, this approach indicates that the plume contains approximately 6×10^7 gr of sediment. Comparison of this value with the above estimate of total suspended load indicates that the dredge has the potential to increase the mass of sediment suspended in the estuary by approximately 25%. In terms of transport, however, these re-suspended sediments must be considered to be of negligible import since they settle rapidly affecting an extremely small area.

Discussion - Dredge vs. Storm Induced Resuspension

The above observations suggest that the effect of dredging on the suspended material field within the Thames River is generally negligible relative to that produced by naturally occurring storm events. The mass of sediment introduced by the storm exceeds that suspended by the dredge by nearly an order of magnitude. In addition the storm affects an estuary-wide increase whereas the dredge impacts an area representing less than 2.5% of the total river. Dredge effects appear to be further reduced by the characteristic frequency of occurrence of storms as compared to dredging. Reviews of the local meteorological data indicate that storms having an intensity similar to that of the February and March 1976 events can be expected to occur 1 to 3 times each year. Dredging, on the other hand, typically recurs at a rate of once every ten years or so. This combination of light sediment load, small spatial extent and low frequency of occurrence effectively limits the impact of the dredge resuspended plume on the local sediment system.

These conclusions, however, cannot be presented without some qualification. In particular, it's important to remember that this analysis concerns only the suspended sediment transport system and the relative effects of dredging and storms on that system. Although this system will also affect the local biological community and the variety of geochemical cycles, conclusions regarding its response to storms and/or dredging should not be applied haphazardly to these latter systems. The processes governing the interactions between sediment resuspension and the local biological community and geochemistry are clearly complex and require additional work. The above comparison is only intended to provide some initial physical insights to complement this work.

SEDIMENTATION IN CHANNELS AND TRENCHES

E.W. Bijker*

1. Introduction

In this paper the siltation in approach channels and trenches due to cross currents and waves is discussed. It is in this respect not necessary that the current crosses the channel at a right angle. When the current crosses the channel obliquely simply a greater distance over which the water flows over the greater depth is introduced. Deviations in the flow pattern - see figure 1 - due to the channel are neglected. When the flow pattern is known, either from measurements in nature or in model this effect can easily be introduced. The influence of the waves is introduced through the introduction of an increased bed shear and subsequently higher diffusion coefficient (see Bijker, 1971, [3]).

figure 1. Flow pattern.

Although computer programs are available to compute the siltation under the above described circumstances, an attempt will be made to come to a relatively simple method which enables a quick estimate of the siltation to be expected without the requirement of a big computer. This method could be especially usefull for the engineer in the field who has to make the first appraisal for the various solutions.

2. Basic equations

For the water motion a logarithmic velocity profile and a first order linear wave theory are applied. The vertical distribution of the suspended sediment is described by:

$$w c + \epsilon dz/dz = 0, \quad (1)$$

with w = fall velocity of the sediment in still water, c = concentration at height z above the bed and ϵ = diffusion coefficient for the suspended material at height z . For ϵ the same value as for the diffusion coefficient for the momentum is used, which is acceptable for relative fine material ($D \leq 300 \mu\text{m}$). Applying the logarithmic velocity distribution and the linear shear stress distribution the following expression of ϵ is obtained.

$$\epsilon = \kappa v_* z(1-z/h), \quad (2)$$

in which v_* = the bed shear velocity, κ = the constant of Von Karman and h = the total water depth.

This expression of the diffusion coefficient gives the well known concentration gradient which is after Einstein also used by Bijker (1971, [3]). However, experiments by Coleman (1970, [4]) indicate that with reasonable accuracy a constant diffusion coefficient for the whole depth can be applied. Kerssens and Van Rijn (1979, [7]) use a constant value for the upper half of the depth and a logarithmic distribution for the lower half. Although this represents the available data certainly better, in this case nevertheless one constant value is assumed in order to keep the procedure as simple as possible. This gradient of ϵ determines the vertical sediment concentration. Since in this case the decrease of this vertical sediment concentration with the distance over the channel is, rather than the actual form, the main item, this inaccuracy is accepted. For the constant value of ϵ is assumed:

$$\epsilon = \kappa v_* h/2,5 = 0,16 v_* h = 0,16 \bar{v} h \sqrt{g/C}, \quad (3)$$

in which \bar{v} = the mean value of the uniform flow, g = acceleration of the earth gravity and C = the resistance coefficient after Chezy and equal to $18 \log(12h/r)$ with r as apparent bed roughness. With this value of ϵ the following expression for the vertical sediment concentration is obtained:

$$c = c_b \exp(-w z/\epsilon), \quad (4)$$

with c_b = concentration at the bed.
The average silt concentration is

$$\bar{c} = (c_b \epsilon/w h) [1 - \exp(-w h/\epsilon)] \quad (5)$$

With this it is implicitly assumed that the total suspended load is $S_s = \bar{c} h$. This assumption is checked against the strict computation $S_s = \int_0^h v c dz$. Although for current alone the errors are less

then 10%, it can be expected that for conditions with waves and currents the errors could be more. In that case the form of the decrease of the sediment load and therefore the mechanism of the siltation will, nevertheless, be the same. The actual values of the transport can be calculated then with the more strict formula, while for the decrease the method described in this paper is used. This will be demonstrated in the example with waves and currents. When the suspended load is related to the bed load, the concentration c_b at the bed is calculated from this bed load. Bijker (1971, [3]) found for this relation via the velocity distribution close to the bed:

$$c_b = S_b / 6,34 r \sqrt{\tau_c / \rho} = S_b C / 6,34 \bar{v} r \sqrt{g} \quad (6)$$

in which S_b = bed load, τ_c = bed shear and ρ = density of the water. As well the bed load as the concentration are expressed in volumes of deposited material with the normal porosity coefficient. The wave influence is taken into account through an increased bed shear as derived by Bijker originally in 1966 and 1967 ([1] and [2]). According to this derivation

$$v_{*cw} = v_{*c} \left[1 + \frac{1}{2} (\xi u / \bar{v})^2 \right] \quad (7)$$

in which v_{*cw} and v_{*c} are the bed shear velocities due to waves and current and current alone, \hat{u} = amplitude of the horizontal orbital velocity at the bed and

$$\xi = C \sqrt{f_w / 2g}, \quad (8)$$

with f_w = friction coefficient as derived by Jonsson (1966, [6]). (See Swart, 1974, [8], and Van de Graaff and Van Overeem, 1979 [5]). This friction factor can be written as:

$$f_w = \exp \left[-5,977 + 5,213 (a_o / r)^{-0,194} \right] \quad (9)$$

in which a_o = amplitude of horizontal orbital motion at the bed. This adjusted value of u_{*} is introduced in the formula for ϵ .

Since, as has been demonstrated by Van de Graaff and Van Overeem (1979, [5]), the transport formula as given by Bijker in 1971 [3] gives for the combination of waves and current better results than the adapted Ackers and White and Engelund and Hansen formulae, this formula is also used here. The bed load is then written according to the adjusted Kalinske-Frijlink formula as:

$$S_b = (B D \bar{v} \sqrt{g} / C) \exp \left[-0,27 \Delta D C^2 / \mu \bar{v}^2 \left(1 + \frac{1}{2} (\xi \hat{u}_o / \bar{v})^2 \right) \right] \quad (10)$$

in which B = coefficient ≈ 5 , D is the grainsize of the bed material, Δ = relative density of the bed material and μ = a ripple coefficient = $(C_{D90} / C)^{3/2}$, with C_{D90} = bed resistance coefficient for a flat bed consisting of grains with a diameter of D_{90} ; that is that grainsize which is exceeded by only 10% of the bed material.

3. Sedimentation

The sedimentation in the channel is determined by an equation of the type of eq. (1).

So the first thing to do is to study the behaviour of ε and dc/dz above the channel. Since c is a property of the water, the value of c will remain constant in the first instance. The vertical gradient of the sediment concentration will, however, immediately decrease by a factor h_1/h_2 , h_1 and h_2 being the depth upstream and in the channel. (See figures 2 and 3).

figure 2. Mechanisme of sedimentation.

figure 3 Concentration verticals.

Since the actual sedimentation, or vertical transport is determined by the condition just above the bed this vertical transport reads then

$$S_v = w c_{b2} + \epsilon (dc/dz)_b, \quad (1)$$

in which the subscript b indicates the situation at the bed and ϵ is not yet determined. Due to the greater depth ϵ will eventually decrease. It is not known with certainty how fast this will happen. Since it is assumed that with normally occurring slopes of the channel banks the current will follow the bed, it is assumed that also ϵ will adapt immediately to the new situation. The value to be used above the channel will be then

$$\epsilon_2 = 0,16 v_{*2} h_2 = 0,16 \bar{v}_2 h_2 \sqrt{g/C_2} = 0,16 q \sqrt{g/C_2} \quad (11)$$

The vertical sediment concentration distribution at the most upstream side of the channel, before any sedimentation has taken place, is:

$$c = c_b \exp(-w h_1 z / \epsilon_1 h_2). \quad (12)$$

The vertical gradient is in this case:

$$(dc/dz) = -(h_1 w / h_2 \epsilon_1) c_b \exp(-w h_1 z / \epsilon_1 h_2). \quad (13)$$

The average sediment concentration is at that moment:

$$c_2 = (\epsilon_1 / w h_1) c_{b,1} \left[1 - \exp(-w h_1 / \epsilon_1) \right] \quad (5)$$

which is - as it should be - equal to the average sediment concentration just upstream of the channel. Since it is assumed that the value of the diffusion coefficient would adjust itself rather soon to that for the situation above the channel, the sedimentation - or vertical transport - at the most upstream side of the channel is:

$$\begin{aligned} S_v &= w c_{b,2} + \epsilon_2 (dc/dz)_b = \\ &= w c_{b,2} - w \frac{h_1 \epsilon_2}{h_2 \epsilon_1} c_{b,2} \exp(-w h_1 z (=0) / \epsilon_1 h_2) = \\ &= w c_{b,2} \left(1 - \frac{h_1 \epsilon_2}{h_2 \epsilon_1} \right) \end{aligned} \quad (14)$$

With $w h / \epsilon = h_{*}$, this equation reads

$$S_v = w c_{b,2} (1 - h_{*,1} / h_{*,2}) \quad (14)$$

The vertical transport S_v is expressed in m^2/s per unit of bed surface. The suspended load of the stream will decrease as result of the sedimentation until a new equilibrium is obtained.

This equilibrium is determined again by equation (1) which reads

$$w c_3 + \varepsilon_2 (dc/dz)_3 = 0 \quad (15)$$

with subsequently:

$$c_3 = c_{b,3} \exp(-w z/\varepsilon_2). \quad (16)$$

$$\bar{c}_3 = (c_{b,3} \varepsilon_2/w h_2) \left[1 - \exp(-w h_2/\varepsilon_2) \right] = (c_{b,3}/h_{x,2}) \left[1 - \exp(-h_{x,2}) \right] \quad (17)$$

$$(dc/dz)_{b,3} = -(w/\varepsilon_2) c_{b,3} \quad (18)$$

The vertical transport at that moment is

$$S_{v,3} = w c_{b,3} - \varepsilon_2 (w/\varepsilon_2) c_{b,3} = 0 \quad (19)$$

A positive value for S_v indicates a downward transport, that means sedimentation. The value of $c_{b,3}$ is for the moment unknown, but it is assumed that in the equilibrium situation it is again determined by the relationship of equation (6), and it will be written as

$$c_{b,3} = \alpha c_{b,2} = \alpha c_{b,1} \quad (20)$$

The equation of motion for the suspended load is

$$dS_s(x)/dx + S_v(x) = 0 \quad (21)$$

in which x = distance along the flow line from the upstream side of the channel.

For the solution of the continuity equation (21) two possibilities exist.

a). Assume that $S_s(x)$ decreases exponentially with x , so

$$S_s(x) = f (\exp(-\beta x)) \quad (22)$$

With the boundary conditions:

$$S_s(0) = S_{s,1} \quad (23)$$

$$S_s(\infty) = S_{s,3} \quad (24)$$

equation (22) can be written as

$$S_s(x) = (S_{s,1} - S_{s,3}) (\exp(-\beta x) - 1) + S_{s,1} \quad (25)$$

When this is substituted in the continuity equation (21) the following expression for β in S_s and S_v is obtained:

$$-\beta (S_{s,1} - S_{s,3}) \exp(-\beta x) + S_v(x) = 0 \quad (26)$$

$$-\beta (S_s(x) - S_{s,3}) + S_v(x) = 0 \quad (27)$$

$$\begin{aligned} \text{For } x = 0 & \quad S_v = S_v(0) \\ \text{For } x = \alpha & \quad S_v = 0 \end{aligned}$$

This results in the following expression for β .

$$\beta = S_v(0)/(S_{s,1} - S_{s,3}) \quad (28)$$

- b). Assume that the sedimentation, that is the vertical transport S_v , is linearly proportional to the ratio between the differences between the actual and equilibrium concentration and the original and equilibrium concentration.

Then the following equation will hold:

$$S_v(x) = S_v(0) \left[\frac{(\bar{c}(x) - \bar{c}_3)}{(\bar{c}_1 - \bar{c}_3)} \right] \quad (29)$$

And with $S_s = \bar{c} q$ this equation can be written as

$$S_v(x) = S_v(0) \left[\frac{(S_s(x) - S_{s,3})}{(S_{s,1} - S_{s,3})} \right] \quad (30)$$

Equation (30) is also obtained after substituting eq (28) in eq (27), so both approaches give the same result.

When $S_v(0)$, $c(x)$, \bar{c}_1 and \bar{c}_3 are expressed in the bed concentration the following expressions are obtained.

$$\begin{aligned} S_{v,0} &= w c_{b,1} (1 - h_{*,1}/h_{*,2}) \\ \bar{c}(x) &= (c_b(x)/h_{*,2}) \left[1 - \exp(-h_{*,2}) \right] \\ \bar{c}_1 &= (c_{b,1}/h_{*,1}) \left[1 - \exp(-h_{*,1}) \right] \\ \bar{c}_3 &= (c_{b,3}/h_{*,2}) \left[1 - \exp(-h_{*,2}) \right] \\ c_{b,3} &= \alpha c_{b,1} \end{aligned}$$

$$\begin{aligned} S_v(x) &= w c_{b,1} (1 - h_{*,1}/h_{*,2}) \frac{\bar{c}(x) - \bar{c}_3}{(c_{b,1}/h_{*,1})(1 - \exp(-h_{*,1})) - (\alpha c_{b,1}/h_{*,2})(1 - \exp(-h_{*,2}))} = \\ &= w (\bar{c}(x) - \bar{c}_3) \frac{h_{*,1}(h_{*,2} - h_{*,1})}{h_{*,2}(1 - \exp(-h_{*,1})) - \alpha h_{*,1}(1 - \exp(-h_{*,2}))} = E w (\bar{c}(x) - \bar{c}_3) \end{aligned} \quad (31)$$

Equation (27) can be also written as follows:

$$S_v(x) = \beta q (\bar{c}(x) - \bar{c}_3)$$

from which follows that $\beta = E w/q$, (32)
and the equation (25) for $S_3(x)$ reads than

$$(S_{s,1} - S_s(x))/(S_{s,1} - S_{s,3}) = 1 - \exp(-E w x/q) \quad (33)$$

Or also

$$(S_s(x) - S_{s,3})/(S_{s,1} - S_{s,3}) = \exp(-E w x/q) \quad (34)$$

These equations make it possible to compute in a quick and simple manner the sedimentation above the channel or trench.

4. Results

In this chapter two cases will be computed and the results will be compared by those computed with the program "Susleuf" of the Delft Hydraulics Laboratory, which is described by Kerssens, Prins and van Rijn [7].

For only current the following situation has been computed:

$$\begin{aligned} D_{50} &= 0.2 \cdot 10^{-3} \text{ m} & r &= 0.1 \text{ m} & w &= 2.5 \cdot 10^{-2} \text{ m/s} & D_{90} &= 0.3 \cdot 10^{-3} \text{ m} \\ h_1 &= 5 \text{ m} & \bar{u}_1 &= 1 \text{ m/s} & q &= 5 \text{ m}^2/\text{s} & h &= 10 \text{ m} & \bar{v}_2 &= 0.5 \text{ m/s} \\ C_1 &= 50 \text{ m}^{1/2}/\text{s} & C_{D90} &= 95 \text{ m}^{1/2}/\text{s} & \mu &= 0.38 \\ v_{*1} &= 6.3 \cdot 10^{-2} \text{ m/s} & \epsilon_1 &= 0.16 v_{*1} & h_1 &= 5 \cdot 10^{-2} \text{ m}^2/\text{s} & h_{*1} &= w h/\epsilon_1 = 2.5 \\ C_2 &= 55 \text{ m}^{1/2}/\text{s} & C_{D90} &= 101 \text{ m}^{1/2}/\text{s} & \mu &= 0.40 \\ v_{*2} &= 28 \cdot 10^{-2} \text{ m/s} & \epsilon_2 &= 0.16 v_{*2} & h_2 &= 4.5 \cdot 10^{-2} \text{ m}^2/\text{s} & h_{*2} &= 5.56 \end{aligned}$$

With $B = 5$;

$$\begin{aligned} S_{b,1} &= 3.486 \cdot 10^{-5} \text{ m}^2/\text{s} & \text{and } c_{b1} &= 0.88 \cdot 10^{-3} \\ S_{b,3} &= 0.192 \cdot 10^{-5} \text{ m}^2/\text{s} & \text{and } c_{b3} &= 0.106 \cdot 10^{-3} \\ \alpha &= 0.12 & E &= 1.59 \end{aligned}$$

For the Susleuf program the following distribution of the diffusion coefficient has been applied.

$$\begin{aligned} z/h < \frac{1}{2} & \epsilon_1 = v_*^4 z(1-z/h) \left[0.13 + 0.20(w/v_*)^{2.12} \right] \\ z/h \geq \frac{1}{2} & \epsilon_2 = v_*^4 h \left[0.13 + 0.20(w/v_*)^{2.12} \right] \end{aligned}$$

Although this expression for ϵ gives an illogical trend for ϵ from upstream of the channel to above the channel, the most important value of ϵ , namely ϵ_2 is in reasonable agreement with the ϵ applied in the method of this paper.

In the following tabel the values of $(S_{s,1} - S_s(x))/(S_{s,1} - S_{s,3})$ as follow from the Susleuf computation and this method are given.

Deposit of suspended material as fraction maximum possible deposit as function of distance from upstream edge of channel.

x (m)	Susleuf program	This method
25	.22	0.18
50	.37	.33
75	.47	.45
100	.55	.55
125	.62	.63
150	.67	.70
175	.71	.75

The correspondence is reasonable.

For the combination of waves and current the following conditions are applied.

$$D_{50} = 0.2 \cdot 10^{-3} \text{ m} \quad r = 0.05 \text{ m} \quad w = 2.5 \cdot 10^{-2} \text{ m/s} \quad D_{90} = 0.27 \cdot 10^{-3} \text{ m}$$

$$h_1 = 5 \text{ m} \quad \bar{v}_1 = 1 \text{ m/s} \quad q = 5 \text{ m}^2/\text{s} \quad h_2 = 10 \text{ m} \quad \bar{v}_2 = 0.5 \text{ m/s}$$

$$C_1 = 55.4 \text{ m}^{1/2}/\text{s} \quad C_{D90_1} = 96.2 \text{ m}^{1/2}/\text{s} \quad \mu = 0.44$$

$$C_2 = 60.8 \text{ m}^{1/2}/\text{s} \quad C_{D90_2} = 101 \text{ m}^{1/2}/\text{s} \quad \mu = 0.46$$

$$H = 1 \text{ m} \quad T = 6 \text{ s}$$

For the Susleuf program the following distribution for ϵ has been applied this time

$$z < h/2 \quad \epsilon = \kappa \bar{v}_* z(1-z/h)$$

$$z \geq h/2 \quad \epsilon = 0.25 \kappa \bar{v}_* h$$

This results in $\bar{\epsilon} = 0.0883 \bar{v}_* h$ which is about half the value which is suggested by the author. In order to be able to compare the results of this method with that of Susleuf here also this lower value of $\bar{\epsilon}$ will be applied. The various values are given upstream and above the channel.

upstream of the channel
depth 5 m

$$u_o = 0.568 \text{ m/s}$$

$$a_o = 0.542 \text{ m}$$

$$v_{*cw} = 0.093 \text{ m/s}$$

$$C_1 = 55.4 \text{ m}^{1/2}/\text{s}$$

$$C_{D90_1} = 96.2 \text{ m}^{1/2}/\text{s}$$

$$\mu_1 = 0.44$$

$$\bar{\epsilon}_1 = 0.0388 \text{ m}^2/\text{s}$$

above the channel
depth 10 m

$$u_o = 0.309 \text{ m/s}$$

$$a_o = 0.295 \text{ m}$$

$$v_{*cw} = 0.0557 \text{ m/s}$$

$$C_2 = 60.8 \text{ m}^{1/2}/\text{s}$$

$$C_{D90_2} = 101.1 \text{ m}^{1/2}/\text{s}$$

$$\mu_2 = 0.46$$

$$\bar{\epsilon}_2 = 0.0464 \text{ m}^2/\text{s}$$

$$\begin{aligned}
 h_{*1} &= 3.22 & h_{*2} &= 5.39 \\
 S_{b1} &= 4.49 \cdot 10^{-5} \text{ m}^2/\text{s} & S_{b2} &= 1.4 \cdot 10^{-5} \text{ m}^2/\text{s} \\
 c_{b1} &= 2.51 \cdot 10^{-3} & c_{b2} &= 1.71 \cdot 10^{-3} \\
 \alpha &= 0.78 \\
 E &= 2.33
 \end{aligned}$$

The suspended load is computed with the original procedure as suggested by Bijker in 1971 [3] and described also by Van de Graaff and Van Overeem [5].

The following values are then obtained

$$\begin{aligned}
 w/\kappa v_{*wc1} &= 6.72 \cdot 10^{-1} & w/\kappa v_{*wc2} &= 1.12 \\
 S/S_b &= 19 & S/S_b &= 7 \\
 S_{s,1} &= 8.53 \cdot 10^{-4} \text{ m}^2/\text{s} & S_{s,3} &= 0.98 \cdot 10^{-4} \text{ m}^2/\text{s} \\
 S_{s,1} - S_{s,3} &= 7.55 \cdot 10^{-4} \text{ m}^2/\text{s} \\
 S_{\text{tot}}(x) &= S_s(x) + S_{b,2}
 \end{aligned}$$

In order to calculate the transport in ton/ms, a porosity of 0.4 and a density of the dry material of 2.65 is assumed.

Deposit of material as fraction of maximum possible deposit as function of distance from upstream edge of channel.

This method			Susleuf		
$S_{\text{tot}}(x)$	$\frac{S_{\text{tot}}(x)}{S_{\text{tot},1}}$	Fraction of deposit	$S_{\text{tot}}(x)$	$\frac{S_{\text{tot}}(x)}{S_{\text{tot},1}}$	Fraction of deposit
in ton/m's					
$1.43 \cdot 10^{-3}$	1.00		$1.5 \cdot 10^{-3}$	1.00	
$1.13 \cdot 10^{-3}$.79	.21	$1.20 \cdot 10^{-3}$.75	.25
$0.93 \cdot 10^{-3}$.65	.35	$0.92 \cdot 10^{-3}$.58	.42
$.78 \cdot 10^{-3}$.55	.45	$0.72 \cdot 10^{-3}$.45	.55
$.65 \cdot 10^{-3}$.45	.55	$0.61 \cdot 10^{-3}$.38	.62
$.55 \cdot 10^{-3}$.38	.62	$0.53 \cdot 10^{-3}$.33	.67
$.48 \cdot 10^{-3}$.34	.66	$0.46 \cdot 10^{-3}$.29	.71
$.42 \cdot 10^{-3}$.29	.71	$0.41 \cdot 10^{-3}$.26	.74
$.36 \cdot 10^{-3}$.25	.75	$0.36 \cdot 10^{-3}$.23	.77

The agreement is again reasonable.

In the case the transport is calculated via $S = q \bar{c}$ higher values for the actual transport are obtained. This last approximation is apparently - as was expected - acceptable for the computation of the rate of sedimentation, but not for the actual transports.

Acknowledgement:

I like to thank the Delft Hydraulics Laboratory for the runs of the Susleuf program they made available for comparison with this method and Mr. J. van Overeem for the discussions on this subject.

CHAPTER 105

SEDIMENTATION IN DREDGED NAVIGATION CHANNELS

BY

Lars Mikkelsen *

Preben Mortensen *

Torben Sorensen **

1. INTRODUCTION

The feasibility of a harbour project, which involves dredging of an access channel, may to a large extent depend on the future maintenance dredging in the channel. It is therefore important to be able to calculate sedimentation in dredged channels with sufficient accuracy.

In 1974 and 1975 the Danish Hydraulic Institute (DHI) carried out a study of the most feasible access channel to Warri Port situated in the Western Niger Delta, Nigeria. Two alternative entrances were studied and in conclusion it was recommended to improve the existing access channel through Escravos Entrance

* Senior Hydraulic Engineer, M.Sc., Danish Hydraulic Institute, Copenhagen, Denmark.

** Director, Danish Hydraulic Institute, Copenhagen, Denmark.

Fig. 1 Location Map

as this solution would yield much smaller maintenance dredging quantities as compared to an access channel through Forcados Entrance, see Ref. /1/

In 1978 it was decided to improve the accuracy of the sedimentation estimates for a dredged channel through Forcados Entrance and therefore it was recommended by DHI to dredge test pits in the alignment of the channel and to carry out a pertinent monitoring programme.

The paper presents

- The test pit monitoring programme and results including a discussion of measurement techniques.
- calculation of sediment transport in combined currents and waves and comparison with the monitoring results.

- discussion of some important sedimentological aspects.

2. SUMMARY AND CONCLUSIONS

On the basis of the test pit monitoring and the measured current and wave parameters it has been possible to calibrate the sediment transport rates in combined waves and currents. The test pit results has been used to obtain a satisfactory expression for the sediment diffusion coefficient ϵ_s and hence the concentration profile.

Using the calibrated transport rates, the theoretical sedimentation model and the wave and current statistics it has been possible to calculate the expected annual sedimentation in the dredged channel. Further, it has been possible to predict the consequences of changes in the depth ratio D_1/D_2 and in the channel width and hence to produce an optimal design of the channel.

In conclusion the sedimentation model has proved itself to be a very useful tool for studies of expected sedimentation quantities, particularly if the transport rates can be calibrated through pertinent field studies.

3. TEST PIT LOCATION AND PLANNING OF MONITORING

A test pit was dredged outside Forcados Bar at an undisturbed depth of app. 7 m MSLW (Mean Spring Low Water), see location map. The aim of the test pit investigation was not to provide a direct estimate of the future annual maintenance dredging quantities. This would be unrealistic due to the following reasons:

- 1) The test pit experiment took place during a limited part of the year only.
- 2) The depth in the test pit was decreasing contrary to the maintained depth of the access channel.
- 3) Suspended sediments would settle from the test pit ends contrary to the settling in a continuous access channel.
- 4) A continuous channel could tend to "attract" the current in the alignment of the channel.

The aim of the test pit investigation was therefore to calibrate a sedimentation model and thereby be able to understand and control the effects mentioned under 1 through 3.

Based on experiences from channels under similar conditions it was estimated that the effect mentioned under 4 was of minor importance.

In conclusion it was decided to dredge a rectangular test pit with bottom width 200 m equivalent to the future access channel width and bottom length 400 m in order to eliminate the major part of the "artificial" infill from the ends of the pit (effect 3). The test pit volume was about 350.000 m^3

4. FIELD MEASUREMENTS

The test pit was dredged in April 1979 and a monitoring programme was carried out from May to September 1979. Below is briefly outlined the most important hydrographic parameters and the methods of test pit monitoring.

Hydrographic Parameters

Currents

Recording current meters and float trackings revealed current velocities of 10-30 cm/sec without any dominating direction at the location of the pit. Some deviation between the surface and bottom current directions could be observed.

Waves

The wave trains consisted of swell waves approaching from W-SW with typical periods between 10 sec. and 18 sec. superimposed by local wind waves with periods between 3 sec. and 8 sec.

The wave heights (spectrum derived significant wave height H_{mo}^{mo}) varied between 0.7 m and 2.2 m. About 70% of the time H_{mo} was between 0.8 m and 1.4 m.

Bottom Material

At the location of the test pit the seabed consisted of coarse silt with fine sand and minor portions of finer sediments could be found. A median grain size of 0.05 mm was characteristic.

Suspended Sediment Sampling

The suspended sediment sampling was carried out by using a tripod frame, see fig. 2.

Fig. 2 Tripod Frame

The tripod was lowered to the undisturbed seabed and samples were sucked from fixed levels above the bottom layer, the lowest level being 0.1 m above bed. Results are presented in section 5.

MONITORING OF SEDIMENTATION

Methods

Preliminary calculations had revealed severe potential sedimentation, but even with high sedimentation rates it was foreseen to be difficult to detect the sedimentations with sufficient accuracy due to the swell waves. It was decided to measure the sedimentation by using two different methods:

- 1) Echo-sounding in lines crossing the test pit. The wave disturbance of the echo-sounding was eliminated by repeating the lines a sufficient number of times, see data processing below.
- 2) A pressure cell mounted on a sledge was pulled across the pit at the bottom. By averaging over a sufficient period of time the waves were eliminated. The position of the sledge was determined by underwater positioning equipment, see fig. 3.

Fig. 3 Pressure Cell Method

DATA PROCESSINGEcho-soundings

The wave disturbed depth soundings of the echosounders (200 khz and 30 khz) were smoothened out for the individual sounding lines, see fig. 4. The repetitions of the same line were plotted to the same scale and an average of the cross section was elaborated, see fig. 5.

Fig. 4 Echogramme

Fig. 5 Characteristic Profiles.

It is seen in fig. 5 that the deviations of the individual soundings from the average is in the order of 10 cm. The pitch and roll of the ship had some effects at the slope of the pit. However, performing echosounding during relatively calm periods it was concluded that repetition of each sounding line three times yielded satisfactory results.

Since the middle of the pit was flat and the velocity of the waves large compared to the speed of the survey vessel, this method was in principle the same as the averaging of the pressure cell at a specific position, see below.

Pressure_Cell_Method

In fig. 6 the cross section obtained from the average of the three cross sections shown in fig. 5 is compared to the results of pressure cell soundings in a number of check-points.

Fig. 6 Comparison of Sounding Methods

It is seen that the differences are small, averagely in the order of 5 cm.

The points were obtained by averaging over 30 seconds which was an adequate timelength, but the method as such turned out to be fairly complicated and time consuming.

Sedimentation_Rates

The soundings of the pit took place with app. 3 weeks interval. The cross section of the middle of the pit is presented

in fig. 7.

Fig. 7 Sedimentation in the middle cross-section of test pit.

The sedimentation was fairly evenly distributed over the width of the pit indicating slow settling of fine suspended sediments.

During the first period a sedimentation rate of app. 1.7 cm/day was observed, while later on a rate of 1.2 cm/day appeared. Using the sedimentation model this decrease was explained by the depth reduction in the pit.

Also longitudinal profiles of the pit showed that the sedimentation was fairly evenly distributed, see Fig. 8

Fig. 8 Longitudinal test pit profile.

Fig. 9 shows the sedimentation rate between two soundings. The rates are seen to be strightly higher along sides of the pit than in the centerline of the pit.

Fig. 9 Sedimentation between two soundings

5. SEDIMENTATION MODEL

In Ref /1/ it was shown that the sedimentation in a dredged channel, q_r , originating from settling of suspended sediments could be calculated as follows

$$q_r = \left\{ q_{10} \left(1 - e^{-\frac{w}{\epsilon} \frac{w}{v} \frac{D_1}{D_2} \frac{B}{\cos \alpha}} \right) - q_{20} \left(1 - e^{-\frac{w}{\epsilon} \frac{w}{v} \frac{B}{\cos \alpha}} \right) \right\} \cos \alpha$$

- where:
- q_{10} = transport of suspended sediments, equilibrium conditions at depth D_1
 - q_{20} = transport of suspended sediments, equilibrium conditions at depth D_2
 - w = settling velocity of suspended material
 - ϵ = eddy viscosity
 - v = current velocity
 - B = channel (test pit) width at the middle of the slope
 - α = angle between the direction of the current and normal to the test pit alignment
 - D_1 = undisturbed depth
 - D_2 = channel (test pit) depth

The calculation of the equilibrium transports q_{10} and q_{20} of suspended sediments in combined currents and waves has mainly been based on parameters calculated from field data. Further, the measured sedimentation in the test pit has offered a possibility to determine the unknown sediment diffusion coefficient ϵ_s near the bottom. In the following some of the basic parameters are discussed.

Fig. 10 Parameters

Wave Parameters

The thickness δ of the wave boundary layer was calculated by formulae given in /2/. In the calculation it was assumed that the wave amplitude a and the horizontal particle velocity U_w could be determined by sinusoidal wave theory.

Current Velocity Profile

The description of the current velocity profile at the bed is essential as the concentration of suspended sediment near the bed increases enormously.

The friction velocity $U_f = \sqrt{\frac{\tau}{\rho}}$ (where τ is the shear stress and ρ the density of water) in combined currents and waves can be determined by iteration in the following way:

1. The instantaneous particle velocity U_0 just above the wave boundary layer is determined by adding the current velocity U_c and the wave particle velocity U_w vectorially
2. The instantaneous shear stress is found by using U_0 and Johnsons wave friction factor f (/2/) calculated from:

$$\frac{1}{4\sqrt{f}} + \log \frac{1}{4\sqrt{f}} = -0.08 + \log \frac{A}{k}$$

where k is the bed roughness. The amplitude A may be taken as one half of the maximum excursion of a particle in the combined currents and waves.

3. The instantaneous shear stress projected in the current direction is integrated over a wave period yielding an expression for U_f .
4. The current velocity profile $U = U(z)$ near the bottom is then determined by

$$U_f^2 = \epsilon \frac{\partial U}{\partial z}$$

where ϵ is the total turbulent eddy viscosity in the current direction and z the distance above the bottom. The eddy viscosity for waves has been determined from /3/.

5. Finally current velocity U_0 just above the wave boundary layer is used in 1. for the determination of U_f and the "circle" is closed.

Above the wave boundary layer the current velocity profile has been assumed to be logarithmic.

Suspended Sediment Concentration Profile

Bottom Concentration

The bottom concentration has been assumed to be a function of the dimensionless shear stress (Shield's Parameter):

$$\theta = \frac{1}{2} f \frac{U_0^2}{(S-1)gd}$$

where U_0 is the instantaneous particle velocity just above the wave boundary layer, f the friction factor, S the relative density, g acceleration of gravity and d the grain diameter. By using formulae in /4/ and integrating over a wave period the average bottom concentration were obtained.

Concentration at the bed (wave boundary layer)

The time-averaged concentration C of suspended sediment a distance z above the bed was determined by

$$\epsilon_s \frac{\partial C}{\partial z} + WC = 0$$

W being the settling velocity of the grains and ϵ_s the sediment diffusion coefficient.

Laboratory experiments have indicated that for specific conditions ϵ_s is constant near the bed. However for the present study conditions none of the experiments were pertinent and instead another approach was needed.

Since no ripples were present it was natural to assume that ϵ_s at the bed basically could be expressed as a product of a characteristic length, a, characteristic velocity, U_f , i.e.:

$$\epsilon_s = n_1 (aU_f)^{n_2}$$

n_1 and n_2 being constants, n_1 nondimensionless.

n_1 and n_2 were then determined from the results of the test pit monitoring as they should satisfy the following conditions:

1. Integration of the sedimentation with current and wave statistics should yield measured sedimentation.
2. The calculated sediment concentration profiles should correspond with the measured profiles.

n_1 has been calculated to be $2.4 \times 10^{-4} \text{ (m}^2/\text{s)}^{0.45}$, n_2 to be 0.55

Concentration above the wave boundary layer

Above the wave boundary layer the sediment diffusion coefficient has been assumed to be equivalent to the momentum exchange coefficient

$$\epsilon_s = 0.4 U_{fcw} z \left(1 - \frac{z}{D}\right)$$

U_{fcw} being the time-integrated "friction velocity" without projection in the current direction.

6. DISCUSSION

Suspended Sediment

Fig.11 shows the suspended sediment concentration as function of wave height and current velocity as well as the theoretical concentration lines. A large scatter is observed but it can be concluded that

- The current has no significant effect on the amount of sediment in suspension.

The amount of sediment in suspension increases with increasing wave height (determining n_2 , discussed above).

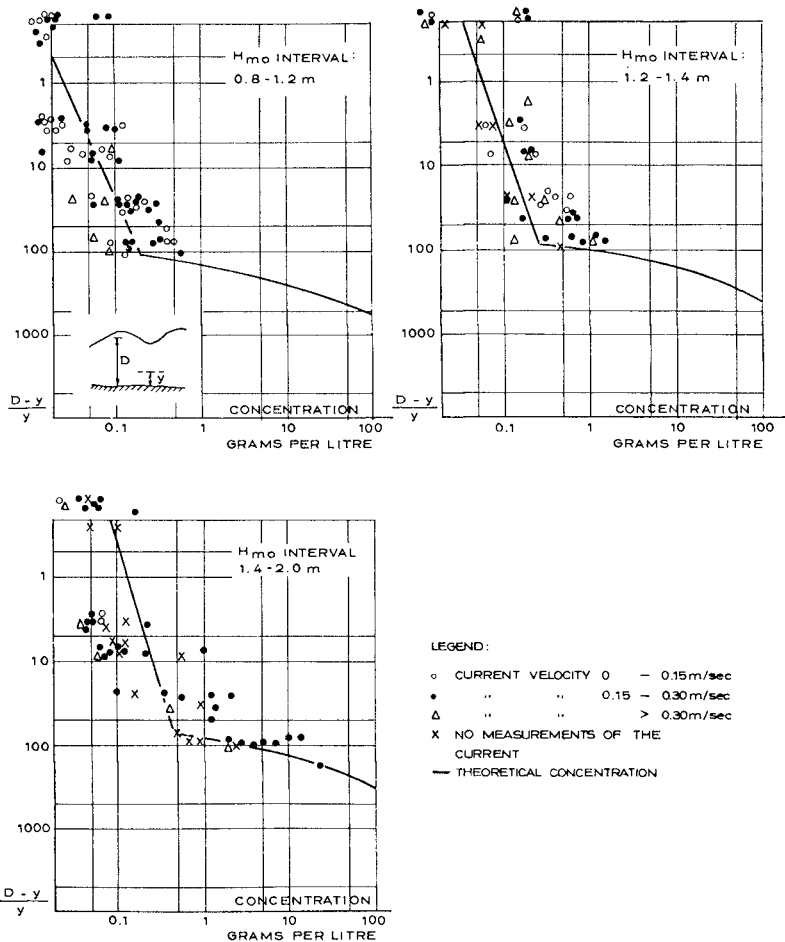

Fig. 11 Suspended Sediment

On the basis of the information that

the field measurements revealed that fairly large quantities of sand was settling in the pit and practically no sand in suspension was found above level 0.1 m above the bed and the concentrations of suspended sediment above this level were too small to explain the sedimentation -

it was concluded that very large concentration gradients exist at the bed in the wave boundary layer (5-10 cm thickness) and that it is essential to have a description of the suspension within and above the boundary layer.

Fig. 12 shows theoretical concentration profiles. The extreme concentration gradient at the boundary layer clearly proves the importance of the waves as the determining parameter.

Fig. 12 Theoretical concentration lines

Sedimentation in the Test Pit

The rates of sedimentation as function of wave and current parameters calculated from the sedimentation model is shown in Fig. 13 (only one current direction shown).

The sedimentation model yielded that the current was hampered by the waves at the bed mostly when current and wave particle motion was parallel. Hence the sedimentation in the pit was

significantly largest when the current was perpendicular to the alignment of the pit and the wave direction parallel to it.

Fig. 13 Sedimentation Rates

Using the sedimentation model the decrease of the sedimentation rate in the pit in the monitoring period was very satisfactorily explained as caused mainly by the depth reduction of the pit and not because of changes of wave and current climate.

7. ACKNOWLEDGEMENT

The test pit investigations has been carried out on the demand of the Nigerian Ports Authority, whom we thank for the opportunity of working with a very interesting programme.

CHAPTER 106

SOME ASPECTS OF COASTAL ENGINEERING RESEARCH WORKS IN CHINA

by

Professor Yen Kai

China has a long coastline. Only for the continental part of China, the length of coastline amounts to 18,000 km and, when including the coastline of more than 6,400 islands, an overall length of more than 32,000 km may be counted. As far as the geographical features are concerned, China is characterized by the prevalence of plateaux in the west, such as plateaux of Tibet and Sinkiang regions and plateaux of Yunnan and Kweichow provinces. There are nearly a hundred rivers, the most prominent of which are: the Yangtze River, the Yellow River, the Pearl River etc., flowing from west to east into the Pacific, and carrying about 2,000 million tons of sediment each year to the sea. As a result, silty coasts prevail in the vicinity of estuaries while sandy coasts emerge from a distance away. Generally speaking, the depth of coastal waters is comparatively small, especially along the silty coasts, where the beach profile presents a very gentle slope, varying from 1/50 to 1/500, and in some extreme cases even to 1/2000. Hence the maintenance of water depth in coastal harbours and estuaries has become one of salient problems of coastal engineering in our country. A brief description of our research on the sedimentation of harbours along silty and sandy coasts as well as rivermouth regulation, wave protection etc. is given as follows:

President, Chinese Society of Ocean Engineering, Nanking, China
President, East China College of Hydraulic Engineering, Nanking, China
Director, Nanking Hydraulic Research Institute, Nanking, China

(A) Research on siltation of harbours on silty coasts

To this the New Port of Tianjing may be taken as a typical example. This harbour was constructed on a mud flat, the material composing the beach is very fine, with mean particle diameter of 0.005 mm, and the beach slope is only 1/1000 to 1/2000. Heavy siltation took place in the water area of the harbour due to the combined action of waves, tidal currents and river discharge. Therefore, the study of reduction of harbour siltation becomes an urgent task. The key to solving such a problem lies in gaining a clear idea of the cause and process of siltation. For this reason we must get an insight into the physico-chemical properties of the sediment deposited in the harbour, have a thorough understanding of the behavior of sediment movement under the action of waves and currents, and investigate the inflow process of the sediment and estimate its rate of transport on the basis of the analysis of field measurements so as to devise the siltation reduction schemes. According to the requirements mentioned above systematic experimental studies of the sediment deposits in the port were performed and then siltation reduction schemes developed on the basis of the comprehensive analysis of field observation data and scale model studies as well. These projects have been carried out in succession over the past decade. At present the water depth in the navigation channel has been increased to 9.0 m below mean L.W., and is safe for vessels of 15,000 tons to enter the port at any time, while general cargo carriers of 40,000 tons can enter at high water.

(B) Research on siltation of harbours on sandy coasts

Along sandy coasts runnels are generally formed on the beaches due to the breaking of waves, and littoral transport of sediment comes into being. Natural coasts are in a state of relative equilibrium when a material balance is reached after a long-term interaction between the dynamic forces of the sea and the coasts. The construction of port results in disturbing the original state of equilibrium and, consequently siltation takes place. Experiments with scale models were conducted with several

sandy coast harbours, indicating that the locations and shapes of runnels were basically similar to those in nature. Despite difference in harbour layouts, such as the use of detached breakwaters, jetties, or even open-type structures, the littoral drifts were more or less intercepted and deposition on the updrift side would occur. The sediment accumulation gradually extends seawards, leading to the formation of a new coastline. It is the depositional behavior of the sediments and the rate of siltation as well as the measures to reduce siltation that are stressed in our present studies.

(C) Research on estuary regulation

Along the Chinese coast about 100 rivers empty into the sea. All the chief rivers, such as the Yangtze River, the Pearl River, the Chientang River, the Liao River etc., are navigable and highly important to the development of our national economy and the realization of four modernizations. A brief description of the regulation of some main estuaries is given as follows:

(1) Yangtze River Mouth

The Yangtze, more than 6,300 km long, is the first largest river in China. The Yangtze River Mouth, serving as a vital passage for the foreign trade of six provinces and the gateway to the biggest port of China, the Shanghai port, is of great concern to the development of our national economy. The Estuary is bifurcated into the North Branch and the South Branch. The South Branch is again bifurcated into the North Pass and the South Pass, and the latter in turn is divided into the North Channel and the South Channel. At present the South Channel is the main entrance channel. Because of the high river discharges and strong tidal currents, drastic channel changes take place, which has become a hindrance to navigation. For the purpose of improvement, large quantities of field observation data have been collected since 1958. Based on the analysis of the data, a relatively comprehensive knowledge of the characteristics of the channel process has been gained.

Diversified as the phenomena are, they can be classified as two problems. One is the susceptibility of the channels of the south branch to changes, and the other is the difficulties of maintaining adequate depths at the entrances of the navigation channels due to severe siltation. Now a tidal model with a horizontal scale of 1:1600 is available, its overall length is some 140 m and the maximum width is 34 m. A comprehensive experimental study is being performed for the planning of regulation works. The regulation works will be carried out in stages in combination with farmland reclamation.

(2) Chientang River Mouth

The Chientang River Mouth is famous for its strong tide. Low river discharge, strong tidal current and high sediment transport from the sea are the contributing factors in the formation of a huge sandbank inside the entrance. Owing to the fact that the river there is very wide and shallow, along with strong tidal currents and roaring bores, the main channel swings frequently between the two banks, and severe scour takes place once a new channel is formed. In conformity with these natural features our principle of regulation is such that at first we confine the tidal flow by reclaiming the foreshore of the river mouth, so as to reduce the inflow of water and sediment during the flood tide. It is hoped that by so doing the main channel will be stabilized and sandbank lowered. The final program consists of building tidal gates at the mouth of the river (in the vicinity of Jianshanhuang) to control the river discharge and tidal flow. A series of theoretical analysis and model studies have been performed for the above-mentioned programs. In the meantime, reclamation of the foreshores has been carried out in stages. Up to now 50,000 hectares of land has been reclaimed, and the river mouth has got its course initially stabilized.

(D) Research on wave protection works

Along the Chinese coast water depths and wave heights are comparatively small and most of the breakwaters are of rubble-mound type. Apart from model tests of rubble type breakwaters,

large numbers of experiments have been conducted to investigate the stability of artificial armor units such as tetrapod blocks, Akmon blocks, tetrapod hollow blocks, I-blocks, wing blocks, frog blocks etc., as well as breakwaters armoured with the artificial units mentioned above. Some of the above types have already been adopted in engineering practice. In addition, wall type breakwaters of caisson and concrete block construction are also in use at many harbours. Recently not a few experimental studies have been performed with a view to further improving the stability of the breakwater, reducing its cross section and saving its engineering costs. For instance, owing to the adoption of a sloping breast wall, we got chamfered upright breakwater which, as compared with the conventional wall type breakwater, bears a low horizontal wave pressure at high water and, what is more, the vertical wave pressure is increased, thus resulting in much improvement in the stability of the breakwater. This kind of breakwater is already in use in Tsingtao, Proving successful in withstanding the attack of severe waves. Recently the construction of deep water harbours has given a stimulus to the study of floating breakwaters.

The problem of the effect of typhoon waves on breakwaters and the damage resulting therefrom has aroused broad interest of all the coastal engineering circles both at home and abroad since the attack of Typhoon No.3 on the Gulf of Pohai with associated heavy damage in 1972. Special technical discussions were held and, later, special studies made on the selection of the frequency of occurrence of design waves. Now a method, which conforms to the particulars of China, has been developed of selecting wave height and wave period corresponding to a certain frequency.

In the field of theoretical investigation on waves, methods which conform to China's particulars, are developed for sea wave prediction, calculation of wind wave elements and so on. Our research work also includes some basic problems such as loss of wave energy due to turbulence and the like.

Furthermore, in the aspect of coast protection and seawalls, systematic studies of the height of wave run-up on sloping,

embankments have been conducted by laboratory tests along with analysis of field data. The results of investigation are already used in the design of seawalls.

Above is only a brief account of our research works on coastal engineering. As China has a long coastline, many problems remain to be solved. Despite all the above efforts we still lag behind what the development of our national economy demands of us. Now, it is for the first time that we, the Chinese delegation, take part in the activities of the International Conference on Coastal Engineering. We come here chiefly for the purpose of learning the advanced experiences from our friends, as well as carrying on academic exchanges, which, we think, would further promote the friendship and mutual understanding among us.

INTRODUCTION

The hydrodynamic loads on an offshore pipeline resting on the ocean bottom are a function of parameters associated with waves and currents acting near the pipeline. There have been many studies conducted to develop the criteria needed to estimate the hydrodynamic loads imposed by waves and currents. Many of these studies have investigated the effect of these phenomena individually, but to date only limited research has been directed towards evaluating the combined effect. In general, the investigations of the interaction of waves and currents and their effect on the fluid force have been directed toward vertical piles^{1,2,3,4,5} and structures in a random wave field with a current present;^{6,7,8,9} however, the fluid force of waves in the presence of currents on pipelines has not been directly addressed.

The purpose of this research was to investigate the interaction of waves and currents and its relationship to the forces on submerged pipelines. A model pipeline in a wave-flume was used to obtain experimental values which were compared to values predicted by the Morison equation in conjunction with the superposition of the waves and a current.

The Morison equation¹⁰ was used to evaluate the forces on a horizontal cylinder resting on the bottom. The two major input parameters required by this equation are (1) the water particle kinematics of velocity and acceleration; and (2) the coefficients of drag and inertia. The testing program investigated the drag forces developed by the combined waves and a current. The inertia forces were assumed small when compared to the drag forces since a relatively small diameter cylinder was used in the experiments, thus the accelerations were small.

The coefficient of drag was obtained directly by simultaneous measurements of the water particle kinematics and the fluid force on the cylinder. The horizontal velocity, predicted by Airy and Stokes third order wave theories in still water, was combined with a current by the algebraic addition of their respective horizontal velocity fields at a specific elevation. These velocities were compared directly to experimentally-determined values. Measured forces were then compared

to the forces obtained by the Morison equation, using the coefficients determined in this research and the kinematics of the modified Airy and Stokes third-order wave theories. The error associated with the algebraic addition assumption was investigated.

Many wave and current orientations are possible in the field, but only the case of a wave propagating in the direction of the current was investigated. It is felt that this orientation represents the most severe conditions that will be experienced in the field. Further investigations will be needed to verify this assumption. In order to develop the basic knowledge needed to understand the error associated with the superposition-principle assumption, the fundamental problem of mono-chromatic waves and currents must be evaluated before other effects such as random waves can be attempted.

The primary purpose of this research was not to develop explicit prototype design criteria, but to provide the design engineer with an insight into the parameters governing fluid force in combined wave and current conditions. The parameters for fluid force are affected by the interaction of waves and currents and the variation of these parameters are presented.

DATA ANALYSIS

The definition sketch of the idealized two-dimensional wave-current problem for offshore pipelines is given in Fig. 1. This

DEFINITION SKETCH OF THE PIPELINE PROBLEM

FIGURE 1

configuration may represent a pipeline resting on the ocean bottom. The cylinder has both horizontal and vertical forces acting on it due to the passing wave and current. Only the horizontal drag force is investigated in this research.

The Morison equation considers the total horizontal force (f_H) as the sum of the horizontal drag force (f_D) and the horizontal inertial force (f_I)(all forces expressed per unit length of cylinder):

$$f_H = f_D + f_I \dots \dots \dots (1)$$

The drag force is a function of both a drag coefficient (C_D) and the horizontal component of the water particle velocity if the structure were absent (u), or:

$$f_D = \frac{C_D}{2} \rho D u |u| \dots \dots \dots (2)$$

where D = diameter of cylinder
 ρ = mass density of the fluid

The inertia force is a function of the inertial coefficient (C_I) and the horizontal particle acceleration (\dot{u}), or:

$$f_I = C_I \frac{\rho \pi D^2}{4} \dot{u} \dots \dots \dots (3)$$

Two of the major input parameters required by the Morison equation are the coefficients of drag and inertia. These coefficients must be determined experimentally. This is accomplished by measurements or theoretical predictions of the horizontal water particle kinematics in conjunction with fluid-force measurements. The coefficient of drag can be determined when the horizontal acceleration equals zero by the following equation:

$$C_D = \frac{2f_D}{\rho D u |u|} \dots \dots \dots (4)$$

when $f_I = 0$.

The coefficient of drag is generally presented as functions of two dimensionless parameters. The first parameter is the Reynolds number (N_{RE}). The Reynolds number indicates the dimensionless ratio of the inertial forces to the viscous forces in fluid motion, or:

$$N_{RE} = \frac{Du}{\nu} \dots \dots \dots (5)$$

where D = characteristic length (diameter)
 u = horizontal component of the particle velocity if the structure were absent at the time of interest
 ν = kinematic viscosity

The second parameter, developed by Keulegan and Carpenter, is related to the coefficients of drag and inertia. This dimensionless parameter is also known as the "period parameter" and it relates the maximum amplitude of the oscillating particle velocity, including both wave and current (u_{max}), the period of the oscillatory motion (T) to the diameter of the cylinder (D):

$$N_{KC} = \frac{u_{max}T}{D} \dots \dots \dots (6)$$

This parameter has been found to be related to the coefficients of drag and inertia for a very wide range of data.

The coefficient of drag determined experimentally in this research is presented as functions of these parameters.

Two other major input parameters required by the Morison equation are the particle kinematics of velocity and acceleration.

For a pipeline located near the ocean bottom, the water particle orbits are flattened (parallel to the bottom) for waves where the wave lengths are large compared to the water depth. The orbital motion changes to a horizontally oscillating flow when the water depth is small compared to the wave length; therefore, in this condition the variation of velocity over the height of the pipe is insignificant. This fact allows the velocity at the mid-point of the cylinder to represent the velocity used in the calculation of the fluid force by the Morison equation.

Airy and Stokes third-order wave theories are used in conjunction with the current to predict the combined flow field. In this case the parameters of wave height (H) and period (T) are considered to be the properties of a wave progressing in still water. These parameters are used with the water depth (d) to predict the velocities under a wave if no current were present. These resulting wave velocities are combined algebraically with the current velocity profile to predict the combined velocity profile. The equations and methods to determine the horizontal wave particle velocities predicted by Stokes third-order wave theory were those presented by Skjelbreaia¹¹.

The effect of the viscous boundary layer of the wave was neglected in the calculation of the horizontal velocity near the bottom. Since the actual current velocity profile was used for superposition, the boundary layer due to the current was taken into account. Therefore, any error in the boundary layer was due to neglecting the boundary layer in velocity prediction of the wave theories.

The forces on submerged pipelines are related directly to the velocity field near the structure. Accurate prediction of the horizontal velocity fields is essential for the proper prediction of the forces on submerged pipelines. The error associated with the prediction of the combined horizontal velocity field is directly related to the error in the calculation of the horizontal force of a submerged pipeline.

EXPERIMENTAL METHODS AND EQUIPMENT

The experimental study was conducted in a two-dimensional wave-flume facility of the Ocean Engineering Program at Texas A&M University. The dimensions of the wave flume are 45.72 m (150 ft) in length, 0.46 m (1.5 ft) in width, and 1.22 m (4.0 ft) in depth. The test section was located approximately 18.29 m (60 ft) from the wave generator. Fig. 2 shows the general layout of the test facilities.

WAVE-CURRENT TEST FACILITY

FIGURE 2

The wave flume is constructed of a metal and wood frame, with one wall consisting of plywood and the other of plexiglass. Currents are produced by a pumping system capable of developing currents of 1.22 m/sec (4.0 ft/sec). The water depth for any specific flow rate was controlled by an adjustable weir located at the end of the tank.

A wave absorber was specially constructed for this investigation to reduce the reflection of the waves as shown in Fig. 3. The design permitted large volumes of water to be transmitted through the absorber so that significant currents could be produced.

The facilities included two measurement stations. Station one was for the measurement of surface parameters and water particle kinematics and station two was for fluid-force determination. Station one was used to gather the information for comparing the predicted water particle to the theoretical values. Station two was used to determine the fluid force on the test structure. Since the distance between the two stations is 1.26 m (4.13 ft), it is assumed that the wave characteristics do not change between the stations. Therefore, the results obtained at station one can be used at station two.

FIGURE 3

The test cylinder was constructed of polyvinyl chloride (PVC) pipe. Its outside diameter was 44.5 mm (1.75 in). The pipe was located 1.58 mm (.0625 in) above the bottom of the tank. This small gap provided for the free movement of the cylinder so that the unrestricted movement was transmitted to the load cell which converted this movement to an applied force. Since only horizontal components of force were being measured the effect of the gap was minimized. The test cylinder extended through the walls of the test tank. This extension helped to reduce end effects, which supported the two-dimensional assumption.

Measuring devices at station one consisted of a capacitance-type wave gauge and a hot-film anemometer probe as shown in Fig. 4. The capacitance-type wave gauge was used for surface profile measurements of wave height and period because of its availability and linearity. The results were recorded on a Hewlett Packard Model 74024 oscillographic strip recorder. This recorder was capable of providing a time reference on the recorded data. The period of the wave was determined by measuring the time between two successive wave crests. The capacitance-type wave gauge was used with a Hewlett Packard Model 17403A Carrier preamplifier. This preamplifier contained the full-bridge network required by the capacitance-type wave gauge. The output of the hot-film anemometer was amplified by a Hewlett Packard Model 17402A Low-Gain preamplifier before the output was recorded on the strip recorder.

A Thermo-Systems Model Series 1050 hot-film anemometer was used for the particle velocity measurements. This series consisted of a Model 1050A constant-temperature anemometer, a Model 1051 monitor and power supply, a Model 1055 linearizer, and a Model 1057 signal conditioner.

STATION ONE, SURFACE PROFILE AND VELOCITY MEASUREMENTS

FIGURE 4

The transducer used with the anemometer is a small resistance element which is heated and controlled at an elevated temperature. A Model 1210-20 hot-film transducer (probe) was used in this research. The amount of electrical energy dissipated in the sensor is a measure of the cooling effect of the fluid flowing past the heated sensor. The cooling effect of the fluid passing over the sensor depends on both the mass flow and temperature difference between the sensor and the fluid.

In operation, a current flows through the bridge. The amplifier senses any off balance, and feeds back more or less current until the bridge comes into balance. This additional electrical energy is outputted as a bridge voltage which is amplified and recorded on the oscillographic strip recorder.

It can be seen from Fig. 4 that three locations were used for water particle measurements. They were at 0.61 m (2.0 ft), 0.31 m (1.0 ft) and at the mid height of the cylinder at the bottom of the tank. The particle kinematics were compared at these elevations. The particle velocity at the mid height of the cylinder was used with the measured fluid force to determine the coefficient of drag. The probe was extended into one side of the tank a distance of 0.15 m (0.5 ft). This distance was selected so that the measured particle velocity would be out of the boundary layer, but the distance was short enough to reduce the effect of probe vibrations due to vortex shedding. The orientation of the probe in the fluid flow is important, because by aligning the probe perpendicular to the flow, only the horizontal component of the velocity is measured. The velocity parallel to the probe is not significant and can be assumed to be zero. With the orientation shown in

Fig. 4, only the horizontal velocity component was recorded. Only horizontal velocities and forces were investigated in this research.

Measurements at the second station consisted of a capacitance-type wave gauge and a mechanism to transmit the horizontal forces on a horizontal circular cylinder resting near the bottom to a load-cell device. A sketch of station two is shown in Fig. 5. The cylinder was connected

**SCHEMATIC DIAGRAM OF STATION TWO,
MODEL LOAD TEST STATION**

FIGURE 5

by two arms which rotated about a pivot point. This rotation transmitted the horizontal fluid force on the cylinder to a load cell located on the top of the tank. The load cell had a capacity of 1500 grams (≈ 3.0 lbs). The load cell was connected to the rotating mechanism by a rod which was pointed on both ends and which was held in place by a stiff spring. These pin-point connections were used to reduce friction. This total mechanism was capable of transmitting the positive or negative fluid force to the load cell without disrupting the fluid flow near the model. This device was found to be very effective in measuring the fluid force on the horizontal cylinder.

CALIBRATION AND PROCEDURE

All the equipment used in this investigation was calibrated using known values which were related to the output on the oscillograph recorder. All equipment was re-calibrated at each major test except for the hot-film anemometer which had to be calibrated periodically during the testing due to drift of the output.

The load cell was calibrated and balanced in a manner recommended by Hewlett-Packard. A known load was applied to the test cylinder, and

the output of the bridge network was recorded on the oscillograph recorder display. The applied load was transferred through a system of pulleys and weights described by the schematic diagram shown in Fig. 6.

SCHEMATIC DIAGRAM OF LOAD-CELL CALIBRATION APPARATUS

FIGURE 6

The total force applied to the cylinder was equal to the suspended weight multiplied by the length ratio of the arms around the pivot point. Any losses due to friction were neglected. The known load was related to the output voltage recorded on the oscillography display by a linear ratio.

Calibration of the hot-film anemometer proved to be difficult, due to its non-linear output and the constant drift of the output voltage. The hot-film anemometer was calibrated by means of known velocities created by a forced pendulum. A schematic of the forced pendulum is shown in Fig. 7. The angular velocity (ω_1) of the driving mechanism is related to the velocity of the probe by the following equation:

$$V_p = \text{velocity of probe (ft/sec)} = 0.7857 (\omega_1) \dots \dots \dots (7A)$$

$$V_p = \text{velocity of probe (m/sec)} = 0.2395 (\omega_1) \dots \dots \dots (7B)$$

Four known velocities were used as calibration points for the hot-film anemometer. These velocities were measured using the same apparatus as the wave particle kinematics. The number of divisions for each calibration point was related to the velocity by fitting the data to a power curve.

An inherent problem of the hot-film anemometer is that the calibration will drift in a relatively short period of time. It was determined that significant drift occurred in a period of several hours. To

SCHEMATIC DIAGRAM OF THE FORCED PENDULUM FOR VELOCITY CALIBRATION

FIGURE 7

overcome this problem, the drift as a function of time was investigated. The drift was determined by running successive calibration tests during a period of one hour. The drift during the hour period was reasonably linear. Calibration tests were run periodically during the test periods. This procedure proved successful for calibrating the hot-film anemometer.

The testing program was divided into two major stages. One stage was the determination of the water particle kinematics at three elevations with the wave surface parameters; the other was the measurement of the simultaneous fluid-force measurements and particle kinematics measurements required to determine the coefficient of drag.

All data were recorded on the oscillograph recorder and digitized and then used as input for a computer program which fitted the velocity data to a power curve. This program then wrote the calibrated data and other parameters of the particular test to a computer data file, where it was stored for computer analysis.

DATA ANALYSIS AND RESULTS

The results obtained from the testing program were based on several assumptions. First, the wave reflections from the sides and end of the wave tank were considered to have very little effect on the measurements. Secondly, the flow was assumed to be essentially two-dimensional. This was supported by the fact that the aspect ratio of the model was 10.274. Thirdly, the flow was considered irrotational, and the fluid was

inviscid. This assumption, which is vital for the validity of the superposition principle, has been found to be incorrect for currents with a varying velocity profile. The quantification of the error associated with this assumption was the basic goal of the research.

The thrust of the data analysis was two-fold. One task was to determine the error associated with the superposition of the current velocity field and the velocity field generated by a wave propagating in still water. This was accomplished by directly measuring the error over a specific range of waves and currents. The velocity field of the waves was predicted by both Airy and Stokes third-order wave theories.

The other task was a comparison of the measured forces on the pipeline model with the forces predicted by this superposition principle. The experimental drag coefficients were determined by simultaneous measurements of horizontal fluid velocity and fluid force. Comparisons were then made to the coefficients determined from the superposition principle using Airy or Stokes third-order wave theories.

For the first task, kinematic measurements were taken at three elevations as discussed previously. The second task employed a fourth test to measure forces on the model pipeline. The range of wave parameters and currents tested are presented non-dimensionally in Table 1. Since tests Nos. 3 and 4 were conducted simultaneously, the range of values for both tests were identical.

TABLE 1
RANGES OF WAVE AND CURRENT
PARAMETERS FOR TESTING PROGRAM

TEST	$\frac{H}{d}$	$\frac{H}{gT^2}$	$\frac{d}{gT^2}$	$\frac{U}{u}$	$\frac{H}{L}$
1. HORIZONTAL PARTICLE VELOCITY MEASUREMENT ELEVATION = 0.61 M (2.0 FT.)	0.1358-0.291803	0.0415-0.0230	0.0639-0.1102	0.1439-1.0179	.09896-.09186
2. HORIZONTAL PARTICLE VELOCITY MEASUREMENT ELEVATION = 0.30 M (1.0 FT.)	0.1715-0.2912	0.0107-0.0238	0.0561-0.1253	0.0000-5.3316	.07265-.12429
3. HORIZONTAL PARTICLE VELOCITY MEASUREMENT ELEVATION = 0.02 M (0.145 FT.)	0.1155-0.2407	0.0128-0.0197	0.0563-0.1155	0.0000-4.9602	.06899-.12508
4. HORIZONTAL FORCE MEASUREMENT	0.1155-0.2407	0.0128-0.0197	0.0563-0.1155	0.0000-4.9602	.06899-.12508

The raw data for tests Nos. 1-3 consisted of wave heights, wave periods, and a continuous measurement of horizontal fluid velocity over the wave period. The raw data for test No. 4 included a continuous record of horizontal fluid force over the period. The estimated error associated with each of these input variables is presented in Table 2.

TABLE 2
ESTIMATED ACCURACY OF
EXPERIMENTAL MEASUREMENTS

VARIABLE	MAXIMUM ERROR	MAJOR SOURCE OF ERROR
WAVE HEIGHT	2 TO 5 PERCENT	STABILITY AND LINEARITY OF BRIDGE NETWORK AND RECORDING DEVICE; WAVE REFLECTION
WAVE PERIOD	± .05 SECONDS	DETERMINATION OF WAVE CREST FROM RECORDING DEVICE
WATER DEPTH	6 MM (.25 IN.)	VARYING WATER DEPTH DUE TO CURRENT
FLUID FORCE	2 TO 3 PERCENT	DETERMINATION FROM RECORDING OUTPUT; STABILITY AND LINEARITY OF BRIDGE NETWORK
FLUID VELOCITY	1 TO 8 PERCENT	CALIBRATION AND DRIFT OF HOT-FILM ANEMOMETER (THIS ERROR IS GREATEST AT LOW VELOCITY DUE TO CURVE FIT PROCESS OF OUTPUT VOLTAGE TO VELOCITY)

The largest error was associated with the fluid velocity measurements of the hot-film anemometer. The error reached its maximum at the lower velocities, which were not within the range of the calibration curves.

The relative error of the superposition principle of the horizontal velocities can be expressed as a dimensionless difference (E):

$$E = \frac{u_{mea} - u_{tot}}{\frac{\pi H}{T}} \dots \dots \dots (8)$$

- where u_{mea} = the measured horizontal velocity at elevation (z),
- u_{tot} = the algebraic sum of the horizontal particle velocity at elevation (z) predicted by either Airy or Stokes third order wave theory and the current velocity,
- H = wave height, and
- T = wave period.

Dividing by the Airy deepwater horizontal velocity at the still water elevation the difference was non-dimensionalized.

The dimensionless difference (E) was found to be a function of a dimensionless parameter (R) relating the magnitude of current to the horizontal particle velocity of the wave in still water:

$$R = \frac{U}{u_{calc}} \dots \dots \dots (9)$$

where U = current velocity at elevation (z),
 u_{calc} = horizontal particle velocity predicted by either Airy or Stokes third order wave theories in the absence of a current at elevation (z).

The relationship between the dimensionless difference (E) and the velocity ratio (R) for an elevation of 1.0 ft above the bottom under the wave crest is shown in Fig. 8 for Airy wave theory and Fig. 9 for Stokes third-order wave theory.

DIMENSIONLESS DIFFERENCE VERSUS THE VELOCITY RATIO FOR AIRY WAVE THEORY AT ELEVATION 1.00 FT (THETA = 0.00)

FIGURE 8

Several interesting results can be noted from these figures. The wave theories tend to under-predict (positive dimensionless difference) the horizontal velocity at elevation (z) when no current is present ($R = 0.0$). As the current velocity increased relative to the wave particle velocity, the error decreased to approximately zero for values of $R > 1.0$. This trend is represented by the dotted lines on each of the figures. This trend seems to indicate that the superposition of the velocity fields approaches reasonable agreement with the measured values for $R > 1.0$.

A slight tendency exists for Stokes third-order wave theory to predict the superimposed velocity superior to that of Airy prediction. This can be seen by the mean error which is closer to the zero error line.

The fluid force data were analyzed at the crest to determine the drag coefficient. At this point the acceleration is equal to zero and

**DIMENSIONLESS DIFFERENCE VERSUS VELOCITY
RATIO FOR STOKES THIRD ORDER WAVE THEORY
AT ELEVATION 1.00 FT. (THETA = 0.00)**

FIGURE 9

only the drag force is present. The coefficients of drag were determined by three methods. The first method used simultaneous measurements of the horizontal fluid force and velocity.

The second and third methods were based on the predicted velocities of the superposition principle using Airy and Stokes third-order wave theories to calculate the coefficient of drag. A comparison of the three methods was made to demonstrate the differences in the coefficient of drag.

The coefficient of drag is related to the Reynolds Number (N_R). The coefficient of drag was plotted as a function of the Reynolds number in Fig. 10 as computed by the simultaneous measurements of fluid force and fluid velocity; Fig. 11 as computed using the superposition principle with Airy wave theory; and Fig. 12 as computed using Stokes third-order wave theory.

These figures all show the same general trend of reduction in the coefficient of drag with increasing Reynolds numbers.

Figures 10 and 11 show that the coefficient of drag was less when computed from the measured velocity as opposed to the Airy or Stokes III velocities for the range of Reynolds numbers shown. This is related to the fact that the wave theories used in conjunction with the superposition principle have a tendency to under-predict the horizontal velocity near the bottom boundary.

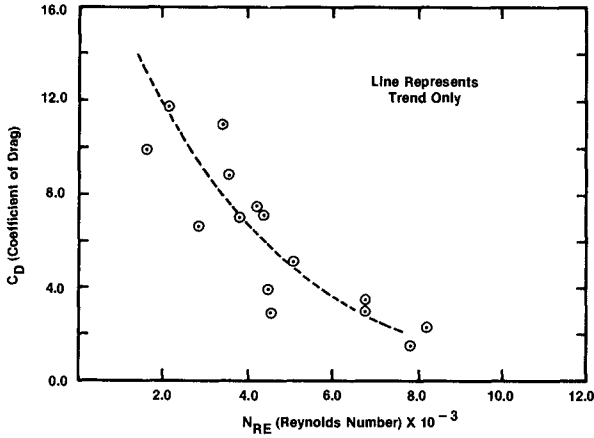

COEFFICIENT OF DRAG VERSUS REYNOLDS NUMBER FROM SIMULTANEOUS FORCE AND VELOCITY MEASUREMENTS

FIGURE 10

COEFFICIENT OF DRAG VERSUS REYNOLDS NUMBER FROM COMPUTATIONS USING AIRY WAVE THEORY

FIGURE 11

COEFFICIENT OF DRAG VERSUS REYNOLDS NUMBER FROM COMPUTATIONS USING STOKES THIRD ORDER WAVE THEORY

FIGURE 12

The relative difference between the coefficients of drag computed by Airy wave theory and those computed from measured values are shown in Fig. 13. This figure demonstrates at low velocity ratios (R) the coefficients computed using Airy wave theory are greater than the actual values, but this difference decreases with increasing currents.

RELATIVE DIFFERENCE OF C_D FOR AIRY WAVE THEORY AND MEASURED VALUES VERSUS THE VELOCITY RATIO

FIGURE 13

The coefficients of drag computed by the simultaneous measurements of the horizontal fluid force and velocity are, by definition, the actual values. These coefficients can only be used if the actual horizontal velocity can be predicted. This supports the fact that the coefficients of drag are dependent on the method used to determine the horizontal velocity. Therefore, the prediction of forces on a cylinder should be consistent with the method which was used to determine the coefficients.

For the steady-state current condition, Fig. 14 shows the actual coefficient of drag for the horizontal cylinder.

COEFFICIENT OF DRAG VERSUS REYNOLDS NUMBER (STEADY-STATE CURRENT CONDITION)

FIGURE 14

The primary purpose of this research was to determine the drag forces associated with the horizontal velocity. The drag forces were determined when the velocity was maximum and the acceleration was zero. Therefore, no inertial effects were present and the coefficient of drag was unaltered by this effect.

CONCLUSIONS AND RECOMMENDATIONS

The following conclusions were evident from the testing program for the range of values tested.

1. Airy and Stokes third-order wave theories in conjunction with the superposition principle predict the horizontal velocity reasonably well for velocity ratios ($R = \frac{U}{u}$) greater than one. The velocities are under-predicted for u values of R less than one.

2. The coefficients of drag computed from Airy and Stokes third order wave theories in conjunction with the superposition principle are greater in magnitude than the values determined by the simultaneous force and velocity measurement. This difference decreases with increasing velocity ratios.

The conclusions were based on a limited testing program. These results can be extended over a greater range of waves and currents by further tests. These additional tests will indicate whether any scale effects are important.

Other conditions related to the pipeline problem, such as the distance of the cylinder from the boundary, the transverse (lift) force, relative roughness and orientation angles, should be investigated for the combined wave-current condition.

Other theories developed for the interaction of waves and currents should be tested experimentally to determine their accuracy for the prediction of fluid force and particle kinematics.

WAVE FORCES ON AN INCLINED CIRCULAR CYLINDRICAL PILE

by

Toshiyuki Shigemura
Associate Professor of Ocean Engineering
National Defense Academy, Yokosuka, Kanagawa, Japan

ABSTRACT

This paper describes experimental results on the in-line and lift forces acting on inclined circular piles which are placed in two different planes: (1) a vertical plane parallel to the direction of wave propagation; and (2) a vertical plane parallel to the wave crest.

The in-line and lift force formulas for an inclined pile are formulated by referring to the conventional Morison and lift force formulas, respectively. Stokes third order wave theory is used for the estimation of flow kinematics induced around a pile. Based on these formulas, the time-independent and time-dependent values of the drag, mass and lift coefficients are determined by using several methods. Further, the time-dependent coefficients are expanded into Fourier series which consist of several significant components.

Reliability of these coefficient values are studied by examining the relative deviation of the predicted wave forces based on these coefficient values from the measured ones. The analysis finds that relative deviations of the in-line and lift forces exceed in many cases 15% and 100%, respectively, when the time-independent coefficients are used for the prediction of wave forces, but that they are reduced to 5% and 15%, respectively, when the time-dependent coefficients are used for it.

INTRODUCTION

It is commonly recognized that two types of wave forces are induced on a slender cylindrical pile subject to the motion of unbroken waves. One is called in-line force which acts on the pile to the direction of wave propagation and the other is called lift force which acts on the pile transversely to the direction of wave propagation. For the present, the in-line force is calculated by the Morison formula which evaluates the in-line force as a linear sum of the drag force and the inertia force. The lift force is calculated by the lift force formula which is same as that in a steady flow. However, when one attempts to predict these wave forces by the above formulas, one has to get reliable information on: (1) the flow kinematics induced around an inclined pile; and (2) the values

of the hydrodynamic coefficients $[C_D]$ and $[C_M]$ included in the Morison formula and of the lift coefficient $[C_L]$ included in the lift force formula. It is currently common practice to estimate the flow kinematics by using appropriate wave theories. Airy's wave theory has been widely used because of its simplicity although Stokes wave theory of higher order and Dean's stream function theory have also been used recently for the estimation of the flow kinematics. Hence, determination of C_D , C_M and C_L values experimentally has become one of the major themes in the present research of the wave forces.

Since Morison(1950) developed his unique method of determining C_D and C_M values experimentally, many distinguished works have been conducted on wave forces and coefficient values have been determined by several methods. Table 1 summarizes some of the representative works in which unique methods have been either developed or used to determine the coefficient values. Through a brief review of these previous works, the following facts can be noted:

1. Coefficient values for either vertical or horizontal piles have been determined mainly by the methods shown in Table 1.
2. There has not been sufficient study conducted to determine which method will provide the most reliable coefficient values for the prediction of wave forces.
3. Inasmuch as only a few works have been done on the wave forces acting on inclined piles, there is a limited amount of information available on the coefficient values for inclined piles.

It should be noted, however, that jacket-type offshore structures generally consist of many steel piles which are inclined in various planes at different angles. Thus, it is quite doubtful whether the coefficient values determined for either vertical or horizontal piles can be used directly for the evaluation of wave forces exerted on inclined piles.

Based on this, a basic experiment is performed in this study to investigate the characteristics of in-line and lift forces which act on inclined piles placed in two different planes: (1) a vertical plane parallel to the direction of wave propagation; and (2) a vertical plane parallel to the wave crest. The conventional Morison and lift force formulas are modified, respectively, to predict the in-line and lift forces acting on the inclined piles which are placed in each of both vertical planes. Further, Stokes third order wave theory is used to estimate the flow kinematics induced around the inclined piles. Based on these formulas, the time-independent and time-dependent values of C_D , C_M and C_L are determined by using either the methods shown in Table 1 or the methods which are derived by modifying the previous ones.

The analysis is focussed to determine: (1) whether the inclinations of piles affect the coefficient values; (2) which method will provide the most reliable coefficient values for the prediction of respective wave forces; and (3) how the inclinations of piles affect the ratio of the maximum lift force to the maximum in-line force exerted of an inclined pile over a wave cycle.

Table 1. Representative works on the wave forces acting on the piles.

Authors	Contents of investigations	Methods used for determining coefficient values
Morison (1950)	Circular and H-shaped piles and flat plates were placed vertically in progressive waves, and total in-line forces on them were measured.	C_D and C_M values were determined at two specific phases within a wave cycle where either the drag or inertia term became zero, respectively. This method determines time-independent values of each coefficient, and is called hereafter the "two-point method".
Keulegan and Carpenter (1958)	Circular piles and flat plates were placed horizontally at the nodal points of standing waves, and total in-line force on them were measured. Flow patterns were also observed photographically.	C_D and C_M values were determined by Fourier analysis: (1) by the primary coefficient of Fourier series; and (2) by the Fourier series of fully expanded. The former method determines time-independent values, and does the latter time-dependent values of each coefficient. The former method is called hereafter the "Fourier-averaged method".
Al-Kazily (1972)	Circular piles were placed horizontally in progressive waves, and total in-line, transverse and uplift forces on them were measured. Some experiments were also made on wave forces exerted on inclined piles.	C_D and C_M values were determined by the two-point method. These values were also determined by solving Morison formulas provided at successive phases, t and $(t+\Delta t)$ simultaneously where Δt is an incremental phase. This method determines the time-dependent values of each coefficient, and is called hereafter the "Al-Kazily's method".
Sarpkaya (1975)	Circular piles and spheres were placed horizontally in oscillatory flows generated in the U-shaped tunnel, and total in-line and lift forces on them were measured.	C_D and C_M values were determined by the Fourier-averaged method and C_L values were determined at a specific phase where the lift force became maximum. This method also determines time-independent values of C_L , and is called hereafter the "one-point method".
Chakrabarti et al (1976)	Circular piles were placed vertically in progressive waves, and total and sectional in-line and lift forces on them were measured.	C_D and C_M values were determined by the least square method, which also determines time-independent values of them. This method is called hereafter "the least square method". C_L values were determined by the Fourier analysis.

THEORETICAL CONSIDERATION

This study employs an essential assumption that the in-line and lift forces exerted on any inclined piles can be evaluated by the conventional Morison and lift force formulas if certain modifications are made on them. This assumption is the basis of this research.

Wave Force Formulas for an Inclined Pile

Figure 1 shows a sketch of a circular pile with an outer diameter, D , placed in a vertical plane parallel to the direction of wave propagation at an inclining angle, θ , and the coordinate system used for the analysis. For the convenience of later discussion, this vertical plane will be called hereafter the "Plane A".

In this figure, u and v represent the horizontal and vertical velocity components of an induced flow at an arbitrary position, (x, z) on the circular pile, at an arbitrary phase, t . Similarly, \dot{u} and \dot{v} represent the acceleration components of u and v , respectively. Here assume that the velocity component normal to the pile axis, U and its acceleration, \dot{U} can be composed into the following equations:

Figure 1. Schematic drawing of an inclined pile placed in the Plane A.

$$U = u \cos\theta + v \sin\theta \dots\dots\dots(1)$$

$$\dot{U} = \dot{u} \cos\theta + \dot{v} \sin\theta \dots\dots\dots(2)$$

Then, the total in-line force, $F_{txA}(t)$ which acts on the inclined pile at an arbitrary phase, t , will be evaluated by the following equation:

$$F_{txA}(t) = \int_{-h}^{\eta} C_{DU} \frac{1}{2} \rho D U |U| \sec\theta dz + \int_{-h}^{\eta} C_{MU} \frac{1}{4} \rho \pi D^2 \dot{U} \sec\theta dz + \frac{1}{4} \rho g \pi D^2 \eta \tan\theta \dots\dots\dots(3)$$

where C_{DU} and C_{MU} represent the drag and mass coefficients of the inclined pile, and the last term represents the buoyancy caused by the fluctuation of the surface elevation, η .

Similarly, the total lift force, $F_{tLA}(t)$ which acts on the inclined pile at the same phase, t will be evaluated by the following equation:

$$F_{tLA}(t) = \int_{-h}^{\eta} C_{LU} \frac{1}{2} \rho D U^2 \sec\theta \dots\dots\dots (4)$$

where C_{LU} is the lift coefficient of the inclined pile.

Figure 2 shows a sketch of a circular pile with an outer diameter, D , placed in a vertical plane parallel to the wave crest at an arbitrary inclining angle, θ , and the coordinate system used for the analysis. For the convenience of later discussion, this vertical plane will be called hereafter the "Plane B".

Figure 2. Schematic drawing of an inclined pile placed in Plane B.

In this figure, u and v represent the horizontal and vertical velocity components of an induced flow at an arbitrary position, (y,z) on the pile at an arbitrary phase, t . Similarly, \dot{u} and \dot{v} represent the acceleration components of u and v , respectively.

Here assume that the in-line force which acts on the inclined pile consists of the in-line force caused by u and \dot{u} , and the lift force caused by v . Similarly, assume that the lift force which acts on the inclined pile consists of the in-line force caused by v and \dot{v} , and the lift force caused by u .

Then, the total in-line force, $F_{txB}(t)$ which acts on the inclined pile at an arbitrary phase, t , will be evaluated by the following equation:

$$F_{txB}(t) = \int_{-h}^{\eta} C_{Du} \frac{1}{2} \rho D u |u| \sec\theta dz + \int_{-h}^{\eta} C_{Mu} \frac{1}{4} \rho \pi D^2 \dot{u} \sec\theta dz + \int_{-h}^{\eta} C_{Lv} \frac{1}{2} \rho (v \sin\theta)^2 \sec\theta dz \dots\dots\dots (5)$$

where the first two terms in the right-hand side of Eq.(5) represent the in-line force caused by u and \dot{u} , and the last term represents the lift force caused by v .

Similarly, the total lift force, $F_{tLB}(t)$ which acts on the inclined pile at an arbitrary phase, t , will be evaluated by the following equation:

$$F_{tLB}(t) = \int_{-h}^{\eta} C_{Lu} \frac{1}{2} \rho D u^2 \sec\theta \, dz + \int_{-h}^{\eta} C_{Dv} \frac{1}{2} \rho D v |v| \sin\theta \tan\theta \, dz + \int_{-h}^{\eta} C_{M\dot{v}} \frac{1}{4} \rho D^2 \dot{v} \tan\theta \, dz + \frac{1}{4} \rho g D^2 \eta \tan\theta \dots\dots\dots(6)$$

where the first term in the right-hand side of Eq.(6) represents the lift force caused by u and the second and third terms represent the in-line force caused by v and \dot{v} . Eqs. (3), (4), (5) and (6) were all derived by referring to the Morison and lift force formulas.

Determination of Coefficient Values

It is known that the coefficients in each of the above equations are functions of certain variables associated with the characteristics of the flow kinematics induced around a pile and of the pile itself. Thus, these coefficients may have different values from one point to another over the submerged portion of the pile.

In this study, however, the representative values of each coefficient over the submerged portion will be determined. Thus, the coefficients in each integral term of Eqs.(3), (4), (5) and (6) can be taken out of each integral sign. Consequently, Eqs.(3) and (4) can be rewritten as follows:

$$F_{txA}(t) = C_{Du} F_{Du}(t) + C_{M\dot{u}} F_{I\dot{u}} + F_B(t) \dots\dots\dots(7)$$

$$F_{tLA}(t) = C_{Lu} F_{Lu}(t) \dots\dots\dots(8)$$

where $F_{Du}(t)$ and $F_{I\dot{u}}(t)$ in Eq.(7) represent the corresponding integral terms in Eq.(3), and $F_B(t)$ represents the buoyancy term in Eq.(3).

Similarly, Eqs.(5) and (6) can be rewritten as follows:

$$F_{txB}(t) = C_{Du} F_{Du}(t) + C_{M\dot{u}} F_{I\dot{u}} + C_{Lv} F_{Lv}(t) \dots\dots\dots(9)$$

$$F_{tLB}(t) = C_{Lu} F_{Lu}(t) + C_{Dv} F_{Dv}(t) + C_{M\dot{v}} F_{I\dot{v}}(t) + F_B(t) \dots\dots(10)$$

where $F_{Du}(t)$, $F_{I\dot{u}}(t)$ and $F_{Lv}(t)$ in Eq.(9) represent the corresponding integral terms in Eq.(5), and $F_{Lu}(t)$, $F_{Dv}(t)$ and $F_{I\dot{v}}(t)$ in Eq.(10) represent the corresponding integral terms in Eq.(6).

As it can be noted from these equations, both time-independent and time-dependent values of each coefficient can be determined once the flow kinematics around an inclined pile and measured values of the wave forces are known. In advance of determining these coefficient values, all integral terms in Eqs.(7), (8), (9) and (10) are calculated at every incremental phase of 0.01 second over a wave cycle, based on the information of flow kinematics estimated by the Stokes third order wave theory.

Further, recorded data of incident waves and wave forces are quantized at the corresponding phases and punched on input cards automatically by a special A-D converter.

1. Coefficient Values for Inclined Piles Placed in Plane A

Based on the data provided previously, the time-independent values of C_{DU} and C_{MU} in Eq.(7) are determined in this study by the two-point method and by the least square method which are shown in Table 1. Similarly, the time-independent values of C_{LU} in Eq.(8) are determined by the one-point method and by the least square method.

The time-dependent values of C_{DU} and C_{MU} at every incremental phase are also determined in this study by Al-Kazily's method which is shown in Table 1. Similarly, the time-dependent values of C_{LU} are determined by solving Eq.(8) directly at the same incremental phases. The time-dependent coefficients are all expanded into Fourier series in which several significant components are involved. The details of this method has been shown in Shigemura and Nishimura's paper(1979).

2. Coefficient Values for Inclined Piles Placed in Plane B

Eqs.(9) and (10) include three unknown coefficients in themselves. Thus, data should be provided at least at three successive phase for each equation to determine these coefficient values.

The time-independent values of these coefficients are determined by the following procedures:

1. Divide a wave cycle into four equal divisions. Further, determine three phases in each division by dividing it into four equal subdivisions.
2. At each division, establish three equations for both of Eqs.(9) and (10), based on the data provided at the three phases mentioned above.
3. Solve each pair of three equations simultaneously to determine the respective coefficient values in each division.
4. Calculate the arithmetic means of the respective coefficient values obtained in the four divisions.

This method will be called hereafter the "three-point method". The least square method is also used to determine the time-independent values of these coefficients.

The time-dependent values of each coefficient in Eqs.(9) and (10) are also determined by a method similar to the Al-Kazily's method. Namely, three equations are provided first for each of Eqs.(9) and (10), based on the data provided at three successive phases, $(t-\Delta t)$, t , and $(t+\Delta t)$ where Δt is an incremental phase. Two pairs of these three equations are then solved simultaneously under the assumption that each coefficient

keeps constant value at the three successive phases. The coefficient values determined by this method are also expanded into Fourier series which consist of several significant components.

Reliability of Coefficient Values

Based on the coefficient values determined, theoretical values of each wave force are calculated at every incremental phase of 0.01 second over a wave cycle by Eqs.(7), (8), (9) and (10), respectively. To determine the reliability of each coefficient value quantitatively, relative deviations of theoretical wave forces from the measured ones are calculated by the following equation:

$$\delta F(\%) = \frac{\sqrt{\sum_{t=1}^N [F_m(t) - F_t(t)]^2 / N}}{[F_t]_{\max} - [F_t]_{\min}} \times 100 \quad \dots\dots\dots(11)$$

In this equation, $F_m(t)$ and $F_t(t)$ represent the measured and theoretical values, respectively, of a wave force at an arbitrary phase, t . Further, $[F_t]_{\max}$ and $[F_t]_{\min}$ represent the maximum and minimum values, respectively of the theoretical wave force over a wave cycle, and N is sample number used for the calculation of δF . Note that δF also measures the propriety of formulation of each wave force formula.

EXPERIMENTAL SETUP AND PRECEDURES

A 4.5 meters wide, 1.2 meters deep and 12.0 meters long wave channel was used for this experimental study. This wave channel has a flap-type wave generator at the back of the channel. A self-driven truck sits astride the channel so that it can run from the wave generating paddle to the wave absorber installed at the front end of the channel. This truck was locked at a position of 6 meters from the wave generating paddle.

At a point below the main beam of this truck, a chuck was fixed in such a way that it could rotate around an axis parallel to the direction of wave propagation and around an axis parallel to the wave crest. This chuck allows placing a force meter on the beam. A commercialized force meter, or a three-component loadcell was clamped firmly by this chuck. This loadcell is designed to detect the electrical signals produced by two components of forces, F_x and F_y which are perpendicular to each other, and by a component of the bending moment caused by either F_x or F_y , simultaneously. This force meter was connected to an oscillograph through proper amplifiers.

A total of twelve model piles used in this experiment were made of aluminum and acrylic acid resin tubes having circular cross sections. The upper portion of each pile was fabricated so that it could be connected to the force meter, and its lower portion was cut off so that the cut face

would be parallel to the bottom of the channel when the pile was connected to the force meter. The cut face of each pile was also shielded by vinyl sheet to avoid edge effects.

It was decided to give seven different angles of 0° , $+10^\circ$, $+20^\circ$ and $+30^\circ$ to each model pile placed in an allotted plane. These angles are those measured against an axis normal to the still water surface. Here, the plus sign in front of each angle indicates that a pile is inclined away from the direction of wave propagation and the minus sign means that a model pile is inclined towards the direction of wave propagation. This is the case when a model pile is placed in Plane A. In the case of model pile placed in Plane B, the plus sign indicates that a model pile is inclined towards the left side of the wave channel when one views the channel from the side of wave absorber, and the minus sign means that the pile is inclined towards the right side of wave channel. It was also decided to perform all tests at a constant water depth of 0.8 meters and seven waves were chosen as the experimental waves. Table 2 summarizes experimental conditions used in this study.

Table 2. Experimental conditions used in this study.

Characteristics of Model Piles				
Materials of Model Pile		Aluminum Tube	Acrylic Resin Tubes	
Outer Dia. of Model Pile(cm)		2.2	3.0	4.0
Inner Dia. of Model Pile(cm)		1.9	2.2	3.2
Placement of Model Piles				
Planes for Placing Model Pile		Plane A and Plane B		
Inclining Angles of Model Pile		0° , $\pm 10^\circ$, $\pm 20^\circ$ and $\pm 30^\circ$		
Characteristics of Experimental Waves				
Wave No.	Wave Period T(sec)	Wave Height H(cm)	H/L	h/L
1	0.86	2.8	0.024	0.693
2	0.94	4.4	0.032	0.576
3	1.02	5.9	0.036	0.489
4	1.14	6.7	0.033	0.395
5	1.27	8.3	0.034	0.325
6	1.46	8.3	0.027	0.257
7	1.69	9.2	0.024	0.208

A total of 273 tests were conducted. In each test, both in-line and lift forces exerted on the model pile were recorded on the oscillograph. Characteristics of the incident waves were also measured simultaneously by a capacitance-type wave gage which was placed at a position 15 cm from the right side of the model pile by aligning the gage front carefully with the intersection of model pile and still water surface, and were recorded on the same oscillograph.

RESULTS AND DISCUSSIONS

Values of Drag, Mass and Lift Coefficients for Inclined Piles

Time-independent and time-dependent values of drag, mass and lift coefficients were determined for inclined piles placed in both Plane A and Plane B, by using the methods described in the previous Chapter, and characteristics of these coefficient values were studied.

1. Time-Independent Values of Drag, Mass and Lift Coefficients for Inclined Piles Placed in Plane A

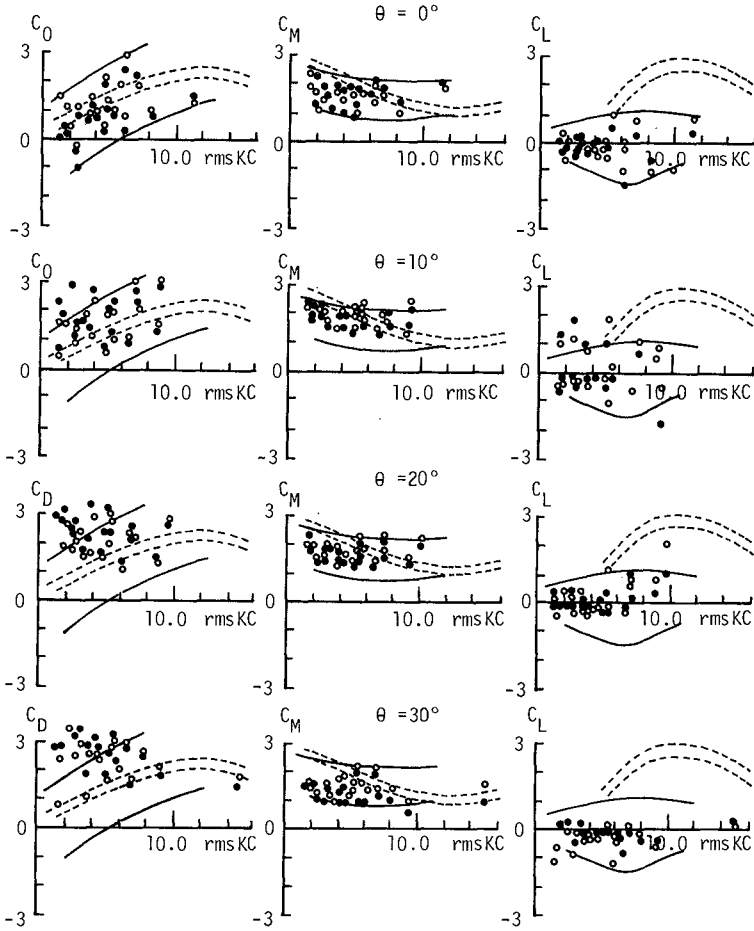

Time-independent values of the drag and mass coefficients in Eq.(7) were determined by the two-point method and by the least square method, respectively. Similarly, those of the lift coefficient in Eq.(8) were determined by the one-point method and by the least square method, respectively. For the convenience of later discussion, the following notations were given to the values of these coefficients:

- C_{DU2} : value of the drag coefficient determined by the two-point method.
- C_{DUL} : value of the drag coefficient determined by the least square method.
- C_{MU2} : value of the mass coefficient determined by the two-point method.
- C_{MUL} : value of the mass coefficient determined by the least square method.
- C_{LU1} : value of the lift coefficient determined by the one-point method.
- C_{LUL} : value of the lift coefficient determined by the least square method.

As mentioned previously, it has been pointed out by many researchers that the time-independent values of drag, mass and lift coefficients for either vertical or horizontal piles have some functional relationships with the period parameter or the Keulegan-Carpenter number. To determine whether this is true in the case of the coefficient values for inclined piles, coefficient values determined were plotted against the value of the rmsKC number, at every inclination of the pile. Here, the rmsKC number is the Keulegan-Carpenter number evaluated by $\sqrt{U^2} T/D$ where $\sqrt{U^2}$ is the root mean square of the velocity component, U, T is a wave period and D is a pile diameter.

Figure 3 shows the plots of the coefficient values determined for the piles inclined away from the direction of wave propagation. In this figure, the dotted lines show the Sarpkaya's results(1975) which were obtained for the piles placed horizontally in oscillatory flows, and the solid lines represent the variation ranges of each coefficient obtained in this study for the vertical piles. From this figure, the following facts were noted:

- (1). Both C_{DU2} and C_{DUL} increase their values first as the rmsKC number

- :variation curves of each coefficient determined by either the one-point or the two-point method.
- :variation curve of each coefficient determined by the least square method.
- :variation curves found by Sarpkaya for horizontal piles.
- :variation curves found by the writer for vertical piles($\theta=0^\circ$).

Figure 3. Variations of the coefficient values versus rmsKC number for circular piles placed in Plane A at plus inclination.

increases its value up to approximately 10.0, then start decreasing their values as the rmsKC number increases its value farther, although values of both coefficients scatter considerably.

- (2). Variations of C_{DU2} and C_{DU1} values versus rmsKC number agree considerably well to that found by Sarpkaya except for some data obtained for the piles inclined at 20° and 30°. It should be noted that these coefficients tend to decrease their values as the rmsKC number increases its value up to approximately 6.0.
- (3). Both C_{MU2} and C_{MU1} decrease their values first as the rmsKC number increases its value up to approximately 10.0, then start increasing their values as the rmsKC number increases its value farther. In this case, both coefficient values do not scatter as greatly as the values of drag coefficient.
- (4). Variations of C_{MU2} and C_{MU1} values versus rmsKC number agree considerably well to that found by Sarpkaya although inflection points of each variation curve appear at smaller value of the rmsKC number than the value of the KC number at which inflection point appears in the variation curve found by Sarpkaya. Further, distinct effect of pile inclination is not found on the variations of these coefficient values versus rmsKC number.
- (5). Many of C_{LU1} and C_{LU2} take minus values over the whole range of the rmsKC number. Further, the values of both coefficients scatter considerably over the whole range of the rmsKC number.
- (6). Variations of C_{LU1} and C_{LU2} values versus rmsKC number do not show any agreement with the variation curve found by Sarpkaya, although distinct effect of the pile inclination is not found on the variations of these coefficient values versus rmsKC number.

Similar plots were also made for the coefficient values of the piles inclined towards the direction of wave propagation. These plots found that variations of each coefficient value versus rmsKC number were quite similar to those found for the coefficient values of the piles inclined away from the direction of wave propagation except for the fact that many of the drag coefficient took minus values in the range where the value of the rmsKC number was smaller than approximately 6.0.

These facts found above may be caused partially by the following reasons:

- (1). Coefficient values determined here are a sort of representative values averaged over the submerged portions of inclined piles. Thus, effects of the water depth for these coefficient values are not evaluated properly.
- (2). The rmsKC number is used for the analysis of these coefficient values instead of the conventional period parameter.
- (3). Experiments have been conducted in the range of relatively small values of rmsKC number where the inertia force is predominant in comparison to the drag force.

2. Time-Independent Values of Drag, Mass and Lift Coefficients for Inclined Piles placed in Plane B

Time-independent values of drag, mass and lift coefficients in Eqs.(9) and (10) were determined by the three-point method and by the least square method, respectively. Many of these coefficients, however, took incredibly large values. This might be caused by the defect of the determination methods which require each force term in Eqs.(9) and (10) to share equal weight for the determination of each coefficient value regardless to its magnitude. Then, the following ratios were calculated to find some information which help minimize this defect:

$$RX1(t) = F_{Du}(t)/F_{mxB}(t) \times 100(\%)$$

$$RX2(t) = F_{I\dot{u}}(t)/F_{mxB}(t) \times 100(\%)$$

$$RX3(t) = F_{Lv}(t)/F_{mxB}(t) \times 100(\%)$$

$$RL1(t) = F_{Lu}(t)/F_{mLB}(t) \times 100(\%)$$

$$RL2(t) = F_{Ov}(t)/F_{mLB}(t) \times 100(\%)$$

$$RL3(t) = F_{I\dot{v}}(t)/F_{mLB}(t) \times 100(\%)$$

In the above equations, $F_{mxB}(t)$ represents measured value of the in-line force exerted on a pile placed in Plane B at an arbitrary phase, t , and $F_{mLB}(t)$ represents measured value of the lift force on the same pile at the same phase. Hence, these six ratios measure the relative magnitude or the contribution rate of each force term in Eqs.(9) and (10) to the corresponding wave forces. These calculations found that values of $RX3(t)$ were always quite small comparing to the values of the other ratios. Namely, the maximum values of $RX3(t)$ within a wave cycle were always smaller than 5% when piles were inclined at an inclination less than or equal to 20°. Further, some of $RX3(t)$ surely exceeded 5% when piles were inclined at 30°, but they did not exceed 10% in these cases.

Based on this finding, it was assumed that contribution rate of $F_{Lv}(t)$ in eq.(9) to its total in-line force, $F_{tXB}(t)$ is negligibly small in the cases of runs where the maximum value of $RX3(t)$ is less than 5%, and the values of only C_{Du} and $C_{M\dot{u}}$ in Eq.(9) were determined in these cases again by the two-point method and by the least square method, respectively. For determining the coefficient values in Eq.(10), it was further assumed that the values of $C_{M\dot{v}}$ in Eq.(10) are approximately equal to the values of $C_{M\dot{u}}$ determined previously since values of $C_{M\dot{u}}$ were almost constant over the range of rmsKC number experienced in this study. Based on this assumption, values of only C_{Lu} and C_{Dv} in Eq.(10) were determined again by the two-point method and by the least square method, respectively.

Coefficient values determined by these procedures were also plotted similarly against the values of the rmsKC number. As a result, it was found that the values of these coefficients also showed quite similar variations to those of the corresponding values of the coefficients found for the inclined piles placed in Plane A.

3. Time-Dependent Values of Drag, Mass and Lift Coefficients for Inclined Piles

Time-dependent values of drag, mass and lift coefficients for inclined piles placed in Plane A were determined by the same methods as described in the previous Chapter. Namely, time-dependent values of drag and mass coefficients in Eq.(9) were determined by the Al-Kazily's method, and those of the lift coefficient in Eq.(8) were determined by solving Eq.(8) at every incremental phase of 0.01 second over a wave cycle.

In the determination of time-dependent values of each coefficient for the piles placed in Plane B, however, coefficient values were determined by using the same procedures as developed previously for the determination of their time-independent values. Namely, the time-dependent values of each coefficient in Eqs.(9) and (10) were determined by the Al-Kazily's method when the contribution rate of each force term was less than 5%, although coefficient values were determined by the three-point

method described in the previous Chapter when the contribution rates of all force terms were greater than 5%.

Coefficient values determined by these methods were expanded into Fourier series which consist of six significant components whose frequencies are the multiples of the frequency of incident wave. As a result, it was found that correlation coefficients between determined values of each coefficient and the values of the corresponding coefficient estimated by the Fourier series reached approximately 0.8 in average.

Figure 4 shows some comparisons of the time-dependent values of each coefficient determined by the Al-Kazily's method, with those estimated by the Fourier series mentioned above. It can be noted clearly from this figure that coefficient values are not constant but vary considerably within a wave cycle, and that Fourier series of significant components can trace determined values of each coefficient quite satisfactorily.

Figure 4. Variation of the time-dependent coefficients ($\theta = +20^\circ$, $D = 4.0\text{cm}$, rmsKC No. = 2.80)

Reliability of the Coefficient Values

To check the reliability of the time-independent and time-dependent values of each coefficient determined above, quantitatively, relative deviations of the calculated wave forces from the measured ones were computed by Eq.(11) which was shown previously. This computation was made for both in-line and lift forces exerted on all piles placed in Plane A and Plane B. To distinguish these relative deviations, two suffixes were further added to the notations indicating the relative deviations of the in-line force, δF_x and that of the lift force, δF_L , respectively. Namely, the first suffix of the two indicates the plane where piles were placed: suffix [A] represents Plane A; and suffix [B] represents Plane B. On the other hand, the second suffix indicates the coefficients used for the calculation of wave force: suffix [1] represents the coefficient determined by the one-point method; suffix [2] represents the coefficients determined by the two-point method; suffix [L] represents the coefficients determined by the least square method; and suffix [F] represents the coefficients determined by the Fourier series of six significant components. These values were plotted against the rmsKC number at every inclination of a pile.

Figure 5 shows the relative deviations of the in-line force exerted on the piles placed in Plane A and Plane B at plus inclinations, respectively. Namely, the left half of this figure shows the variations of relative deviations versus rmsKC number in the cases when the time-independent coefficients were used for the calculation of in-line force, and the right half of it shows the variations of the relative deviations versus rmsKC number in the cases when the time-dependent coefficients determined by the Fourier series were used for the calculation of in-line force. From this figure, the following facts were noted:

- (1). Relative deviations calculated basing on the time-independent coefficients are less than 10% mostly, regardless of the placing plane or the inclination of the piles, although some of them exceed 10% in the case of vertical pile ($\theta = 0^\circ$). It is further noted that these relative deviations tend to increase slightly as the rmsKC number increases although some scatters are found among them in the range of the rmsKC number smaller than approximately 4.0.
- (2). Relative deviations calculated basing on the coefficients determined by the least square method are always few percents smaller than those calculated basing on the coefficients determined by the two-point method, regardless of the placing plane or the inclination of the piles.
- (3). Relative deviations calculated basing on the time-dependent coefficients determined by the Fourier series are less than 5% mostly over the whole range of the rmsKC number, regardless of the placing plane or the inclination of the piles.

Similar facts were also found in the cases when piles were placed at minus inclinations. These facts found above may indicate that the time-independent coefficients can be used for the prediction of the in-line force exerted on the inclined piles although usage of the time-dependent coefficients is more desirable for that purpose. These facts may also

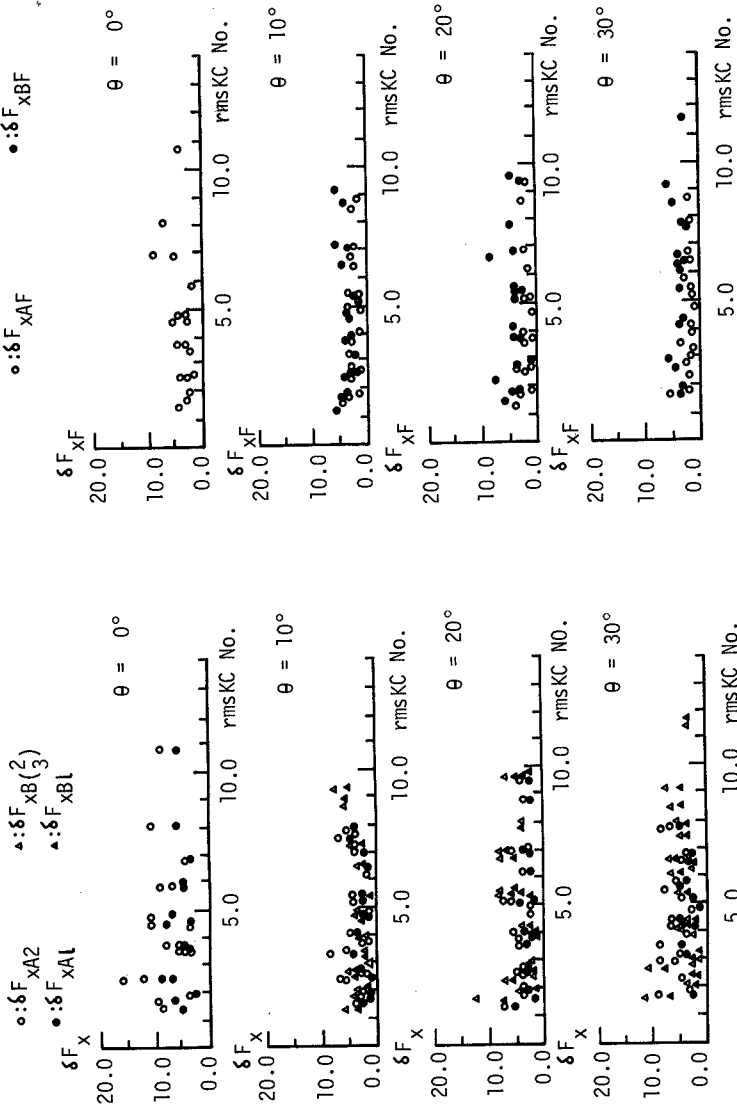

Figure 5. Relative deviation of in-line force plotted against rmsKC number.

endorse the propriety of wave force formulas formulated in this study for the inclined piles.

Figure 6 shows the relative deviations of the lift force exerted on the piles placed in Plane A and Plane B at plus inclinations, respectively. Namely, the left half of this figure summarizes variations of the relative deviations versus rmsKC number in the cases when the time-independent coefficients were used for the calculation of the lift force, and the right half of it summarizes those in the cases when the time-dependent coefficients determined by the Fourier series were used. From this figure, the following facts were noted:

- (1). Relative deviations calculated basing on the time-independent coefficients scatter considerably over the whole range of the rmsKC number, regardless of the placing plane or the inclination of the piles, and some of them exceed 200%.
- (2). Relative deviations calculated basing on the time-dependent coefficients are decreased significantly, irrespective of the placing plane or the inclination of the piles. Further, they tend to decrease as the rmsKC number increases, and most of them become approximately 10% when the rmsKC number reach 10.0.

Similar facts were also found in the cases when piles were placed at minus inclinations. The above facts may indicate that considerable amount of error would be induced if the time-independent coefficients are used for the prediction of lift force acting on the inclined piles, and that it is desirable to use some sorts of time-dependent coefficients such as the ones determined by the Fourier series for the prediction of lift force acting on the inclined piles.

Ratio of the Maximum Lift Force to the Maximum In-Line Force

Bidde(1971) conducted laboratory tests on the lift force acting on vertical circular piles and found that ratio of the lift force to the in-line force increased steadily as KC number increased, and that the ratio reached about 0.6 at the KC number of approximately 15 although it stopped increasing at the range of KC number greater than 15.

Sarpkaya(1975) also measured the lift force acting on horizontal circular piles and found that the ratio of the maximum lift force to the maximum in-line force varied with two humps while KC number increased up to about 30 although it kept almost constant value of about 0.8 at the range of KC number greater than 30. Further, he found that the ratio reached the maximum value of about 1.3 at one of the humps which appeared at the KC number of about 18.

In this study, ratio of the maximum lift force to the maximum in-line force recorded within a wave cycle were checked for all test cases and plotted at every inclination against the rmsKC number. Figure 7 shows these ratios found in the cases of the tests where piles were placed at plus inclination. In this figure, solid lines show the variation range of the ratio found by Bidde(1971). From this figure, the following facts were noted:

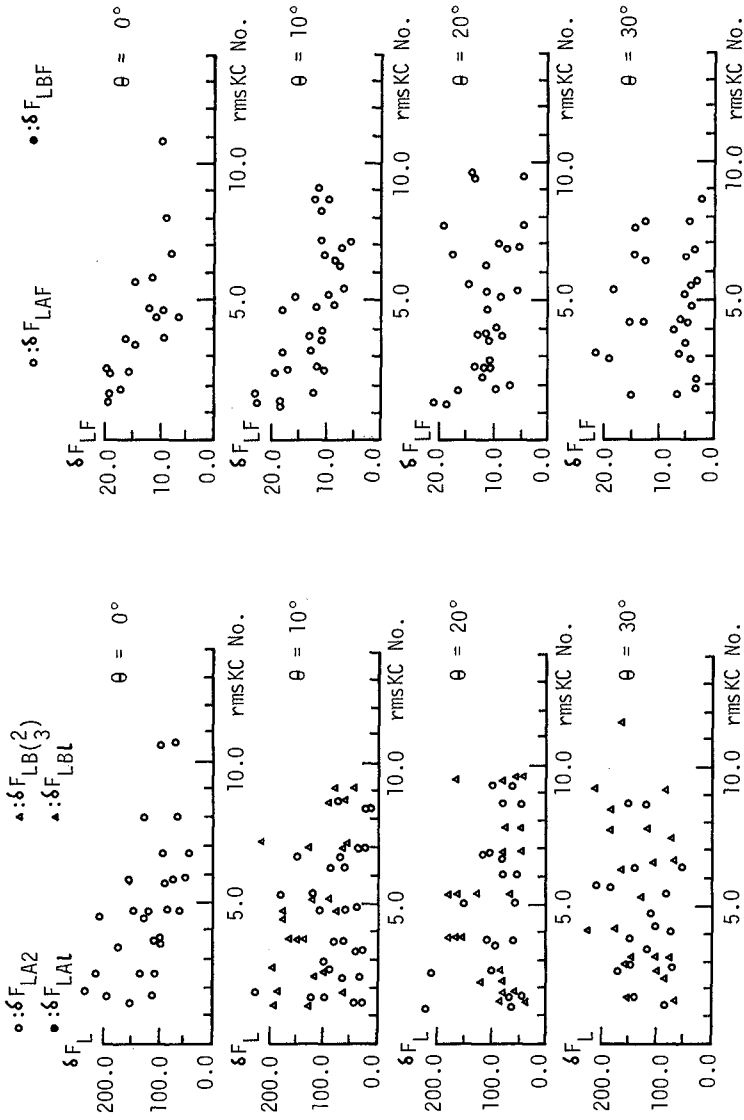

Figure 6. Relative deviation of lift force plotted against rmsKC number.

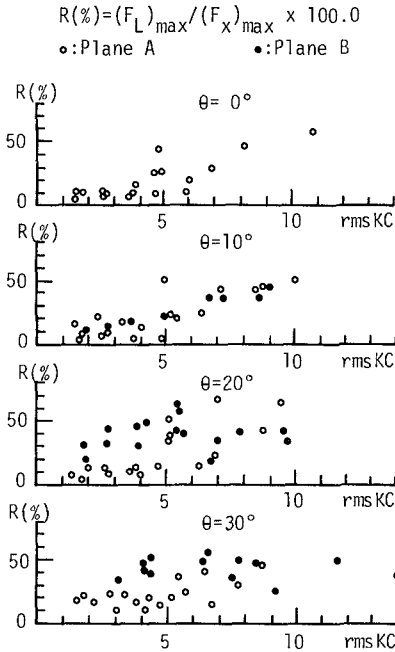

Figure 7. Ratio of the maximum lift force to the maximum in-line force versus rmsKC number (in cases of plus inclinations).

recognize the fact that considerably large lift force may possibly appear even at the small value of rmsKC number when piles are inclined more than 20°.

CONCLUSIONS

Both time-independent and time-dependent values of drag, mass and lift coefficients for inclined piles were determined by several methods, based on the respective wave force formulas which were derived by referring to the conventional Morison and lift force formulas. Reliability of these coefficient values were examined by checking the relative deviations of the calculated wave forces from the measured ones. Further, ratio of the maximum lift force to the maximum in-line force was also studied. As a result, the following conclusions were drawn:

- (1). Time-independent values of drag and mass coefficients can be used for the prediction of in-line force acting on the inclined

- (1). Ratio of the maximum lift force to the maximum in-line force tend to increase generally as the rmsKC number increases. Further, variations of the ratios versus rmsKC number agree quite well to the upper envelope of the variations found by Bidde, when piles are inclined at the inclination equal to or less than 10°.
- (2). When piles are inclined at the inclination equal to or greater than 20°, some scatters appear among the values of the ratios for the piles placed in Plane B. Namely, in this case, the ratios become almost constant ranging from approximately 0.3 to 0.6.

Similar facts were also found in the cases where piles were inclined at minus inclination.

The fact described in (2) may be caused partially by the effect of vertical velocity component of the induced flow. In any rate, readers should

- piles. Relative deviation calculated basing on these coefficients increases as the rmsKC number increases, but it will be 10% at most if the rmsKC number is smaller than about 12.0.
- (2). Time-independent values of lift coefficient can not be used for the prediction of lift force acting on the inclined piles. If they are used for prediction, relative deviation is about 100% in average over the whole range of rmsKC number. Lift coefficient determined by the Fourier series of six significant components will be a good one to be used for the prediction of lift force. If this coefficient is used for prediction, relative deviation is 20% at most. Further, it will decrease as the rmsKC number increases.
 - (3). Ratio of the maximum lift force to the maximum in-line force increases slightly as the rmsKC number increases, and variation of the ratio versus rmsKC number agrees quite well to the upper envelope of the variation of the ratio versus KC number found by Bidde, as long as the pile inclination is equal to or less than 10°. However, considerably large value of the ratio is found at the small value of rmsKC number if the piles are inclined more than 20°.

CHAPTER 109

WAVE-INDUCED SEEPAGE EFFECTS ON A VERTICAL CYLINDER

by

Thomas J.P. Durand¹ and Peter L. Monkmeyster², M. ASCE

ABSTRACT

This study deals with the seepage effects experienced by a large, vertical, circular cylinder resting on a submerged bed of sand when planar water waves interact with it. Potential theory is used to describe the seepage flow field. The sea bottom pressure condition is determined from the water field velocity potential derived by MacCamy and Fuchs (1954) in the case of planar waves diffracted by a large impervious cylinder. Consideration is also given to cylinders with a thin circular base whose diameter exceeds that of the cylinder itself.

The problem formulation as well as the initiation of the analysis apply to the general case of a bed of sand with finite depth.

For the case of infinite depth of the porous medium, theoretical solutions for the seepage pressure are obtained in the form of infinite integrals. Theoretical solutions for the pressure along the cylinder circular base are then derived, leading by integration to closed form expressions for the wave-induced seepage uplift force and overturning moment exerted on the cylinder. These expressions for the force and moment, which are presented in non-dimensional form are shown to be universal functions of a unique variable. Graphs are provided so that very few computations are required to determine the uplift force and overturning moment exerted on a cylinder. A comparison with various approximate theories reveals the present theory to be the only one which gives reliable results in general.

The amplitude and phase angle of the oscillating wave-induced pressure along the cylinder base are determined numerically. Results for the pressure amplitude are presented as non-dimensional ratios to the amplitude of the pressure that would prevail if no cylinder were disturbing the wave field.

Expressions for the exit gradient around the cylinder base are also determined. Contours of the ratio of the exit gradient to the one that would prevail in the absence of a cylinder are presented.

Laboratory measurements of uplift pressure amplitudes on a circular cylinder show good agreement with theoretical calculations.

INTRODUCTION

The rapid development of offshore construction in recent years has led to some complex technological problems, not the least of which are those concerned with the foundation and the possibility of foundation

-
- 1 Research Assistant, Department of Civil and Environmental Engineering, University of Wisconsin, Madison, Wisconsin 53706
 - 2 Professor of Civil and Environmental Engineering, University of Wisconsin, Madison, Wisconsin 53706

failure. There is some indication that such failure may be due to wave-induced seepage in the porous sea bed. Dynamic seepage pressures are believed to induce erosion phenomenon around the foundation of some structures as well as the cyclic uplift forces which act on the underside of a structure resting on the sea bottom. As a result, research dealing with the dynamics of wave-induced seepage in sea beds has been conducted by a number of investigators.

Most of the past research on the subject has focused upon the mathematical formulation required to obtain a realistic model of the physical phenomenon involved. Although work on this matter is still in progress, it may be useful to summarize the assumptions and governing equations used by some of the contributors. Sleath (1970) performed experiments which strongly support Putnam's (1949) use of potential theory, thereby suggesting that elastic effects can be neglected. Later, however, Moshagen and Tørum (1975), by including a water compressibility term in the continuity equation, derived a "heat conduction type" equation for the pressure. In the case of coarse sand, solutions to their equation approach those of Putnam, using potential theory, asymptotically. The results deviate only slightly for fine sands and are quite different for silts and silty clays. Yamamoto (1977), using the consolidation theory of Biot (1941), derived and solved a system of partial differential equations taking into account the compressibility of the water and the skeleton. Interestingly enough his solutions are very similar to those obtained from potential theory in the case of coarse sands and slightly different in the case of fine sands. Madsen (1978) also considered compressibility of water and skeleton as well as other soil properties. He concluded that for fine sands, as well as coarse sands which are isotropic, the effect of compressibility of fluid and skeleton is negligible.

It should be emphasized that all the previously mentioned studies apply only to planar waves unaffected by any structure. No consideration was given to the presence of a structure until Moshagen and Monkmeyer (1979) completed an investigation in which an embedded vertical cylinder was subjected to horizontal, wave-induced seepage forces. For a more detailed literature review the reader is referred to their paper.

The objective of this study is to analyze the dynamic seepage pressures and forces exerted on the base of a single, vertical, circular cylinder resting on a bed of sand when linear progressive waves interact with it. The cylinder does not penetrate the sea bed but its base can have a larger radius than the cylinder body itself. This extended circular base, when it is considered, is assumed to be infinitely thin. (See Fig. 1.)

The good agreement among the solutions of the various theories mentioned previously, when applied to sands (especially coarse sands), together with the great simplification it provides, makes potential theory the logical choice for the present study, especially in view of Sleath's experimental confirmation. The coupling condition between the sea water field and the pore water seepage field is obtained by means of a pressure matching procedure along the sea bottom. To accomplish

Fig. 1. Definition Sketch

this, MacCamy and Fuchs' (1954) potential function, describing both the incident and diffracted waves of the sea water flow field, is used to derive an analytic expression for the sea water pressure on the sea bottom. This pressure distribution provides a coupling boundary condition for the dynamic seepage field. The various additional boundary conditions are also stated for the seepage potential function. Although the analysis is initiated for the general case of a porous medium of finite thickness, theoretical solutions for the seepage pressures in the sea bed are only presented for the case of a porous medium of infinite thickness. Indeed, only in that case do the solutions lead to relatively simple expressions for the pressure distribution along the underside of the cylinder base. The uplift force and overturning moment exerted on the cylinder base by the dynamic seepage can then be obtained by integration.

THEORETICAL ANALYSIS

Governing Equation

The seepage flow field in the porous medium is assumed to follow Darcy's law,

$$\vec{q} = \nabla \phi_2 \quad (1)$$

$$\text{with} \quad \phi_2 = -K[p_2/\gamma + z] \quad (2)$$

where ϕ_2 = velocity potential [L^2/T]

γ = specific weight of water [M/L^2T^2]

p_2 = pressure [M/LT^2]

\vec{q} = specific discharge [L/T]

K = hydraulic conductivity [L/T]

z = vertical coordinate [L]

Assuming a completely saturated soil and neglecting the various effects due to the compressibilities of the water, porous skeleton and sand grains themselves, the continuity equation takes the form:

$$\nabla \cdot \vec{q} = 0 \quad (3)$$

By substitution of Eq. 1 into Eq. 3, the governing equations for seepage then lead to Laplace's Equation,

$$\nabla^2 \phi_2 = 0 \quad (4)$$

so that under the assumption of essentially incompressible water flowing through a saturated, rigid, isotropic porous medium, potential theory may be used to describe the seepage flow field, as noted before.

Boundary Conditions

In order to couple the sea water field to the seepage flow field, the pore water pressure distribution along the mud line is matched to the corresponding sea water pressure distribution. To this end, use is made of the well-known MacCamy and Fuchs (1954) velocity potential for small amplitude water waves diffracted by a vertical circular cylinder of radius b .

$$\phi_1(r, \theta, z, t) = \frac{gH}{2\omega} e^{-i\omega t} \frac{\cosh(kz)}{\cosh(kh_1)} \sum_{m=0}^{\infty} \frac{\epsilon_m i^m C_m(kr)}{H_m^{(1)'}(kb)} \cos(m\theta) \quad (5)$$

where $C_m(kr) = J_m'(kb) H_m^{(1)}(kr) - H_m^{(1)'}(kb) J_m(kr)$

$$\epsilon_m = \begin{cases} 1 & \text{if } m = 0 \\ 2 & \text{if } m \geq 1 \end{cases}$$

and where g = acceleration due to gravity [L/T^2]
 H = wave height [L]
 ω = $2\pi/T$ = wave frequency = [$gk \tanh(kh_1)$] $[T^{-1}]$
 k = wave number [L^{-1}]
 h_1 = elevation of mean sea level above sea bottom [L]
 b = cylinder radius [L]
 $J_m(\)$ = Bessel function of the first kind of order m
 $H_m^{(1)}(\)$ = Hankel function of the first kind of order m

where the primes indicate differentiation with respect to the argument. It should be emphasized at this point that MacCamy and Fuchs' velocity potential is valid for cylinders large with respect to the wave dimensions. More specifically, since the MacCamy and Fuchs theory neglects drag but considers inertial effects it is only valid when drag effects are minimal. As Dean and Harleman (1966) point out, this is the case when H/b is small and kh_1 is large.

By substituting Eq. 5 into the linearized dynamic pressure equation,

$$\frac{\partial \phi_1}{\partial t} + \frac{p_1}{\rho} = 0 \quad (6)$$

where ρ = mass density $[M/L^3]$,

one can derive an expression for the dynamic pressure at the bottom of the sea. The next step is to equate the pore water pressure immediately below the mud line to the corresponding sea water pressure immediately above.

$$p_1 = p_2 \quad \text{at } z = 0 \quad \text{for } r \geq a \quad (7)$$

where a = radius of the cylinder circular base $[L]$.

Making use of Eq. 2 one finally obtains the following condition for ϕ_2 along the mud line

$$\phi_2 = \frac{K}{g} \frac{\partial \phi_1}{\partial t} = -\frac{iK}{g} \omega \phi_1 \quad \text{at } z = 0 \quad r \geq a$$

or, henceforth dropping the subscript 2,

$$\phi(r \geq a, \theta, z=0, t) = -i \frac{KH e^{-i\omega t}}{2 \cosh(kh_1)} \sum_{m=0}^{\infty} \frac{\epsilon_m i^m C_m(kr)}{H_m^{(1)}(kb)} \cos(m\theta) \quad (8)$$

The impervious condition at bed rock is

$$\frac{\partial \phi}{\partial z} = 0 \quad \text{at } z = -h_2 \quad (9)$$

while the impervious condition along the circular disc of radius a on the underside of the base of the structure is

$$\frac{\partial \phi}{\partial z} = 0 \quad \text{at } z = 0 \quad r \leq a \quad (10)$$

It should be noted that the radiation condition associated with the present potential problem - such a condition is needed to insure the uniqueness of the solution - turns out to be implicitly integrated in the pressure matching condition along the mud line so that no additional requirement need be prescribed.

The governing Laplace equation, Eq. 4, is therefore constrained by its boundary conditions, Eqs. 8, 9 and 10. It clearly appears that a Neumann type condition and a Dirichlet type condition are prescribed on different parts of the same boundary, namely the upper plane $z = 0$, so that the potential problem to be solved is of the mixed boundary value type.

Solution

Due to the non-axisymmetric diffracted wave pattern, the analysis is initiated in three dimensions using a non-dimensional coordinate system

$$r^* = r/a \quad z^* = z/a \quad h_2^* = h_2/a \quad (11)$$

The stars are dropped for simplicity of the notation.

The particular form of the pressure matching condition, Eq. 8, suggests that the unknown potential function be expressed in a Fourier expansion of the polar angle,

$$\phi(r, \theta, z, t) = -i \frac{KH e^{-i\omega t}}{2 \cosh(kh_1)} \sum_{m=0}^{\infty} \frac{\epsilon_m i^m \phi_m(r, z)}{H_m^{(1)}(kb)} \cos(m\theta) \quad (12)$$

where the functions $\phi_m(r, z)$ are the new problem unknowns satisfying the reduced partial differential equation

$$\frac{\partial^2 \phi_m}{\partial r^2} + \frac{1}{r} \frac{\partial \phi_m}{\partial r} - \frac{m^2}{r^2} \phi_m + \frac{\partial^2 \phi_m}{\partial z^2} = 0 \quad (13)$$

A solution of Eq. 13, satisfying the bed rock condition, Eq. 9, can be obtained through a Hankel integral transform and is given by

$$\phi_m(r, z) = \int_0^{\infty} p A_m(p) [e^{pz} + e^{-p(z+2h_2)}] J_m(pr) dp \quad (14)$$

where $A_m(\)$ is a new unknown function which can be determined by making use of the remaining boundary conditions, Eqs. 8 and 10,

$$\int_0^{\infty} p \tanh(ph_2) F_m(p) J_m(pr) dp = 0 \quad 0 \leq r < 1 \quad (15)$$

$$\int_0^{\infty} F_m(p) J_m(pr) dp = C_m(kar) \quad 1 \leq r$$

where

$$F_m(p) = p A_m(p) [1 + e^{-2ph_2}] \quad (16)$$

Eqs. 15 are known as Dual Integral Equations. They obviously result from the mixed nature of the boundary value problem. Sneddon (1966) presents a thorough treatment of these equations. Closed form solutions of Dual Integral Equations have been obtained in the case of $h_2 \rightarrow \infty$, which corresponds to the physical case of infinite depth of the porous medium, and therefore this analysis will be restricted to the infinite depth case only.

For $h_2 \rightarrow \infty$, Sneddon reports Titchmarsh's solution as

$$p A_m(p) = -\sqrt{\frac{2p}{\pi}} \int_1^{\infty} t^{m+1/2} J_{m+1/2}(pt) dt \frac{d}{dt} \int_t^{\infty} \frac{C_m(kau) du}{u^{m-1} \sqrt{u^2 - t^2}} \quad (17)$$

which, after some rearrangement and then substitution into Eq. 14, leads to

$$\phi_m(r, z) = \int_0^{\infty} \sqrt{kap} e^{pz} J_m(pr) dp \int_1^{\infty} t J_{m+1/2}(pt) C_{m+1/2}^*(kat) dt \quad (18)$$

where

$$C_{m+1/2}^*(kat) = J_m'(kb) H_{m+1/2}^{(1)}(kat) - H_m^{(1)'}(kb) J_{m+1/2}(kat) \quad (19)$$

It should be pointed out that Eq. 18 together with Eq. 12 provide an exact expression for the wave-induced potential distribution throughout the entire seepage field when a cylinder is resting on a bed of sand of infinite thickness.

Although some simplifications of Eq. 18 can be performed by making use of the Hankel inversion formula and of a known indefinite integral for the inner integral, this would only apply for the Bessel function of first kind, $J_m(\cdot)$, but not for $H_m^{(1)}(\cdot)$ so that no equation for ϕ_m , more suited to computational purposes, could be derived.

RESULTS OF THE THEORETICAL ANALYSIS

Pressure Distribution along the Cylinder Base

Substituting $z = 0$ in Eq. 18, inverting the order of integration, and performing the inner integration leads to

$$\phi_m(r \leq 1, 0) = \sqrt{\frac{2ka}{\pi}} r^m \int_1^\infty \frac{C_{m+1/2}^*(kat) dt}{t^{m-1/2} \sqrt{t^2 - r^2}} \quad (20)$$

which can in turn be transformed into

$$\phi_m(r \leq 1, 0) = C_m(kar) - \sqrt{\frac{2ka}{\pi}} r^m \int_r^1 \frac{C_{m+1/2}^*(kat) dt}{t^{m-1/2} \sqrt{t^2 - r^2}} \quad (21)$$

Hence the exact solution for the wave-induced pressure distribution along the circular base of the cylinder is, dropping the hydrostatic term,

$$p(r \leq 1, \theta, 0, t) = \frac{\gamma_H e^{-i\omega t}}{2 \cosh(kh_1)} \sum_{m=0}^{\infty} \frac{\epsilon_m i^{m+1} \phi_m(r, 0)}{H_m^{(1)'}(kb)} \cos(m\theta) \quad (22)$$

where, for computational purposes, Eq. 21 is transformed into

$$\phi_m(r \leq 1, 0) = C_m(kar) - \sqrt{\frac{2kar}{\pi}} \int_0^{\cosh^{-1}(\frac{1}{r})} \frac{C_{m+1/2}^*(kar \cosh u)}{(\cosh u)^{m-1/2}} du \quad (23)$$

Tabulated numerical results for the wave-induced dynamic pressure amplitude along the cylinder base are presented as non-dimensional ratios to the amplitude of the pressure that would prevail if no cylinder were disturbing the wave field, namely

$$P_{LT} = \frac{\gamma H}{2 \cosh(kh_1)} \quad (24)$$

Hence only the infinite sum in Eq. 22 is tabulated. Table I shows the values of these pressure ratios for $ka = kb = 0.2, 1.0$ and $ka = 2kb = 2.0$.

Uplift Force and Overturning Moment on the Structure

In addition to providing a simplifying transformation, the Fourier expansion, as performed at the beginning of the analysis, also has the well-known advantage of extracting from the pressure the very terms required for calculating the uplift force and overturning moment exerted on the cylinder base. More specifically, when performing the integration of the pressure, only the zero or first order terms of the Fourier infinite series make a non-zero contribution to the force or moment respectively. Furthermore, in both cases, the corresponding integration of Eq. 21 involves two integrations which can be inverted and performed analytically. Various straightforward algebraic manipulations - for the detailed derivation see Durand (1978) - finally yield closed form expressions for the wave-induced seepage uplift force and overturning moment exerted on the cylinder base as follows:

$$F = \frac{\gamma H}{\cosh(kh_1)} \frac{\pi a^2}{ka} A_0(kb) \cos(\omega t + \alpha_0(kb))$$

$$\{J_1(kb) [Y_1(ka) + \frac{2}{\pi} \frac{\cos ka}{ka} + \frac{2}{\pi} \sin ka]$$

$$- Y_1(kb) [J_1(ka) - \frac{2}{\pi} \frac{\sin ka}{ka} + \frac{2}{\pi} \cos ka]\}$$
 (25)

$$M_o = - \frac{\gamma H}{\cosh(kh_1)} \frac{\pi a^3}{ka} A_1(kb) \sin(\omega t + \alpha_1(kb))$$

$$\{J_1'(kb) [Y_2(ka) - \frac{4}{3\pi} (\cos ka (1 - \frac{3}{(ka)^2}) - \frac{3 \sin ka}{ka})]$$

$$- Y_1'(kb) [J_2(ka) + \frac{4}{3\pi} (\sin ka (1 - \frac{3}{(ka)^2}) + \frac{3 \cos ka}{ka})]\}$$
 (26)

where

$$\tan[\alpha_i(kb)] = \frac{Y_i'(kb)}{J_i'(kb)} \quad i = 0, 1$$
 (27)

$$A_i(kb) = [J_i'(kb)^2 + Y_i'(kb)^2]^{-1/2} \quad i = 0, 1$$
 (28)

It should be noted that Eq. 26 can be simplified when $kb = ka$ by making use of the identity,

$$J_1'(ka) Y_2(ka) - Y_1'(ka) J_2(ka) = - \frac{2}{\pi (ka)^2}$$
 (29)

Eq. 25 may be normalized with expressions for the amplitude of the force based on two approximate theories. First, assuming that the oscillating pressure has the same amplitude and phase across the cylinder base, one obtains (see curve A in Fig. 2)

$$F_{LT_1} = \frac{\gamma H}{2 \cosh(kh_1)} \pi a^2$$
 (30)

The second approximate force is derived by taking into account the spatial variation of the pressure that would prevail across the cylinder base if no cylinder were present, (see curve B in Fig. 2)

$$F_{LT_2} = \frac{\gamma H}{\cosh(kh_1)} \pi a^2 \frac{J_1(ka)}{ka}$$
 (31)

Eq. 26 may also be normalized with an approximate expression for the amplitude of the moment derived for conditions similar to those of Eq. 31. (The moment vanishes for the conditions of Eq. 30.)

$$M_{o_{LT}} = \frac{\gamma H}{\cosh(kh_1)} \pi a^3 \frac{J_2(ka)}{ka}$$
 (32)

Fig. 2. Uplift Force Ratios

The ratios of the amplitude of the uplift force and overturning moment to the above normalizing quantities are plotted in Figs. 3 and 4 with ka as the variable and kb as parameter. For the most common case of $a = b$, each result is restricted to a universal graph because the above ratios are universal functions of a unique variable, ka .

Vertical Velocity Distribution along the Mud Line

It is important to note that Sneddon (1966) provides an alternate method to derive Eq. 20 directly from the Dual Integral Equations themselves. Interestingly enough he also provides a direct solution for the vertical velocity $\frac{\partial \phi}{\partial z}$ at the mud line through an expression for $\frac{\partial \phi}{\partial z}^m (r > 1, z = 0)$ which can take the form

$$\frac{\partial \phi}{\partial z}^m (r > 1, z = 0) = ka C_m^*(ka r) + \sqrt{\frac{2ka}{\pi}} r^{-m} \int_0^1 \frac{u^{m+3/2} C_{m+1/2}^*(kau)}{(r^2 - u^2)^{3/2}} du \quad (33)$$

Hence Eqs. 12 and 33 enable one to determine the vertical component of the specific discharge along the mud line and therefore the exit gradient. This quantity obviously appears to become infinite at the end of the cylinder base, $r = a$, but one may extract the singularity from Eq. 33 as

$$\sqrt{\frac{2ka}{\pi}} \frac{C_{m+1/2}^*(ka) r^{-m-1}}{\sqrt{r^2 - 1}} \quad (34)$$

so that the singularity of the seepage velocity field is clearly of the same weak nature as the well-known seepage velocity singularity occurring at the toe of an impervious dam resting on the top of a porous medium.

Fig. 3.a. Uplift Force Ratio: $ka \leq 2.0$ Fig. 3.b. Uplift Force Ratio: $ka \leq 20.0$

Fig. 4. Overturning Moment Ratio

The vertical component of the specific discharge can then be obtained from Eq. 12 so that the exit gradient

$$I_e = \frac{1}{K} \frac{\partial \phi}{\partial z} (r > 1, 0, 0, t) \tag{35}$$

is

$$I_e = - \frac{kH e^{-i\omega t}}{2 \cosh(kh_1)} \sum_{m=0}^{\infty} \frac{\epsilon_m i^{m+1}}{ka H_m(1)'(kb)} \frac{\partial \phi_m}{\partial z} (r > 1, 0) \cos(m\theta) \tag{36}$$

One may use the notion of critical gradient by comparing the amplitude of the oscillating exit gradient as given by Eq. 36 to the well-known expression

$$I_{cr} = \frac{Y'}{Y_w} = \frac{S_s - 1}{1 + e} \tag{37}$$

which for sands is approximately equal to 1.

If no cylinder were disturbing the wave field, the amplitude of the exit gradient to be used in place of Eq. 36 would simply be

$$I_e = \frac{kH}{2 \cosh(kh_1)}$$

so that it appears to be useful to simply compute the quantity

$$S(r, \theta) = \left| \sum_{m=0}^{\infty} \frac{\epsilon_m i^{m+1}}{H_m(1)'(kb)} \frac{1}{ka} \frac{\partial \phi_m}{\partial z} (r > 1, 0) \cos(m\theta) \right|$$

after substituting from Eq. 33.

A stability condition is then given by

$$\frac{kH}{2 \cosh(kh_1)} S(r, \theta) \leq I_{cr} = \frac{S_s - 1}{1 + e} \approx 1$$

in which the cylinder effect has been concentrated in a single coefficient, $S(r, \theta)$.

EXPERIMENTAL STUDY

In order to check the validity of the above theory, actual uplift pressure amplitudes along the base of a rigidly fixed, vertical, circular cylinder resting on a bed of sand were measured in the wave tank of the Hydraulics Laboratory of the University of Wisconsin-Madison. The sand used in the experiments was a fairly uniform coarse sand (about 1 mm in diameter). Although the depth of the porous medium had to be finite, it was kept large enough with respect to the wave length to permit the use of infinite-depth theory. More specifically the quantity kh_2 was equal to 2.1 so that $\tanh(kh_2)$ was close to 1, or more precisely 0.97. The tank used was 26 ft (7.92 m) long, 4 ft (1.22 m) wide and 2 ft (61 cm) deep but the inclusion of a bed of sand reduced the depth to 1 ft (30.5 cm). The sinusoidal progressive waves generated were in the following approximate ranges

$$.7 \text{ s} \leq T \leq .9 \text{ s} \quad 2.4' \leq L \leq 3.5' \quad 2.2'' \leq H \leq 2.85''$$

$$(73.2 \text{ cm}) \quad (106.7 \text{ cm}) \quad (5.59 \text{ cm}) \quad (7.24 \text{ cm})$$

Pressure measurements were made on the underside of the base of a vertical, circular cylinder mounted in the tank on top of the sand bed. Only one cylinder having a diameter of 5.72 in (14.5 cm) was tested with a sea water depth of 8 in (20.3 cm). A Pace transducer was used to measure pressures along the underside of the cylinder base at $r_1 = .991$ in (2.52 cm) and $r_2 = 1.963$ in (4.99 cm) while variation of the polar angle θ was obtained by rotation of the cylinder. The cylinder base had the same radius as the cylinder itself: $b = a$. See Fig. 5.

The measured pressures were normalized with respect to the pressure that would have prevailed if no cylinder had been disturbing the incoming waves. To this end, the normalizing quantities were determined by substituting the physical values into Eq. 24.

Spring and Monkmeyer (1975) studied the effect of wall confinement on pressure measurements along a cylinder placed in a tank of finite width. Correction coefficients resulting from their theoretical analysis of confinement were also used. In all cases, however, this coefficient turned out to be very close to 1 because their results and recommendations had made it possible to avoid those very parameter values based on wave length, tank width, cylinder radius for which confinement effects are important.

In Table II typical laboratory results are compared with the theory. The non-dimensional theoretical results were computed from

DIRECTION OF WAVE ADVANCE
→

Fig. 5. Position of the Pressure Taps

Eqs. 22, 23 and 24. In combination with two values for r , r_1 and r_2 , five values for the polar angle θ were used.

DISCUSSION

Table I clearly shows that the maximum pressure amplitude generally occurs at $r = a$, $\theta = 180^\circ$ while the minimum is generally found at $\theta = 0^\circ$, between $r = 0.0$ and $r = 0.4a$. For small values of $ka = kb$ (cylinder radius small with respect to the wave length) the maximum pressure amplitude is only 1.2 times the minimum so that the pressure amplitude variation across the cylinder base is not very significant in this case. For larger values of ka , e.g. $ka = kb = 1.0$, however, the maximum amplitude may be as much as 7 times larger than the minimum and 1.7 times larger than the value expected if no cylinder were disturbing the incoming wave field. A strong damping effect is also demonstrated by the small value of the amplitude of the oscillating pressure at the point of minimum pressure amplitude (about 25% of the expected value at that point if no cylinder were there). For the same cylinder, $kb = 1.0$, with an extended base, $ka = 2.0$, the pressure amplitudes around the edge of the base are not as affected by the diffracted waves as they are in the immediate vicinity of the cylinder wall, e.g. when $ka = kb$. However the damping effect taking place across the extended base is more striking.

Typically the value of the parameter ka for conditions corresponding to large oil tanks in the North Sea ($2a = 100$ m) with the century wave ($L = 320$ m) is about 1.0. Interestingly it was found that for values of ka of order 1, the pressure amplitude variation across the cylinder base is quite significant.

The graphs presented on Figs. 3 and 4 show how the pressure variation across the cylinder base affects the uplift force and overturning

Note: Waves approach from $\theta = 180^\circ$

moment. The pressure damping in the sea bed as ka increases, clearly has the effect of decreasing the force and moment with respect to what approximate theories would predict. This is consistent with what intuitive consideration would suggest but a quantitative rather than qualitative statement about the uplift force and overturning moment is quite important for design purposes. As an example for $ka = 1$, the force is about 50% smaller than that which simple approximate theories would predict.

Although not presented here in detail, additional studies led to the following conclusion: From the standpoint of minimizing the net uplift force and net overturning moment exerted on a cylinder of given radius b , also taking into account the effect of the pressure distribution along the upperside of the extended base, it appears that a cylinder without an extended base ($a = b$) rather than one with an extended base ($a > b$) is preferable. In the latter case one might have expected the dynamic pressure exerted along the upperside of the extended base to somehow compensate for the increase in the underside contribution from the dynamic seepage. But this was not the case. In other words, to minimize the force and moment, other considerations aside, an extended base should be avoided.

Insofar as an extended base does not remove the seepage velocity singularity occurring around the edge of the cylinder base such a base has little or no value in preventing erosion. Rather the technique of laying a rock filter around the cylinder base would seem more appropriate because it stabilizes the sand, while not increasing the net uplift force and overturning moment on the structure itself. The specific area to be protected around the cylinder base should be determined by calculating the exit gradient. As an example of what Eqs. 12 and 33 can provide, a contour of value 2.0 for the ratio of the hydraulic gradient amplitude to its value if no cylinder were there, namely of the coefficient $S(r,\theta)$, is shown on Fig. 6. Obviously for practical purposes, the critical exit gradient corresponding to the conditions of a specific problem should be determined and thus a critical contour around the cylinder base could be drawn, delimiting the area to be protected. As usual a safety factor should be introduced.

Fig. 6. Hydraulic Gradient Ratio

Table II shows that good agreement was found between experimental and theoretical results. Possible reasons for the small but persistent discrepancies include experimental error, difficulty in achieving a truly isotropic and homogeneous sand bed, and compressibility effects in the porous medium. In general these effects were not very significant.

CONCLUSIONS

1. The theory presented allows calculation of seepage pressure, uplift force and overturning moment values for a single vertical circular cylinder resting on a bed of sand of infinite depth. Evaluation of the exit gradient around the cylinder base is also possible. The nature of the seepage velocity singularity is shown to be similar to the singularity encountered at the toe of an impervious dam.

2. Normalized forms of the force and moment appear to be universal functions of two non-dimensional parameters ka and kb (k is the wave number, b the cylinder radius, and a the radius of the cylinder base), reducing to one when $a = b$. Graphs for these functions are provided so that once the physical characteristics of the problem are known, little additional computation is required.

3. A cylinder base extending beyond the cylinder radius does not remove the exit gradient singularity at the edge of the base. Furthermore, for a given cylinder radius, the effect of an extended base is to increase the maximum value of the net uplift force and overturning moment exerted on the cylinder. As a preferred protection against possible piping below and around the structure foundation, the use of a rock filter is recommended.

4. The theoretical results for the pressure appear to be in good agreement with data from a limited experimental program in a wave tank at the Hydraulics Laboratory of the University of Wisconsin-Madison.

5. The graphs presented in Fig. 2 show that approximate theories generally can not predict the wave-induced seepage effects on the cylinder.

ABSTRACT

Stability analysis of homogeneous and inhomogeneous seabed foundations under attack by storm waves are made by calculating the wave induced effective stresses. Wave induced effective stress analysis of homogeneous seabed is made using the theory previously developed by the senior author which is based on the poro-elastic theory by Biot. Effective stresses in inhomogeneous seabeds induced by waves are calculated by approximating an inhomogeneous bed by many layers of homogeneous soils each of which has different geotechnical properties of soils. A good agreement is obtained between the theory and the pore pressure data in situ field measurements. For a given wave length, it is found that there exists a most unstable thickness of homogeneous seabed when the seabed thickness is one-fifth of the wave length. As a realistic example of an inhomogeneous bed, the effective stresses in a typical seabed formation at the Mississippi Delta area of the Gulf of Mexico under the attack of design storm waves are calculated. The numerical results indicate that the storm waves induce a continuous submarine landslide which extends as deep as 9 m from the mud line. Numerical calculations also indicate that such landslides and liquefaction of seabeds can be prevented by placing a layer of concrete blocks or rubbles on the top of the seabeds.

INTRODUCTION

As ocean waves propagate over the continental shelf, turbulent boundary layers developed on the mud line and submarine sediment deposits experience wave-induced pore pressure and effective stresses. Consequently the wave energy is dissipated by the turbulence in the boundary layers, percolations and soil internal frictions in the seabed and the seabed is disturbed by the wave induced effective stresses. Because overall wave-seabed interaction is rather complicated, only the wave induced effective stresses and pore pressures are considered in this paper. The

problem of the wave damping due to the turbulent boundary layers, percolations and internal friction of seabed soils is out of the scope of this paper.

If the wave induced effective stress state in the submarine soils exceed the limit equilibrium, the seabeds will fail and may result in the liquefaction and submarine landslides. Such wave induced liquefaction and slide of seafloor foundations are evidenced as the flotation of buried pipelines at Australia coasts, the uneven settlements of gravity-type oil drilling rigs at North Sea and toppling of several jacket-type oil drilling rigs and numerous pipeline failures at the Mississippi Delta area.

The senior author has solved the effective stress state in homogeneous and isotropic seabeds induced by ocean waves based on the Biot's (1941) three-dimensional consolidation theory (Yamamoto, 1977). An almost identical theory was later published by Madsen (1978) except he assumed unisotropic soil permeabilities while assuming an isotropical elasticity of the soil. However, as pointed out by Biot (1955) such assumption is physically inconsistent. Mei and Foda (1980) developed the so-called boundary layer method approximating Yamamoto's (1977) exact solution which considerably simplify the numerical calculations. The theory by Yamamoto (1977) has been substantiated by a laboratory experimentation (Yamamoto, et al., 1978). Further verification of the theory is made in this paper by comparing the theory with the pore pressure data from *in situ* measurements in fine-grained sediment bed at the Mississippi Delta area by Bennett and Faris (1979).

The real seabeds on the continental shelves are usually not homogeneous but the geotechnical properties of soils vary with the distance from the sea-seabed interface or the mud line. The purpose of this paper is to extend the existing theory by the author for the homogeneous seabeds to more realistic inhomogeneous seabeds. An inhomogeneous seabed is approximated by many layers of homogeneous soils each of which has different values of geotechnical properties and the thickness of the sublayers. Seed and Rahman (1978) computed the wave induced pore pressures in a multi-layered seabed assuming that soils are rigid and pore water is incompressible. However such solution is only applicable to very permeable seabeds as pointed out by Yamamoto (1978). Furthermore, their theory provides no information on wave induced effective stresses in seabed which are provided by the present theory.

As illustrative examples, the typical seabed formations at the North Sea and the Mississippi Delta area under attack of design storm waves are analyzed. The results indicate high potential of massive landslide and liquefaction of submarine

seabed foundation. The numerical calculations suggest that such liquefactions and landslides of seabed can be prevented by placing a layer of concrete blocks or rubbles on the top of the seabeds.

PORO-ELASTIC THEORY FOR MULTI-LAYERED SEABEDS RESPONSE TO WATER WAVES

An inhomogeneous seabed is approximated by many layers of homogeneous soils each of which has different values of geotechnical properties and thicknesses. Figure 1 shows a definition sketch of a two-dimensional water wave propagating over a multi-layered seabed. The wave propagates from right to left. The x-axis is taken on the mud line and the positive z-axis is taken downward from the mud line. Soils in each sublayer of seabed are assumed to respond linearly to waves. Assuming that displacements of soils and pore water are relatively small, the inertia of soils and pore water are neglected. For soft clays, the inertia terms may not be negligibly small as indicated by Dawson (1978). Nonetheless, the error due to neglect of the inertia terms is considered to be small compared to the errors due to the uncertainty of geotechnical properties of submarine soils. The results including the inertia terms will be published in a future paper.

The continuity equation is given as,

$$\frac{k_j}{\gamma_j} \nabla^2 p_j = \frac{n_j}{K'_j} \frac{\partial p_j}{\partial t} + \frac{\partial \epsilon_j}{\partial t} \quad (j = 1, 2, \dots, N) \quad (1)$$

where p_j is the excess pore-water pressure, ϵ_j is the volume strain of the porous medium, t is the time, k_j is the coefficient of permeability of the soil, γ_j is the unit weight of the pore-water, n_j is the porosity, and K'_j is the apparent bulk modulus of pore-water. The subscript j indicates the j -th layer and N is the total number of layers. The volume strain of the soil matrix for the two-dimensional problem is

$$\epsilon_j = \frac{\partial u_j}{\partial x} + \frac{\partial w_j}{\partial z} \quad (2)$$

where u_j is the horizontal component of soil displacement and w_j is the vertical component of soil displacement.

From the effective stress concept and Hooke's law, the equation of equilibrium is

$$G_j \nabla^2 u_j + \frac{G_j}{1-2\nu_j} \frac{\partial \epsilon_j}{\partial x} = \frac{\partial p_j}{\partial x} \quad (3)$$

$$G_j \nabla^2 w_j + \frac{G_j}{1-2\nu_j} \frac{\partial \epsilon_j}{\partial z} = \frac{\partial p_j}{\partial z} \quad (4)$$

Figure 1. The definition sketch of a multi-layered seabed.

Figure 2. The Mohr's circle diagram of wave induced effective stresses.

where G_j is the shear modulus of the soil, and ν_j is Poisson's ratio for the soil.

Equations (1), (3) and (4) from the governing equations of the pore-water and the soils to be solved for p_j , u_j and w_j .

The effective stresses are related to the strains by Hooke's law as

$$\left(\sigma'_x\right)_j = 2G_j \left[\frac{\partial u_j}{\partial x} + \frac{\nu_j}{1-2\nu_j} \epsilon_j \right] \quad (5)$$

$$\left(\sigma'_z\right)_j = 2G_j \left[\frac{\partial w_j}{\partial z} + \frac{\nu_j}{1-2\nu_j} \epsilon_j \right] \quad (6)$$

$$\left(\tau'_{xz}\right)_j = G_j \left[\frac{\partial u_j}{\partial z} + \frac{\partial w_j}{\partial x} \right] \quad (7)$$

wherein $(\sigma'_x)_j$ is the effective normal stress in the x-direction, $(\sigma'_z)_j$ is the effective normal stress in the z-direction, and $(\tau'_{xz})_j$ is the shear stress in the z-direction on the plane perpendicular to the x-axis.

In the case of a sinusoidal wave propagating over the seabed, the response of the seabed to the wave is considered to be periodic in both time and space. Then, it is reasonable to assume that p_j , u_j and w_j are also periodic in time and space, or

$$p_j = p_j(z) \exp(i\theta) \quad (8)$$

$$u_j = U(z) \exp(i\theta) \quad (9)$$

$$w_j = W(z) \exp(i\theta) \quad (10)$$

where,

$$\theta = \lambda x + \omega t \quad (11)$$

λ is the wave number, ω is the angular wave frequency, and i is the imaginary unit ($i^2 = -1$). The right hand sides of Eqs. (8), (9) and (10) are complex. U_j , W_j and P_j are the function of z only.

Substituting Eqs. (9), (10) and (11) into the governing Eqs. (1), (3) and (4), the three simultaneous ordinary differential equations of second order can be obtained. The differential equations are linear and homogeneous and the characteristic equation is given as:

$$(D^2 - \lambda^2)^2 (D^2 - \lambda_j^2) = 0 \quad (12)$$

where D is the operator, d/dz , and λ_j is given as

$$\lambda_j^2 = \lambda^2 + i \frac{Y_j}{K_j} \omega \left[\frac{n_j}{K_j} + \frac{(1-2\nu_j)}{2(1-\nu_j)G_j} \right] \quad (13)$$

From Eq. (12) the general solutions of U_j , W_j and P_j are:

$$U_j = a_{1j} \exp[\lambda z] + a_{2j} \exp[-\lambda z] + a_{3j} \frac{z}{h_j} \exp[\lambda z] \\ + a_{4j} \frac{z}{h_j} \exp[-\lambda z] + a_{5j} \exp[\lambda_j' z] + a_{6j} \exp[-\lambda_j' z] \quad (14)$$

$$W_j = b_{1j} \exp[\lambda z] + b_{2j} \exp[-\lambda z] + b_{3j} \frac{z}{h_j} \exp[\lambda z] \\ + b_{4j} \frac{z}{h_j} \exp[-\lambda z] + b_{5j} \exp[\lambda_j' z] + b_{6j} \exp[-\lambda_j' z] \quad (15)$$

$$P_j = c_{1j} \exp[\lambda z] + c_{2j} \exp[-\lambda z] + c_{3j} \frac{z}{h_j} \exp[\lambda z] \\ + c_{4j} \frac{z}{h_j} \exp[-\lambda z] + c_{5j} \exp[\lambda_j' z] + c_{6j} \exp[-\lambda_j' z] \quad (16)$$

in which h_j is the depth of the lower boundary of the j -th layer, and a_{mj} , b_{mj} and c_{mj} ($m=1, \dots, 6$; $j=1, \dots, N$) are arbitrary constants. However, the coefficients a_{mj} , b_{mj} and c_{mj} are not independent on each other, and the relationship can be obtained from Eqs. (1), (3) and (4) as:

$$\left. \begin{aligned} b_{1j} &= -ia_{1j} + i(A_{1j}/h_j)a_{3j} \\ b_{2j} &= ia_{2j} + i(A_{1j}/h_j)a_{4j} \\ b_{3j} &= -ia_{3j} \\ b_{4j} &= ia_{4j} \\ b_{5j} &= -i(\lambda_j'/\lambda)a_{5j} \\ b_{6j} &= i(\lambda_j'/\lambda)a_{6j} \end{aligned} \right\} \quad (17)$$

$$\left. \begin{aligned}
 c_{1j} &= -i(A_{2j}/h_j)a_{3j} \\
 c_{2j} &= i(A_{2j}/h_j)a_{4j} \\
 c_{3j} &= c_{4j} = 0 \\
 c_{5j} &= A_{3j} a_{5j} \\
 c_{6j} &= A_{3j} a_{6j}
 \end{aligned} \right\} \quad (18)$$

where

$$\begin{aligned}
 A_{1j} &= \frac{1}{\lambda} \left[1 + \frac{n_j G_j}{K'} \frac{3 - 4\nu_j}{1 - 2\nu_j} \right] / \left[1 + \frac{n_j G_j}{K'} \frac{1}{1 - 2\nu_j} \right] \\
 A_{2j} &= 2G_j / \left[1 + \frac{n_j G_j}{K'} \frac{1}{1 - 2\nu_j} \right] \\
 A_{3j} &= 2\gamma\omega G_j (1 + \nu_j) \left[\frac{n_j}{K'} + \frac{1 - 2\nu_j}{2(1 - \nu_j)G_j} \right] / \left[\lambda k_j (1 - 2\nu_j) \right]
 \end{aligned} \quad (19)$$

Thus, in order to calculate U_j , W_j and P_j , unknown constants a_{1j} , a_{2j} , ..., a_{6j} ($j = 1, 2, \dots, 6$) should be determined in each layer. These $6 \times N$ constants can be determined from boundary conditions at the bed surface, at the interfaces between the sublayers, and at the bottom bed rock boundary.

In general, because of the interaction between the water waves and the seabeds, the properties of the waves will be changed under the influence from the seabeds. In this paper, we assume that the changes of wave properties are negligible, or the relative acceleration between water particles and soils are very small. Therefore, the boundary conditions at the bed surface are that the vertical effective stress is zero, that the shear stress is negligibly small, and that the sinusoidal pressure fluctuation exists, or at $z = 0$.

$$(\sigma'_z)_1 = 2G_1 \left[\frac{\partial \omega_1}{\partial z} + \frac{\nu_1}{1 - 2\nu_1} \left(\frac{\partial u_1}{\partial x} + \frac{\partial \omega_1}{\partial z} \right) \right] = 0 \quad (20)$$

$$(\tau'_{xz})_1 = G_1 \left(\frac{\partial u_1}{\partial z} + \frac{\partial w_1}{\partial x} \right) = 0 \quad (21)$$

$$p_1 = p_0 \exp(i\theta) \quad (22)$$

where $(\sigma'_z)_1$ is the effective normal stress in the z direction in the first layer, $(\tau'_{xz})_1$ is the shear stress in the z direction on the plane perpendicular to the x axis in the first layer, p_1 is the pore-water pressure in the first layer, and p_0 is the amplitude of pressure fluctuation at the bed surface.

The boundary conditions at the interfaces between the sublayers are that of the soil stresses, the pore-water pressures, the pore-water flow, and the soil displacement are continuous, of at $z = h_j$:

$$\left. \begin{aligned} (\sigma'_z)_j &= (\sigma'_z)_{j+1} & , & & (\tau'_{xz})_j &= (\tau'_{xz})_{j+1} \\ p_j &= p_{j+1} & , & & k_j (\partial p_j / \partial z) &= k_{j+1} (\partial p_{j+1} / \partial z) \\ u_j &= u_{j+1} & , & & w_j &= w_{j+1} \end{aligned} \right\} \quad (23)$$

If the lowest layer (N - th layer) is on an impermeable and rigid bed, the boundary conditions are that no soil displacements at the boundary and no flow across the boundary are allowed, or at $z = h_n$:

$$u_N = 0, w_N = 0, \partial p_N / \partial z = 0 \quad (24)$$

For a semi-infinite half-plane, the boundary conditions may be given as:

$$u_N, w_N, p_N \rightarrow 0 \text{ as } z \rightarrow \infty \quad (25)$$

From Eqs. (14), (15), (16), (17) and (18), this means that:

$$a_{1N} = 0, a_{3N} = 0, a_{5N} = 0 \quad (26)$$

FAILURE ANALYSIS

So far, only the wave induced incremental changes in stresses and pressures in soils from the initial equilibrium state have been considered. In this section the failure mechanisms of soils induced by waves are considered. From this point on, the traditional sign convention for stresses in the soil mechanics will be used, i.e., a stress is positive when it acts as a compression. The subscript j

for the effective stresses are omitted for simplicity in the following development.

The total effective stress, $\bar{\sigma}_z$, in the z-direction is given as

$$\bar{\sigma}_z = \bar{\sigma}_{oz} - \sigma'_z \quad (27)$$

where $\bar{\sigma}_{oz}$ = effective normal stress in the z-direction at initial equilibrium and given as:

$$\bar{\sigma}_{oz} = \gamma_b z = \gamma(G_s - 1)z \quad (28)$$

where γ_b = buoyant unit weight of the soil, γ = unit weight of water (9800 N/m³), and G_s = specific gravity of soil grains σ'_z in Eq. (28) is the incremental effective stress given by Eq. (6). The total effective normal stress, $\bar{\sigma}_x$, in x-direction is given by:

$$\bar{\sigma}_x = \bar{\sigma}_{ox} - \sigma'_x \quad (29)$$

where $\bar{\sigma}_{ox}$ is the effective stress at the initial hydrostatic equilibrium and may be given as:

$$\bar{\sigma}_{ox} = K_o \bar{\sigma}_{oz} = K_o \gamma_b z$$

where K_o is the coefficient of earth pressure at rest and is related to the Poisson ratio, ν , as:

$$K_o = \frac{\nu}{1-\nu} \quad (31)$$

σ'_x in Eq. (29) is given by Eq. (5). The values of K_o for soils range from 0.4 to 1.0 (Scott, 1963).

Since the shear stresses on horizontal and vertical planes are zero at the initial equilibrium, the total shear stress, $\bar{\tau}_{xz}$, is related to the incremental shear stress, τ'_{xz} , of Eq. (17) as

$$\bar{\tau}_{xz} = -\tau'_{xz} \quad (32)$$

Equations (27), (29) and (32) may be represented by the Mohr's circles as shown in Fig. 2. The Mohr's circle at a given instance is illustrated by a heavy solid circle passing through points P and Q. The point P and Q rotates on the shear ellipses shown by dashed lines at wave angular frequency, ω , as the waves progress over the seabed.

The failure condition for a given soil may be given as

$$\bar{\tau}_f \geq \bar{\sigma}_f \tan \phi_f + c \quad (33)$$

where ϕ_f = angle of internal friction of the soil, c = cohesion of the soil, τ_f = shear stress on the failure plane, and $\bar{\sigma}_f$ = effective normal stress on the failure plane. The limiting failure condition given by Eq. (33) is shown by the dashed straight line in Fig. 2.

Let the angle, ϕ , between the tangent to the instantaneous Mohr circle from point C (0,c) and the horizontal in Fig. 2 be defined as the "stress angle." Then the failure criteria of the soil element at a given point at a given instance may be defined as

$$\phi(x,z,t) \geq \phi_f \quad (34)$$

The stress angle, ϕ , is related to the stresses on the vertical and horizontal planes as

$$\frac{\bar{\sigma}_z + \bar{\sigma}_x}{2} \sin \phi + c \cos \phi = \left[\frac{\bar{\sigma}_z - \bar{\sigma}_x}{2}^2 + \bar{\tau}_{xz}^2 \right]^{1/2} \quad (35)$$

COMPARISON BETWEEN THEORY AND FIELD DATA

The pore-elastic theory presented in this paper has been substantiated by laboratory experiments of a coarse sand bed and fine sand bed (Yamamoto, et al., 1978). In order to further verify the theory, the theory is compared with the wave induced pore-pressure data from in situ measurements in the field available in the literature. Bennett and Faris (1979) measured the wave induced pore-pressure in fine-grained submarine sediments at the East Bay area of the Mississippi Delta in 12.5 m of water. They measured the 30 min. time history record of the pore-pressures at 6.3 m and 15.3 m below mud line as well as the bottom pressure. The 30 min long records are divided into three and the average values of the peak to peak pressures are calculated. The significant wave length is 52 m from the linear theory. The geotechnical properties of the sediments are estimated as the shear modulus, $G = 1.0 \times 10^6$ N/m², the Poisson ratio, $\nu = 0.333$, the porosity, $n = 0.5$, and the permeability, $k = 1.0 \times 10^{-6}$ m/s. Infinite thickness of a homogeneous isotropic seabed is assumed in the theoretical calculations. Since up to 10% by volume of undissolved gas in the sediments are reported, both saturated case as well as the case of 90% saturation are computed in the numerical calculations. The comparisons between the theory and the field measurements for the ratio, p/p_0 , of the amplitude of pore pressure and the amplitude of bottom pressure vs. the depth d are shown in Fig. 3. The field data fall in between the theoretical curves of 90% saturation and 100% saturation. Considering the limited information about the geotechnical properties of these sediments, Fig. 3 shows an excellent agreement between the theory and the field measurements. This agreement supports the credibility of the present theory in some degree.

Figure 4. The horizontal displacement, u_0 , and the vertical displacement, w_0 , of the soil at the mud line vs. the bed thickness, d .

EFFECTS OF THE BED THICKNESS ON THE BED RESPONSE

In order to investigate the effects of the bed thickness on the bed response to waves, a single homogeneous soil bed with varying bed thickness, d , on an impermeable rigid bedrock is first considered. The North Sea design condition of wave characteristics and the geophysical properties of soil is used in calculations; wave period $T = 15$ s, wave length $L = 324$ m, wave height $H = 24$ m, water depth $h = 70$ m, shear modulus $G = 1.0 \times 10^7$ N/m², permeability $k = 1.0 \times 10^{-4}$ m/s, porosity $n = 0.3$, Poisson ratio $\nu = 0.333$, cohesive strength $c = 0$ bulk modulus of pore water $K' = 2.3 \times 10^9$ N/m³. The amplitude of bottom pressure calculated from the linear wave theory is $p_0 = 5.60 \times 10^4$ N/m².

The plots of the horizontal displacements, u_0 , and the vertical displacement, w_0 , of the soil at the mud line vs. the bed thickness, d , are shown in Fig. 4. The horizontal displacement u_0 first increases as the bed thickness d increases, reaches the maximum value of 4.6 cm at $d = 61.8$ m, then decreases thereafter and vanishes as d tends to infinity. The vertical displacement w_0 monotonously increases with d and reaches a constant value of 14.5 cm as d tends to infinity. This suggests that there exists the most unstable bed thickness when $d = 0.20 L$. Figure 5 shows the distribution of stress angle ϕ in the seabed of infinite thickness which is evaluated from Eq. (35) which represents Mohr's effective stress diagram illustrated in Fig. 2. $x = 0$ represents the location of wave crest and $x = 162$ m represents the location of wave trough. Although the distribution of ϕ in the bed is not exactly symmetrical with respect to $x = 0$, it is nearly symmetrical and only the region of a half wavelength is shown in Fig. 5. The wave induced effective stresses are small for this case and the maximum value of $\phi = 27.2^\circ$ occurs 1.5 m below the mud line under the wave crest. If the failure limit ϕ_f of the soil is 30° , the bed withstands the wave loading and therefore the bed is stable. Figure 6 shows the distribution of ϕ in the bed if bed thickness $d = 61.8$ m. For this case, the stress state becomes most unstable. Under the wave crest, the stress angle ϕ becomes very large near the mud line. If the failure limits, ϕ_f , of the soil is 30° , the top portion of the bed as deep as 15 m fails by wave loading. Since the entire bed continuously fails as the wave progresses, the top portion of bed up to 7 m may be liquefied and result in a continuous landslide if the bed surface has even a slight angle to the horizontal. Therefore, if the footing of an offshore structure is less than 15 m, the structure suffers from an uneven settlement. Pipelines buried shallower than 15 m may float. Since the bed thickness at the North Sea varies from 15 to 80 m, it may be said that the submarine seabed foundation at the North Sea is usually unstable against large storm waves. Some protection work may be needed.

Figure 6. The distribution of the effective stresses in the seabed in terms of stress angle ϕ in degrees for a fine bed thickness $d = 61.8$ m.

RESPONSE OF INHOMOGENEOUS BEDS TO WAVES-STABILITY ANALYSIS
OF MISSISSIPPI DELTA CLAY BED WITH "CRUST PROFILE"

As a practical example of inhomogeneous seabeds, the behavior of the seabed at the offshore area surrounding the Mississippi River Delta under attack of a design storm wave is analyzed. A bottom supported platform and numerous buried pipelines were destroyed by massive submarine landslides in this area induced by the storm waves during hurricane "Camille" in 1969 (Bea and Arnold, 1973). The seabed soil formation is characterized by the so-called "crust profile" where a relatively stiff top soil layer and a very weak sublayer exists above a normally consolidated deeper layer. Some of the geotechnical properties of the soils at the area are given in Bea and Arnold (1973). For the numerical calculations, the seabed is subdivided into five layers with different soil properties and thicknesses which approximates the *in situ* data by Bea and Arnold (1973) and are tabulated in Table 1. For this case the total bed thickness is infinite. The design storm wave condition is; $T = 14$ s, $L = 152.4$ m, $H = 4.52$ m, and $h = 13.5$ m. The bottom pressure amplitude calculated from the linear wave theory is $p_0 = 1.91 \times 10^4$ N/m².

The vertical distributions of the horizontal displacement, the vertical displacement of the soil and the wave induced pore pressure are shown in Fig. 7. Although the total bed thickness is infinite, a large horizontal displacement of 2.2 m exists at the mud line contrary to the case of homogeneous infinite bed. The pore pressure is maximum and equal to 1.7 KN/m² at $z = 20$ m. Therefore, the weak sublayer experiences large horizontal displacements and large pressure fluctuations. The stress distribution is shown in Fig. 8. As can be seen, large stresses penetrate deep in the seabed under the wave crest. Assuming the failure limit of the soils $\phi_f = 25^\circ$, the top portion of the bed up to 12 m below the mud line fails from the wave loading. Since the mud line is sloped in this area, the wave induced stress instability is predicted to induce a massive continuous landslide which causes toppling of bottom based platforms and pipeline failures as has happened during hurricane "Camille" in 1969.

PROTECTION OF SEABEDS BY CONCRETE BLOCKS AND RUBBLES

Stabilizing effects of concrete blocks and natural rubbles on the seabed response to waves are considered in this section. The present theory is applied to the problem of concrete blocks or rubbles placed on the seabeds to protect them from wave actions. The geotechnical properties of the sand used in the calculation are: $k = 10^{-4}$ m/s, $G = 10^7$ n/m², $\nu = 0.3$, $n = 0.3$, $d = 30$ m and $G_s = 2.7$. The seabed is on an impermeable and rigid bed, and the water depth is 10 m. The soil responses to the wave of $T = 8$ s,

Figure 7. The vertical distributions of the horizontal displacement, u , the vertical displacement, w , of the soil and the wave induced pore pressure, p , in the Mississippi Delta clay seabed.

Figure 8. The distribution of the effective stresses in terms of stress angle ϕ in the Mississippi Delta clay seabed.

$H = 4$ m and $L = 71$ m are shown in Figs. 9 and 10. Figure 10 shows the distribution of the stress angle between the wave crest and the wave trough. (The crest exists at $x = 0$ and the wave propagates to the left). The distribution of the stress angle for $x < 0$ is again almost the same as this. Figure 10 shows that if the internal friction of the sand is 40° , the penetration depth of failure zone is maximum at a wave crest and about 1.5 m. Therefore, the seabed will fail in the failure zone and may cause liquefaction and sliding of the bed.

In order to protect the seabed from wave action, concrete blocks may be placed on it. The amplitudes of the soil displacements and pore-water pressure, and the distributions of the stress angle for the seabed covered by blocks of 3.0 m in thickness are shown in Figs. 11 and 12. The physical properties are: $G = 10^8$ N/m², $k = 1.0$ m/s, $\nu = 0.4$, $n_s = 0.4$, $G_s = 2.2$. It can be seen from Fig. 9 and Fig. 11 that the amplitudes of soil displacements and pore-water pressure are hardly influenced by the blocks placed on the seabed. However, the distributions of the stresses shown in Fig. 12 become much smaller than those in Fig. 10. This is due to an increase in vertical and horizontal effective stresses by the weight of concrete blocks.

As discussed above, it has been verified theoretically that covering over seabeds by blocks is effective to protect them from waves. The optimal properties of the blocks can also be determined by using the theory.

We have also analyzed the effectiveness of the asphalt mats laid under the blocks. However, the results for such seabeds are similar to those shown in Figs. 11 and 12, and no additional effectiveness is noticed from the numerical results. It is predicted from the numerical results that the seabeds will fail from the storm waves and continuous landslides may result in the top portion of the bed 12 m from the mud line without a concrete block layer.

The numerical calculations suggest that such liquefaction and sliding of the seabed from waves can be prevented by placing a layer of concrete blocks or rubbles.

SUMMARY AND CONCLUSIONS

The response of multi-layered poro-elastic beds to water waves has been treated analytically in this paper. The number of layers, the thicknesses of the layers and geotechnical properties of the soil in each layer can all be arbitrary. The theory has been verified by the data of wave induced pore pressures from in situ measurements at the offshore area of the Mississippi River Delta by Bennett and Faris (1979).

Figure 9. The vertical distribution of the horizontal displacement, u , the vertical distribution, w , and the wave induced pore pressure, p , in the seabed without a concrete block layer.

Figure 10. The distribution of the effective stresses in terms of the stress angle ϕ in degrees in the seabed without a concrete block layer.

Figure 11. The vertical distribution of the horizontal displacement, u , the vertical distribution, w , and the wave induced pore pressure, p , in the seabed with a concrete block layer.

Figure 12. The distribution of the effective stresses in terms of the stress angle, ϕ , in the seabed with a concrete block layer.

The theory has been applied to the problem of the seabed response to the design waves at the North Sea. The theoretical results indicate that, for a given wave condition, there exists a critical bed thickness, $d_c = 0.20 L$, which creates the most unstable stress state in a homogeneous seabed. It has been indicated that generally the seabeds at the North Sea become unstable from large storm waves due to the relatively thin thickness of the seabeds.

As an example of inhomogeneous seabeds, the response of the soft clay beds with "crust profile" in offshore area of the Mississippi River Delta has been analyzed under attack of design storm wave. The numerical results indicate that large soil displacements, pore pressure fluctuations and stresses are induced by waves in the crust layer and the weakly consolidated sublayer below the crust.

The numerical results indicate that such wave induced stress instabilities can be prevented by covering the bed by a layer of concrete blocks and rubbles.

ACKNOWLEDGEMENTS

This work was entirely supported by the National Science Foundation, Grant No. CME 8009528. The authors are grateful for the support. The authors also wish to thank Dr. Richard Bennett for providing the pore pressure data and consultation on the structure of the submarine sediment.

WAVES FORCES ON OFFSHORE PIPELINES

by

N. Jothishankar* and V. Sundar**

INTRODUCTION

Transportation of offshore oil and gas is mostly carried out by means of offshore pipelines. Depending on the ocean environment these pipelines are either buried or made to rest on the ocean bed or placed on excavated trenches. In cases where the sea bed is mostly of rock, pipelines can be laid on the bed and anchored to the ocean floor by suitable supports. In certain instances pipelines are also placed on saddles leaving a clearance between pipe and the sea floor. The design of these pipelines requires an accurate assessment of wave induced loads acting on them.

The objective of this paper is to present the experimental results of wave forces exerted on a model pipeline, of diameter 5 cms at different clearances from the bed of the flume. Hydrodynamic coefficients namely Drag and Inertia are computed from the measured forces and their correlation with the non-dimensional parameters, Reynold's Number, Keulegan-Carpenter Number and relative clearance from the bed are presented.

LITERATURE REVIEW

The relationship between the hydrodynamic coefficients C_D , C_M , C_L and the environmental forces which can be represented in terms of non-dimensional flow parameters is essential for the prediction of wave forces acting on pipelines. Several investigations (Brater, E.F., and Wallace, R. (1972), Johansson, B. (1968), Keulegan, G.H., and Carpenter, L.H. (1958), Sarapkaya, T. (1976), Nath, J.H. and Yamamoto, T. (1974), Grace, R.A. and Nicinski, S.A. (1976), Wright, J.C., and Yamamoto, T. (1979), have been carried out regarding this aspect and there is a

considerable variation in their results in respect of the coefficients.

Beckmann, H. and Thibodeaux, M.H. (1962) recommended values of $C_D = 0.5$, $C_L = 0.5$ for the case of rough pipes resting on the bed and $C_D = 0.5$ and $C_L = 0$ for a freely suspended pipe. Johansson, B. (1968) performed experiments with 3 inches (7.5 cms) diameter pipeline with Reynold's Number varying from 3×10^3 to 2×10^4 and observed that for a constant clearance varying 0 to 1.0 D. C_M varied from 4.0 to 2.8 and C_L from 6.0 to 1.8. As the clearance increased it was found that values of C_D , C_M and C_L decreased. Grace, R.A. (1971) reanalysed Wallingford wave force data (1961) on a 1-1/2 inches model pipeline just clear of the bed and concluded that C_D roughly decreases with increase in the Reynold's Number from about 3.8 at $Re = 9 \times 10^3$ to 1.8×10^4 . The value of C_L was found to decrease with increase in Reynold's Number from 3.1 at $Re = 7 \times 10^3$ to 0.8 for $Re = 1.8 \times 10^4$. The inertia coefficient varied from 2.4 to 8.5 with an average value of 4.7.

Grace, R.A. (1971) conducted experiments on a 3 inch dia aluminium pipe and obtained the horizontal force coefficients for $Re = 2.5 \times 10^4$ as given in table 1.

Table 1 : Horizontal Force Coefficients
Grace R.A. (1971)

e/D	C_M	C_D
0.042	3.50	2.53
0.083	3.54	2.73
0.167	1.81	3.61
0.292	1.17	3.17

The values of the coefficients were obtained using the data of peak horizontal force and the phase of the peak force.

Several studies on submarine pipelines are reported in literature wherein the viscous effects are negligible and the forces are predominantly inertial (Ref: Nath, J.H. and Yamamoto, T., (1974)). Recently Wright, J.C. and Yamamoto, T. (1979) have reported the results of their study on wave forces on a horizontal cylinder 12 inches dia subjected to regular waves. The variation of force coefficients of inertia, drag and lift with respect to relative clearance (e/D) have been presented.

EXPERIMENTAL SET UP - PRESENT STUDY

Experiments were conducted in a 29 m long x 0.9 m deep x 0.9 m wide wave flume to determine the wave forces acting on a 5 cm dia plexiglass pipe positioned at different clearances from the simulated ocean floor. The pipe was subjected to regular waves produced by a plunger type wave generator with a parabolic section. The wave period ranged from 1.0 to 2.0 secs and the wave height from 5.0 cms to 16.0 cm in a water depth of 40 cm. Force transducers working on strain gauge principle were encased in the model pipeline on cantilever beams which were supported at the sides of the flume on roller bearings. Proper

care was taken to water proof the ends of the pipe. The cantilever beam and the associated strain gauge bridge was used to measure the horizontal and vertical forces. The test module used is similar to the one used by Garrison et al (1975). Suitable arrangements were made for positioning the pipeline at different clearances from the bed of the flume.

The outputs from the two force transducers are fed into a 3 channel carrier frequency amplifier the outputs of which are fed to two channels of Kempf and Remmers three-channel strip chart recorder. A resistance type wave probe is mounted in alignment with the central line of the model to record the time histories of the water surface elevation. The leads from the wave probe are connected to a wheatstone bridge the output of which is fed into the third channel of the recorder.

The model pipeline was kept at spacings of 3 cms, 5 cms and 7.5 cms from the bed of the flume and subjected to the action of regular waves. Fig. 1 shows the definition sketch of the model pipeline subjected to regular waves. The pipeline was immersed atleast five cylinder diameters below the free surface to avoid any free surface effect on the measured forces.

ANALYSIS

Consider a horizontal pipeline of diameter D at a spacing of e from the sea floor subjected to the action of a regular progressive wave train of wave height H in water of depth d as shown in Fig. 1. The

FIG. 1 DEFINITION SKETCH

maximum horizontal or vertical component of force per unit length acting on the pipeline can be expressed as a function of the following physical parameters.

$$\frac{F_x(\max)}{\ell} \text{ or } \frac{F_y(\max)}{\ell} = f(v, g, D, u_{\max}, e, b, T \text{ or } L) \quad (1)$$

in which F_{\max} = maximum force, ℓ = length of cylinder, D = cylinder diameter, g = acceleration due to gravity, T = wave period, L = wave length, e = clearance of bottom of pipe from sea floor, b = depth of submergence of the pipe centre line below the still water level, and ν = fluid viscosity.

Expressing Eq. (1) in non-dimensional form one gets, in the horizontal direction

$$\frac{F_x(\max)}{\frac{\rho}{2} D \ell u_{\max}^2} = f(e/D, D/L, u_{\max} T/D, u_{\max} D/\nu, \frac{u_{\max}}{\sqrt{g(d-b)}}) \quad (2)$$

as drag form or

$$\frac{F_x(\max)}{\rho \left(\frac{\pi D^2 \ell}{4} \right) 2\pi \frac{u_{\max}}{T}} = f(e/D, D/L, u_{\max} T/D, u_{\max} D/\nu, \frac{u_{\max}}{\sqrt{g(d-b)}}) \quad (3)$$

as an inertia form.

For a cylinder far away from the free surface as is the case studied here, the effect of free surface can be neglected, in which case the Froude Number $u_{\max} \sqrt{g(d-b)}$ can be ignored in the equations (2) and (3). For $D/L > 0.2$ the diffraction effects become dominant (Ref: Hogben et al (1977) and for $D/L < 0.2$ Morison Equation is applicable. In the case considered here D/L is less than 0.2 and the influence of D/L in this range may be neglected. With these reasonings equation 2 and 3 can simply be written as

$$\frac{F_x(\max)}{\frac{\rho}{2} u_{\max}^2 (D\ell)} \text{ or } \frac{F_x(\max)}{\rho \left(\frac{\pi D^2 \ell}{4} \right) 2\pi \frac{u_{\max}}{T}} = f(e/D, u_{\max} T/D, u_{\max} D/\nu) \quad (4)$$

DETERMINATION OF HYDRODYNAMIC COEFFICIENTS C_D and C_M

The analysis of the experimental data is based on the wave force trace and wave profile trace obtained at the central line of the pipe for different clearances of the pipeline from the simulated sea floor. The drag and the horizontal inertia coefficient are obtained from the horizontal force trace while the lift and vertical inertia coefficients are computed using the vertical force profile. The coefficients are assumed to be constant over a wave period. The coefficients C_D and C_M

are obtained based on the peak force and the phase at which the peak force occurs. If F_T is the total force per unit length of the pipeline, then using Morison's formula

$$F_T = F_D + F_I$$

in which

$$F_D = \frac{1}{2} C_D \rho D u |u| \quad (5)$$

and

$$F_I = C_M \frac{\pi}{4} D^2 \dot{u} \quad (6)$$

in which D = pipe diameter, ρ = mass density of water; u = horizontal particle velocity at the central line of the pipe; and \dot{u} = corresponding horizontal water particle acceleration. Using Airy's theory it can be shown that the maximum total force on the pipe is

$$\frac{F_{\max}}{\frac{\rho}{2} u_{\max}^2 (D\kappa)} = C_D \left(1 + \frac{C_M}{C_D} \frac{\pi^2}{2} \frac{1}{K^2} \right) \quad (7)$$

where K = Keulegan-Carpenter number = $u_{\max} T/D$. The phase at which the maximum force occurs is given by

$$\sin \theta = \frac{C_M}{C_D} \frac{\pi^2}{2} \frac{1}{K} \quad (8)$$

Using measured values of F_{\max} and θ from the force trace, C_D and C_M can be computed using Equations 7 and 8.

RESULTS

Experimental runs yielded Reynolds Number in the range 5×10^3 to 1.7×10^4 and Keulegan-Carpenter number in the range 1 to 9.

Typical plots showing the variation of C_D and C_M with the wave Reynolds Number $u_{\max} D/\nu$ are shown in Figs. 2 and 3, for a relative clearance of $e/D = 1.0$. The least square fit of the data is also shown in the figures. Similar plots were obtained for relative clearances 0.60 and 1.50. The lines of least square fit for the three clearances tested are shown in Figs. 4 and 5, for C_D and C_M respectively. The results indicate that within the Reynolds number range of data, C_D tends to decrease with increasing Reynolds number. Similar results were obtained by Brater et al (1972) and Grace, R.A. (1971) on analysing Wallingford's (1962) data. It is also seen that for a given Reynolds number the value of C_D decreases with increasing clearance. C_D varies from 4.3 to 0.8 for e/D varying from 0.6 to 1.5.

The variation of C_D with Keulegan-Carpenter Number is shown in Fig. 6 for the e/D ratios tested. Only the lines of the best fit are shown in this figure to simplify the presentation of the data. Within the range of Keulegan-Carpenter Numbers tested (2 to 9) it is observed that C_D decreases with increase in Keulegan-Carpenter Number. Similar results were reported by Grace and Nicinski (1976), who plotted the

FIG. 2 VARIATION OF C_D WITH REYNOLD'S NUMBER

FIG. 3 VARIATION OF C_M WITH REYNOLD'S NUMBER

FIG. 4 DRAG COEFFICIENT Vs REYNOLD'S NUMBER FOR VARIOUS CLEARANCES

FIG. 5 INERTIA COEFFICIENT Vs REYNOLD'S NUMBER FOR VARIOUS CLEARANCES

values of C_D against relative distance of water particle travel. This trend may be due to the interaction between two boundaries (plane bottom boundary and cylinder itself) and the generation and behaviour of eddies. High Drag Coefficients of the order of 3.75 are obtained at Keulegan-Carpenter Number around 3.0 for $e/D = 0.6$. For $e/D > 1.0$ the variation in the value of C_D with e/D tends to become small. This is to be expected since far away from the boundary the effect of boundary will diminish and the C_D values would approach those found for $e/D = \infty$ as pointed out by Sarapkaya, T. (1976).

For a relative clearance of $e/D = 0.6$, C_M is found to decrease from 2.7 at $Re = 5 \times 10^3$ to 1.5 at $Re = 1.6 \times 10^4$. For the other two increasing clearances C_M values are not very sensitive to variation in Reynold's number. It is also inferred that C_M decreases with increase in clearance for the range of Reynold's number tested.

The variation of Inertia Coefficient with Keulegan-Carpenter number is shown in Fig. 7 for the three clearances. It is clearly seen from these plots that the inertia coefficient decreases with increase in the clearance. Within the Keulegan-Carpenter number range of 2 to 9 the variation of C_M is insignificant. For $e/D > 1.0$ the variation of C_M with e/D becomes small. It is also inferred that C_M is dominant at smaller Keulegan-Carpenter number values when the relative clearance is less.

FIG. 6 DRAG COEFFICIENT Vs KEULEGAN-CARPENTER NUMBER FOR VARIOUS CLEARANCES

FIG. 7 INERTIA COEFFICIENT Vs KEULEGAN-CARPENTER NUMBER FOR VARIOUS CLEARANCES

CONCLUSIONS

The analysis of wave forces on pipelines at different clearances from the simulated ocean floor has shown that the hydrodynamic coefficients C_D and C_M computed from measurement of horizontal force are functions of relative clearance, Reynold's number and Keulegan-Carpenter number. The drag coefficient is found to decrease with the Reynold's number while the inertia coefficient is fairly constant over the Reynold's Number range (5×10^3 to 1.7×10^4).

As the Keulegan-Carpenter number increases it is found that the C_D value decreases. However, the variation of C_M with the Keulegan-Carpenter number is insignificant in the range tested. The values of both C_D and C_M are found to decrease with increase in clearance. The analysis of vertical force coefficients namely C_{MV} and C_L will be reported in a future paper.

WAVE IMPACT PRESSURES ON COMPOSITE BREAKWATERS

by

G.R. Mogridge and W.W. Jamieson*

ABSTRACT

Wave impact pressures and forces on composite breakwaters have been measured in the laboratory. A solid wall breakwater and a perforated breakwater were instrumented with small pressure transducers in a study designed to estimate the relative effectiveness of perforated breakwaters in reducing impact loads caused by breaking waves.

Experimental results of maximum pressures and forces measured on the breakwater walls are presented as cumulative probability distributions. It is concluded that the perforated breakwater experiences significantly lower breaking wave loads although local impact pressures may be as high as those measured on the solid wall breakwater. Further studies are required on the perforated breakwater and alternative designs to determine the most suitable caisson type for the reduction of wave impact forces.

INTRODUCTION

With the trend in recent years to deep water harbours exposed to unfavourable wave climates, rubble mound breakwaters have become increasingly more expensive relative to composite breakwaters. The massive quantities of rock required for mounds with the gentle slopes necessary for stability, the limited strength of concrete armour units, and the effect of wave groups on armour unit stability, pose problems in the design of rubble mound breakwaters which are not easily solvable. The composite breakwater, consisting of concrete caissons founded on a rubble mound, does not require large quantities of quarry stone and in addition has a considerable advantage at some locations where the wave climate allows only a short construction time, because the caissons are constructed in dry dock and then towed to the site. However, there are also problems in designing composite breakwaters. In the past, composite breakwaters in deep water have been designed assuming total reflection of the waves, but it is now generally recognized that wave breaking can occur even on a composite breakwater with a low rubble mound in deep water. The resulting impact pressures, although occurring infrequently, for an extremely short

* Associate Research Officers, Hydraulics Laboratory,
National Research Council of Canada, Ottawa, Canada,
K1A 0R6.

duration and over a very localized area, are enormous. Such pressures can cause severe local damage to the structure, and in the case of lower less localized pressures can cause sliding failure of the breakwater. It is apparent that composite breakwaters should be designed to avoid the possibility of severe impact pressures occurring. Thus, Lundgren and Graveson (3), have proposed breakwaters constructed using vertical cylindrical caissons and also caissons with the upper surfaces sloping away from the wave attack. Measurements of impact pressures on cylindrical caissons are described by Graveson et al. (1). Richert (9) has also shown the effectiveness of a sloping wall in reducing impact pressures. Onishi and Nagai (7) and Nagai and Kakuno (6) have conducted studies in which impact pressures were measured on slit-type breakwaters.

In the laboratory study described in this paper, wave impact pressures were measured on a composite breakwater with plane vertical solid walls. Tests were also conducted on a perforated Jarlan-type breakwater with plane vertical walls in order to determine whether impact pressures are reduced on such a breakwater. Although similar comparative tests have not been carried out previously, many others have measured impact pressures on plane solid walls and Nagai and Kakuno (6) have measured impact pressures on walls with perforations consisting of vertical slits. However, there are many inconsistencies in the experimental data produced from previous studies, mainly because of wide differences in the quality of the experimental equipment used.

EXPERIMENTAL EQUIPMENT

It has been found that the same incident waves breaking on a composite breakwater can produce widely varying magnitudes of impact pressure because of slight differences in timing and position of the breaking wave. This phenomenon has been observed by numerous other researchers such as Mitsuyasu (4) and Moutzouris (5). Therefore, it was essential in order to obtain a valid comparison of caisson designs, to run many tests and plot the results as cumulative probability distributions. The height and period of the regular incident waves were chosen such that every wave in the wave train broke on the vertical walls of the breakwaters. Irregular waves were not used in these tests, nor was any effort made to produce different types of breakers. Thus, the possibility should not be overlooked that the results of this study may not be applicable to situations with breaker types other than the plunging breakers produced in the present experiments.

It is well known that the impact pressures measured on composite breakwaters depend on many design variables such as slope and height of the berm, top width of the berm and water depth above the berm. In addition there are the variables describing the incident waves and the caisson design.

In this study, the berm dimensions were chosen to produce severe wave impact conditions to facilitate the comparison of caisson types.

A sketch of the model breakwater is shown in Fig. 1. The water depth in the wave flume was 75.6 cm and the depth above the berm was 29.2 cm. The berm had a slope of 1:3 and was constructed of stone fill with a cement outer layer approximately 4 cm thick. The model breakwaters were 1.22 m wide and were tested in a wave flume 64 m long and the same width as the breakwaters. The caissons were constructed high enough that no overtopping occurred and were held rigidly in position by a massive concrete and steel structure at the rear of the breakwaters. A solid wall caisson was constructed of wood with walls 3.8 cm thick and internal chambers such that after testing as a solid wall caisson, holes were drilled in the front wall so converting it into a perforated wall caisson. The chamber width from front to rear walls was 30.5 cm, giving a ratio of chamber width to incident wave length of 0.06. This is considerably smaller than the ratio of approximately 0.2 usually recommended to minimize wave reflection; however, it is approximately the ratio suggested by Nagai and Kakuno (6) to reduce impact pressures on slit-type breakwaters. Transverse walls with low porosity were included at 23 cm centres for structural rigidity. One of these walls may be seen through a transparent end wall in the photographs in Fig. 5. The perforations on the front wall of the caisson were circular holes 3.8 cm in diameter spaced at 5.7 cm centres giving a relatively high porosity of 34.9%. Pressure transducers mounted on a thick brass plate were located in the centre of the caisson at elevations as shown in Fig. 2. The locations were the same on the front wall for both the solid and perforated breakwaters, being midway between the rows of holes in the perforated wall. A maximum of seven transducers could be used at any one time, so pressure distributions on the front and rear walls of the perforated breakwaters were measured in consecutive test series.

The pressure transducers were 7.6 mm in diameter with semi-conductor strain gauges mounted on a thin metal diaphragm. Temperature compensation was provided but was not entirely satisfactory. The linear range of the transducers was 0-25 psi or 0-172 kPa (kN/m^2) with a combined non-linearity and hysteresis of $\pm 0.25\%$. The transducer calibrations supplied by the manufacturer were confirmed by static pressure tests. The resonant frequency in air was 20 000 Hz and in water approximately 12 000 Hz.

Outputs from the pressure transducers were amplified one hundred times by amplifiers with a frequency response of 15 000 Hz, before going to two transient recorders. Basically, these recorders are high speed analog to digital converters which have a resolution of 10 bits or 1 in 1000. Each transient recorder has four data channels each capable of storing in memory 1024 data words. The sampling rate can

FIG. 1 SKETCH OF MODEL COMPOSITE BREAKWATER

(A) SOLID WALL CAISSON

(B) PERFORATED CAISSON

FIG. 2 LOCATIONS OF PRESSURE TRANSDUCERS

be chosen as high as 100 000 samples per second, which corresponds to a sample interval of 0.01 ms. At this sample interval the total record length is 0.01 s.

Because fast sampling rates are necessary for accurate measurement of sharp pressure peaks, total record lengths are short. Thus, it is important to commence sampling immediately before a pressure peak occurs, to ensure its inclusion in the record. This is possible using the pre-trigger function of the transient recorders. In this mode of operation the recorders sample the pressure transducer outputs continuously and the data simply overflows from the memory. When a rise in pressure exceeding a certain pre-set level is sensed at any input channel, the recorders interrupt sampling after continuing to sample for a pre-set length of time referred to as the pre-trigger delay. For example, in the present experiments with the pre-trigger delay set at 0.90, the recorders continue to sample and store 0.9 times 1024 data words after the pressure rise is sensed. Then on completion, the channel memory contains 0.1 times 1024 data words recorded previous to and 0.9 times 1024 data words recorded following the increase in pressure. The two transient recorders are interconnected so that the time base is identical for all channels and a pressure rise on any one channel will trigger both recorders simultaneously. After the data from one wave is stored in the memories of the two recorders, it is transmitted to the disk of a digital computer for storage. The transfer of 7168 data words is accomplished fast enough that the system is ready for sampling the pressures caused by the next wave impact.

The rate of sampling by the transient recorders must obviously be chosen sufficiently fast that the peak pressures measured are not attenuated. However, because the memory of each data channel is limited to 1024 words, fast sampling rates result in short records. If the record length is too brief, then pressure rises at locations distant from the point of initial contact of the wave will not be recorded. This in turn means that when the pressures are integrated over the breakwater, the resulting force record may not contain the maximum force on the breakwater. Thus, the choice of sample rate is quite important.

Pressure records measured at different sample rates are shown in Fig. 3. The well-known form of the records of wave impact pressure can be seen when the rate of sampling is slow. A rate of 1000 samples per second conveniently includes the complete pressure record for this wave period of 2.1 seconds; however, this speed is not sufficient to accurately define pressure peaks. For the present experiments, a rate of 20 000 samples per second was chosen, that is, a sample interval of 0.05 ms. The total record length is therefore approximately 0.05 s and this length is illustrated on all the pressure records in Fig. 3 to show the relatively small part of the total record being sampled.

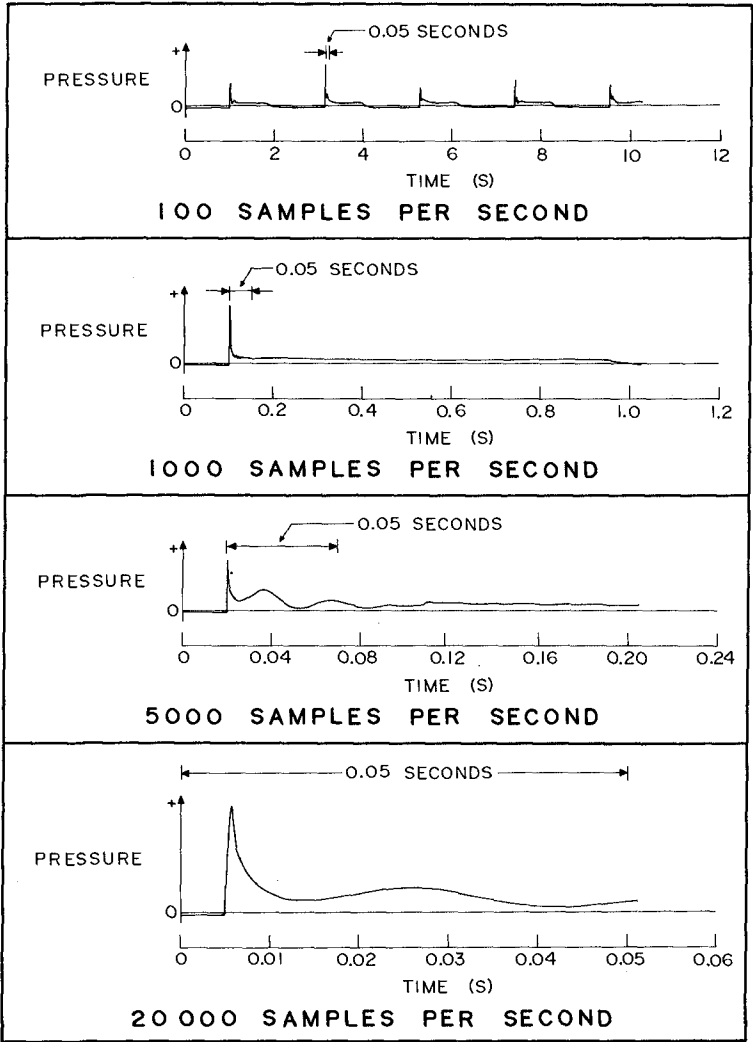

FIG. 3 PRESSURES AT DIFFERENT SAMPLE RATES

TEST PROCEDURE

Scale factors and bias values for the transient recorders were determined at the start of each day. Trigger levels of the recorders were set at approximately 3.5 kPa so that each breaking wave would trigger data collection. Zero readings for the pressure transducers were taken when the water in the wave flume was calm at the beginning of each test series. Thus, zeros were taken with hydrostatic pressure on the transducers so the pressure records produced were the dynamic pressures of the wave impacts.

A train of regular waves was generated using voltage signals produced by a digital computer as input to the wave machine, to ensure repeatable sequences of waves from start-up to finish. A short series of waves was produced so that there would be no disturbance caused by secondary reflections returning from the wave generator board. The height of the incident waves was 37 cm and the wave period was 2.1 s. Wave reflection from the solid wall breakwater was approximately 60% and from the perforated breakwater was 30%.

Ten wave impacts were measured in each wave train, after which it was necessary to allow the agitation in the wave flume to settle before running more tests. The data from sixty wave impacts or 430 000 words were stored on disk before it was necessary to transfer the data to magnetic tape. Because of the wide variation in wave impact pressures even when incident waves varied in height by only $\pm 4\%$, approximately 300 tests were run with pressure transducers on each breakwater wall so that the results could be treated statistically. To estimate the total force on a perforated breakwater, it is necessary to know the pressures on the interior walls of the chamber. Thus, pressures were also measured on the rear wall of the chamber, although it was assumed that pressures on the interior side of the perforated wall were negligible. In all, approximately 900 tests were run to obtain pressure distributions on the solid wall breakwater and the front and rear walls of the perforated breakwater.

The series of photographs in Fig. 4 show how the incident waves broke against the solid wall breakwater. The numerals on the right hand side of each photograph show the locations of the pressure transducers on the brass plate which is just visible in the centre of the breakwater. The first two photographs show the approach of a wave crest to the caisson wall and the instant before impact. An air pocket is just beginning to form and it appears that the maximum pressure in this case will occur where the crest first hits the wall at level 4. Immediately after the wave impact the water surface begins to rise and large pockets of air can be seen plastered against the caisson wall. The remaining photograph shows the wave run-up and the high density of air bubbles in the water caused by the wave breaking.

FIG. 4 WAVE BREAKING ON SOLID WALL BREAKWATE

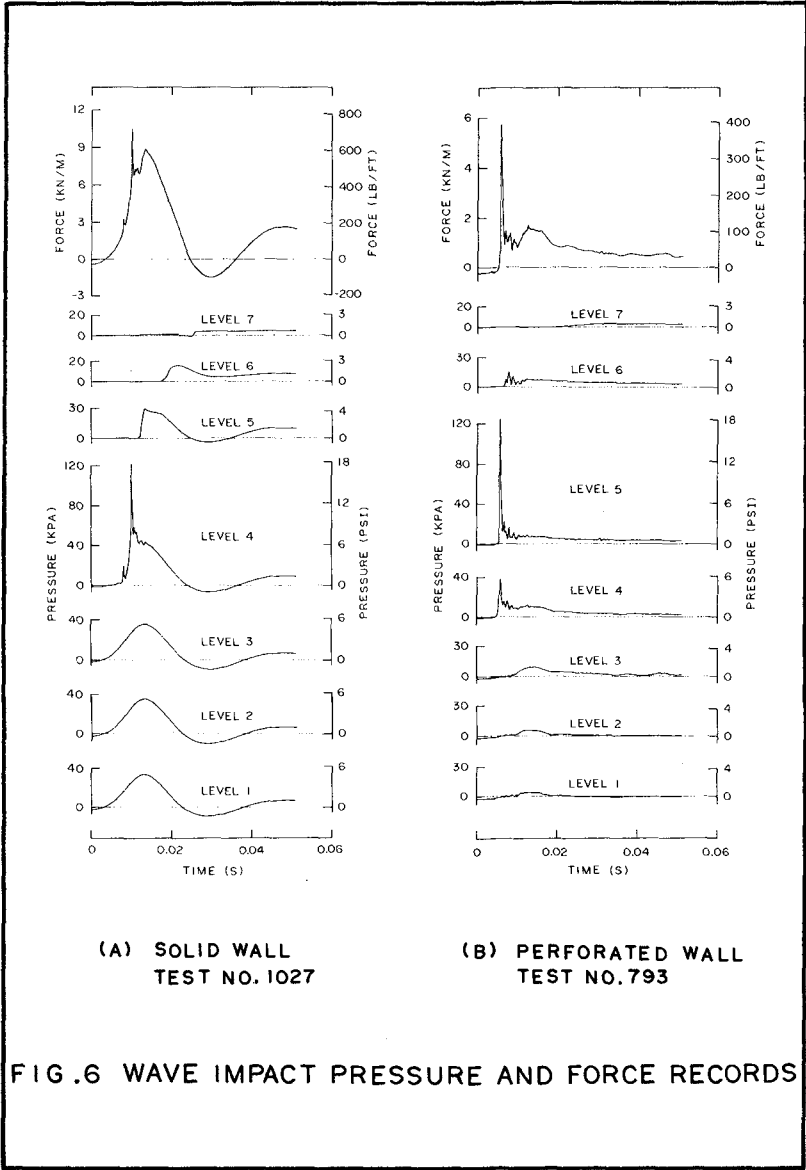

FIG. 5 WAVE BREAKING ON PERFORATED BREAKWATER

A wave breaking against the perforated breakwater is shown in Fig. 5. The first photograph shows the wave crest approaching the caisson and the water still draining from the caisson chamber. The water level inside the chamber does not reach level 3 before the crest hits the wall as seen in the second photograph. A small air pocket is formed between levels 1 and 3. The third photograph shows an instant after the initial impact of the wave crest. Water jets have not yet contacted the rear wall and the water surface inside the chamber has been deformed by jets entering between levels 1, 2 and 3. The remaining photograph shows the continued run-up against the front wall of the caisson with water jets entering at higher levels and the extreme turbulence and high air entrainment of the flow against the rear wall.

EXPERIMENTAL RESULTS

Wave impact pressure records are shown in Fig. 6(a) for tests on the solid wall breakwater and the perforated breakwater. The pressure on the solid wall in this particular test reached a maximum of 122 kPa (17.6 psi) at level 4. The pressure records at levels 1, 2 and 3 show the characteristics of compression shocks caused by the presence of an air pocket, that is, a slow rise and fall of pressure. The record at level 4 is somewhat unusual because it apparently is a combination of a sharp pressure increase caused by a hammer shock and the smoother curve of a compression shock. The similarities in the lower four pressure records indicate that in this case the spacing of the transducers was sufficiently close for a relatively accurate determination of the total force on the wall. The pressure records from levels 4 to 7, in which the pressure increase occurs at progressively later times, show the effect of the run-up of the wave crest on the caisson wall.

Pressures recorded in a test on the front wall of the perforated breakwater are shown in Fig. 6(b). The most obvious difference to the previous records is that compression shocks are absent because of the rapid dissipation of air pockets through the perforations in the wall. However, there is a very large hammer shock present at level 5 with a magnitude of 125 kPa (18.1 psi) and a rise time of 0.25 ms indicating that the perforated wall does not completely eliminate the occurrence of high impact pressures. In fact the highest impact pressure recorded in all tests was 142 kPa (20.6 psi) and occurred on the front wall of the perforated breakwater. Fortunately, such high pressures do not occur over a wide area. In Fig. 6(b) the peak pressure is recorded at level 5, but at level 4 this peak has already dropped to one third and at level 6 it is even less. The high frequency oscillations in these records are due to structural vibration of the breakwater. They are not the compression oscillations measured by many investigators

(A) SOLID WALL
TEST NO. 1027

(B) PERFORATED WALL
TEST NO. 793

FIG. 6 WAVE IMPACT PRESSURE AND FORCE RECORDS

(Mitsuyasu (4) and Rankema (8)) because such oscillations are generally at frequencies less than 500 Hz, although in the present tests similar low frequency oscillations were occasionally observed.

By integrating the pressure over the vertical height of the caisson, the total horizontal force on the wall is obtained in units of kN per metre width of caisson. Thus, the force records for the solid and perforated walls are also shown in Fig. 6. The effect of the compression shock pressures on the solid wall is to produce a force record with a relatively slow rise time. The maximum force is obviously caused by the hammer shock recorded at level 4, but it is important to note that the peak of the force caused by the compression shock is almost 90% of the maximum force. The total force on the model breakwater which is 1.22 m wide is 12.76 kN (2870 lbs) which emphasizes the importance of the massive supporting structure. The maximum force measured in all tests on the solid wall breakwater was 14.78 kN/m or a total force for the width of the model of 18.03 kN (4050 lbs).

The force record in Fig. 6(b) for the perforated wall test has a peak force due to the hammer shock pressure at level 5 which occurs for a short duration of approximately 1 ms. It should be noted in this case that a correction has been made for the porosity of the wall. Thus, the pressure has been integrated only over the solid area of the wall and the resulting force is therefore only 65% of the force that would have been obtained if the wall contained no perforations.

To determine the total force on the perforated breakwater, it is necessary to take into account the additional pressures on the internal walls of the chamber. However, pressures on the interior side of the perforated wall were not measured, as it is thought that these pressures would be small. In any event, it is conservative to omit these pressures as they act in the opposite sense to those on the other surfaces. Approximately 300 tests were conducted with seven pressure transducers located on the rear wall of the perforated breakwater as shown in Fig. 2(b). An example of the type of pressure records measured is in Fig. 7(a). The initial impact of the water jets produced by the perforated wall is sensed at level 4 on the rear wall. The pressure peaks at levels 5 and 6 are displaced in time slightly and are much smaller in magnitude. In a number of the pressure records measured on the rear wall, the rise times were very fast indeed. In fact several were measured with a rise time approaching that of the sample interval. This obviously means that the sampling rate was not nearly fast enough to measure such pressure peaks accurately. In addition, when the pressure rose so rapidly, the transducer diaphragm vibrated giving an oscillation on the pressure record that was unmistakably due to the excitation of the resonant frequency of the transducer.

The pressure records measured on the rear wall of the perforated breakwater were not always as clean as shown in Fig. 7(a). The turbulent fluid motions occurring on the rear wall after the initial wave impact, caused irregular pressure records such as shown in Fig. 7(b). This figure illustrates the time difference between pressure peaks occurring on the two walls of the perforated breakwater. Because pressures could not be measured simultaneously at 14 locations on the perforated and rear walls, an accurate estimate of the total force on the perforated breakwater could not be obtained. However, to help understand how the total force is produced, two pressure transducers were placed at levels 4 and 5 on the perforated wall, and the remaining five at levels 3 to 7 on the rear wall. Triggering of the transient recorders was initiated by either of the two transducers on the perforated wall, and tests were conducted to determine the most suitable sampling rate. The sample interval of 0.05 ms used for the earlier tests was too fast in this case because the water jets did not reach the rear wall within the 0.05 s record length. A sample interval of 0.20 ms was chosen and approximately 60 tests were conducted with the pressure transducers located as described above. A typical set of pressure records is in Fig. 7(b). There is a pronounced time difference between the occurrence of peak pressure on the perforated wall and that on the rear wall. This time difference varies between different records, but it can be estimated as approximately 0.075 s and is the time taken for the jets of water formed by the perforated wall to reach the rear wall. The resulting displacement of pressure records appears to be large enough that as a result of integrating pressure over the two walls, the peak total force on the breakwater would not be significantly greater than the maxima recorded separately on either the front or rear walls. However, further investigations are necessary to obtain accurate estimates of total force on the perforated breakwater. It is important to note that the maximum force on the breakwater will depend on the chamber width, not only because of the effect of wave reflection but because if the rear wall is too close to the perforated wall, peak pressures will occur at approximately the same time.

For comparison of breakwater types, approximately 300 tests were conducted on each of three walls, that is, the solid wall breakwater, and the front and rear walls of the perforated breakwater. For each test the maximum pressure at each transducer was extracted along with the maximum force from the force record. Using these figures, cumulative probability distributions were plotted for the maximum pressures occurring at each level on the walls and also for the maximum forces. Since the transducer elevations for the solid and perforated walls are identical and in order to provide a direct comparison, probability distributions for these two walls are plotted together in Fig. 8. As an exam-

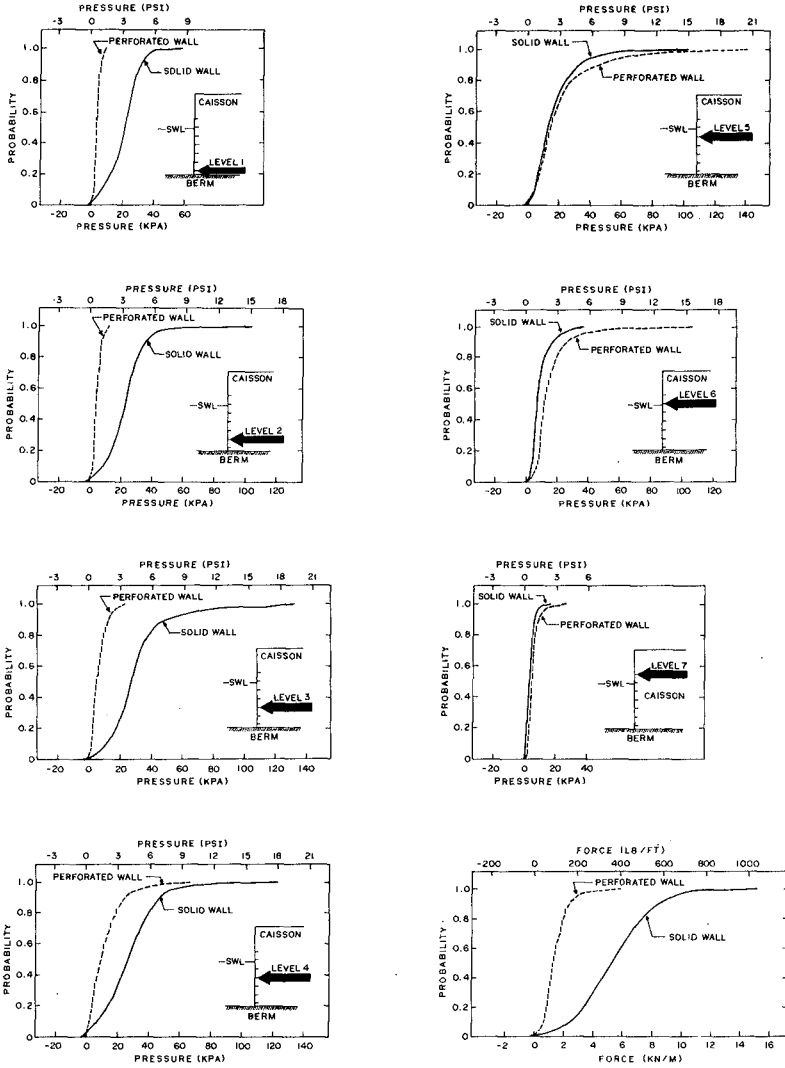

FIG.8 CUMULATIVE PROBABILITY DISTRIBUTIONS
SOLID AND PERFORATED WALLS

ple of how these figures may be read, taking a probability of 0.9 at level 1 on the solid wall shows that 90% of the maximum pressures measured at this location were less than approximately 31 kPa (4.6 psi).

From levels 1 to 4 in Fig. 8, the pressures on the solid wall are considerably larger than those measured on the perforated wall, but from levels 5 to 7 the pressures are larger on the perforated wall. The maximum pressure occurs at level 5 on the perforated wall and is 142 kPa (20.6 psi). However, because the pressures are more localized, the cumulative probability distribution curves show that the force on the perforated wall is very much less than that on the solid wall. At probabilities of 0.5 and 0.9 the maximum force on the perforated wall is consecutively 25% and 29% of that on the solid wall.

Fig. 9 shows the cumulative probability distributions for the maximum pressures measured on the rear wall of the perforated breakwater. These pressures are generally much smaller than those occurring on the front wall; however, peak pressures of up to 100 kPa (14.5 psi) were measured. The probability distribution for force also shows that the force on the rear wall is less than that on the perforated wall. At a probability of 0.9, the maximum force on the rear wall is 58% of that on the perforated wall, and 17% of the force on the solid wall breakwater.

The distributions of maximum pressure in Fig. 10 have been plotted by taking the maximum pressures at probabilities of 0.5, 0.9 and 1.0 for each transducer location from the cumulative probability distributions. The pressure distributions for the three walls are superimposed. The curves for probabilities of 0.5 and 0.9 show that the pressure on the solid wall is usually a maximum at level 3, while that on the perforated wall is usually a maximum at level 5. This is a result of the different characteristics of the breakers striking the two walls. Although the incident wave is the same in both cases, the reflection from the perforated breakwater is about half that from the solid breakwater, causing the wave to trip slightly closer to the perforated wall. The pressure distributions at a probability of 0.9 show pressure peaks similar in magnitude for both the perforated and solid walls, but the solid wall has a higher pressure over a greater area of wall. Pressures are lower at the base of the perforated wall because of the absence of compression shocks. The plot for a probability of 1.0 shows the maximum pressures measured at the pressure transducer locations and so the curves are not as smooth as the previous plots. Also, Fig. 10(d) shows examples of instantaneous pressure distributions. The pressures plotted are from tests 1027, 793 and 1529 for which the pressure records are in Figs. 6 and 7, and are the pressures occurring at the same time as the maximum pressure on the wall which also corresponds to the pressures at the time of maximum force. However, it should be pointed out that in some tests the

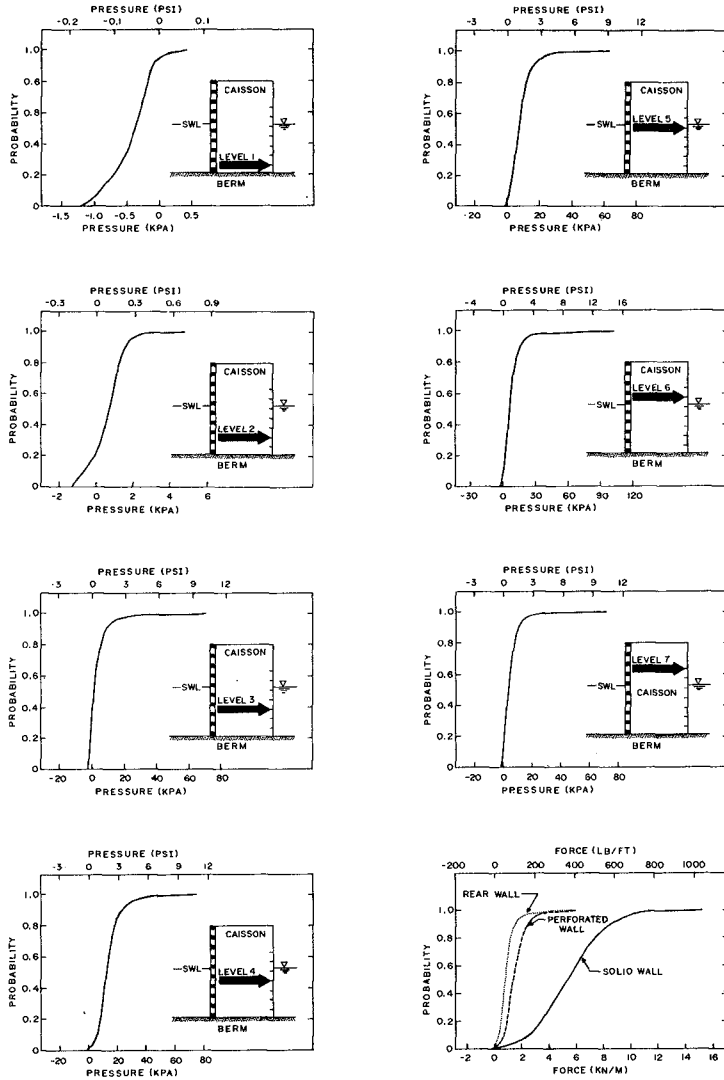

FIG.9 CUMULATIVE PROBABILITY DISTRIBUTIONS
REAR WALL OF PERFORATED BREAKWATER

(C) PROBABILITY = 1.0

(D) INSTANTANEOUS PRESSURE DISTRIBUTIONS

FIG.10 PRESSURE DISTRIBUTIONS

maximum force occurs at a different time to the maximum pressure and therefore would not result in the same pressure distributions.

RESEARCH PROBLEMS

The experimental results clearly show the importance of good instrumentation, since the peak pressures measured are much higher than in many previous studies in which inferior instrumentation was used. The frequency response of all components must be fast enough that resonance problems are eliminated and pressure peaks are not significantly attenuated. Even with the present equipment, these difficulties were obviously present in a number of tests, particularly on the rear wall of the perforated breakwater. However, it is essential to make a decision as to how fast peak pressures need to be measured in view of the probability that breakwaters are not adversely affected by high pressures if the duration of pressure is extremely brief. Evaluation of the relative importance of high frequency pressures and forces is necessary, but unfortunately the response of breakwaters to wave impact loads has received little attention in the literature. However, breakwater response must be considered using the latest wave impact pressure data before more highly sophisticated instrumentation is deemed necessary.

The estimation of total force on breakwaters as complex as the perforated breakwater, requires numerous pressure transducers to give reasonable accuracy. This could be an unnecessarily expensive proposition when it may be possible to design force dynamometers which are sufficiently stiff for high frequency response. Also an alternative to the use of pressure transducers is the possibility of strain-gauging the structure itself, as described by Graveson et al. (1).

There is still no generally accepted method of scaling impact pressures from model to prototype conditions. The compression laws of Lundgren (2), Mitsuyasu (4) and Rankema (8) may improve predictions but still rely on measurements in models which are not dynamically similar to the prototype. Consideration should be given to very large model tests and the measurement of impact pressures on existing full-size breakwaters.

The data presented in this paper demonstrates the extreme variability of impact pressures and forces under controlled conditions, when attempting to reproduce exactly the same incident waves. Natural sea states are so much more complex that the frequency of occurrence of high impact pressures in real seas is still largely a matter of speculation.

CONCLUSIONS

1. A large variation was observed in the impact pressures caused by incident waves with a variation in height of only $\pm 4\%$ at the most. For example, extremes of maximum pressure occurring at a single location on a breakwater were as much as ten times the average peak pressure. Means and standard deviations (S.D.) of maximum pressures and forces are as set out in Table I.

TABLE I
MEANS AND STANDARD DEVIATIONS
OF MAXIMUM PRESSURES AND FORCES

2. The perforated wall virtually eliminated compression shocks caused by the entrapment of air pockets.
3. Although impact pressures were generally lower on the perforated wall than on the solid wall caisson, there were locations where the pressures recorded were higher than on the solid wall. In fact, the highest pressure recorded in all tests, that is 142 kPa (20.6 psi), was measured on the perforated wall. However, the frequency of occurrence of high pressures on the perforated wall was lower than that on the solid wall.
4. Peak pressures measured on the rear wall of the perforated breakwater were significantly less than those occurring on the front wall and occurred at a time displaced from the peaks on the front wall dependent on the chamber width.
5. The mean force measured on the perforated wall was only 28% of that on the solid wall caisson. The total force on the perforated breakwater was not measured but is estimated to be considerably less than the force on the solid breakwater.

- 6.⁶ This experimental study has enabled an evaluation of the advantages of the perforated breakwater over the solid wall breakwater, but further investigations are necessary before it can be concluded that the structurally complex perforated caisson would be preferable to other alternative caisson designs.

ACKNOWLEDGEMENTS

Although the task of high speed transmission of data from two transient recorders a distance of 120 m to a digital computer, may not seem difficult, it caused much grief particularly for Arnold Wiegert and Tony Edwards. The authors appreciate their perseverance in developing a data acquisition system which made possible the rapid processing of vast quantities of experimental data.

CONSTRUCTION AND MODEL INVESTIGATION
OF STORMWATER OUTFALL

by
K A Heathcate¹ and G W Brittan²

1. INTRODUCTION

Posford Povry Sinclair and Knight were commissioned in 1976 to design a new stormwater outfall off one of Sydney's surfing beaches. The location of the outfall was dictated by a previous outfall which had been built in the dry when the beach line was much further seaward but which had been destroyed by wave action when the beach line retreated to the 1976 position (a distance of approximately 50 metres (Figure 1)).

FIGURE 1 LOCATION PLAN OF OUTFALL

2. B.E.(Civil), Engineer, Department of Public Works, NSW, Australia

2. CONSTRUCTION

Because of difficulties in locating plant in the surf zone, it was decided to construct the outfall out of precast reinforced concrete box sections (Figure 2) using a "leopfrogging" method of construction whereby all construction operations were carried out by a crane/pile driver located on top of previously placed units.

FIGURE 2 CROSS-SECTION OF BOX UNIT

The first stage of construction involved building a temporary support platform to enable a crane to get from the corpark to the waterline. This ramp was built level with the top of the concrete box units. A crane travelled down this ramp and proceeded to drive the two pile bents (Figures 3 and 4). Each pile bent consisted of two steel H piles of 1 metre centres. Precast unreinforced concrete protective jackets were then jettied around the H piles to provide scour protection (Figure 5).

The second stage involved placing precast reinforced concrete headstocks (Figures 6 and 7) on top of the pile bents, levelling them off by means of a special level adjustment device, locking them into place to prevent their displacement by waves, and then grouting them up to form a fixed connection with no pile steel exposed (Figure 7).

The third stage in the construction process necessitated the crane lifting up a box unit which had been wheeled down from the costing yard to a position behind the crane, swinging it around and placing it on the headstocks (Figure 9). The stainless steel bolts in the headstocks were fed through slatted holes in the base of the box units and stainless steel pods clamped the box units to the headstocks once in place (Figure 8). The slotted holes accounted for any longitudinal misalignment of the piles.

FIGURE 6 STAGE 2 CONSTRUCTION PROCEDURE

FIGURE 7 PRECAST REINFORCED CONCRETE HEADSTOCKS

FIGURE 8 SECTION THROUGH HEADSTOCK IN PLACE

This procedure was repeated for a total of nine box units (each approximately 4.9 metres long) and a special precast outlet unit was then placed on four piles at the seaward end (Figure 10). This outlet unit was designed to prevent blockage of the outlet should the shoreline extend out to its previous level. At the shoreward end, a transition piece connected the box units to the existing circular 1.83 metre diameter reinforced concrete stormwater pipes.

STAGE 3--WHEN IN-SITU CONCRETE IN HEADSTOCK HAS ATTAINED A STRENGTH OF AT LEAST 30 MPa, LIFT PRECAST BOX UNIT INTO PLACE AND BOLT DOWN. ADVANCE CRANE AND REPEAT PROCESS.

FIGURE 9 STAGE 3 CONSTRUCTION PROCEDURE

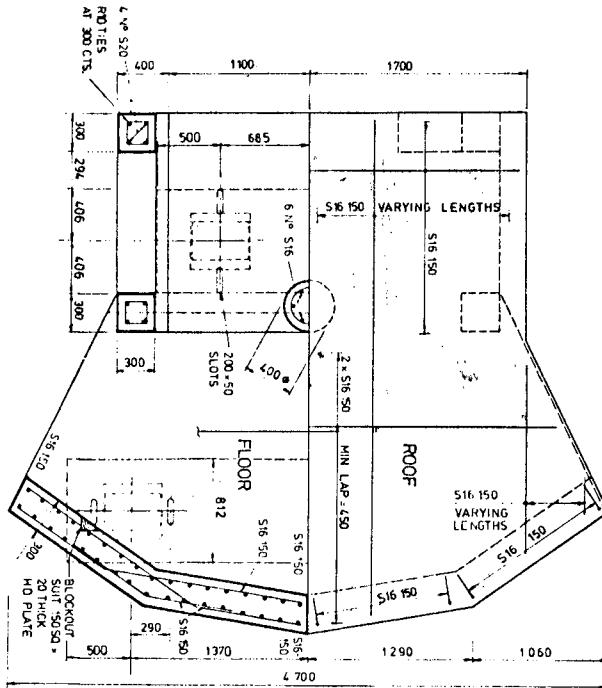

FIGURE 10 SPLIT PLAN OF OUTLET UNIT

In retrospect, the construction procedure worked very well. However a short time after the sixth box unit had been placed, reasonably heavy seeps were experienced. This particular unit broke up in the region of the holding down bolts. Evidence of site stiff present at the time indicated that the nuts of the holding down bolts had worked loose and the unit had been pounding up and down under the action of the waves. It was at this stage that the possibility of high shock pressures on the slab immediately adjacent to the headstocks occurred to us, and a rough model test was carried out to indicate the magnitude of this effect. The tests indicated that the wave pressures on the underside of the slab were sufficiently high (of the order of 60 KPa prototype) to warrant a full scale model investigation. Details of this investigation are presented in Section 3.

At the same time as the work was being carried out to determine what wave loading to use in checking the box units, further investigation and analysis was carried out to determine the inherent strength of the box units. It had been assumed in the design stage that the

outlet unit would shield the box units from direct wave attack and no allowance had been made for any vertical wave loading. The box units had been designed for a static water pressure of 12 kPa and were only nominally reinforced in the base slab. A finite element analysis was carried out for a wave loading of around 360 kPa (based on an increase in wave energy as water depth increased) and for the crane loading during construction. The analysis revealed a shear weakness in the construction case and indicated that for the assumed wave loading, the box unit would stay intact but with severe cracking occurring. Both these problems were exacerbated by the Contractor's omission of reinforcement in critical areas. The problem of the shear weakness during construction was easily remedied by the insertion of packing plates and further holding down bolts were put in to enable the bottom of the box units to act more as a two way slab and thus have greater flexural strength under wave attack.

The outfall was completed on this basis and it was decided to re-evaluate the question of further strengthening when the detailed model tests were completed.

3. HYDRAULIC MODEL INVESTIGATION

3.1 Model and Instrumentation

The nature of the breaking wave uplift pressures on the underside, or soffit, of the stormwater outfall was investigated in a laboratory wave flume 0.9 m wide using a model of two bays of the stormwater outfall constructed at a scale of approximately 1 in 12 (Figure 11).

NOTE

1. Location for transducer and number shown thus 

FIGURE 11 MODEL OF OUTFALL

To enable measurement of the uplift pressure a total of 18 holes were drilled through the horizontal platform of the model, comprising 9 through the centre-line and 9 along the edge, in which could be positioned a pressure transducer flush with the platform soffit. Only one single pressure transducer was used throughout the investigation and therefore simultaneous measurement of uplift pressures over the platform could not be achieved.

The pressure transducer was a Stothom differential pressure transducer Model PM1311C. This transducer is a flush diaphragm construction with a working range of ± 175 cm H₂O and natural frequency 3,500 hertz. The response of the transducer to wave pressures was amplified and displayed on a Tectronix 912 storage cathode oscilloscope via a low pass filter. The low pass filter attenuated the effects of component frequencies above 1,000 hertz which it was thought could excite vibration of the transducer at its natural frequency.

3.2 Experimental Conditions and Procedure

The model was placed centrally in the wave flume on a beach slope of 1 in 20, approximately 17.5 m from a periodic progressive wave generator. Throughout the testing the model wave period was maintained constant at 2.3 seconds (8 seconds prototype). Incident waves were always made to break seaward of the model by variation of the stroke of the wave paddle. The wave motion impinging on the model was therefore the surge formed after breaking.

The work of previous researchers had shown that wave pressures exerted on horizontal platforms (and vertical walls) were characterised by an initial impact pressure of high magnitude and short duration followed by a pressure of longer duration and lesser magnitude. The nature of the initial short duration impact pressure was the prime concern of this investigation and was studied in two stages. The first stage was aimed at establishing temporal characteristics of the impact pressure and involved simultaneous measurement of both impact pressure rise time and magnitude. Readings were taken for only the centre-line transducer locations and for still water levels 10 mm and 20 mm below the soffit of the platform. The elevation of the soffit above the bed of the flume was such that the most seaward headstock rested on the bed (Figure 1).

The second stage of testing was concerned with determining the distribution of the magnitude of the impact pressure over the platform as well as a study of the slowly varying pressure. In this case readings were taken at each of the 18 locations for the transducer. The difference between the soffit and still water level was varied, in steps of 10 mm, between a lower water level value at which no contact occurred between the incident wave and the soffit and an upper water level value at which impact pressures ceased to occur (see Section 1.3.4). In addition, two elevations of the

platform soffit above the bed of the flume were considered. Initially the elevation of the soffit was set as described for the first stage of testing. A second series of tests was then undertaken with the soffit raised 25 mm by insertion of spacers into the support piles.

Both the magnitude and rise time of the initial impact pressure were subject to considerable variation from impact to impact for a given test condition. In order that meaningful average values were obtained 20 readings of impact pressure magnitude and rise time were taken for each combination of transducer location, difference between soffit and still water level and soffit elevation above the bed. The magnitude of the slowly varying pressure was much more regular and a representative value was taken from the display of 3 to 4 waveforms only.

Over the range of conditions studied in the model investigation the variation in the breaking wave height in the model was from 7 cm to 19 cm (0.85 m to 2.3 m prototype) and in the water depth along the structure was from 2 cm to 15 cm (0.25 m to 1.8 m prototype).

3.3 Results and Discussion

3.3.1 General

Although the experimental equipment comprised essentially only a single pressure transducer and storage cathode ray oscilloscope, several informative and interesting conclusions could be drawn from the hydraulic model investigation.

As expected, when impact occurred, and irrespective of the location of the transducer on the platform, the recorded pressure in general comprised an initial impact pressure of potentially high magnitude and short duration (of the order of milliseconds) followed by a slowly varying pressure of longer duration, which was typically first positive then negative.

The nature of the slowly varying pressure is fairly well understood and can be related to the hydrostatic effects with due allowance made for the influence of vertical fluid acceleration. It is therefore proposed only to discuss here some of the important aspects of the impact pressure. Accurate measurement of the impact pressure is difficult because of its extremely short rise time and the finite size of the pressure transducer's sensitive diaphragm. Together these factors may lead to a so called "transducer area defect", related to the transducer's spatial resolution (French, 1969).

French proposed that a transducer would not accurately record a pressure distribution unless the characteristic half-length of the pressure pulse (the product of the rise time and wave celerity) was greater than about three times the radius of the pressure transducer's sensitive diaphragm. If this was not the case a record of

time-dependent pressure would be produced in which the recorded pulse was of longer duration and of lesser amplitude than a record produced by a transducer of vanishingly small area or simply of somewhat smaller area. A correction procedure developed by French increased the recorded impact pressures in his study by a few percent to as much as 50% although it is stated that the procedure cannot be applied with certainty.

The Statham PM131TC transducer used in this investigation did not satisfy the above criterion for "accurate measurement" proposed by French. As the purpose of the investigation was to establish the nature of the breaking wave impact pressures no attempt has been made to correct the results for the above factors. It is therefore likely that the results presented in the following sections may tend to underestimate the magnitude of the impact pressure and overestimate its rise time. Use of the low pass filter could be expected to contribute to this tendency.

3.3.2 Rise Time of Impact Pressure

The rise time of the impact pressure was defined as the duration of time between the initial sharp rise of the pressure above static level and the peak of the pressure response.

For the centre-line gauges and the two water levels tested the average rise time of the impact pressure varied between 1.8 milliseconds and 8.5 milliseconds. Although subject to considerable variation from impact to impact there did appear to be a relation between the rise time and magnitude of the impact pressure, such that the shorter the rise time the higher was the magnitude of the impact pressure. This relationship has in fact been reported by previous researchers, notably Bagnald (1939) and Rass (1954), who found that the area enclosed by the pressure-time curves tended to approach, but never exceed, a definite value. This area of the pressure-time curves up to the peak of the impact pressure was found to be a fraction of the wave momentum and is thought to be related to the destruction of the original momentum of the kinetic mass involved in the impact.

3.3.3 Longitudinal Variation of Impact Pressure Head

Figure 12 shows the variation in magnitude of the impact pressure head along the centre-line of the structure for the two elevations of the soffit relative to the bed of the flume. Impact pressure head is measured in centimetres of water and each plotted point represents the average of twenty readings of the impact pressure for a given difference between the soffit and still water level.

It should be noted that the plotted points do not represent a simultaneous envelope of impact pressure on the structure. The impact pressure is in fact considered to be a phenomenon travelling with the line of initial contact between the wave and the soffit and at any one time to be confined to this immediate vicinity. (This was

FIGURE 12 LONGITUDINAL VARIATION OF IMPACT PRESSURE HEAD

first proposed by French and confirmed by observation during this investigation.) An estimate of the spatial extent over which the impact pressure acts can be obtained from the product of the wave celerity and the rise time. From the results of this investigation the extent is of the order of only millimetres (model). This means that only very localised regions of the structure, each of wave length order, are subject to the impact pressure at any one instant. Quite a considerable length, however, could be subject to the slowly varying pressure at any one time.

The effect of the headstocks on the magnitude of the impact pressure head is immediately evident. Impact pressures are higher in the regions immediately seaward and shoreward of the headstocks with the effects most pronounced immediately seaward of the headstocks. (Note that the plotted points represent pressures caused by incoming waves and not backwash. The effect of backwash for the conditions tested was found to be negligible.) The influence of the headstocks appears to extend over a region either side of the headstock, equal to about the projection of the headstock below the soffit.

The highest average magnitude of the impact pressure head recorded in the model was 123 cm H₂O (or about 12 kPa) at transducer location 6 immediately seaward of the most shoreward headstock (Figure 12). If scaled according to Froude's Law, which is generally considered to overestimate pressures of this type (Richert, 1974), a prototype pressure of 150 kPa would be predicted. These pressures are clearly extremely high in comparison to normal design loads and their magnitude alone suggests that they would be of concern in the design of prototype structures. Before their effect on a structure could be evaluated, however, the structure's response to the spatial and temporal characteristics of the pressures would need to be established.

In regions of the platform remote from the effect of headstocks the magnitude of the impact pressures are much lower. The results of this investigation are in agreement with the work of previous researchers who studied impact pressures on horizontal platforms (without vertical obstructions) and found that the magnitude of the impact pressure head rarely exceeded 5 times the height of the incident wave above still water level (French, 1969; Wong, 1970; Massel et al, 1978).

3.3.4 Variation of Impact Pressure Head with Difference Between Soffit and Still Water Level

Figure 13 shows the manner of the variation of average impact pressure head with difference between the soffit and still water level for transducer locations 6 and 3. The manner of the variation is typical for each of the transducer locations but is best illustrated by the results of locations 6 and 3 due to the wide range in the magnitude of the impact pressure head recorded at these locations.

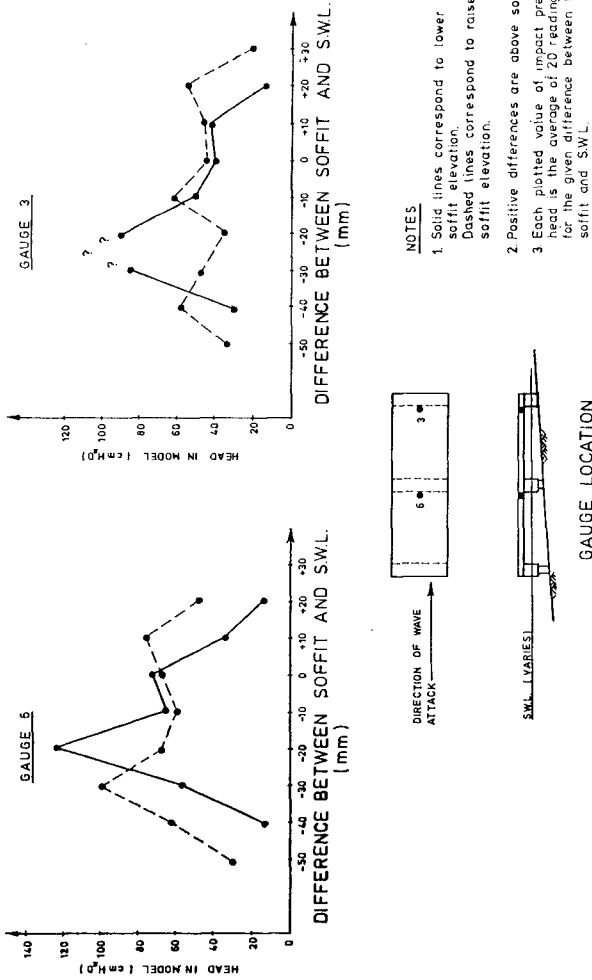

FIGURE 13 VARIATION OF IMPACT PRESSURE HEAD WITH DIFFERENCE BETWEEN SOFFIT AND S.W.L.

The highest single impact pressure recorded in the model was 300 cm H_2O , also at transducer location 6, and if scaled in the same way corresponds to about 360 kPa in the prototype.

Most evident from Figure 13 is that impact pressures at a location on the platform occur only over a certain range of differences between soffit and still water level (or alternatively, for a certain range of water depths). The lower limit of the range is the trivial case of when the water level is so low that no contact is made between the incident wave crest and soffit of the platform. The upper limit of the range appears to be for the case of when there is no air gap between the body of water in front of the incident wave and the soffit of the platform. In this case the impact pressure appears to be "drowned" and the record of wave pressure comprises the slowly varying pressure only. This observation lends support to French's conclusions that impact pressures on a horizontal platform are associated with a wave propagating into an empty air filled space (French, 1969).

An important inference from the above results is that providing wave activity is present and the water level is within the "critical range" wave impact pressures will always occur and furthermore will continue to occur, at the wave frequency, until the water level varies outside the limits of the "critical range" or the waves themselves cease to propagate. This is in direct contrast to breaking wave impact pressures on vertical obstructions which are extremely sensitive to the form of the breaking wave at the point of contact with the obstruction and are therefore by nature infrequent.

4. CONCLUSIONS

The main conclusions of the hydraulic model investigation are:

- (1) Short duration impact pressures occurring on the soffit of the precast units vary in magnitude along the unit. Prototype pressures predicted by Froude's law are of the order (maximum) of 150 kPa seaward of headstocks, 60 kPa shoreward of headstocks and 20 kPa in the central region between headstocks. (It should be remembered that the equivalent prototype height of incident breaking waves was of the order of only 1 to 2 metres.) The region of influence of the headstocks appears to extend from the face of the headstock for a distance about equal to the projection of the headstock below the soffit of the units.
- (2) The rise time of the impact pressure is extremely short, of the order of milliseconds and observation during testing confirmed that the impact pressure is a phenomenon confined to the immediate vicinity of the wave front and travelling with the wave velocity. These two aspects imply that only a narrow lateral strip of the box units is subject to wave impact loading at any one instant.

- (3) Impact pressures on the soffit at the precast box units occur for only a certain range of water levels and can be related to the difference in elevation between the soffit of the box units and the still water level. Within the range of water levels there is a "critical" water level for which maximum impact pressure occurs. Far lower or higher water levels the impact pressure is reduced even though for the case of the higher water level the breaking wave height is increased. For the particular conditions studied in this investigation the water levels within which impact pressures occurred extended over a vertical range of about 65 mm in the model, corresponding to approximately 0.75 m in the prototype.

The above conclusions have the following implications with respect to the prototype:

1. The wave loading predicted by the model tests is much higher than that assumed in design. The finite element analysis showed that the structure can safely withstand an overall pressure of around 10 kPa on the underside of the units combined with an impact pressure peaking from 10 kPa at a distance equivalent to the headstack depth away from the headstack to a maximum of around 60 kPa in the region of the headstack. This is significantly less than the maximum pressure envelope predicted by the model tests.

FIGURE 14 WAVE IMPACTING ON OUTLET UNIT

2. Because of the location of the soffit of the units at mean sea level combined with a tidal range of 1.33 metres it is extremely likely that the units have in the two years since completion been frequently subjected to wave forms which the model tests indicate produce high impact loading (Figure 14). For example 8 second waves over a tidal period of 6 hours represent 2700 waves and a significant proportion of these would strike the headstock when the water level was at or around the critical level.

Despite the above the structure has remained intact and a recent inspection revealed no obvious signs of distress. One can only assume from this fact that:

- (i) Non-idealised conditions in the prototype and/or the use of Froude's law result in the model tests overestimating actual prototype wave impact pressures.
- (ii) The response of the structure to the temporal and spatial disruption of actual wave pressures is such that significant redistribution and damping of internal stresses result.

It is likely that in practice a combination of the above factors probably occurs. The relative importance of these two factors is expected to become clearer when a prototype wave pressure study of the outfall (planned to be undertaken shortly by the Department of Public Works, NSW) is completed.

The aim of the paper has been to highlight the manner in which site-specific conditions govern design and construction in the surf zone, and in particular the need for wave loading to be fully evaluated in addition to normal functional loads. The results of the model tests have given the authors a valuable insight into the nature of wave loading on horizontal platforms in the surf zone and, whilst several questions still remain unanswered, it is hoped that the paper will be of assistance to designers and provide the basis for a better understanding of the performance of structures located in the surf zone.

FULL SCALE NEAR SURFACE WATER PARTICLE VELOCITIES AND
PRESSURES ACTING ON AN INCLINED TUBULAR MEMBER

by

Fritz Büsching ¹⁾ and Eckehard Martini ²⁾

ABSTRACT

A field investigation programme on simultaneous wave force and water particle velocity measurements is described with reference to an inclined tubular member subjected to offshore wave kinematics. First measurements at supercritical Reynolds numbers indicate strong irregularities in successively taken pressure distributions on the circumference of the test section as well as in the velocity vectors.

The influence of superimposed tidal currents is obvious.

1. INTRODUCTION

For want of anything better, MORISON's equation is still used for the calculation of wave forces on circular cylindrical structural members. Most experiments are based on it both in the laboratory and in the field. However, usually only water level deflexions and wave forces on a test section are measured, and the velocities and accelerations as input to MORISON's equation are determined using some suitable wave theory. As is well known, this procedure turns out to be one of the reasons for the wide range of scatter in the reported force coefficients.

Contrary to the respective investigation technique, DEAN (1976) pointed out the necessity of also measuring undisturbed flow characteristics down in the fluid. KIM and HIBBARD (1975) measured the local water particle velocities in a full scale experiment and similar measurements are being carried out at present in the Christchurch Bay Tower experiment, see for instance PEARCY and BISHOP (1979) and HOLMES and TICKELL (1979).

High enough REYNOLDS's numbers in the laboratory experiments to be applicable to prototype were only obtained by applying special model techniques for instance SARPKEYA (1976), HOGBEN (1976), YAMAMOTO and NATH (1976).

It remains, however, still a question as to how well the laboratory results apply to real wave motion, and especially to irregular waves with varying directions of propagation.

¹⁾ Chief-Engineer, Dr.-Ing. ; ²⁾ Dipl.-Ing.

Div. of Hydrodyn. and Coastal Eng. Techn.Univ.Braunschweig, F.R.G.

Being also aware of additional uncertainties arising from

- a) different roughness characteristics due to marine fouling,
- b) the coincident presence of waves and (tidal and wind induced) currents,
- c) different shapes of test sections (vertical or inclined),
- d) different wave kinematics (deep versus shallow water) etc.

the authors initiated a field wave force investigation programme which is sponsored by the GERMAN MINISTRY OF RESEARCH AND TECHNOLOGY (project number MTK 0053).

The experiments are performed on the GERMAN RESEARCH PLATFORM "Nordsee" about 100 km offshore in a water depth of approx. 30 m. There is also another measuring programme under way on the island of NORDERNEY (German North Sea Coast) involving substantially differing kinematics of shallow waves.

Both investigation programmes are at first restricted to the measurement of near surface wave forces (derived from the measured pressure distribution on the circumference of tubular members), water level deflexions (waves) and to the measurement and analysis of the ambient flow characteristics including tidal, wind and wave induced currents.

In the future the research programmes will be extended by the measurement of directional spectra (from an array of 3 sonar devices) in the offshore programme and the near shore measuring configuration shall be combined with measurements of additional forces exerted by wave spray loadings, see FÜHRBÖTER (1977).

At present the MTK-project deals with the wave loadings exerted on an inclined member of a platform leg, and the near shore measuring configuration consists of a vertical pile structure for the force measurement with a satellite measuring station for the measurement of water level deflexions and particle velocities.

Because of the lack of space, only the offshore measuring configuration is described in the following including the test structure, the measuring devices, some data processing routines and preliminary evaluations are outlined. Additional remarks on the near shore measuring configuration are contained in BÜSCHING, MARTINI and SPARBOOM (1979).

2. MEASURING CONFIGURATION

The measuring devices of the test section (Fig. 1) consist of a packing ring clamped on a member of a platform leg which is inclined 30.225° with reference to the vertical axis. This tubular structure (5 m long, 1.92 m diameter) contains 24 KISTLER-pressure transducers on its circumference centered about 5 m below mean low water spring (MLWS).

Fig. 2 : Test section clamped on an inclined member of the platform substructure to be seen on extremely low tide water level at storm conditions. Baylor wave staff on the left hand side.

Fig. 1 : Sketch of the measuring configuration

At the same elevation are located 3 two-component electromagnetic COLNBROOK-current meters (No. 1 - 3) oriented in such a way (angular spaced 22.5° and 2.5 m distant from the test section) that the particle velocities in certain vertical planes containing the respective main wave propagation direction can be determined from the measurements to a high degree of reliability. For the direct measurement of the wave propagation direction and the phase velocities, the current meters No. 7 and 8 are used, each measuring two velocity components in a horizontal plane 3.5 m below MLWS.

Additionally only 2 m below MLWS, there is a third horizontal measuring plane again containing 3 current meters (No. 4, 5 and 6) for another measurement of the water particle kinematics in vertical planes with reference to the above mentioned current meter positions No. 1, 2 and 3.

The corresponding water level deflexions are measured at a certain distance from the test section by a BAYLOR wave staff, see Fig. 2. Additional wave data can also be received from a set of 3 sonar devices fixed to different members of the platform structure, see LONGREE (1976).

3. MEASUREMENTS

Because of the many interpretation difficulties arising due to the inclination of the tubular member, superimposed currents and reflexion effects (resulting from the neighbouring platform substructure elements) etc. the authors found it to be reasonable as an initial attempt at data interpretation to consider the simplest loading case in which the main wave propagation direction is in the vertical plane of the inclined member.

As can be seen from Fig. 3, such a configuration occurs when wind and waves come from south westerly directions which unfortunately are not in correspondence with the direction of maximum reliability of current meters 1 - 6 measuring rotating orbital vectors in vertical planes. Hence, the description of actual force creating wave kinematics can only be based on the measurement of

- the water level deflexions,
- the pressure distribution on the circumference and
- the horizontal velocity components (of current meters No. 7 and 8),
which are most reliable for maximum values only.

As an example, such an irregular wave trace measured by the BAYLOR wave staff on November 15th, 1978, 10.11 p.m. at a distance of about 2 m from the test section is shown in the upper part of Fig. 4, and the total set of synchronously taken pressure traces from the circumference of the test section is shown below. Additionally Fig. 5 and 6 contain the corresponding velocity traces of current meters No. 7 and 8 respectively each split into magnitude and direction. All of these traces cover a measuring period of 12.8 sec which are sampled at intervals of 0.2 sec giving 64 phase points also indicated in the graphs.

Fig. 3: Orientation of the test section with reference to different directions of wave propagation

The pressure measurements shown in Fig. 4 do not contain any different hydrostatic components corresponding to their respective location below the water level. Hence, the zero mark shown is arbitrary only. The different behaviour of the curves is due to the processes taking place in the boundary layer at specific transducer locations on the circumference and depends on the actual wave propagation direction. This is examined in detail in Fig. 7 showing the pressure distributions (on the circumference of the test section) corresponding

Fig. 4 : Synchronously measured wave trace and pressure traces on the test section circumference on November 15th, 1978, 10.11 pm

Fig. 5 : Synchronously measured wave and velocity traces on November 15th, 1978, 10.11 pm

Fig. 6 : Synchronously measured wave and velocity traces on November 15th, 1978, 10.11 pm

Fig. 7 : Variation of pressure distributions on the circumference of the test section with wave phase

to phase intervals of 0.4 sec. The respective development from phase Na. 2 to No. 20 (marked by numbers on the left hand side), is shown in the upper part of this Fig. and the measurements corresponding to phase numbers 22 to 44 are shown below.

For example, pressure sensor Na. 5 (indicated by arrows) located at the highest point on the circumference (see also Fig. 1) shows the absolute maximum pressure value near the first wave crest position (phase No. 2), intermediate values (with respect to other transducers) corresponding to trough phase numbers 18 to 26 and comes back to a relatively high value at the next crest position (phase No. 44).

Because of erroneous offsets in some of the transducer signals in this case all the distributions refer to that of phase no. 30 whose raw data showed minimum deviations from zero. As a consequence in this kind of presentation its pressure values are zero everywhere, cf. lower part of Fig. 7.

4. CONCLUSIONS

With the vertical distance between the first wave crest and the following trough

$$H \approx 4.75 \text{ m}$$

and the time between the two crests

$$\begin{aligned} T &\approx 8.8 \text{ sec} && \text{corresponding to a wave length} \\ L &\approx 113 \text{ m} && \text{(at a water depth of about 30 m)} \end{aligned}$$

both taken from Fig. 4 and

$$\max. u_c \approx 1 \text{ m/sec}$$

from Fig. 5, the data may be characterized roughly by calculating the following quantities :

REYNOLDS's number

$$R_n = \frac{\max u_c \cdot D}{\nu} \approx \frac{1 \cdot 1.92}{10^{-6}} = 1.92 \cdot 10^6$$

KEULEGAN-CARPENTER number

$$N_{KC} = \frac{\max u_c \cdot T}{D} \approx \frac{1 \cdot 8.8}{1.92} = 4.58 \text{ and}$$

DEANS's reliability ratio (cf. DEAN (1976) Fig. 5)

$$R_D = \frac{F_{D \max}}{F_J \max} \approx 0.4$$

Hence, at least at the wave crest position the conditions are well within the rough turbulent flow regime and the data turn out to be more appropriate for extracting C_M rather than C_D . Because of the insufficient velocity measurement, however, at the present stage the authors do not find it reasonable to apply routines for extracting any force coefficients until the actual flow pattern around the inclined member can be described in general and particularly with reference to varying directions of wave propagation. The following remarks contribute to that aim.

Although there are strange irregularities to be seen from the pressure distributions in Fig. 7, a certain similarity to the well known supercritical stationary flow case is obvious. This is most distinct at the wave crest position (phase no 2) with maximum pressures at the front face and a secondary pressure maximum on the opposite side of the test section circumference. With the flow direction changing the secondary pressure maximum becomes the absolute maximum (near sensor numbers 15 and 17 at phase numbers 22 and 24 respectively) and vice versa, however with its exact location changing from wave to wave. After integrating the pressure distributions (at phase intervals of 0.2 sec), the irregular behaviour can also be observed in the resultant force vectors which are plotted with the wave phase in the two alternative presentations of Fig. 8.

The trace of successive force vectors is shown in the upper part and the same data are given below with reference to 0. Both traces are numbered consecutively.

Up to phase number 8 the forces are directed easterly and have south-westerly components at phases 9 to 30.

Maximum forward and backward force vectors differ by angles of $\alpha = 69^\circ$ and $\beta = 91^\circ$ respectively (see lower part of Fig. 8). A similar change can be seen from the following wave cycle. An inspection of the velocity data is helpful in order to check out how much these changing force directions are influenced by the inclination of the tubular member.

The respective presentations - similar to that of the resultant forces - are shown in Fig. 9 and 10 respectively. It is apparent from these graphs that there also exist differences in the forward and backward directed flow, but the difference angles between maximum velocities (most reliably measured) are in the range of 13° to 30° only (see upper part of Fig. 9).

A speculation that the deviations are due to superimposed currents can be true, if tidal velocities are considered:

As an example Fig. 11 shows the behaviour of the tidal currents at the same location as during the measuring period from February 15th to 20th, 1977. In particular it can be seen from this graph that maximum tidal velocities (1 hour average values) occur with magnitudes of about $V_T \approx 0.3$ m/sec setting easterly at increasing water levels and north-westerly with the water level decreasing. By inserting the vectors U_{CR} and U_{TR} from Fig. 9 into Fig. 11 at a tide phase similar to that of the measurements on November 15th, 1978, the asymmetry between U_{TR} and U_{CR} can be explained by a superimposed tidal current of $V_T \approx 0.3$ m/sec. The even stronger asymmetry in the force vectors of Fig. 8 than in the velocity vectors (of Fig. 9 and 10) is because an inclined member

Fig. 11 : Variation of tidal stream vectors from February 15th to 20th, 1977

is (more) sensitive to an asymmetric flow condition resulting in an amplification of the force creating processes.

The evaluations shall be continued in the future. In particular, the synchronous measurements, reported here, shall be compared to the actual tidal velocity as calculated from the long term velocity measurements.

ENERGY TRANSMISSION OVER BREAK WATER
- A DESIGN CRITERION ? -

- P. BADE, Research Assistant, Technical University of Berlin, Federal Republic of Germany
- H. KALDENHOFF, Professor of Hydraulic Engineering, Technical University of Berlin, Federal Republic of Germany

1. INTRODUCTION

The wave transmission from seaside to lee of break waters depends on structural parameters as well as on the initial wave climate. Transmission coefficients for special boundary conditions are known, but information about wave parameters are often not available or they cover often only special cases. Again a case study, undertaken for the break water at the proposed deep water harbour at Scharhoern/Neuwerk, Germany, documented this lack. The results of the case study using conservative wave parameters did not answer the important questions of energy transmission sufficiently, thus we investigated the characteristics of the initial and transmitted wave spectra. A special case was treated initially and subsequently more general situations were examined. These tests were carried out using a physical model of a length scale of 1:10 under conditions described by Froude's law.

2. MODEL TESTS

The cross section of the proposed break water is seen in Figure 1. It consists of several layers with a cover layer of concrete cubes. The break water was built into the wave channel under simulated prototype conditions, i.e. under water and having waves in the flume. This was done to simulate also the settling of the structure.

The wave flume itself is about 90 m long, 4 m wide and has a water depth of 1.6 m. The model was located about 60 m away from the wave generator. A dividing wall was set up so that the width of the structure was only 2 m. Thus it was possible to measure the wave heights in front and

beside the break water as well as behind in order to get information about the energy transmission and reflection.

Figure 1: Cross section of the break water
Scharhoern/Neuwerk

In order to avoid misleading test results, wave groups which were reproducible but limited in time length were used. The main reason for using this kind of model waves is to compensate the effects of energy reflection. Figures 2 to 5 show four different wave trains with the time-amplitude relation of the wave board, initial wave and transmitted wave.

The wave train is generated by the superposition of different wave packets, which gives two advantages:

1. The wave train can be limited in time to avoid the influence of reflection at the wave board, but all wave components are simulated.
2. The oscillation of the water surface at any point of the channel can be predetermined in period and amplitude.

Assumption of this method is that the wave packet is describable by an analytical function. It was proved and

WG 903 C

Figure 2: Wave group 903 C

WG 903 D

Figure 3: Wave group 903 D

WG 912 A

Figure 4: Wave group 912 A

WG 915 A

Figure 5: Wave group 915 A

analyzed by Coulson 1949 that the Gaussian wave packet does fulfill this assumption. Additionally it has the following characteristics:

- The energy peak is well marked and travels with the group velocity adequate to the wave length of the energy peak.
- The amplitudes in front of and behind the energy peak decay exponential. The wave length in front of the energy peak increases, and behind it the wave length decreases.
- This kind of Gaussian wave packet describes the surface motion of the sea in shallow waters pretty well, specially a wave train with a well marked energy peak. The energy spectra covers a wide frequency band and the amplitude distribution does follow the Rayleigh distribution.

The superposition of several of these wave packets results in the wave train which statistical and group properties can be varied in a wide range. But this variation is not random but predetermined.

The water depth was varied from $h/d = 0.9$ to $h/d = 1.0$ and $h/d = 1.1$ that is 10 % below break water crest even and 10 % over. Each test series consisted of 16 different wave trains (those four already shown but each of it with four different frequencies). The runs were controlled by an 'on line' computer. The data were collected and stored by magnetic tape for later analysis.

3. EVALUATION OF MODEL TESTS

The conventional evaluation of the damping efficiency of break waters relates the transmitted wave height to the initial wave height. But this method gives no information about possible relationships of wave period and steepness in the luv and lee of the structure. Thus, a frequency analysis was included in the programme for the data analysis. The spectral distribution of the wave energy gives some information about the transmission which is indeed dependent on the wave frequency. The transmission coefficient is defined as $K_t = H_t/H_1$. Using its regular waves the coefficient was calculated by comparing the mean values of waves, i.e.:

$\bar{K}_t = \bar{H}_t / \bar{H}$ and in an analog manner, the transmission coefficient for 33 % and 10 % highest waves. The wave generation system enabled us to shift the energy maximum to different frequencies and to test the influence of wave grouping.

4. RESULT OF MODEL TESTS

The transmission coefficients evaluated for different water depth and wave heights as a function of the normalized run-up $\Delta h = 1 - h-d/H_{1/3}(n)$ is given in Figure 6.

Figure 6: The results and regression of the transmission coefficient $K_T(n)$ for the normalized run-up

This graph includes the linear regression, which has an interesting behaviour, particularly at $\Delta h = 0.88$. At values of $\Delta h < 0.88$, the transmission coefficient drops for extreme values of $H_{1/3} = H_{1/10}$ faster than for $H_{1/3} = H_{1/3}$. At higher values of Δh the depending is vice versa.

That means, that if $h-d = 12\%$ of H_i (which is $H_i^{1/3}$, $H_i^{1/10}$ or \bar{H}) the transmission coefficient has the same value of about 0.4 no matter of the kind of significant wave we were looking at. In front of this point, the K_T values are smaller for higher significant waves when the difference ($h-d$) is about 60% of H_i . This is a quite amazing result, but it may be explained by the energy dissipation of the breaking waves which are of course the higher ones. If $(1 - h-d/H)$ raises, that is if the break water crest is not significantly above the still water level, the assumed result can be found: the higher the waves, the higher the K_T -values.

The scatter of K_T -values is considerable and does not allow an exact calculation of the influence of wave grouping, but the trend is obvious, i.e. wave trains of significant grouping characteristic create higher K_T -values. Because the wave train portions of different frequency and different energy percentage do not provide useful results by means of an extreme value analysis, a spectral analysis became necessary. The test results showed a strong amplitude and energy damping near the energy maximum of the initial wave train but the damping rate depends on the mean frequency of the wave train. An example is given in Figure 7, $h/d = 1.0$

Figure 7: Transmission function $K_T(f)$ of one wave train generated by four different frequencies, $h/d = 1.0$

All tested wave trains had almost an equal character of the $C_{1/3}$ -quotient $H_{1/3}/\bar{H} = 1.5$, but the frequency of the maximum energy was different. The transmission function $K_T(f)$, assumed to be linear in the range of the energy peak, increases with decreasing frequency.

Taking a brief look to the spectra analysis we will see on Figure 8 to 11 the energy spectra of the initial and the transmitted waves and the transmission function.

The higher curve in the first graph is the auto spectrum which is the magnitude squared of the linear: spectrum which is the Fourier transform of the signal $x(t)$, thus $S_x(f) = F(x(t))$, that is

$$G_{xx}(f) = S_x(f) \cdot S_x(f)^* \quad * = \text{conjugate of function}$$

The second curve in the first graph and the second graph shows the cross power spectrum which is a measure of the mutual power between two signals at each frequency and it is defined as:

$$G_{yx}(f) = S_y(f) \cdot S_x(f)^*$$

The transfer function in the third graph is the mathematical description of the input - output relationship of a system. For single inputs and outputs it is defined to:

$$H(f) = \frac{G_{yx}(f)}{G_{xx}(f)}$$

The frequency range, which includes about 95 % of the wave energy is marked. Each wave train gives a different transfer function. They are taken together to show the frequency behaviour of the transmission function and are plotted in Figure 12 to 15.

There seems to be a general tendency. In case of relative low water ($h/\bar{d} = 1.1$) the group characteristic dominates the wave transmission in such a way, that wave trains of strong grouping create higher $K_T(f)$ values, and there is also the frequency related tendency for the transmission

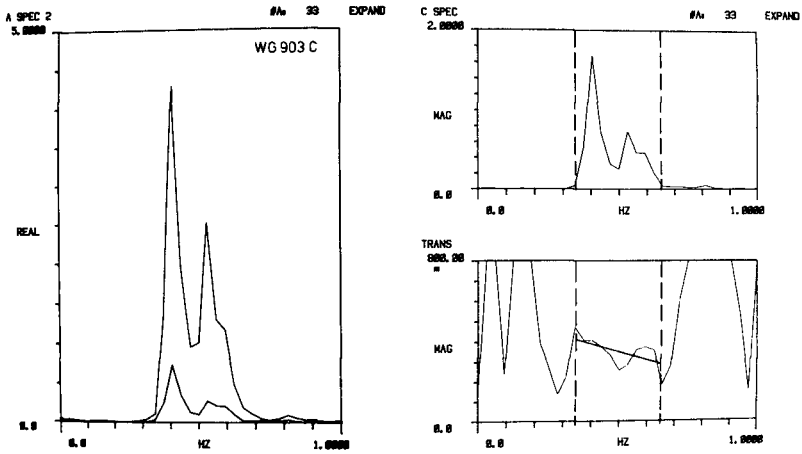

Figure 8: Energy spectra of the initial and transmitted waves and the transmission function, wave group 903 C

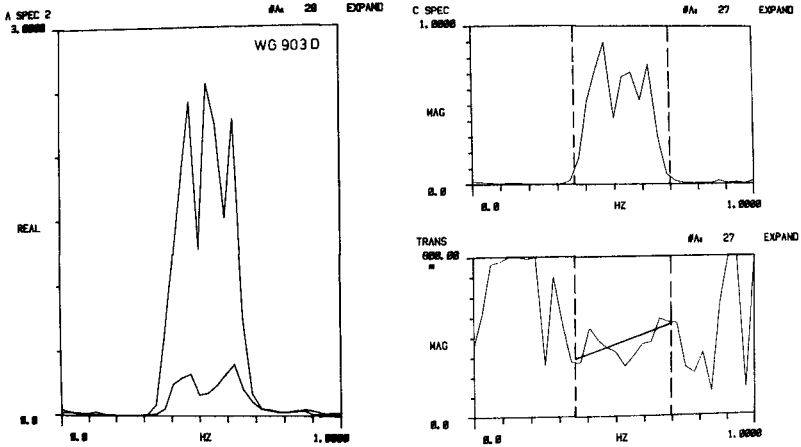

Figure 9: Energy spectra of the initial and transmitted waves and the transmission function, wave group 903 D

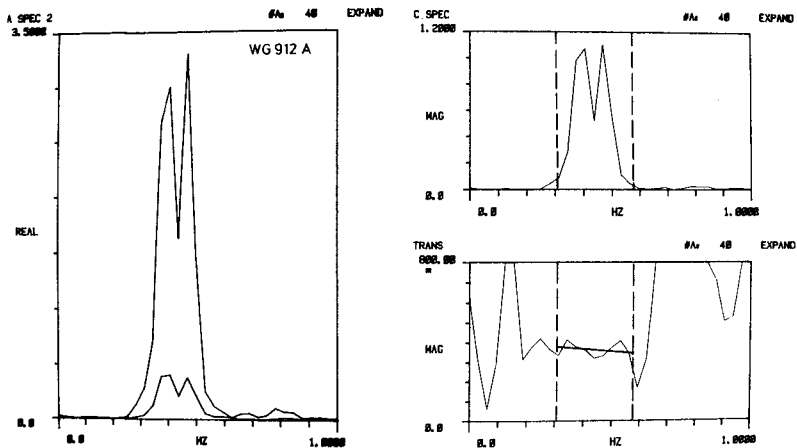

Figure 10: Energy spectra of the initial and transmitted waves and the transmission function, wave group 912 A

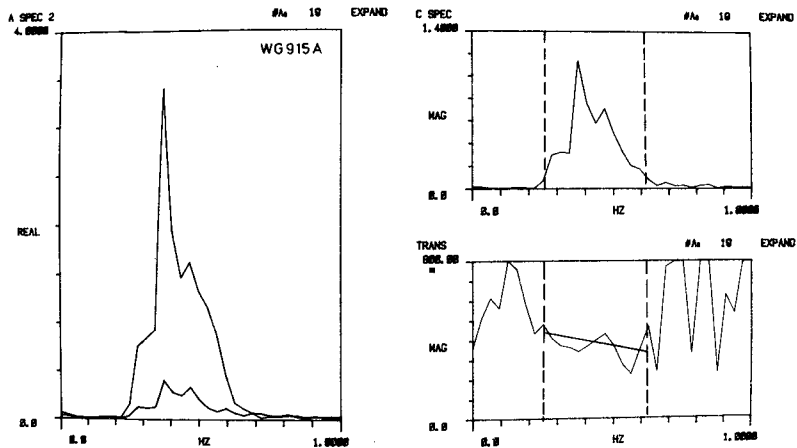

Figure 11: Energy spectra of the initial and transmitted waves and the transmission function, wave group 915 A

Figure 12: Transmission function of different wave trains, $h/d = 0.9$

coefficient. In case of high water ($h/d = 0.9$) the frequency relation is not obvious. This may be explained by energy fronts, which are more marked in wave trains of high waves and strong grouping. These energy groups transmit a large amount of wave energy during a small time range. Additionally, the peak of energy density function is shifted to higher frequencies.

As H/gT^2 , the so called normalized wave period, is an indicator of frequency dependence, the test results were evaluated to prove a frequency relationship.

$h/d = 1.10$

Figure 14: Transmission function of different wave trains, $h/d = 1.1$

$h/d = 1.00$

Figure 13: Transmission function of different wave trains, $h/d = 1.0$

It could be shown that the normalized wave period H/gT^2 of the significant wave height $H_{1/3}$ is not a sufficient parameter to indicate the frequency behaviour, see Figure 15.

Figure 15: Wave transmission depending on normalized wave period, wave group 903 C

The results for the other wave groups look more or less the same.

Summarizing, it may be stated that the damping efficiency of overtopped break waters is related to the wave height and its distribution as well as the frequency of the energy maximum. Moreover, a grouping characteristic of the initial wave train is of influence. More research on this phenomenon is of high interest.

The Design Concept of Dual Breakwaters
and its Application to Townsville, Australia.

W. Bremner⁽¹⁾, D.N. Foster⁽²⁾, C.A. Miller⁽³⁾ and
 B.C. Wallace⁽⁴⁾.

1. Introduction

In Central and North Queensland the coastline is protected by the Great Barrier Reef over a length of some 1900km from Gladstone in the south to the tip of Cape York (Fig. 1).

The fetch distance from the reef to the coastline is very variable from about 15km to 140km. Hence the coastal areas north of Gladstone have moderate to low wave climates except during abnormal weather events such as cyclones or long time interval bands of strong winds. In these events larger storm waves of significant wave heights of 10m may be superimposed, in the case of cyclones, on storm surges several metres in height.

The design of breakwaters and shoreline structures for protection against all except cyclonic and strong wind band effects requires, in the main, readily available sizes of armour rock and relatively low crest elevations.

To offer similar protection against cyclonic weather events often requires the use of artificial armour units of concrete and a substantial increase in crest heights. The resulting increase in costs makes many of the small projects uneconomic.

In this paper the concept of using an offshore breakwater which is designed to fail under extreme wave conditions to protect an inner breakwater or revetment is examined and the results applied to Townsville Harbour where cost savings of the order of 40 percent were achieved over a conventional design.

2. Rossllyn Bay Breakwater

The design concept arose from studies and observations of the damage to the Rossllyn Bay breakwater during cyclone David (see Fig. 2) and the subsequent protection provided by the breakwater following damage (Foster, Bremner and McGrath, 1978). Features of this damage were:-

- (1) Principal, Blain Bremner & Williams, Consulting Engineers
- (2) Associate Professor, Water Research Laboratory, University N.S.W.
- (3) Principal, C.A. Miller & Associates, Associate Consultant to WRL
- (4) Principal, B.C. Wallace & Associates, Associate Consultant to WRL

FIGURE 1: LOCALITY SKETCH

TYPICAL CROSS SECTION

FIGURE 2: DAMAGE TO ROSSLYN BAY BREAKWATER BY CYCLONE DAVID

- (i) Failure occurred in a controlled manner with material being displaced from the crest and deposited on the leeward slope, forming a widened and lowered profile. The breakwater was composed of 3t nominal armour rock on the seaward face, $\frac{1}{2}$ to 1 tonne filter rock and less than 150mm core material.
- (ii) Failure to the breakwater was closely simulated by model studies.
- (iii) Reconstruction of the breakwater was not commenced until 2½ years after failure. During this period the breakwater acted as a submerged breakwater and continued to provide substantial wave protection within the harbour. Over this period waves of up to 1.8m height were experienced. All small boats continued to stay on their piled and bottom moorings and there was no damage to boats, moorings or shoreline revetments.

These observations triggered the idea that if a controlled submerged breakwater could successfully be built then a significant reduction in costs may well be possible. The interesting design problem was then posed of building a breakwater of sufficient initial stability to allow safe construction but when subjected to the designed forces, due to carefully chosen extreme and fairly rare weather events that result from cyclones, it would be reshaped in a controlled and predictable manner to become a stable and partially submerged structure and retain its wave attenuation ability.

(It should be noted that in Australia large floating plant is not available for breakwater construction and all breakwaters are constructed in the dry. This precludes the construction of an initially stable offshore submerged breakwater).

It is of interest to note that the repair to the Rosslyn Bay breakwater as reported by Bremner, McGrath and Foster (1978), which used a combination of rock and modified cubes, has been completed and in 1980 was subjected to waves of 3.2m in height during cyclone Simon. There was no damage to the breakwater.

3. Townsville Harbour

3.1 General

To provide additional port facilities it is proposed to reclaim a significant area on the eastern side of the harbour as shown in Figure 3. Wave protection to this reclamation was to be provided by an offshore breakwater or by conventional armouring of the seaward face of the revetment. Initial design and economic assessment showed that the second proposal was approximately 60 percent more expensive and detailed designs were not undertaken. This cost saving resulted from:-

- (i) use of locally available low cost rock in the offshore breakwater which was designed to "fail" under extreme wave and storm surge conditions and provide a partially submerged offshore breakwater;

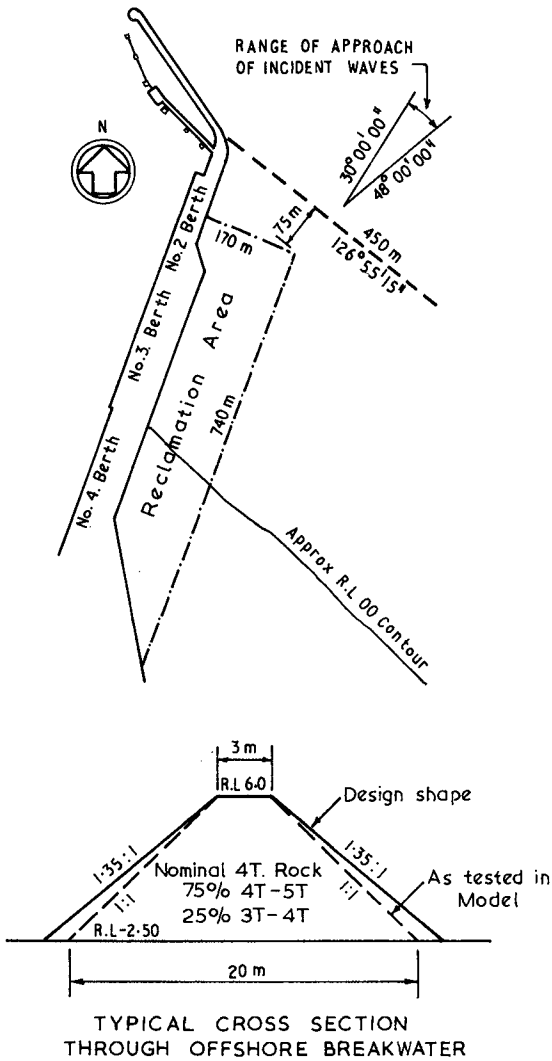

FIGURE 3: TOWNSVILLE HARBOUR

- (ii) reduction in wave height at the revetment thereby reducing the height of reclamation required and the use of low cost readily available rock armour.

3.2 Design Conditions

Design wave and surge conditions have been extensively studied by Blain Bremner and Williams (1978), Harper and Stark (1977), Sobey, Rossow and McConagle (1978), and are summarised in Table 1 below:-

Table 1: Design Storm Conditions

Return Period (yrs)	Tide (MHW) (RLm)	Cyclonic Conditions			
		Storm Surge (m)	Design SWL (RLm)	H _s (m)	T _s (sec)
50	2.45	1.68	4.13	3.76	6.0
100	2.45	2.00	4.45	4.15	6.3
500	2.45	2.76	5.21	5.26	7.2

Tidal data based on Townsville Harbour Board datum of RL0.0 are as follows - HAT 3.6m, MHWS 2.9m, MHW 2.0m, MSL 1.6m, MLWN 1.2m, MLWS 0.4m, LAT -0.2m.

3.3 Offshore Breakwater

A typical section through the proposed offshore breakwater is shown in Figure 3. It basically is composed of nominal 4t rock placed at its natural angle of repose with a range of rock sizes between 3 and 5t. Crest level at completion of construction is at RL 6.0 which will be overtopped only under extreme wave and surge conditions.

3.4 Model Tests

Extensive model tests of the scheme were undertaken by the Water Research Laboratory of the University of N.S.W. (Foster, Miller and Wallace 1980). A summary is given in this paper and the reader is referred to the above reference for more complete details.

Preliminary stability tests were run at constant water levels for the design peak water levels and wave heights shown in Table 1. The tests were run for two nominal rock sizes (M) of 2t and 4t, having approximate gradings of 75% between M and 1.25 M and 25% between 0.5M and M. Test duration was 7 hours. (Prototype).

Collapse of the breakwater was ordered with some stone being displaced seaward, flattening the seaward slope and the remainder being displaced landwards resulting in a broadening and reduction in elevation of the crest which is similar to that observed during the failure of the Rosslyn Bay breakwater (Foster, Bremner and McGrath 1978). The majority of damage occurred in the first two hours and basically stopped when a water cushion formed over the crest. Because of the higher water levels damage was less for the less frequent events, the highest damage being associated with the 1 in 50 year event. All further tests

FIGURE 4: VARIATION OF CREST STABILITY WITH WAVE HEIGHT—CONSTANT WATER LEVEL

FIGURE 5: BREAKWATER DAMAGE

were undertaken with tide variation reproduced in the model so that the structure was subjected to the design wave under varying water levels.

The relation between crest level and S.W.L. at stability under constant water level is shown in Figure 4 together with results of similar studies undertaken by U.S. Army Corps of Engineers (1953) and Foster (1972) using Froudian scale factors to convert the results to equivalent 2 and 4t nominal rock. Figure 5 indicates that the results are within the range obtained in previous studies. However, the difference in damage for the 4t and 2t rock sizes is smaller than indicated by the lines of best fit (exponential). This may be due to the fact that the previous studies were carried out on conventional breakwaters having separate core, filter and primary armour layer.

In the second series of tests the breakwater was subjected to the design wave height and storm tide resulting from tide plus the design storm surge. Wave period was 10 seconds. Spring, neap and mean tidal cycles were tested. Typical results are shown in Figure 6. The mode of failure was similar to that for the constant water level tests but the degree of damage was substantially larger as the crest is exposed to higher wave forces as the tide changes. Damage was not strongly dependent upon the tidal cycle chosen.

During the tests maximum incident and transmitted waves were monitored and the results are shown in Figure 7. Wave breaking occurred over the crest and the transmitted wave was measured 65m landward of the structure after the wave had reformed.

Rather surprisingly these results indicate that the transmitted wave is not strongly dependent upon the amount of damage and implies a considerable degree of safety in the design. The reason for this appears to be, that the effect of increasing crest width as a result of failure tends to largely counterbalance the effect of increasing water depth relative to the crest. Similar results have been observed by Saville (1963) (see Appendix 1). The overtopping tests were undertaken in the laboratory's 1m wide monochromatic wave flume. The model scale was 1 to 27.4.

The three dimensional model tests to study the effects of diffraction around the head of the breakwater and wave heights along the revetment were undertaken at a scale of 1 to 57. In these tests the transmitted waves past the breakwater agreed closely with the larger scale tests which indicates that scale effects are small and that the major component of the transmitted wave results from wave overtopping.

The three dimensional tests undertaken to study diffraction indicated that during overtopping wave heights were not substantially increased in the lee of the breakwater as a result of diffraction which enabled the initial design length of the breakwater to be substantially reduced in the final design.

4. Conclusion

Model tests have shown that the concept of constructing a break-

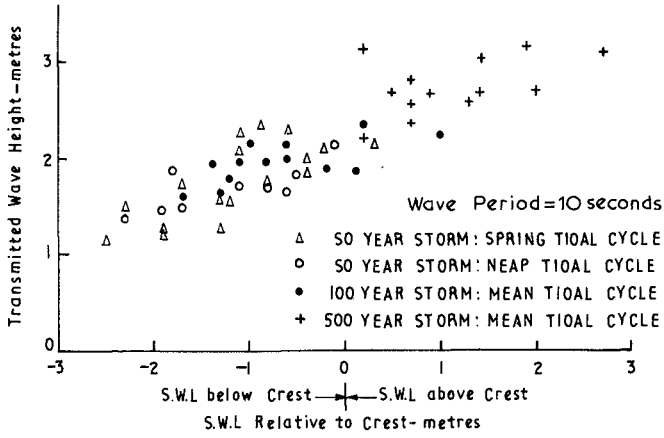

FIGURE 6: VARIATION OF TRANSMITTED WAVE HEIGHT WITH S.W.L. RELATIVE TO CREST

FIGURE 7: WAVE TRANSMISSION FOR VARYING CREST WIDTH

water to form a submerged structure after failure is an effective method of reducing wave heights at inshore structures. Tests indicate that the transmitted wave past the breakwater is relatively independent of incident wave conditions, rock size and depth over the crest. Although more damage occurs for the longer return period events and the smaller rock sizes the correspondingly wider crest tends to counterbalance the increased depth over the crest resulting in relatively small increases in the transmitted wave. Hence a considerable degree of safety is provided against the design conditions being exceeded.

In the view of the authors the important features of the design concept are:-

- (i) The high degree of tolerance inherent in the design against the design conditions being exceeded.
- (ii) The relative ease of construction which does not require large radius heavy cranes and leads to rapid construction and substantial cost benefits.
- (iii) The size of rock is contained to economic winnable and handable natural rock sizes.
- (iv) Wave run-up on the inshore structure is reduced, enabling lower crest levels to be adopted.

FIGURE 8: WAVE TRANSMISSION FOR VARYING CREST WIDTH

FIGURE 9: WAVE TRANSMISSION FOR VARYING CREST WIDTH

Appendix 1.

There are little data on wave transmission coefficients over permeable breakwaters of relatively narrow crest widths. Model tests for substantially broader crest widths are described by Saville (1973). These show that the transmitted wave is reduced with increasing width of crest. This fact has been used to explain why the present results indicate only a slow change in the transmission coefficient even though the breakwater crest is substantially lowered during failure.

In order to quantify the comparison with Saville's results supplementing tests were undertaken on the rock used in the model studies for the same dimensionless geometric and wave parameters. Results are shown in Figures 6 - 8. All tests follow similar trends to that observed by Saville. However, for S.W.L. below the crest transmission coefficients were found to be 20 to 40 percent higher. For S.W.L. above the crest the results agree closely. The differences are believed to result from the different rock sizes used in the tests. The results for SWLs below the crest tend to indicate that permeability and therefore wave energy transmission through the structure are higher for the submerged breakwater in the present studies. For SWLs above the crest, difference in permeability has only a marginal effect on transmitted wave since the majority of energy is transmitted by overtopping.

DESIGN OF AN OVERTOPPING BREAKWATER

- B. NAGLE, Design Engineer, The Maritime Services Board of N.S.W., Australia.

1. INTRODUCTION

The Maritime Services Board of New South Wales, Australia, is constructing a major new port facility on the northern foreshores of Botany Bay. A principal part of this project has been the construction of a large armoured revetment from the northern shores.

The entrance to Botany Bay faces south-east and it is from this direction that a large proportion of offshore wave energy arrives. Some of the wave energy which is directed onto the Bumborah Point revetment is reflected towards Yarra Bay on the northern shores of Botany Bay. Yarra Bay is largely undeveloped, but a sailing club has stood for many years on the beach at the southern end. As a consequence of this reflected wave energy being directed towards Yarra Bay, its wave climate has been changed considerably so that during the storms of May-June, 1974, Foster (6), damage was suffered by the club-house. Additionally the more severe wave climate and consequent steeper beach have made it much more difficult to launch sailing boats. The Maritime Services Board is charged with the responsibility to carry out remedial works where damage is caused by the port development. Figure 1 shows the revetment and sailing club site.

To assist in coastal engineering design aspects of the port development, a large fixed bed wave model of Botany Bay has been built to an undistorted scale of 1:120. This model, some aspects of which have been described by Lawson (4), has pneumatic wave generators which enable offshore wave directions between east-north-east and south to be generated with prototype periods in the range of 5 to 16 seconds. A pneumatic tide generator enables a sinusoidal tide to be generated.

FIG. 1

PORT BOTANY

The effect of tide stage and velocity on wave propagation is important in Botany Bay because it is relatively shallow.

Wave-height exceedance statistics have been gathered for a number of years using Datawell Waverider Buoys. The installation has been maintained for more than 8 years about 2 kilometres offshore of the entrance to Botany Bay and programmed gathering of data 4 times a day for 20 minutes carried out. Another buoy was installed in Yarra Bay for about 2 years.

The breakwater had to fulfill the following requirements :-

- (a) Return wave climate and run-up in front of the club house to pre-port-works condition;
- (b) Offer adequate rigging area on the beach;
- (c) Provide an adequate gap between its outer end and the shoreline to provide a 10 boat-length space, based on a 5 metre boat length;
- (d) Be no more visually obtrusive than necessary.

This last requirement meant than an over-topping breakwater would be desirable.

2. HYDRAULIC STUDIES

The hydraulic studies required for successful design of a shore structure must investigate the following aspects :-

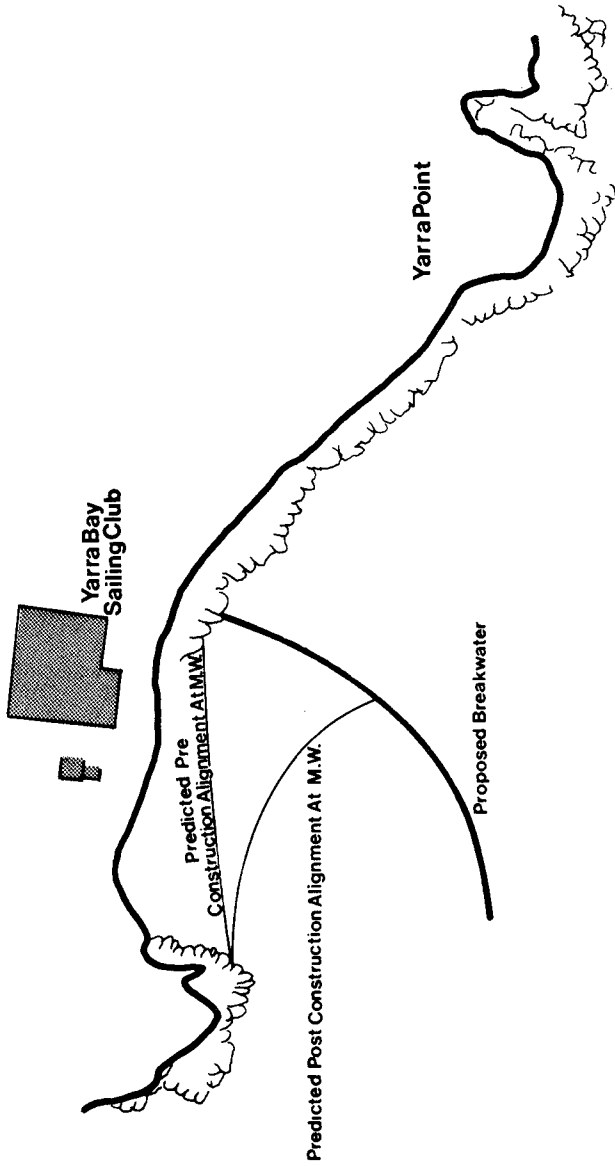

- (a) optimisation of the performance of the breakwater taking due consideration of benefit-cost relationships.
- (b) provide design wave-height data based on probability levels.
- (c) investigate the changes in beach alignment which construction of the breakwater will cause.

2.1 Breakwater.

In order to determine a suitable breakwater length and alignment, various breakwaters were constructed in the Botany Bay Hydraulic Model. These were built so that no overtopping occurred. It was decided to calculate this aspect separately; the scale of 1:120 being considered too small for adequate run-up and overtopping determinations. Figure 2 shows the final design alignment. Breakwater lengths of 10m greater and smaller length were also tested in the model. The alignment shown in Figure 2 is the centre-line and fulfils the 10 boat length requirement taking into consideration the physical size of the structure.

Previous testing in the Botany Bay Hydraulic Model enable wave-height coefficients to be determined for the offshore directions east-south-east, south-east and south-south-east, combined with periods of 8, 10, 12 and 14 seconds at position A shown in Figure 2. These conditions contribute the major proportions to the wave energy reaching Yarra Bay as the entrance to Botany Bay faces south-east. The direction of reflected waves arriving in Yarra Bay varies very little with offshore direction-period combination and there is very little incident wave energy. It was therefore decided not to carry out this full range of 12 tests for the breakwater, but instead examine results available for position A and then, on the basis of partial probabilities of wave-height exceedance, carry out tests for the 5 most important conditions.

Two positions on the lee side of the breakwater were chosen and wave-height coefficients measured relative to position A, Figure 2. The tests were conducted at tide levels of 0.2m, 0.9m (M.W.) and 1.5m, these levels allowing probabilities of occurrence to be apportioned as 0.25, 0.5 and 0.25 respectively for tide level intervals spanning these values. Highest Astronomical Tide is 1.9m and the datum is Indian Springs Low Water, 0.0m. Depth at the breakwater head was 3.1m at I.S.L.W. Coefficients for the untested wave conditions were estimated by extrapolation.

● A
FIG. 2

Overtopping coefficients, K_t , were determined following Cross and Sollitt (3). Their envelope equation is :-

$$K_t = 0.65 \left(1.1 - \frac{H_b}{R} \right) \quad (1)$$

where H_b is breakwater crest elevation above Still Water Level.

R is run-up.

Run-up was determined using data presented in the Shore Protection Manual (7) for run-up on permeable rubble slopes, a slope of 1:1.5 being used. K_t values were determined for a range of unrefracted deep water wave-heights at the same tide levels used in the model tests.

It was then assumed that wave coefficient in the lee of the breakwater, K , could be conservatively estimated by :-

$$K = K_A K_t + K_A K_{di} \quad (2)$$

where K_{di} was determined from model tests.

K_A is the wave coefficient at position A, seaward of the breakwater.

Adoption of this method is considered to be conservative. K was evaluated for the different tide levels and for different breakwater crest elevations, 2.0m and 3.0m above I.S.L.W. Equations like (2) were used to determine plots of lee-side wave-height versus offshore wave-height; this not being a linear relationship. Then, following Lawson, (4), and applying weights of 1, 2 and 1 to the low, mean and high water level tests, partial probabilities of wave-height exceedance for the two lee positions were obtained. Summation of all these partial probabilities produced wave-height climate data which could then be used to calculate expected wave run-up on a statistical basis. The breakwater length and crest height were chosen to provide acceptable wave run-up conditions to the clubhouse.

However, wave run-up (i.e. in the horizontal plane) depends upon beach alignment and it was necessary to determine the expected ultimate mean alignment to be able to finalize the design. Additionally, in the final design, tribar armour units were used at the outer end of the breakwater. Run-up on these units is approximately 20% greater, Foster (5), than on rubble mound structures and so this change had to be included in the final calculations.

2.2 Beach Alignment.

Following the beginning of construction of the Bumborah Point revetment and the consequent change in wave climate in Yarra Bay, the beach was forced to realign, Treloar (8). In general this produced a wider beach in front of the sailing club, but the much higher waves and steeper beach lead to run-up being increased and dangerous boat launching conditions. A beach survey programme was begun in 1971 with surveys being at 3 monthly intervals. These surveys recorded beach levels at 12 cross-sections along the beach and extended from the frontal dune to a depth of about 4m below I.S.L.W. At the northern end the frontal dune soon disappeared and storm waves began eroding the bund protecting an old rubbish tip. Curve fitting to the survey data and calculations based on data measured in the Botany Bay Hydraulic Model were carried out to determine the expected ultimate mean beach alignment, Treloar (8). Statistical analysis of the survey data enabled the 95% confidence limits, based on a postulated normal distribution of beach width, to be obtained. This figure is approximately + 10m and results from onshore-offshore movement of sand, slope changes, alignment fluctuations and survey error. It is believed that this is a good estimate of the width band within which a beach contour (at Mean Water) will lie in Yarra Bay.

In 1974 about 30,000 cubic metres of sand were placed on the beach in Yarra Bay to overcome the problems caused by re-alignment. Beach surveys were continued and inclusion of this sand quantity in the beach alignment calculations enabled a predicted pre-construction alignment to be determined.

The pattern of diffracted waves behind the breakwater was used to determine an estimate of ultimate beach alignment. Circular wave fronts were drawn, centred at the breakwater seaward end and tangential to the predicted ultimate mean beach at the limiting orthogonal. This procedure assumes that the sand volume which will move in behind the breakwater will be sufficiently small to produce minimal narrowing of the beach in the remainder of the bay. The process of sand moving in behind the breakwater commenced soon after construction began. However, the plan shape of this "fillet" developed beyond the calculated circular arc alignment, this development being caused by the radiation stress resulting from the lee-side wave-height gradient. Sand will be transported by the current caused by this radiation stress gradient until the lee beach develops sufficiently for the gradient to become zero and a condition of stability established. Based on the circular arc beach and wave data on the lee side, run-up to the clubhouse was established for the various test conditions.

On the exposed side a complicated wave pattern was to be expected. An interference zone, formed essentially from waves reflected from the Bumborah Point revetment and waves reflecting again from the curved alignment of this breakwater, would cause further re-alignment of the small beach area between the breakwater and Yarra Point to the south. This re-alignment would take the form of a reduction in beach width near the breakwater. In order to avoid undermining of the breakwater toe 3,000 cubic metres of sand were placed on this beach area after construction was completed. It was considered that a larger quantity would not remain "entrapped" on the beach and might tend to move away around the rocky headland of Yarra Point.

2.2 Design Wave-Height.

The design wave-height information was obtained using wave-height coefficients at position A, Figure 2, and 5 years of Waverider buoy data obtained from the offshore deep water installation. This data has been collected with directional information and log-normal wave-height

exceedance distributions determined for direction - average zero crossing period combinations. The model mono-chromatic wave periods were related to the prototype zero crossing periods by considering proportions of energy in frequency bands spanning each monochromatic frequency in a Moskowitz spectrum defined for each zero crossing period. These data were used in the structural design of the breakwater. Table 1 shows wave-height exceedance data for significant wave-height as well as data obtained from 440 days of wave records measured by a Waverider buoy installation at position A. These latter data were not available at the design stage but confirm, with reasonable accuracy, the model results.

<u>Probability of Exceedance in Days/Year</u>	<u>Significant Wave-height (m)</u>

TABLE 1: Design and Measured Wave-Height Data

3. STRUCTURAL DESIGN

As indicated earlier the need to construct this breakwater became more urgent as the work on the major revetment in the port development progressed (Figure 1).

Increasing lengths of exposed core and completed armour at different construction stages of the revetment, and their various effects on reflection of waves to this site during the storms which occurred in the years 1974-75, produced damage to the club house resulting in the urgent need for ameliorative works to be undertaken.

In order that protection could be afforded prior to the principal storm period of May-June 1976 the design of the breakwater was completed without wave flume tests.

The structural design of the breakwater was thus based on a survey of information contained in the literature. Figure 3 indicates

site details for the final design.

3.1 Materials Available.

At the wave heights indicated, use of concrete armour tribars sized at 2½ tonnes and 6 tonnes was possible as a result of their use on the main revetment in the Port.

Rock armour sizes of 1 and 2 tonnes were similarly being used in that project. This material was being won from a quarry on the south coast of N.S.W., a road haul of approximately 120km.

Suitable core material was available up to 2 tonnes R.O.Q. within 60km from the site. Sizing of this material was 65% finer than 1 tonne.

The urgency of construction indicated the need for use of these available materials, if possible, in this breakwater.

3.2 Wave Height

In keeping with design wave heights for other port works, the significant wave height corresponding to a 0.01% probability of exceedance was considered appropriate for the structural design of the breakwater. At this probability, significant wave height is exceeded for a total of nine hours in 10 years.

As earlier indicated overtopping to some extent could be tolerated.

3.3 Crest Elevation.

A major requirement for this breakwater construction was to keep the crest elevation as low as possible. Additionally, so that the core material could be placed at normal stages of the tide, a crest elevation of approximately 3 metres above I.S.L.W. would achieve this aim. The depth at the breakwater's head is approximately 3.1 metres below I.S.L.W.

3.4 Head.

As reflected in the Shore Protection Manual's recommendations, (7), a structure head

is more conservatively treated for armour design.

The most commonly used formula for estimating armour sizes for non-overtopped breakwaters subject to breaking and non-breaking waves is the Hudson formula. This formula is based on a no damage stability criterion, defining permissible damage as displacement of up to 5% of the armour cover layer.

The largest available rock armour size was 3 tonnes for placing in two layers, but at the design stage this size of rock was not stockpiled at any possible source. Data available indicated that the cost increased by 50% for 3 tonne rock above 1 to 2 tonne size.

For minor overtopping, the Shore Protection Manual (7), recommends a K_d of 2.9 on a slope of $1\frac{1}{2}$ to 1 with levels of damage from 0 to 5%.

Foster (5), indicated damage co-efficient K_d values of 4 and 8 for 3 tonnes rock at slopes of $1\frac{1}{2}$ to 1 and 2 to 1 would lead to damage levels of 10% and 5% respectively for no overtopping. The data compares favourably with the Shore Protection Manual recommendations.

A conclusion reached by Lording (2), indicated that damage of a rock armour breakwater head should be restricted to 3%. Even though the testing in that report was limited, it was concluded that the most critical design for the tested structure was for S.W.L. just below crest level. For all tide stages this condition applies at the site of this breakwater for the design crest level.

Thus on the above data it appeared that damage levels of 3% for 3 tonne rock might occur at the 0.01% probability wave height.

Investigation of a concrete armour alternative was then pursued as flatter slopes than 2 to 1, and larger rock size may not have ensured the desirable lower damage levels of 3% at the head. Additionally, rubble deposited in the lee of the breakwater head may need to be removed to ensure adequate navigation.

Construction of the major port works, having included the use of single layers of tribars of 2½ and 6 tonne, enabled easy availability of these armour unit forms. For the 0.01% exceedance wave height the co-efficient of damage for 2½ tonnes tribars is 6.9, just below recommendations in the Shore Protection Manual (7) for minor overtopping. It is noted that in these recommendations the margin of uniform tribars (1 layer) over random placed tribars (2 layers) on the structure trunk is not maintained for the structure head. This presumably results because uniform placing makes greater use of frictional resistance than does random placing and this gain becomes less significant when the breakwater face is convex and the lateral reactions between blocks are somewhat reduced. For overtopping the damage co-efficient of 6.9 is not conservative for a breakwater head when looking at the Shore Protection Manual recommendations, (7) if the tribars are placed in one layer. However, the construction cost saving in placing tribars in one layer is significant.

To increase the size of tribar units for which forms were readily available, namely 6 tonnes, meant that the elevation of the core material would be below M.H.W.M. as armour unit and underlayer size is increased and this would be an unsatisfactory working level for a contractor.

In tests by Jackson (1), random placing of tribars in two layers on a convex surface of 1½ to 1 slope indicated a crest level to block dimension (C/D) ratio of 0.5 and still water level radius to block dimension ratio of 5. In this design these ratios are 0.8 and 3.4 indicating a tighter proposed head geometry when compared to the tests. Jackson recommended a damage co-efficient of 6 based on the Shore Protection Manual density of placement for two layers of random placed tribars.

In other work in the port tribars have been pattern placed ensuring leg to leg contact between adjacent tribars. This technique achieves lower placing densities and higher stability than placing uniformly to the Shore Protection Manual recommendations (7), Foster (5). However, pattern placing is difficult below water and a pattern could not be achieved in construction on the convex face at the head.

Foster's data (5), indicates for single layer tribar tests a damage co-efficient, K_d of 7 for a damage percentage level of 2%. That level of model damage is viewed by the writers to indicate a virtually maintenance free structure.

While Lording's data (2) applied to a rubble mound structure it indicated that critical damage occurred more to the crest and lee side for water levels just below the crest. Movement of tribars would be restricted in these areas by ensuring that :-

- (a) they were anchored in a substantial toe, achieved during excavation for trimming of the core; and
- (b) at the intersection of the sloping face and the crest adjacent tribars would be placed under close supervision to ensure leg to leg contact.

It was concluded that, provided tribars were placed to achieve the density stated in the Shore Protection Manual, with tight packing on the head, armouring of the crest, seaward and lee slopes in 2½ tonnes tribars would give an economical maintenance free head. The design adopted at the head is indicated in Figure 4.

3.5 Trunk.

The head design adopted continued for approximately 44 metres along the centreline of the breakwater where the bed is reasonably level. From that point, chainage 100m, water depth decreases rapidly.

For the design of the trunk it was proposed to use an armour stone of similar size for both crest and side slopes due to the short length to be armoured. Lording (2), concluded that a limit of 6% displacement of rock armour would ensure structural integrity of the trunk. At the design stage the Maritime Services Board had a commitment for over supply of 1 tonne rock in other port works.

Lording (2) indicated that crest armour size necessary for stability with 6% displacement

FIG. 4

appeared more critical at critical still water depths. Additionally identification of the critical still water depth for a given armour zone may permit estimation of armour sizes for that zone by an empirical formula (such as Hudson's) with a degree of accuracy not greatly inferior to that achieved for the non-overtopped criteria. For the $1\frac{1}{2}$ to 1 seaward and leeward slopes tested, a K_d of 7 corresponds to a satisfactory displacement of 6%. The maximum armour size was less than that required for non-overtopped breakwater.

The 1 tonne armour size, readily available, corresponded to a 6% damage level, at a wave height of 2.5 metres on a $1\frac{1}{2}$ to 1 slope, equivalent to a damage co-efficient, K_d of 7.

The structural integrity of the breakwater would not be lost at that damage level. In view of the low probability of higher wave heights mentioned herein, greater damage could be expected, but the structure would protect the club house to allow repair when necessary.

The trunk design adopted is shown in Figure 5.

3.6 Post Construction Performance.

Since completion of the breakwater, damage to the trunk section only has occurred following a storm of maximum significant wave height of 2.5 metres at position A (Figure 2). The principal reason for damage was undersize rock in this area. However, the breakwater was not breached and damage occurred to the seaward part of the crest and the seaward face between chainages 70 and 90 metres. At the area of damage, during construction, some slumping of the unprotected core occurred due to inferior quality of core rock. If all the unsatisfactory rock was not detected and replaced prior to armouring the breakwater, storm damage may have been triggered by local slumping of the core during the storm in question.

The quantity of rock placed to repair this section represented less than 3% of the total 1 tonne rock placed on the seaward and lee slopes and the crest of the trunk. The repair rock was sized 2 to 3 tonnes and the cross section (Figure

FIG. 5

5) was reinstated.

On the cost information available, the repair demonstrated the saving in construction cost if the trunk had been armoured in larger rock size, and/or by using a flatter slope. However this saving is demonstrated only for this short breakwater trunk.

For an overtopped breakwater it is not recommended that reduction of rock armour size below that for a non overtopped breakwater be adopted unless wave flume tests are undertaken. Additional protection would have certainly been given to this breakwater because of depth limitations at the site.

FULL SCALE TRAILS OF DOLOSSE TO DESTRUCTION

by

Hans F. Burcharth*

ABSTRACT

It is well known that the relative dynamic strength of unreinforced slender concrete units decreases as the size increases. Big units can resist relatively smaller movements than small units. When model tests of cover layer stability are performed the determination of the damage criterion that should be adopted must therefore be based on knowledge of the dynamic strength of the corresponding prototype units.

With the purpose of establishing a relation between the size and the dynamic strength of unreinforced units some full scale tests to destruction of 1.5 and 5.4 t units were performed. The set up and the procedure of the tests which simulates the impact from rocking of the units and from concrete pieces that are thrown against the units are designed to make a comparison between the behaviour of units of different sizes possible. The test method is described and proposed as a standard method.

The theoretical expression for the dynamic strength is compared with the test results and it is shown that if the units are allowed to move there is an upper limit for the size of unreinforced units where a balance between the hydraulic stability of the cover layer and the strength of the units exists. Different ways of improving the strength of the units are discussed on the basis of the results from tests with different types of concrete.

The tests included an investigation of the influence of reinforcement, and of different types of concrete and surface cracks on the performance of the units.

1. INTRODUCTION

It is well known that rubble mound breakwaters with armour layers of relatively small Dolos units - say up to 10 tons weight - have proved to be very successful structures, while there have been problems in a number of cases where very big Dolos units have been used.

There are probably many reasons to account for this. This paper deals with one of them, which could be expressed as the "lack of balance between the hydraulic stability of the units and their physical strength".

From hydraulic model tests it is known that the hydraulic stability of Dolos armour layers is extremely good if we allow the units to move, and usually a damage criterion is adopted where rocking of a number of units and displacement of a few units take place. The model units can be moved around during the tests without going into pieces, but in nature it is different as we know from experience that especially big slender units cannot resist much movement.

Unfortunately nobody has been able to make model block material with strength properties scaled correctly and it is doubtful whether it can be done at the moment at reasonable costs as for theoretical reasons both the compression and the tensile strength, the density and the dynamic Youngs modulus must be controlled in a certain combination.

In 1978 the Hydraulics Laboratory, Ottawa, Canada made a very good attempt to simulate the strength by inserting a thin slice of a weak material into the stem of the model units, but correct, quantitative data cannot be obtained from this type of model units.

There is, therefore, a missing link. This in fact makes it impossible to apply the model test results directly for the design of big, slender concrete units, and at the moment sufficient practical experience of the behaviour of these units does not exist.

On this background some full scale tests of the dynamic strength of 1.5 and 5.4 t Dolos units have been performed with the purpose of getting a better understanding of the behaviour of big units and thereby find ways for an improvement of the units.

2. TEST SET UP

Two different types of tests were used. A drop test, which simulates the wave introduced rocking of the units, and a pendulum test, which simulates the impact from pieces of broken units that are thrown around by the waves.

Figure 1 shows the drop test and Figure 2 the pendulum test.

Figure 1 Drop test set up

Figure 2 Pendulum test set up

In the drop test one end of the unit is lifted a predestinated height and then dropped by means of a quick release hook. In the pendulum test the weight is pulled back a certain distance and then released.

From practical experience it is known that in most cases when a Dolos is damaged it is fractured through the stem at a position close to the fluke. Therefore, the support of the unit and the direction and point of attack of the hitting force must be chosen in such a way as to ensure breakage in the stem. Besides this the support system should be well defined, thus allowing for the calculation of stresses in the unit. Figure 1 and Figure 2 show set up systems that make allowance for these points of view.

It is seen from the figures that all the dimensions of the test rig and the pendulum weight are related to the size of the Dolos unit. The idea is to introduce a standard method that makes it easier to compare the behaviour of units of different sizes, cf. the theory in chapter 5. This is a very important point since it is known that the strength of relatively small units is satisfactory, and by testing such small Dolosse and comparing the results with the results from tests of bigger Dolosse one can obtain information on the relations between the strength and the size and material of the units. Only if based on such information can a relation be established between the size of the units and the damage criterion which should be used in the hydraulic model tests.

The horizontally placed stem has the advantage that the height to which the unit can be lifted in the drop test without shifting the point (or line) of support is sufficient to ensure fracture. The unit will also hit the base with the full area of the fluke end and thus prevent that crushing in the contact zone takes place. The base should be made of good quality reinforced concrete to avoid cracking after a few drop tests.

Full scale drop tests of Dolos units have been performed by others before the tests described in this paper. But to the author's knowledge the test set up has been as shown in Figure 3. Here the unit is resting on the ground or on a relatively thin steel or concrete slab and one end of the unit is lifted and dropped.

Figure 3 Inappropriate drop test set up

However this set up makes it impossible to compare different test results. This is mainly because the impact force will not be well defined, since the deformation from the crushing of the end of the Dolos leg and the deformation of the ground vary too much. Moreover, a test procedure where the threshold of the fall height is determined by increasing the fall height gradually cannot be used because of the uncontrolled crushing of the Dolos.

It may be argued that also the set up shown in Figure 1 implies uncontrolled impact forces caused by unknown variations in the soil characteristics at different sites. This is true, but for practical and economic reasons a much thicker concrete base, which is desirable, is not realistic. It is believed that the proposed relatively heavy and thick base will ensure applicable results as long as the base is founded on normal soils.

As the purpose of the pendulum test is to simulate the impact from a piece of a Dolos, e.g. a leg, thrown around by the waves a pendulum weight of $1/5$ of the Dolos weight is chosen. From an experimental point of view the same weight is adequate when combined with a pendulum length of 1.5 to 2 the Dolos height, since the draw back distance - or lifted height - of the pendulum required to destruct the unit will then be of a magnitude that can be measured accurately.

The pendulum should be made of the same type of concrete as used for the units and should be cast in a steel plate cylinder with wall

thickness of approximately 1/50 of the pendulum diameter. The steel cylinder serves as a mould and prevents damage of the surface from taking place during the tests.

A control of the impact energy from the pendulum is possible only if the movement of the pendulum when released is guided to ensure a central hit. The pendulum is therefore suspended in two non-parallel wires, the length of which should not be more than twice the Dolos height, see Figure 2. In this respect it is also important to use a good quality trigger mechanism (quick release hook) which does not cause undesirable movements of the pendulum when released. The mutual position of the Dolos and the pendulum should be so that the pendulum, when hanging at rest in vertical wires, should just touch the Dolos.

3. TEST PROCEDURE

Before the tests the surface of the units was carefully examined and photos were taken of possible surface cracks.

Since the influence of the load history on the dynamic strength was not known the load history was kept the same for each size of units. The history was chosen in such a way that failure occurred after approximately 6 to 8 impacts. In the drop tests the fall height, which was defined and measured as the vertical distance from the base to the centre of the fluke end, was gradually increased. For the 5.4 t units the initial drop was 100 mm, the second drop was 150 mm, and thereafter the increment was 20 mm. In the pendulum tests for the 5.4 t units the draw back distance, which was defined and measured as the shortest distance between the surface of the weight and the struck point on the Dolos unit, was gradually increased from 400 mm in the first strike to 450 mm in the second strike, and thereafter in increments of 20 mm.

Because of the rebound the unit was jerked back against the steel packing block after each pendulum blow.

The concrete surface was carefully examined after each stroke and in the case of reinforced units the width and the extent of the cracks were registered.

For the unreinforced units failure was taken as occurring at the first sign of fine cracks appearing in the unit. By soaking the unit with water these fine cracks could be seen as dry lines as the water was sucked by capillary action into the cracks.

For the reinforced units failure was taken as occurring when the crack width exceeded 0.1 mm. According to recent investigations of concrete structures in the North Sea this is a conservative value where no corrosion takes place.

With the purpose of examining the fracture the loading was continued until the unit broke into two pieces.

Where the fracture went through the surface cracks that existed before the test started the approximate extension of these cracks could be seen as wet areas.

For each unit the age and the specifications and density of the concrete mix were registered. The tensile strength was found indirectly from cylinder splitting tests and/or estimated from cylinder or cube compression strengths. The dynamic modulus of elasticity (the dynamic Youngs modulus) was found partly from the measurement of the velocity of ultrasonic pulses in the concrete and partly from static stress - strain graphs.

4. TEST PROGRAMME

Besides some pilot tests a total of 62 units were tested. Of these 27 were 1.5 t units and 35 were 5.4 t units. The tests were divided into

Figure 4 Geometry of Dolos units

6 series each containing approximately 10 units, of which one half was used for drop tests and the other half for pendulum tests. The geometry of the units is shown in Figure 4 and the specifications for the different series are given in Table 1.

Series No.	1	2	3	4	5	6
Weight of unit $M(\text{kg})$	1500	1500	1594	5400		
Density $\rho(\text{kg mm}^{-3})$	$2.33 \cdot 10^{-6}$	$2.33 \cdot 10^{-6}$	$2.47 \cdot 10^{-6}$	$2.4 \cdot 10^{-6}$		
Height of unit $H(\text{mm})$	1650			2320		
Waist ratio $\tau = a/H$	0.303			0.350		
Weight of pendulum $m(\text{kg})$	294			990		
Cement content (kg m^{-3})	291	291	392	385		
Water-cement ratio	0.50	0.55	0.24	0.46	0.46	0.44
Aggregate	Not crushed, max. 32 mm			Crushed basalt, max. 40 mm		
Additives	4-5% air	4-5% air	78 kg fine particles (mainly Silicadust) and 23 kg plastisizer per m^3	1% Plasto- crete OC	1% Plasto- crete OC	4-5% air and 1% Plasto- crete OC
Mean static compression strength; 100 x 200 mm cylinder. $\sigma_c(\text{Nmm}^{-2})$	28.9	26.6	88.4	45.5*)	45.5*)	39.2*)
Mean static tensile strength; cylinder splitting test. $\sigma_T(\text{Nmm}^{-2})$	2.95**)	2.79**)	5.74**)	4.38***)	3.56***)	4.18***)
Mean dynamic modulus of elasticity $E(\text{Nmm}^{-2})$	$3.6 \cdot 10^4$	$3.6 \cdot 10^4$	$7.0 \cdot 10^4$	$5.2 \cdot 10^4$	$4.96 \cdot 10^4$	$4.50 \cdot 10^4$
Particulars	Reinforcement of stem, see Figure 6			Cracks in stem-fluke corners, see Figure 5		

*) Calculated from 150 mm cube tests by multiplying the cube strength by 0.74.

***) Determined from cylinders cast during the production.

***) Determined from cores taken from the units.

Table 1 Specifications of the test series

As seen from Table 1 different concrete mixes with a considerable variation of the strength properties were used. Also a test series with units exhibiting serious surface cracks in the stem fluke corners was performed.

Figure 5 Typical extension of surface cracks in test series No. 5

Different degrees of reinforcement were used in some of the 1.5 t units with the purpose of investigating the relation between development and sizes of cracks and degree of reinforcement, see Figure 6. Because of limitations in the test program only the stem, being the weaker part of the unit, was reinforced. As a reinforced stem is much stronger than an unreinforced leg these tests could also give information about the dynamic strength of unreinforced legs. The concrete cover layer thickness was chosen to 70 mm in accordance with recommendations for concrete structures in the North Sea.

Figure 6 Reinforcement of 1.5 t Dolos units in test series No. 2

5. THEORETICAL BACKGROUND FOR ANALYSIS OF THE TESTS

5.1 Dimensional Analysis of Impact.

Consider a class of geometrically similar systems, in which the size of a structure and the size of an impinging body are both determined by a characteristic length and both made of the same material.

If the moving body strikes the structure the maximum stress σ at any point of the structure depends on the mass m and the velocity V of the incident body, the characteristic length L , the elastic modulus E , Poisson's ratio ν , and the mass density ρ . As an approximation E and ν are taken as constants that characterize the material, which means that the effects of rate of strain on stress are not taken into account.

By dimensional analysis we obtain,

$$\frac{\sigma}{mV^2L^{-3}} = f\left(\frac{EL^3}{mV^2}, \frac{m}{\rho L^3}, \nu\right) \quad (1)$$

As the proposed test system implies a constant ratio between the masses of the impinging body and the structure, and also because ν has a negligible influence on the phenomenon (we are dealing with concrete mixes with small variations in ν) equation (1) takes the simpler form,

$$\frac{\sigma}{mV^2L^{-3}} = f\left(\frac{E}{\rho V^2}\right) \quad (2)$$

This equation can be used to describe both the drop test and the pendulum test.

5.2 Drop Test Formular

In the case of the drop test the unit itself is the impinging body having a mass of M and a potential energy of Mgh , when the unit's centre of gravity is lifted vertically a distance h . As $V^2 = gh$ equation (2) yields,

$$\frac{\sigma}{MghH^{-3}} = f\left(\frac{E}{\rho gh}\right) \quad (3)$$

Until now only geometrically similar units have been considered. However, Dolos units are not always geometrically similar since the waist ratio $\kappa = a/H$ (see Figure 4) varies from 0.30 to 0.35 or more.

By calculating the unit's momentum as a function of M , H , κ and h and taking the duration of the impact as proportional to H/c , where $c = \sqrt{E/\rho}$ is the speed of a longitudinal wave in the concrete, an expression for the mean impact force can be established. From this the maximum stress in the stem cross section close to the fluke corner is found to,

$$\frac{\sigma}{MghH^{-3}} = C \frac{1+\kappa}{\kappa^2} \sqrt{\frac{E}{\rho gh}}, \quad 0.3 \leq \kappa \leq 0.4 \quad (4)$$

where C is a constant factor. Equation (4) does not include the negligible stresses caused by the weight of the unit.

5.3 Pendulum Test Formular

In this case the impinging body is a pendulum with a mass m equal to or approximately equal to 1/5 of the mass of the Dolos unit. The potential energy of the pendulum is mgh when pulled back to a position where the centre of gravity is lifted vertically a distance h . The maximum velocity of the pendulum is $V = (2gh)^{0.5}$. Equation (2) is valid only if the size of the pendulum and the Dolos are both determined by a characteristic length. Since Dolos units have varying waist ratios and also because the size and the weight of the pendulum for practical reasons are not always fixed parts of the size and the weight of the Dolos, equation (2) is not suitable for practical calculations. By using the same assumptions and calculation procedure as described for the drop test the following formula for the maximum stress in the stem cross section close to the fluke corner is obtained,

$$\frac{\sigma}{mghH^{-3}} = K \frac{1}{\kappa^3} \sqrt{\frac{E}{\rho gh}}, \quad (5)$$

where K is a constant factor. Equation (5) does not include the negligible stresses caused by the weight of the unit.

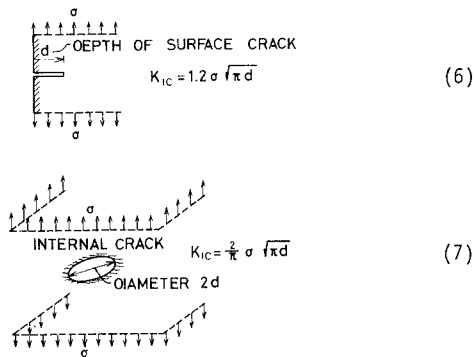

5.4 Analysis of the Influence from Cracks on the Dynamic Strength

The influence from cracks on the strength of the units can be looked into by means of fracture mechanics theory. An estimate on this influence can be made by using the fracture toughness parameter K_{IC} (critical stress intensity factor) for a static load situation on a linear elastic body of homogeneous and isotropic material. In K_{IC} the subscript I refers to the crack opening mode of crack propagation and the subscript C refers to the critical value of K_I , i.e. the onset of rapid fracture.

Although the assumptions related to K_{IC} are incorrect for concrete, many investigators have generally assumed that the approximations involved in the application of linear elastic fracture mechanics to concrete are reasonable.

For concrete K_{IC} values are found in the range from about 0.45 to 1.40 $\text{MN m}^{-3/2}$ for a static load situation. As an approximation the static load theory and the mentioned range of K_{IC} values are assumed valid for a dynamic load situation.

For plain strain conditions the critical sizes of surface cracks and internal cracks can be found from the equations (6) and (7), (see Figure 7), in which σ is the tensile stress at some distance from the crack.

(6) $K_{IC} = 1.2 \sigma \sqrt{\pi d}$

(7) $K_{IC} = \frac{2}{3} \sigma \sqrt{\pi d}$

Figure 7 Fracture toughness parameters

As the tensile stress σ generally varies between 2.5 and 5 Nmm^{-2} the range of the critical crack sizes will be as shown in the diagram, Figure 8.

Figure 8 Critical sizes of surface cracks and internal cracks

It is seen from the graphs that if the tensile strength of the concrete is approximately 3 Nmm^{-2} and K_{IC} is in the range from 1 to 1.4 $\text{MNm}^{-3/2}$ then the surface cracks can have depths of up to 25-50 mm without altering the performance of the unit.

6. TEST RESULTS

6.1 Unreinforced Units

The test results are summarized in Table 2. C and K are found by replacing the tensile stress by the static tensile strength in eq. (4) and eq. (5). This is an approximation but since it is believed that the ratio between the static and the dynamic tensile strength is constant the approximation is acceptable.

The average and the standard deviation of C are 0.16 and 0.02 respectively, and the average and the standard deviation of K are 0.69 and 0.14 respectively.

Series No.	1	3	4	5	6
Drop height h for centre of gravity in drop tests. Average (mm)	153	171	117	115	138

Table 2 Test results for unreinforced units

In the drop tests, the cracking started at the top of the stem and spread to the bottom of the stem leading to a fracture of the type shown in Figure 9. The start of the cracking at the top side instead of at the bottom side is due to the big horizontal momentum of the top leg caused by the pivoting of the unit. In a few of the drop tests (mainly in series No. 1) the fracture developed first through the middle part of the stem and not in the stem-fluke corner.

In the pendulum tests the cracking started at the bottom of the stem and spread to the top, leading to a fracture of the type shown in Figure 9.

Figure 9 Typical fractures in unreinforced units

6.2 Reinforced Units

The results from test series 2 are summarized in Table 3 a and b.

Drop test No.	Reinforcement, deformed bars, steel 42		Drop height h for centre of gravity (mm)	Observations
	Size	%		
1	8 \emptyset 10 mm	0.29	160	fine crack in stem
	-	-	174	fine crack in top leg
	-	-	222	top leg fractured, crack width in stem ≤ 0.1 mm
2	8 \emptyset 12 mm	0.41	206	fine crack in stem
	-	-	238	crack in top leg
	-	-	268	top leg fractured, crack width in stem ≤ 0.07 mm
3	8 \emptyset 16 mm	0.73	181	fine crack in top leg
	-	-	210	fine crack in stem
	-	-	286	bottom leg crushed, crack width in stem ≤ 0.01 mm
4	8 \emptyset 20 mm	1.14	201	top leg fractured, no visible cracks in stem

7. CONCLUSIONS AND RECOMMENDATIONS

The presented theory for the dynamic loading of Dolos units should be regarded as a first approximation. In spite of this and in spite of the scatter in the values of C and K (Table 2), it is believed that the theory (eq. 4 and eq. 5) can be used to estimate the relative dynamic strength of units of different sizes, different waist ratios, and different concrete mixes. It should be noted that a considerable

scatter in the C and K values is expected because the determination of the tensile strength and of the dynamic modulus of elasticity is subject to big uncertainty. A careful determination of these two quantities is therefore an important part of the full scale tests.

Before a final conclusion about the presented theory can be made tests with big units (10-30 t) should be done and the influence of the load history should be investigated. This can be done by determination of the relation between the number of blows that will lead to fracture and different loads, e.g. 60%, 70%, 80% and 90% of the failure load that corresponds to the load history in the presented tests:

Both the test results and the theory show that the relative dynamic strength of unreinforced units decreases considerably with increasing size of the unit, other things being equal. Although the strength can be improved by increasing the waist ratio it is not always possible to compensate for the reduction of the strength. This can be explained by an example.

Let us assume that we know from experience that the dynamic strength of some 7.5 t Dolos units with a waist ratio of 0.3 is just sufficient to resist the rocking that takes place when the units are exposed to the design storm waves. Let us then assume that we perform some hydraulic model tests for a Dolos breakwater on a much more exposed place. In the model tests, units with a waist ratio of for example 0.34 is used, and from the tests it is concluded that the weight of the prototype units will be 26 t if the damage criterion that corresponds to the design wave situation for the 7.5 t units is used. For simplicity we will now assume that the same concrete mix is used for both sizes. From the drop test formula it is then found that the big Dolos unit must have a waist ratio of 0.39 to resist the same rocking - or angle of rotation - as the small units. From Figure 11 it is seen that by increasing the waist ratio that much, the shape of the unit is completely altered, and so is the hydraulic stability. Therefore, a new series of hydraulic model tests with more bulky Dolos units has to be done, but since such tests lead to a demand for even heavier units than the 26 t, a bigger waist ratio than 0.39 must be applied to obtain sufficient strength of the prototype units, etc.

Figure 11 Influence of waist ratio on Dolosse of the same weight

From this it can be concluded that the design criterion which are adopted in hydraulic model tests must correspond to the dynamic strength of the prototype units.

Moreover it can be concluded that if a design criterion which implies movements of the units is adopted there will exist a maximum size of unreinforced units for which there is a balance between the hydraulic and the physical stability. Units heavier than this maximum size can, of course, be used if a non-rocking design criterion is adopted. However, this will lead to a demand for relatively heavier units.

From the test series No. 1 and No. 3 and from the theory it is seen that it is difficult to improve the dynamic strength by using a stronger concrete, even if a super-strong concrete, as the one in series No. 3, is used. This is so, because stronger concrete mixes are more brittle as they have relatively poorer tensile strength and relatively higher modulus of elasticity. It should be stressed that this conclusion must not lead to the use of weak concrete mixes, because the surface resistance and the long term durability of the units are very much dependent on the strength and the compactness of the concrete.

From a comparison of the test series No. 4 and No. 5 it can be concluded that an unreinforced unit can suffer from relatively deep surface cracks, even in the stem-fluke corners, without losing much of its dynamic strength. This matter, which can be explained by fracture mechanics theory, is caused by the low stress level and the relatively good fracture toughness of concrete. From the theory it can also be

concluded that even relatively big internal cracks have a negligible influence on the strength of the units. It should be noted that surface cracks should of course be avoided, since the freeze-thaw resistance and the long term durability of the units are affected by the cracks.

The age of the units, when tested, varied from 28 days to half a year. No correlation between age and dynamic strength was found.

On exposed locations, where very big armour units are needed, it is presumably advantageous to improve the dynamic strength by reinforcing the units. From test series No. 2 it can be concluded that, even with a small degree ($\leq 1\%$) of ordinary reinforcement, it seems possible to double the impact energy and still restrict the width of the cracks to sizes well below the critical size (0.1-0.3 mm), where corrosion of the bars takes place. This conclusion holds also for the more realistic situation where a unit, besides the dynamic loading, must carry a static load, e.g. from the weight of one or two other units. By comparing the test results from series No. 1 and No. 2 it is seen that the legs of a Dolos are considerably stronger than the stem. It is therefore a question whether it does pay to reinforce the legs (or some part of them) as it complicates the production of the units considerably. Very little is known about reinforced Dolosse, but in the few places where they have been used, e.g. in the Humboldt Jetties, investigations of the state including recording of the width of possible cracks should be performed.

Prestressed, posttensioned and fibre reinforced concrete are other possibilities, which should be looked at, but in this respect the importance of an easy production method should be stressed, since the production of ordinary Dolos units is difficult enough.

Although the described tests were performed with Dolos units the qualitative results and conclusions hold also for other types of slender concrete armour units.

8. ACKNOWLEDGEMENTS

The tests were performed in co-operation with mr. Hans Halskov (formerly student at Aalborg University Center), The Danish Governmental Coast Authority, Aalborg Portland Cement and Concrete Laboratory, Denmark, South of Scotland Electricity Board, James Williamson & Partners, Scotland and Sir Robert Mc Alpine and Sons, U.K.

DOLOSSE

PAST, PRESENT, FUTURE?

by

J.A. ZWAMBORN, D.E. BOSMAN AND J. MOES*

SUMMARY

Information is presented on 38 dolos projects in various parts of the world. Some of the data were collected by means of questionnaires and the remainder are based on publications, reports and personal visits. Information is given on design conditions, structure details, model tests and site experiences. *Past* dolos research is discussed briefly.

Present experience of damage to various dolos structures is described, particularly that to the 2 km long Sines main breakwater. The results are discussed of research initiated by differences in accepted design and model test conditions and the recent dolos failures. This research concerned dolos packing densities, dolos movements (damage criteria) and structural failure of armour units.

There is little doubt that dolosse will be used effectively and economically, in the *future* for many small and medium-sized coastal structures. However, special attention will have to be given to deep-water structures of any kind, with regard to representative design conditions, the effect of the larger waves in the spectrum and the possibility of structural failure of armour units. A few practical suggestions are made for the design of safer dolosse, in the interim, but it is recommended that a major effort be made to collect reliable data on existing structures as well as to develop representative and, preferably, standardized design and model test techniques.

1. INTRODUCTION

The dolos, invented by East London Harbour Engineer E.M. Merrifield, was used for the first time in 1964 when 18 t dolosse were placed on the East London breakwater to repair sections of the 37 t rectangular block armour which had sustained serious storm damage. After 15 years in service, this dolos protection is still in satisfactory condition while sections of the breakwater where there is no dolos protection have been damaged further.

This early success led to the mounting of a series of hydraulic model tests with dolosse at the CSIR laboratory in Pretoria in 1965; these tests showed that dolosse have very high stability factors of between about 20 and 40 for small percentages of damage. After the first publication on dolosse appeared in 1966 (Merrifield and Zwamborn) the results of the initial tests were substantially confirmed by other laboratories and, thereafter, dolosse have been used for coastal works in numerous parts of the world.

* Coastal Engineering and Hydraulics Division, National Research Institute for Oceanology, Stellenbosch, South Africa.

Because of the high stability of the dolosse found in the model tests these units have been used for ever-larger projects, in greater water depths and in more severe wave climates. The major dolos failure at Sines, Portugal, however, has thrown serious doubts, *firstly*, on the reliability of accepted model test techniques, *secondly*, on the adequacy of generally-accepted design criteria and, *thirdly*, on the suitability of concrete armour units, in general, and dolosse, in particular, under these severe conditions, especially with regard to their structural behaviour.

2. PAST EXPERIENCES

2.1. Dolos Structures

A survey has been made of existing dolos structures by means of a detailed questionnaire. Detailed information was received on 18 projects (Table I) of the 38 known to the authors.

Note : The names of projects for which data were obtained solely from questionnaires, are typed in italics.

The questionnaire included questions on *design conditions, structure details*, including information on the *dolos armour*, and the *underlayer stone, hydraulic model tests, construction methods, in-service performance and costs*. A summary of the available detailed information is given in Table II (blank spaces indicate no information available while '-' was used in some returned questionnaires instead of 'no' or 'negligible'). Information gathered on the other 20 projects is summarized in Table III.

The following are extreme values of some of the main parameters:

- design-wave height (H_s or H_{mo}) 2 to 11 m
- dolos masses (W) 0,5 to 56 t
- water depths at the structures 0,8 to 52 m

Figure 1 shows a correlation between water depth and dolos mass. It will be seen that all the structures were built in relatively shallow water, except for the Sines breakwater.

Fig. 1 Dolos mass versus water depth

The dolos protection designed for the St. Thomas Runway in the Virgin Islands runs into a water depth of 27 m and falls also outside the general trend shown in Figure 1. The actual water depth at the breakwater at Baie Comeau is 10 m but only 100 m away from the breakwater, the depth is about 30 m and this project could therefore be affected by deep-water conditions.

A correlation of dolos mass versus design wave height is shown in Figure 2. The figure again shows definite trends but the variation in dolos mass for a given design wave height is very large. It is interesting to note that Sines follows the general trend.

TABLE II. SUMMARY OF RELEVANT INFORMATION ON KONGS INDOUS PROJECTS

Project & details	Design conditions			Structure geometry			Dolos armouring particulars					
	Wave height H(m)	Wave period T(s)	Wave angle to structure (°)	Armour layer height (m)	Structure depth (m)	Structure width (m)	Block height (m)	Block width (m)	Block density (t/m ³)	Block spacing (m)	Block density (t/m ³)	Block spacing (m)

Fig. 2 Correlation of dolos mass with design-wave height

Table II shows that the relative packing densities, ϕ , are generally above $\phi = 1,0$ (ϕ is defined by $N = \phi V^{-2/3}$ where N is the number of dolosse per unit area and V is the dolos volume). They range from 0,73 for Hay Point harbour to 1,47 for Cape Town harbour; well outside the values $\phi = 0,83$ for *light*, 1,00 for *mean* and 1,15 for *dense* packing, as defined by Zwamborn (1978).

Table II also indicates that only two projects were tested using fully irregular waves while a large number of projects were not model-tested at all (only limited irregular-wave tests were done for Sines).

Total breakage of dolosse during manufacture and handling never exceeded 5 per cent and, on average, was between 1 and 2 per cent. Breakages during initial shake-down were also *estimated* to be below 5 per cent, with an average of 1 to 2 per cent.

Apart from at Sines, very *little general damage* has been reported on dolos structures (the Sines breakwater was built in very deep water, see Figure 1). Storm damage occurred at Baie Comeau where deep water is close to the breakwater, while the damage at Gans Bay was concentrated at the junction between the rubble mound and the vertical wall sections of the breakwater.

It may, therefore, be *concluded* that the approximately 173 000 dolosse of various sizes have generally performed satisfactorily in water depths of up to about 20 m.

A correlation of dolos mass versus the cost, in U.S. dollars, for one unit is shown in Figure 3.

Fig. 3 Unit cost, in U.S. \$ versus dolos mass

2.2. Dolos Research

Most of the research carried out on dolosse was applied research, that is, specific projects were model tested for stability. Details of these model tests are given in Tables II and III.

Basic model test results on dolos stability have been reported by Merrifield and Zwamborn (1966), Ouellet (1972), Foster and Gordon (1973), Brorsen (1977), Carver and Davidson (1977 and 1978) and Zwamborn (1978).

The high stability factors found in the original tests (minimum $K_D \approx 25$ for 2 per cent damage) were confirmed by Ouellet ($K_D \approx 25$ both for regular and irregular waves), Carver and Davidson ($K_D \approx 31$ for non-breaking waves) and Zwamborn (average $K_D \approx 24$ based on 2 per cent displaced units). However, there are large variations in individual tests results ($15 < K_D < 40$ for 2 per cent displacement) and in test conditions as well as damage criteria, making direct comparisons between test results of different laboratories, at least, questionable. Inconsistency in dolos packing densities and corresponding layer thicknesses were also found to be responsible for large differences (Zwamborn, 1978).

Clear definitions for packing densities have therefore been proposed and *standardization* of this aspect to ensure compatibility of test results is being pursued (Zwamborn, 1978 and 1980).

In the original model tests, dolosse which were *seen* to be rocking, were also included in the total damage because it was considered that these units would probably break (Merrifield and Zwamborn, 1966). However, insufficient attention has been given to the structural strength of armour units, in general, and to that of dolosse, in particular, since that time (Magoon and Baird, 1977 and Brindley, 1977).

3. PRESENT SITUATION

3.1. Damage to Dolos Structures

Unfortunately, the amount of data on the performance of the various structures is extremely limited and damage figures are often only *estimates* (Table II).

It has been reported that there has been moderate damage to the 4,5 t and 7,3 t dolos armour of the Baie Comeau breakwater (Québec), and minor damage (10 per cent) to the 42 t Crescent City dolosse and to the 38/39 t Humboldt breakwater dolos armour (Edge and Magoon, 1979).

A detailed above- and underwater survey of the main *trunk* section of the Gans Bay breakwater provided *quantitative* data on the performance of the 17,1 t dolos (Bosman and Zoutendyk, 1979). The survey showed a total breakage of about 10 per cent but shank breakages amounted to only 0 to 2 per cent. This breakwater was built some nine years ago and wave heights of up to the local design wave height of 8,5 m have been recorded on various occasions during this period.

The partial failure of and major damage to the 42 t dolos armour of the Sines breakwater during a near-design storm in February, 1978, is by far, the most important (Figure 4). From a detailed analysis of the causes of the damage Zwamborn (1979) concluded that failure of the armour was caused mainly by:

- (i) *large and long waves* in the spectrum which, because of the great depth of water in front of the breakwater (Figure 1), were not reduced in height by breaking;
- (ii) wave concentration due to *refraction*;
- (iii) *breakage* of dolosse caused by excessive movement of the units during the storm.

Fig. 4 Peak storm waves, Berth No. 1, 26 February 1978

The damage to the Sines breakwater came as a shock because the design wave height ($H_s = 11$ m) was not exceeded during the storm while conventional model tests, including irregular wave tests, had indicated that the dolos armour would be stable under wave conditions up to the design wave height.

Surveys after the storm, however, showed that dolos armour had been removed completely over a distance of approximately 0,5 km of the 2 km long breakwater, resulting in the collapse in the superstructure of two sections, 150 and 300 m long, while a significant percentage of the dolosse in the non-failed areas had been broken and moved down the slope. Although the incident significant wave height during the storm did not exceed 10 m, waves of maximum height of up to about 17 m must have occurred, and these, due to refraction, may have increased in height to 20 m at certain points along the breakwater. Combined with peak energy periods of 18 to 20 s these large waves had lifted single or clusters of dolosse out of the slope and when these waves retracked, the dolosse had either rolled down the slope or had dropped back and probably broken on impact.

The Sines disaster highlighted again the importance of *reliable field data*. For most damaged dolos structures, available information is very incomplete, making it difficult to draw definite conclusions regarding the underlying causes. Much work was done *after* the Sines failure to establish the causes of the damage but uncertainties in the final conclusions will remain because of, *inter alia*, the lack of such basic data as 'as-built' surveys of the armour and wave records during the storm.

3.2. Recent Research

In the past, differences in dolos packing densities were largely responsible for differences in reported stability factors (K_D).

Carver and Davidson (1978), using data from different laboratories, suggested that the K_D value of dolosse increases with relative packing density, ϕ . They considered ϕ values from 0,6 to 1,0 with corresponding K_D values from 16 to 38 (Figure 5).

Zwamborn (1978) has suggested that there should be an *optimum* packing density for dolosse, namely, $\phi = 0,87 \approx 0,9$ when the layer thickness is equal to the dolos height, because such conditions would result in maximum interlocking.

A series of comparative model tests was therefore carried out in a 3 m wide regular-wave flume using relative packing densities $\phi = 0,65; 0,83; 0,87; 1,00; 1,15$ and 1,50. Results of the tests, Figure 5, show the mean K_D values, corresponding to different ϕ values for 2 per cent damage (displaced units).

The data reveal some interesting trends, namely,

- (i) an increase in stability from low ϕ values to $\phi = 0,87$, which corresponds to the optimum double-layer packing ($\phi \approx 0,9$);
- (ii) reduced stability for $\phi = 1,15$;
- (iii) increased stability for $\phi = 1,50$, which is close to that for a four-layer system ($\phi \approx 1,7$).

Figure 5 shows the results of the tests as well as the extreme values, from which it is clear that the results can, at the most, show only general trends. The tests were done under closely *controlled conditions*, but the variation in individual test results was nevertheless very large, which is worth noting. Notwithstanding these large variations the general trend is displayed, not only by the mean, but also by the extreme values.

In practical terms it means that one should aim at a packing density of $\phi = 0,9$ but, because it will be virtually impossible to achieve the ideal packing in the field, it would be better to use $\phi = 1,0$ as a minimum *average* relative packing density for the design. Even if $\phi = 0,9$ is used, it would be unwise to adopt a *mean* value of K_D greater than about 24 (Zwamborn, 1978) or a *minimum* K_D factor greater than about 16.

Differences in stability, particularly for the lower damage levels, are also caused by *differences in packing*. Because the stability of the dolos armour depends in part on the degree of interlocking of the units, randomly-placed units will, inherently, show considerable variations in the stability of the uppermost layer of dolosse. This was shown effectively in recent tests carried out by Price (1978) who measured the forces required to lift different blocks of various types off an armour slope. These tests also indicated an optimum slope for dolosse of between 1 in 1,5 and 1 in 2,5 for a static force normal to the armour slope which was applied in the tests.

Fig. 5 Dolos stability versus packing density - test results for 2 per cent damage

Damage to armouring is related normally only to the percentage of displaced units, mainly because of the difficulty in measuring accurately the percentage of moving and rocking units. A time-lapse cine technique, however, makes it possible to get reliable data on *continuously* and *intermittently rocking* units. This provides a more accurate picture of the damage to the armouring. It was found, in regular-wave model tests, that the extent of damage based on the number of displaced and rocking dolosse was about *twice* that derived from only the number of displaced units (Zwamborn, 1978). This applies to the lower damage levels (2 per cent displacement); for the higher damage levels, the increase was much smaller.

If the design of a dolos structure is to be safe, knowledge of the percentage of rocking dolosse is essential; this knowledge is also an important factor in understanding the structural failure of dolosse.

An attempt was made by Mansard and Ploeg (1978), to reproduce dolos breakage by means of a model. A breaking plane was introduced in the shank of the model dolosse which had a linearly-scaled tensile strength, so that the units would break under wave action. The results showed clearly the effect on stability of dolos breakage, but this technique needs further development because a single breaking plane does not simulate accurately the *initiation of breakage*, which should form the basis of safe design.

Much of this work was initiated as the result of, or intensified after, the Sines disaster, which, together with the preceding (1976) damage to the Bilbao (35 m depth, 65 t cubes) breakwater in Spain (Tørum *et al.*, 1979) emphasized the lack of knowledge of representative *design-wave conditions* and the inadequacy of present *model-test techniques*.

Successful dolos-armoured structures were built in relatively shallow water which masked possible shortcomings in the designs. Since most stability factors (K_D) are based on tests done with relatively shallow conditions in which regular waves represent natural conditions reasonably well, they *cannot* be applied to structures built in deep water. Moreover, structural damage to artificial armour units, particularly those of the interlocking type such as the dolos, must be taken into account in the design stage.

4. FUTURE APPLICATIONS

4.1. Shallow- Versus Deep-Water Structures

There is little doubt that dolosse provide an effective and economic means for protecting many small and medium-size coastal structures, although more attention should, in future, be given to the effect of rocking motions of *all* artificial armour units, particularly when the design-wave height is not depth-limited. Rocking can be reduced by using *heavier units* which, in many instances, could still provide an optimum solution and, in some cases, may even be more economical.

For major structures in *deep* water realistic and representative *design-wave conditions* will have to be adopted. It must be realized that, if a Rayleigh wave-height distribution is assumed, 5 per cent of the waves will exceed $1,22 H_s$ and 1 per cent $1,52 H_s$ and, when there is no depth limitation, these waves will attack the breakwater armour.

Figure 6 shows curves for the reserve stability for non-breaking dolosse, based on regular wave tests at a slope of 1 in 1,5 (Zwamborn, 1978), and a Rayleigh wave-height distribution. This figure shows that a dolos armour designed on the basis of 2 per cent damage for a regular wave of height H_s , may fail when the wave height is barely 25 per cent higher than the design-wave height. In the case of breakable units, the reserve stability will be even less. As may be seen from other data plotted in Figure 6, which is also based on tests with regular waves but using a slightly steeper slope of 1 in 1,33 (Paape and Walter, 1962), this problem is not unique to dolosse.

The obvious answer is to *increase* the unit *mass*, for instance by basing the initial design on H_5 or even H_1 instead of H_s ($H_s = H_{1,3,5}$). The design must then be carefully model tested, using realistic waves (e.g. time series) up to and well in excess of the design wave condition. Both displaced and rocking units should be counted and, when deciding on an acceptable percentage damage, possible cumulative effects must also be taken into account.

When the mass of dolosse is increased, however, tensile stresses should increase linearly with the height of the dolos, if the basic shape remains the same (Figure 7). This applies to above-water conditions (free-fall). If the dolosse are under water, drag resistance will reduce impact forces and under-water stresses will therefore increase with a lower power of the dolos height, say, a power of 0,5 (Figure 7).

Fig. 6 Dolos reserve stability

To reduce the stresses in the larger dolosse, the dolos *waist thickness* could be *increased*, for instance, in accordance with the earlier suggested relationship $r = 0,34 \sqrt[6]{W/20}$, where r is the waist ratio and W the dolos mass (t) (Zwamborn and Beute, 1972). This formula is based on the assumption that a 20 t dolos with a waist ratio of 0,34 is sufficiently strong to avoid breakage during design load conditions, an assumption which is supported by considerable prototype evidence. Figure 7 shows the effect of the increased waist ratio. If these dolosse are under water, the stresses do not increase with dolos mass and if they are above water, the increase is drastically reduced. Waist ratios of up to about 0,4 do not materially affect the shape of the dolos (Figure 8) but their hydraulic efficiency may be reduced at the higher r values (model tests with dolosse of waist ratios from 0,27 to 0,35 showed no measurable difference in porosity, layer thickness and stability; Zwamborn and Beute, 1972 and Zwamborn, 1978).

Another method of increasing the strength of large dolosse is to *increase* their *tensile strength*, either by using better quality concrete, or by using, for example, steel fibres. Figure 7 shows that with an increase in tensile strength of 10 to 20 per cent, the dolos size could be increased safely by, at least, a factor of two. The original 20 t dolosse used at

East London had a rupture strength $< 3,5$ MPa. If these dolosse are accepted as being sufficiently strong, which they appear to be, 40 t dolosse with $r = 0,38$ would also be satisfactory, provided a minimum rupture strength of about 4 MPa could be achieved (Figure 7).

Conventional steel-reinforced dolosse were used at Humboldt Bay, Kahului (Hawaii) and for the provisional repair work at Sines. This type of reinforcing is, however, neither very effective (Figure 9), nor economical. For example, a 0,6 per cent reinforcing (by volume) used at Sines resulted in a 20 to 25 per cent increase in strength while the cost of a 42 t dolos increased by 50 per cent. There is also the problem of corrosion, and central reinforcing, using for instance, scrap rails may be more attractive (Standish-White and Zwamborn, 1978).

This paper deals with past, present and possible future use of dolosse. It goes without saying that particularly for deep-water conditions, *alternative structures* should also be considered. Moreover, because deep-water design conditions are, inherently, ill-defined the adopted structure should have considerable reserve stability, that is, complete failure should not occur with higher than design waves.

4.2. Research Needs

In the above, problems relating to deep-water breakwater structures have been discussed and some practical suggestions made to allow for the typical deep-water effects in the design of dolos structures.

After the Sines disaster, designs will, however, tend to be conservative and there is thus an urgent need for more research to ensure *safe* and yet *economic designs*, namely:

- (i) more information is required on realistic design wave conditions and representative reproduction of these conditions in, preferably, three-dimensional models;
- (ii) research into the structural behaviour, under extreme load conditions, of artificial armour units, in general, and dolosse, in particular, is needed; such studies should include surveys of existing dolos structures (Bosman and Zoutendyk, 1979), hydraulic model tests to determine the loads on the units, stress analysis for these load conditions and structural tests (Tait and Mills, 1980) to determine acceptable degrees of movements;
- (iii) for deep-water conditions, structures with a high reserve stability should be developed;
- (iv) model test techniques should be investigated further and standardized as far as possible to ensure compatibility between test results of different laboratories (Zwamborn, 1980).

A DETACHED BREAKWATER SYSTEM FOR BEACH PROTECTION

by James R. Walker¹, Denton Clark², and Joan Pope³

SUMMARY

Three segmented, detached breakwaters were constructed in the fall of 1977 at Lakeview Park, Ohio, on Lake Erie, to protect a beachfill to be used for recreation and shore protection. This paper documents the design procedures which established the configuration of the breakwaters and the beachfill, and determined the need for a terminal groin. The beachfill has been monitored by aerial photography and bathymetric profiling. During the second year, a storm of near design intensity generated severe waves concurrently with high Lake levels and eroded the updrift beach; however, the initial beach configuration was partially restored by natural processes during the following summer season. The project has functioned well, with very little loss of sand from the system and without adverse impacts on the downdrift coast.

INTRODUCTION

Lakeview Park is a lakeside recreational area in Lorain, Ohio, on the southern shore of Lake Erie (figure 1). The Park provides 1,500 feet of beach serving the recreational needs of north central Ohio. Prior to implementation of this project, the beach had eroded due to high Lake levels and an inadequate supply of littoral drift.

Studies were conducted in 1974 to plan and design a beach-restoration project within the Park boundaries to satisfy the recreational needs of the tributary area. The study was undertaken at the request of the City of Lorain and was authorized by Congress. Alternative designs included groin fields and artificial headlands. An existing groin field at the project site had not worked well, although properly designed groins and heavy nourishment may have retained a beach. The potential for offshore loss of littoral drift with a groin field would result in innumerable greater annual costs for groin-field shore protection than for protection with offshore breakwaters. Artificial headlands (see Silvester, 1972) were a relatively new concept during the planning process. Although the headland plan would probably have functioned properly, it would have affected reaches of shoreline both up- and downdrift of the project. These up- and downdrift shorelines are privately owned. The Federal

Government does not cost-share in developing recreational beaches for protecting private property.

The design procedures presented herein are therefore state-of-the-art as of 1974 for construction of a small project. The design was done in less than a year without the use of mathematical or hydraulic models, which were not available during the design period. The project construction was completed in October 1977 and a post-construction monitoring program was initiated.

DESCRIPTION OF PROJECT SITE

Location

The project site is located in Lakeview Park in the city of Lorain, Ohio, which is 25 miles west of Cleveland. Lakeview Park is a lakeside recreational facility situated $\frac{1}{2}$ mile west of Lorain Harbor as shown in figure 2. Lorain Harbor has several breakwaters that extend 5000 feet lakeward from shore. The shoreline in the vicinity of the project site comprises both heavily protected and eroding glacial till and shale bluffs on reaches to the west. The preproject site had six existing groins of various construction, ranging in length from 70 feet to 150 feet. The groins which did not represent a consistent design, were not long enough to trap the meager littoral transport in sufficient quantity to provide an adequate recreational beach, nor were they high enough to prevent sand from moving over them during extremely high Lake levels.

Geology

Lake bottom surveys indicated the bottom 300 feet offshore is 8 feet below low water datum (LWD) and comprises a 12- to 18-inch stratum of medium to coarse sand with gravel and traces of laminae of silty clay. Underlying this stratum is 2 to 12 feet of stiff-to-hard, gray, silty clay. Shale bedrock underlies these strata.

Lake Levels

Water levels on Lake Erie vary from year to year and from month to month, and fluctuate on an hourly basis. The yearly variations are due to long-term climatic cycles. The seasonal variations consist of high levels in the spring and early summer and low levels in the winter. Short-term hourly fluctuations are caused by local meteorological disturbances. Astronomical tides are negligible. Low water datum, LWD=0, is 568.6 feet above the International Great Lakes Datum, 1955, (IGLD) based on mean water level at Fathers Point, Quebec. The highest recorded monthly mean Lake level was 573.5 feet and the lowest was 567.5 feet. The monthly mean was 570.4 feet from 1960 to 1970. The greatest annual fluctuation of monthly mean lake level was 2.75 feet. A 1.5-foot storm surge has a recurrence interval of 1 year.

The design water level with a statistical recurrence period of 20 years is 5.5 feet above LWD and comprises a 2.0-foot storm surge and 3.5-foot LWD monthly mean lake level.

Waves

The project site is directly exposed to fetches from the west clockwise through the north. The fetch length to the west is 36 miles and that to the north is 55 miles. The fetches in the Lake for directions east of north are 150 miles; however, the Lorain Harbor breakwaters shelter the project site from direct northeasterly wave attack. The wave climate used for the design of structural features was done by hindcasts that used a 24-year wind record taken at Cleveland. Calculation of littoral transport potential was derived from refraction, shoaling, and diffraction transformations of a 3-year hindcast of waves on Lake Erie by Saville (1953). The published data were for a station 28 miles east of Lorain; therefore, appropriate corrections were made to reflect the differences in fetches between the two sites. The hindcast data were corrected for effective fetches and a 44-foot Lake depth over the generating area. The wave heights approaching the project site range up to 8 feet annually, and periods range up to 7 seconds. The wave climate for littoral transport calculation assumed waves arrived at the shore only during the typical ice-free period from April through November. The 20-year recurrence design wave was from the northwest with a height of 10 feet and a period of 8 seconds.

Littoral Transport Analysis

Analysis of the potential for littoral transport is a key element in designing beach-stabilizing structures. The analysis was conducted by reviewing historical aerial photographs, site observations, and calculations of the potential littoral transport rate by wave-energy flux methods.

The existing preproject beach at Lakeview Park comprises a medium sand with traces of gravel, some of which is debris derived from remnants of decomposing updrift to the west shore-protection structures. The beach slope is 1 on 12 above water and 1 on 18 below water. Immediately west of the project site, the shoreline comprises eroding shale bluffs. Glacial till and decomposing bulkheads on the bluffs are a source of littoral drift. The west Lorain Harbor breakwater, 1,500 feet east of the project site, has been accumulating a fillet of sand on its west side at a rate of between 5,000 and 8,000 cubic yards per year. The existing groins in the project site had trapped some sediment out of the littoral system, but material apparently was bypassing them to deposit in the fillet at the west Lorain Harbor breakwater.

The general trend of the shoreline is an orientation of a 58-degree relative to north. The analysis of aerial photographs taken in 1948, 1956, 1968, and 1974 indicates that the preproject groin

field trapped fillets aligned on 50- to 55-degree azimuths. This indicates a west- to-east littoral transport.

The potential littoral transport rate was estimated by determining the longshore component of wave-energy flux. This was accomplished by transforming the incident waves to their breaking properties of height and direction of propagation. The energy flux is given by:

$$P = \frac{\rho g}{8} H_b^2 C \cos \alpha_b$$

where ρ is the density of water;

g is the acceleration due to gravity;

H_b is the breaking wave height;

α_b is the angle of the wave crest relative to depth contours at breaking; and

C is the wave celerity.

The incident deep water wave climate was transformed to the project site by diffraction about the Lorain Harbor breakwaters and by refraction and shoaling analyses. The sheltering effect of the Lorain Harbor breakwaters decreases with distance to the west. This is illustrated in figure 3, which plots the total and longshore components of energy flux as a function of distance from the west Lorain Harbor breakwater. The plot indicates a net eastward littoral transport at the project site; however, the net transport reverses to the west 1,500 feet west of the site. Furthermore, the total energy flux increases with an increase in distance from east to west. This clearly illustrates the influence of the Lorain Harbor breakwaters. The potential littoral transport rate is estimated by multiplying the longshore energy flux by an empirical coefficient described in the Shore Protection Manual (1974), where the potential longshore transport rate (Q_s) is

$$Q_s = 7.5 \times 10^3 P_{1s}$$

where Q_s is in cubic yards per year and

$$P_{1s} = P \sin \alpha_b \text{ (where } P_{1s} \text{ is the longshore component of energy flux in foot-pounds per second per foot of beach.)}$$

The potential longshore rate is 21,500 cubic yards per year to the east project site. This potential is not realized due to an inadequate supply of littoral drift. The 5,000 to 8,000 cubic yards per year that is accreting in the west Lorain Harbor-breakwater fillet is a more reliable indication of the actual transport rate. Figure 4 shows the distribution of total energy flux and the longshore component of energy flux at the project site. The distribution of wave-energy flux indicates a well-balanced potential for littoral

FIGURE 3: WAVE ENERGY FLUX ALONG COASTLINE

FIGURE 4: ENERGY-FLUX P_{25} AT THE PROJECT SITE

transport; i.e., the tendency for reversals in littoral transport due to waves from the east is nearly two-thirds of the potential transport for waves from the west. The sheltering effect of the Lorain breakwater therefore is partially offset by the greater fetches to the east.

PROJECT DESIGN

Alternative Studies

The primary purpose of the project is to provide a recreational beach and protect the Park from erosion. Beach-protection structures should not increase the erosion of up- and downdrift properties. This is a Federally sponsored project, which can protect only publicly owned lands. This ruled out the use of a massive beachfill or a large groin field extending to the Lorain breakwater. Artificial headlands would also affect a larger segment of shoreline than just the Park. Several groin fields of various lengths and spacing were considered; however, detached breakwaters were selected because they would decrease offshore sand movement. Each alternative considered would require imported sand to nourish and maintain the beach.

Plan Description

The detached-breakwater configuration is shown in figure 5. Three detached rubble-mound breakwaters, each 250 feet long, are arranged along a flat-arc alignment convex lakeward in water with a depth of -8 feet LWD. The breakwaters are spaced 160 feet apart. The west end of the west breakwater is 450 feet offshore and the east end of the east breakwater is 500 feet offshore. The breakwaters protect 1,500 feet of shoreline. An existing groin on the east side of the project site was increased in elevation and extended from 150 to 350 feet offshore. The crest of one of the groins on the west side of the park was also raised 2 feet to maintain the updrift beach profile during periods of high Lake levels. A medium-sand beachfill with an average of 200 feet, was placed behind the breakwaters. The initial beachfill of 110,000 cubic yards was placed on a 1 on 5 slope, with a berm elevation of +8 feet LWD. The project was completed in October 1977 at a cost of about \$1,700,000. The Federal Government paid for 70 percent of the construction costs and the local government paid for 30 percent. The planning document also allowed for periodic nourishment, at a rate of 5,000 cubic yards per year, to be placed on the beach as nourishment, or on the downdrift beach if the project induces downdrift erosion.

Design Analysis

Several configurations of detached breakwaters were investigated. The primary function of the breakwater is to regulate incident waves and to reduce offshore littoral transport. For initial design, the breakwaters were assumed to be situated in constant water depth, to be impermeable, and to not be overtopped. The shoreline was assumed

FIGURE 5: PLAN OF IMPROVEMENTS

to adjust to equilibrium in response to the predominant waves. The shoreline planform was assumed to be in equilibrium when the shoreline is coincident with the transformed wave crests; otherwise, waves arriving at an angle to the shore would induce longshore transport. The predominant wave was selected as being the wave from the direction associated with the net direction of energy flux. Figure 6 shows one of the simple diffraction analyses used in the design analysis. The heavy lines of variable thickness are wave crests that are weighted according to the diffraction coefficient. The resultant shoreline is shown to generally parallel the incident wave crests; however, the salients are more accentuated to account for refraction effects. A salient is located near the center of the geometric shadow of each breakwater. The apex of the salient shifts in response to incident waves. The updrift shoreline (to the west) must have continuity with the existing shoreline. The downdrift shoreline, similarly, must have continuity with the project shoreline. This was not feasible; therefore, the existing east groin was extended in length from 150 feet to 350 feet. The toe of the beach at the east groin had to intersect the existing Lake bottom at the groin head as shown in figure 7 to stabilize the project beach with a desired 200-foot width.

The salient in the geometric shadow of each breakwater is formed by littoral drift being transported into the sheltered region by diffracted wave crests. If the breakwaters are too close to shore, or are too long, the shadow region becomes too effective a barrier, and insufficient wave energy is left for littoral transport. The salient continues to grow and eventually becomes a tombolo. Once a tombolo is formed, natural nourishment of the downdrift beaches is denied, increasing the tendency of these beaches to erode. Because this is naturally an eroding reach of shoreline with a limited supply of littoral drift, a considerable period of downdrift starvation would be experienced before tombolo formation and before natural bypassing would continue. Therefore, formation of a tombolo was not considered desirable.

A tombolo can be prevented from forming by designing the breakwater lengths and distances offshore such that variation in directions of incident waves will allow sufficient energy to enter the shadow to transport littoral drift. The variations in wave attack were incorporated into the design by considering the net westerly and net easterly directions of energy flux, as shown in figure 4. The net easterly and westerly components each represent a weighted, long-term average potential to transport littoral drift. The predominant waves move sand toward the salients. If the variations in wave energy from various directions are adequate to move appreciable material past the salients, no tombolos should form.

FIGURE 6: DIFFRACTION ANALYSIS

The amount of wave energy required to prevent tombolo formation is not accurately known; however, observations of several detached breakwaters in southern California by James Dunham^{1/}, led to the hypothesis that if the shoreline were landward of the intersection of the diffraction coefficient (K_D) isolines where $K_D = 0.3$ for the easterly and westerly wave components derived from the energy-flux analysis, a tombolo would not form. A case-in-point is the Venice, California, detached breakwater. This breakwater, built about 1902, is 600 feet long and was then 1,200 feet offshore. A small salient formed in the lee of the breakwater; however, the salient never advanced to more than 200 feet from the original shoreline. A 14 million-cubic yard sandfill, placed along 5 miles of the local beach in 1947 and 1948, advanced the shoreline about 500 feet, and a tombolo soon formed in the lee of the breakwater. Dunham discovered that the intersection of $K_D = 0.3$ isolines of waves diffracting about the heads of the breakwater was just shoreward of the advanced shoreline when the fill was first placed. This finding roughly checked with beach built-outs behind other breakwaters in southern California, and the principle was used successfully in siting two new breakwaters in the next few years so as to prevent unwanted tombolo formations. As a result of this experience, the same principle was adopted for design in Lake Erie. Apparently, the rule works because the wave energy is nearly an order of magnitude less than the incident wave energy where $K_D = 0.3$. Storm waves generally have an order of magnitude more energy than the daily predominant waves. Therefore, during storm conditions, there would be as much wave energy reaching the apex of the salient as the prevailing waves bring to unshielded segments of the beach. This energy is adequate to prevent tombolo formation.

The intersections of the $K_D = 0.3$ isolines for waves from directions representative of the net easterly and westerly component of the energy-flux waves vectors are shown in figure 6. The intersections are well offshore, thus ensuring that, even at low Lake levels, a tombolo should not form. The $K_D = 0.6$ isolines from the predominant wave direction are also shown for reference. The primary function of the breakwaters is to regulate the direction of wave approach. The lengths of the breakwaters, the distance offshore and the spacing between the breakwaters dictate the shape of the beach. The updrift and downdrift shorelines also control the lakeward extent of the shoreline behind the breakwaters.

The resultant beach was designed to be normal to the predominant wave approach. The flat-arc configuration of the breakwaters resulted from the design process of matching adjacent shoreline boundary conditions in the project area. In order to maintain natural transport to downdrift beaches, the net transport behind the breakwater had to

^{1/} Senior Coastal Engineer, Moffatt & Nichol, Engineers, Long Beach, California; formerly with the U.S. Army Corps of Engineers

be slowly eastward. With the east end of the project shoreline designed to be 300 feet lakeward of the natural shoreline, blending of adjacent shore segments as was done at the west end was not feasible, therefore, a terminal groin at the east end was designed to maintain the advanced position of the beach in that area. This groin was designed to be impermeable to sand, but short enough to allow the littoral drift that enters the system from the updrift shoreline to bypass around its head. This would prevent any acceleration of erosion of the downdrift beaches due to the project structures.

Figure 7 illustrates the design of the east groin. The pre-project concrete-sheet-pile groin was raised 2 feet to prevent sand from overtopping it during high Lake levels, and it was extended lakeward sufficiently to retain the new beach in its design configuration. An important feature of this groin is the impermeable diaphragm along its centerline. This membrane is of steel-sheet-pile construction; however, concrete poured in place between the voids in armor rock could also have been used.

The typical breakwater cross section is shown in figure 8. The crest elevation, at +8 feet LWD is designed to allow minor wave overtopping during storm conditions. A transmitted height of 1 foot was allowed. A lower crest elevation would have resulted in greater wave overtopping, which would induce a higher wave runup on the lee beach and generate a wave setup in the water. The setup would induce rip currents between the gaps and around the ends of the two outboard breakwaters, thereby increasing offshore loss of littoral drift. The rip-current scour might also undermine the breakwater ends. This actually occurred in model studies of an offshore breakwater system designed and tested by the Corps of Engineers in conjunction with erosion-prevention planning for Imperial Beach, California (U.S. Army Corps of Engineers, 1978).

MONITORING PROGRAM

Description of Program

The Corps of Engineers initiated a 5-year monitoring program immediately after construction to document littoral transport and the wave climate in the vicinity of the project site. The purpose of the monitoring program is to provide information on required operations and maintenance, such as beach-nourishment needs, to assist in developing design criteria for detached breakwater systems, and to provide data that will lead to a better understanding of nearshore processes in the Great Lakes.

The monitoring program comprises aerial photography, bathymetric and topographic surveys, sand samplings, Littoral Environment Observations (LEO), site inspections, and installation of a wave gage. Color aerial photographs are taken three times a year over a 6-mile reach of shore to document morphological changes. The photographs are at a scale of 1:4800 and have 60 percent overlap. Surveys are

FIGURE 7: EAST GROIN PLAN

FIGURE 8: DETACHED BREAKWATER PLAN

taken twice a year, once in the spring and once in the fall. The survey area extends 2,000 feet east and 3,000 feet west of the project site, and range lines are at 100-foot intervals within the project site. Each line is surveyed from the backshore out to a depth of -20 feet LWD. Surface sediment grab samples are taken once a year, in the fall.

A local observer documents daily wave and beach conditions under the LEO program. The LEO data have not yet been reduced nor analyzed at the time of this writing. Site inspections are made three times a year to describe beach morphology and conditions. A wave gage will be installed in 1981 and records kept for a period of 1 year.

FINDINGS

The project construction was completed in October 1977. Photograph 1 shows that the planform quickly adjusted to the shape predicted by the design. Salients soon formed in the lee of each of each breakwater, and the beach slopes flattened. Photograph 2 shows the configuration of the beach in May 1980. Figures 9 and 10 show the morphology of two representative beach and offshore profiles. Figure 9 was a section taken in the gap between the east and central breakwater and figure 10 was a section taken behind the west breakwater. The profiles in these figures show that the offshore slope during the first 6 months adjusted to 1 on 20 behind the breakwaters (figure 10), and to 1 on 15 in the gaps (figure 9). The foreshore slopes in both cases are 1 on 12. These slopes remained essentially the same, although the most recent survey (in November 1979) showed that the west end of the beach had eroded to within 20 feet of a seawall on the east side of the west groin at station 13 + 75. (Stations are at 100-foot incremental distances west of the east end of the Park, as shown in figure 5).

The project was subjected to a storm from the west in May 1979. The storm generated waves of near design conditions at near record high Lake levels. The west end of the beach eroded severely; however, normal wave action restored much of the beach later in the year. Since that storm, other storm waves from the west have eroded the west end, but, again, the normal wave activity partially restored the lost sand.

A volumetric analysis was made to determine the changes in quantities of sand within the project boundaries. October 1977 was the base year. The initial beachfill comprised 110,000 cubic yards of medium sand. The volume of sand was measured by topographic and bathymetric surveys along the range lines shown in figure 5. Volumes were computed by the average-end-area method. The downdrift shoreline did not experience noticeable erosion. The total project area behind the breakwaters has accumulated sand. Figure 11 summarizes the volumetric changes behind each of the breakwaters as a function of time. The changes indicate that the project rapidly gained 4,000 to 6,000 cubic yards of sand, but that the volume of sand retained

(IN LEE OF WEST BREAKWATER)

FIGURE 11: CHANGES IN LEE OF BREAKWATERS

behind the structures fluctuates. Both the central and eastern breakwaters now retain more material than was initially installed; however, the west breakwater has lost material. The areas of gain and loss can be seen in figure 12 as a function of survey period.

The overall project has gained about 5,000 cubic yards of material. The beach has become aligned in a slightly more westward-facing orientation than predicted. This is evident by erosion of the west end. Although the project has been in place for 2 ½ years, no maintenance has been performed. Nourishment is planned for 1980 to replenish the west end of the project with 6,000 cubic yards of sand.

The project has been exposed to several severe storms from the west during periods of high Lake levels, but no damage to the breakwaters or groins has resulted.

Proper analysis of the project will require several years, in order to include observations during periods of low Lake levels. The intensity and frequency of storms from the west during the early years of the project may not be representative of the relative frequency of long-term, typical wave conditions. Furthermore, the winter of 1979-1980 was very mild, and Lake ice which normally protects the shoreline from severe winter storms did not form. Therefore, the project was subjected to severe winter storm waves had not been taken into account in the design analysis.

CONCLUSIONS

The beach-restoration project performed well despite being subjected to atypical severe westerly storms, high Lake levels, and a winter with no ice. The beach is the focal point of a popular recreational facility. The project has required little maintenance and has not induced erosion of the downdrift shoreline.

The simplified diffraction analysis using the predominant wave direction from the littoral transport analysis for prediction of beach planform appears to have worked reasonably well. Designing the beach landward of the $K_D = 0.3$ isoline intersections of diffraction diagrams drawn for the easterly and westerly resultants of wave-energy flux has precluded formation of a tombolo. The effects of wave attack due to severe individual storms may have a significant impact on localized areas such as the west end of the beach. Perhaps a greater safety margin should have been provided by making the initial beach wider or by extending the breakwater system farther westward.

Significant erosion has not been induced on the Lake bottom between the breakwater gaps. The height of the breakwater was sufficient to preclude wave overtopping from inducing a strong rip current that would scour the Lake bottom.

FIGURE 12: SAND VOLUME CHANGES RELATIVE TO OCTOBER 1977

RECOMMENDATIONS

The beach project at Lakeview provides a case history of a beach protection design using detached breakwaters. Insufficient funding was available to conduct a hydraulic model study or to develop a rigorous mathematical model prior to project implementation. Since the Lakeview design, Dean (1978) and others have developed shoreline evolution mathematical models that more accurately incorporate the effects of wave diffraction through segmented breakwaters. It would be useful to use a case study such as the Lakeview Park project to calibrate movable- or semimovable-bed hydraulic models and mathematical models.

Detached breakwaters have been shown to be a feasible method of protecting a beach. They should be considered where strict regulation of the beach planform is required. The gap spacings, the length and distance offshore, and the crest height should be designed by use of a rational procedure, giving adequate attention to sediment supply, the potential for littoral transport, variations in wave direction, the potential effects of single storms, and the consequences of variation in planform resulting therefrom.

ACKNOWLEDGEMENTS

The authors wish to thank Col. G.P. Johnson, District Engineer, Buffalo District, Corps of Engineers, for permission to publish this paper, and to thank Mr. James Dunham for extending the benefits of his experience in the project design and the review of this paper.

STABILITY OF RUBBLE MOUND BREAKWATER

J. FEUILLET*

M. SABATON*

ABSTRACT

The stability of a rubble mound breakwater section, with 3 in 2 armour slope, was tested under random waves attack. Tests analysis shows that the equivalent wave height characterizing the spectrum to be used in a stability formula elaborated with regular waves (for instance the Hudson's formula) is the upper twentieth height of the distribution for a storm duration of 6 hours. An analytical expression of the damage evolution as function of time modulates this choice according to the storm duration. The same rubble mound breakwater was also tested under the action of regular breaking waves. The damage was expressed in terms of the four following parameters :

H_0 : wave height

T : wave period

D_p : water depth at the toe of the structure

D_b : breaker depth without the breakwater

For a given wave height, the most important damage occur when :

$$\frac{D_p}{D_b} = 1$$

In this case the design wave height must be increased by about 30 % when using a stability formula elaborated for non breaking waves.

1 - INTRODUCTION

The use of breakwater stability formula (e.g. Hudson's formula) [1] to determine the weight of armour units of rubble mound breakwater raises two questions :

What wave height do we have to choose to represent the action of a random sea and is this dependant upon the duration of the design storm ?

* Laboratoire National d'Hydraulique - E.D.F. CHATOU FRANCE.

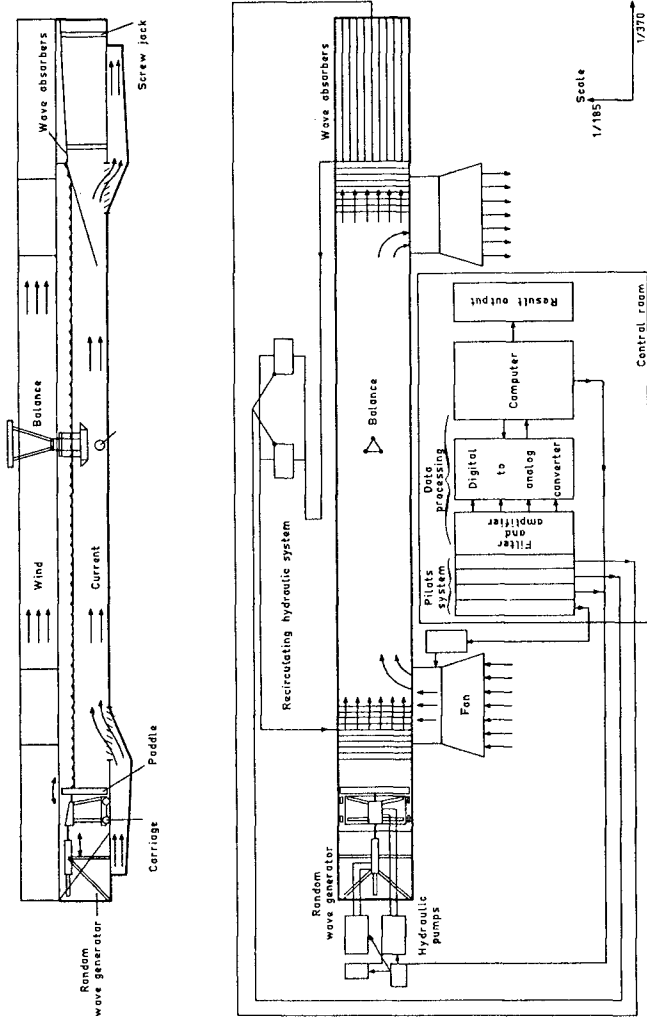

Figure 1

SCHEMATIC OF THE EXPERIMENTAL INSTALLATION

How can we take into account the effect of breaking waves ?

It has been generally accepted that the destructive effect of random waves is equivalent to that of regular waves having a height equal to the significant wave height characterizing the real sea state and the armour blocks weight is often calculated with this criterium. Is this approach correct ? The paper presents the results of three series of tests of breakwater stability on a reduced scale model with random non breaking waves, regular non breaking waves and regular breaking waves.

II - DAMAGE EVOLUTION IN RANDOM WAVES AS COMPARED WITH REGULAR WAVES

II.1 - Test procedure

. wave flume : A sketch of the wave tank layout is shown in figure 1. The flume is sixty meters (185 ft) long, five meters wide (15,4 ft) and 1,6 meters (4,9 ft) deep. The wave generator consists of a carriage rolling on rails laid on the flume bottom and of a plane paddle, hinged on this carriage, swinging around an axle located near the flume bottom. Carriage and paddle are operated by hydraulic pistons fed with two variable output pumps. The two movements, translation and rotation are independant. This wave generator is able to simulate random or monochromatic waves. In random waves the control signal is provided directly by a digital computer. Wave heights and periods were measured with resistance type wave gages. A fast measurement central unit ensures the analog switching and the analog digital conversion of wave data. These last one are analysed by the computer which gives harmonic, spectral, and statistical analysis of the data.

Figure 2

BREAKWATER MODEL FOR RANDOM WAVES

. Breakwater model : A simplified sketch of the cross section of the model studied is shown in figure 2. The scale was 1/40. The armour layer was composed of blocks with a weight in the range 2-4 T (mean 2.6 T) and a specific weight of 2.6 T/m³. Its slope was 3 in 2. The water depth at the toe of the breakwater was 10 m (30,8 ft). The bottom slope in front of the breakwater was 1 in 10.

. Test conditions : In order to make comparisons possible, the same model was submitted to the attack of regular waves and irregular waves. The storm duration was lower than 20 hours (30 mn at model scale).

The incident wave was measured using 3 wave gages, according to the method described by GODA [7].

II.2 Test results and analysis

II.2.1 - Results in regular waves

Figure 3 shows that the results obtained in regular waves compare well with Hudson's results. The stability number N_s is defined as :

$$N_s = \frac{H}{\left(\frac{w}{\gamma_r}\right)^{1/3} (S_r - 1)} \quad \text{with} \quad S_r = \frac{\gamma_r}{\gamma_w}$$

The damage D is defined as the ratio of the number of removed blocks to the total number of armour layer blocks.

II.2.2 - Results in irregular waves for a storm duration of 6 hours.

In order to define a design wave height in random waves for a storm duration of 6 hours, we have compared the values of N_s obtained by Hudson in regular waves to the values obtained in random waves for different typical wave heights :

$$\left(H_{Z, \frac{1}{3}}, H_{Z, \frac{1}{10}}, H_{Z, \frac{1}{20}}, H_{Z, \frac{1}{50}} \right)$$

The best agreement between N_s values calculated in regular waves and random waves is obtained for the wave height $H_{Z, 1/20}$ (figure 4), which characterizes the action of random waves for a storm duration of 6 hours. This wave height will be noted H_D . But this result has to be modulated because the storm duration has a great effect upon the rubble mound breakwater stability.

III.2.3 - Effect of the storm duration in random waves

The purpose of this study was to compare the damage evolution in regular and irregular waves, considering random waves as a succession of independant waves, and to obtain a literal formula expressing the damage evolution under random waves action as function of a characteristic height and of the storm duration. Two different methods have been explored. In the first one we determine in regular waves a law describing evolution as a function of the wave height and the time, and then deduced by integration a law in irregular waves.

This method leads to the following expression :

$$D = \frac{1}{T_{\text{moy}}} \int_0^t \int_0^{\infty} DPV \cdot p(h) \, dh \, d\tau. \quad (1)$$

Figure 3

COMPARISON OF EXPERIMENTAL RESULTS WITH HUDSON'S
FORMULA IN REGULAR WAVES.

with $p(h)$: probability law of wave height ;

T_{moy} : mean period ;

D : damage ;

t : storm duration ;

DPV : function expressing damage provoked by one wave of height h attacking the breakwater at time τ .

The values given by this formula compare well with experimental results (figures 5 and 6).

In the second method we have obtained directly a literal formulation of damage evolution in random waves by a statistical adjustment of the experimental results with a least squares fitting through all the experimental points.

By this method we have obtained the following expression [5] :

$$D = \frac{2.78}{T_p} H_{Z, \frac{1}{10}}^{3.9} t^{0.37} \quad (2)$$

with D : damage expressed as number of removed blocks ;

t : storm duration in hours ;

T_p : peak period ;

$H_{Z, \frac{1}{10}}$: the upper tenth mean height of the distribution.

This statistical adjustment has been obtained with a good correlation coefficient ($\rho \approx 0,96$).

The results obtained by this method are represented in dashed lines on the figures 5 and 6.

II.2.4 - Application to the determination of the design wave height H_D

The results obtained in [4], and presented in II.2.2, lead for a storm duration of 6 hours to the relation :

$$H_D = H_{Z, \frac{1}{10}} \# 1.1 H_{Z, \frac{1}{10}} \quad (t=6) \quad (3)$$

expressing the equivalence (for the damage) between a regular wave of height H_D acting till the stabilization of the breakwater and a random wave of height $H_{Z, \frac{1}{20}}$ acting during 6 hours.

From equation (2) can be derived the relation :

$$H_{Z, \frac{1}{10}} = kt^{-0,095} \quad (4)$$

Which expresses that for given blocks and damage (e.g. $k = \text{constant}$)

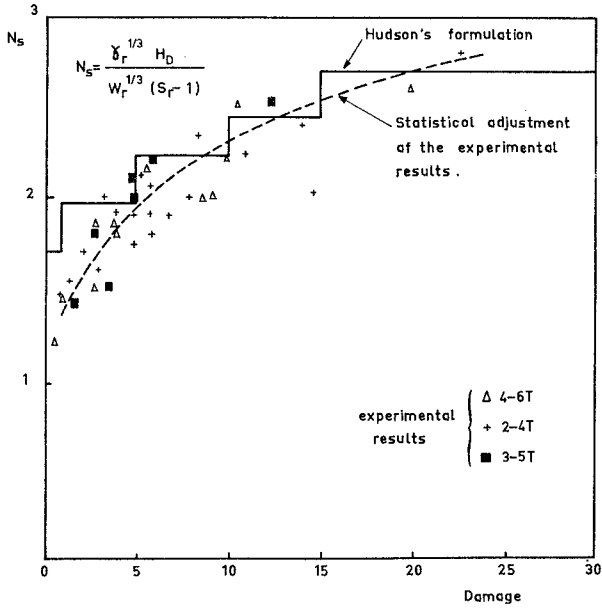

Figure 4

COMPARISON OF EXPERIMENTAL RESULTS
 WITH HUDSON'S FORMULA

N_s estimated with $H_z \cdot \frac{1}{20}$ for a storm
 duration of 6 hours

Quarry stones 2-4T
 $H_s = 2.70\text{m}$

Quarry stones : 2-4T
 $H_s = 2.27\text{m}$

Figure 5

DAMAGE EVOLUTION IN RANDOM WAVES

Figure 6

DAMAGE EVOLUTION IN RANDOM WAVES

the wave height $H_Z, \frac{1}{10}$ at which the rubble mound breakwater resists, decreases when the storm duration increases.

The relation (4) allows us to write (figure 7) :

$$H_Z, \frac{1}{10} (t=6) 6^{0,095} = H_Z, \frac{1}{10} (t) t^{0,095}$$

and, taking into account the relation (3) :

$$H_D = f(t) H_Z, \frac{1}{10} t^{0,095}$$

with $f(t) = 0,93 t$

This last formula expresses the design wave height H_D to be used in a stability formula established in regular waves as a function of storm duration and wave height $H_Z, \frac{1}{10}$ characterizing the random sea spectrum.

The variations of the design wave height with the storm duration (for a duration greater than 3 hours) are relatively small (figure 8).

Figure 7 : Method used for the determination of H_d for a storm duration t .

But the choice of $H_Z, 1/3$ as design wave height usually adopted seems to underestimate the effect of random waves, whatever the storm duration may be. $H_Z, 1/20$ is approximately 40 % higher than the significant wave height and this leads to an important difference in armour units weight, this last one being generally proportionnal to the height to the cube (figure 8).

III - EFFECTS OF BREAKING WAVES

These tests were conducted only in regular waves, in a smaller flume which is 50 m long and 0,60 m wide. The rubble mound breakwater model was the same as the one describes above but the median armour stone weight was 5,37 T.

Figure 8

DETERMINATION OF THE DESIGN WAVE HEIGHT AS A
FUNCTION OF THE STORM DURATION

The water depth at the toe of the structure varied from 3 m to 10 m and the wave height from 3 m to 5 m. Three periods were tested : 8, 10, 12 s.

Damage was expressed in terms of the four following parameters :

- wave height H_0 ;
- wave period T ;
- water depth at the toe of the structure D_p ;
- breaker depth D_b without the rubble mound breakwater.

III.1 - Multicomponents analysis

The statistical study of all the results has pointed out that the stability is strongly influenced by two parameters : the height H_0 as usually expressed by the stability formula and the ratio D_p/D_b characterizing the position of the breakwater in the surf zone. This result is illustrated by the figure 10.

Interpretation of the figure 10 :

- the correlation coefficient between two variables may be characterized by the distance separating these variables ;
- each axis may be interpreted as a variable to be defined ;
- the correlation coefficient between an axis and a variable is given by the projection of the variable on the axis.

So the observation of the figure 10 allows to establish that :

- the damage D and the wave height H_D are strongly correlated ;
- Oy axis may be interpreted as the ratio $\frac{D_p}{D_b}$;
- the correlation coefficient between the damage D and the ratio D_p/D_b is important.

III.2 - Expression of the damage D as a function of $\frac{D_p}{D_b}$ an H_0

Although there is a great scatter of the tests results, a statistical adjustment has been made (figure 9). For a given wave height, the most important damage occurs when $\frac{D_p}{D_b} = 1$.

So a rubble mound breakwater is submitted to the worst attack of waves when it is located just in the breaker zone corresponding to design storm conditions.

When the ratio $\frac{D_p}{D_b}$ is great, that is when in non breaking conditions, the curves presented on the figure 9 are in good agreement with Hudson's results.

Figure 9

DAMAGE EVOLUTION WITH THE BREAKWATER
 POSITION AND THE WAVES HEIGHT

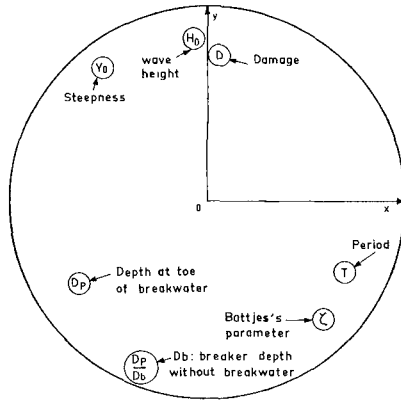

Figure 10 : Détermination of the most influencing parameters (multicomponents analysis)

III.3 - Application to the determination of the design wave height

This statistical adjustment has permitted to express the design wave height as a function of $\frac{D_p}{D_b}$ and H_0 . This function is represented graphically on the figure 11.

This figure shows that in the most unfavourable case ($\frac{D_p}{D_b} = 1$), the design wave height must be increased by about 15 to 40% when using a stability formula elaborated for non breaking waves. Again this leads to significantly increased armour units weights.

Figure 11

Variations of the ratio $\frac{H_d}{H_0}$ versus $\frac{D_p}{D_b}$ and H_0

IV - CONCLUSIONS

However these tests have been run for conditions which are limited in comparison with the range of conditions to be handled in practice, (e.g. artificial blocks eventually with interlocking effects), they have pointed out that the design wave height to use in a stability formula is higher than the significant wave height of the spectrum and depends of the storm duration.

For a storm duration of 6 hours the design wave height should be approximately $H_z \frac{1}{20}$.

Furthermore this choice must be modulated according to the location of the rubble mound breakwater in the breakwater zone of the most severe storms.

ARTIFICIAL RESORT BEACH PROTECTED BY
OFFSHORE BREAKWATERS AND GROINS

by

Shoji SATO and Norio TANAKA
Port and Harbour Research Institute, Ministry of Transport
1-1, 3-chome, Yokosuka, JAPAN

INTRODUCTION

In Japan, area of natural beaches has decreased in the vicinity of cities, towns and villages, in consequence of constructing ports and harbours, reclaiming shore and beach, and building storm-surge prevention structures like sea dikes and sea walls. On the other hand, the demand of people for recreation area is increasing year by year with the improvement of living and economic conditions. Therefore, since several years ago, local governments have extensively been constructing artificial beaches and restoring eroded beaches on many places by the aid of the central government.

Such artificial beaches, however, need large amount of natural sand, in spite of the deterioration of sand supply and the soaring of sand price. Moreover, local governments are able to get subsidiary payments of the central government for the construction of artificial sand beach, but not for replenishing sand lost by wave action after the completion of the construction works. Therefore, most artificial beaches in Japan are usually protected by groins and offshore breakwaters in order to retain artificially filled sand. But in summer when sea is in calm condition, pollutant produced by sea-bathing people or discharged from the land is likely to stagnate in the vicinity of the shoreline on account of such structures.

From the above-mentioned, coastal engineering problems on construction and restoration of sand beach in Japan are:

- (1) suitable arrangement of offshore breakwaters and groins from standpoint of artificial beach protection
- (2) keeping the sea water of the beach clean
- (3) estimation of profile change of the artificial beach due to wave action after its construction.

This paper presents the results of investigations conducted with the aim of solving the above coastal engineering problems related to artificial beach constructions at Suma and Ito beaches. The investigations are mainly conducted using model experiment.

SUMA BEACH

Natural Condition of Suma Beach

Suma Beach is located in the western portion of Kobe City along Osaka Bay as shown in Fig. 1. Fig. 1 shows a bathymetric map of Suma Coast surveyed just before the start of the construction of the

Fig. 1 Bathymetric map of Suma Coast

Fig. 2 The scheme of artificial beach at Suma of Kobe City

artificial beach, in 1973. The height of the backshore is 3 m above L.W.L., and the beach slope is nearly 1/10 on the foreshore and 1/20 - 1/30 between 1 and 6 m deep. The median diameter of the beach materials are several mm on the foreshore and 0.3 to 0.5 mm between 1 and 6 m deep. Usually waves are so small and significant wave heights are less than 0.5 m. Waves of more than 1.5 m in $H_{1/3}$ come only a few times a year. But, in very rare cases, the beach is attacked by severe waves due to typhoons. The estimated past maximum $H_{1/3}$ is 4.75 m. Tidal currents are going and returning in parallel with the shore, showing maximum velocity of about $50 \text{ cm}\cdot\text{s}^{-1}$ on the offshore of about 10 m deep at spring tide. The mean spring tidal range is 1.8 m.

Scheme of The Artificial Beach Construction

In 1973, Kobe municipal city has decided to construct the wide artificial beach on the stretch of about 2 km long between Suma Port, which is a leisure and fishery port, and the pier, which is a permeable type and is used to load materials for the reclamation of the area of Kobe Port. At that time, short groins of several ten meters long had existed on the whole stretch of the beach with space intervals of 100 m or so in order to prevent beach erosion, and behind the beach there was sea wall of 5 m high above L.W.L. in its crown height.

Fig. 2 shows the present scheme of the artificial beach designed on the basis of the model experiment which will be mentioned in the following paragraphs. The beach is divided into five parts by five long groins of No. 1 to 5, and there are six offshore breakwaters in order to protect the artificial beach from the wave action. The groins are of impermeable cellular type and the offshore breakwaters of composite type. The beach is filled with natural sand to form arch-shaped plane shape. The beach width, from the promnade way to the shoreline of mean water level, is about 50 m at the center of arch-shaped beach in the east portion. The green belt is behind the promnade way. In the west part of the stretch, the width of the coastal area is increased by the reclamation and the artificial beach is made in front of the reclaimed land, because houses densely exist just behind it. Therefore, the width of artificial beach become so narrow that submerged rubble mound is constructed between the offshore breakwaters so as to retain the seaward end of the beach slope. The construction of the artificial beach began in 1973 and the most of the east portion in the figure will be completed in 1980 fiscal year.

Model Test on Sea Water Exchange in The East Part of The Beach

Model tests on sea-water exchange between inshore and offshore have been conducted using a fixed bed model with the reduced scale of 1/100 in both vertical and horizontal. Fig. 3 shows a pattern of the currents measured in the model of the east part of Suma Beach without the artificial beach, which corresponds to the state of the maximum of current velocity in flood tide at the site. There is a circulation of currents at the lee of the breakwater of Suma Port while the tidal currents in the offshore zone flow in parallel with the shore line. Under the steady current with such flow pattern, the dispersion of fluorescent

Fig. 3 Pattern of the fastest currents during flood tide at the east part of Suma Beach before the beach nourishment

Fig. 4 Dispersion patterns of dye discharged on the shoreline in the east part of Suma Beach

Fig. 5 Current patterns of the cases with and without offshore breakwaters

dye discharged on the shoreline has been investigated for cases with and without the artificial beach.

Fig. 4 shows the patterns of spreading dye at 60 minutes after the start of discharge of dye, though the dye of 500 ppm in density has been discharged only during the first 15 minutes at 8 points on the shoreline. The discharging rate is $0.222 \text{ cm}^3\text{s}^{-1}$ per point. These diagrams were drawn by eyes on the base of colored pictures taken from the ceiling together with dye samples of 0.1, 1, 10 and 100 ppm in density placed on the edge of the model. In the figure, Case (b) of artificial beach with only groins is worse in offshoreward dispersion of dye than Case (a) without artificial beach, but Cases (c) and (d) with offshore breakwaters in addition to groins are better in it than the Case (a). It is because there are fast currents along the landward side of offshore breakwaters as well as circulating currents between offshore breakwaters and the shoreline at Cases (c) and (d), as seen from the patterns of currents shown in Fig. 5. The figure shows the result of test conducted under the same hydraulic condition as the above-mentioned Fig. 3. In comparison of Cases (c) and (d) in Fig. 4, the latter is better than the former. In these cases, the offshore breakwater is apart from the tip of the groin because it had been verified in the preliminary test that attaching them makes the water exchange worse between inshore and offshore.

Model Test on Beach Evolution in The Eastern Part of The Beach

Model tests on the beach evolution have been conducted using a movable bed model of 1/60 in vertical and horizontal scales. Fine sand of 0.19 mm in median diameter was used as sediments. Fig. 6 shows the comparison of depth contour lines before and after 6 hours run of waves of 4 cm in height and 1.03 s in period, which correspond respectively to 2.4 m and 8 s in the prototype on the basis of Froude's law. The direction of wave is south, and the still water level is equal to M.W.L. which is 1 m above L.W.L. in prototype. In the figure, the part of 1 to 3 m deep in the vicinity of the beach center is eroded by the wave action. The counter measures to prevent such erosion were tested under the same wave condition.

Fig. 7 shows the changes of the levels of the bottom between before and after 6 hours run of the same wave as Fig. 6 for each counter measure. Case 1 in the figure has a submerged breakwater of 3 m deep in crown level between offshore breakwaters, Case 2 it of 2 m deep in crown level on 6.5 m deep contour line, and Case 3 it of 2 m deep in crown level on 4.5 m deep contour line. In these cases having a submerged breakwater, the foreshore in the center of the arched beach erodes, and its backshore and the foreshore of both ends of the beach accrete. Case 3, which has a submerged breakwater in the nearest place to the foreshore, is the most elosive at the foreshore in the center of the arched beach. The submerged breakwater seems to be difficult to prevent the recession of the center part of the shoreline. Therefore, a small breakwater of 2 m above L.W.L. in crown level was placed in front of the foreshore, that is, on the 2 m deep contour lines. Its result is shown at (d) of the figure, where there are seen no erosion on the foreshore

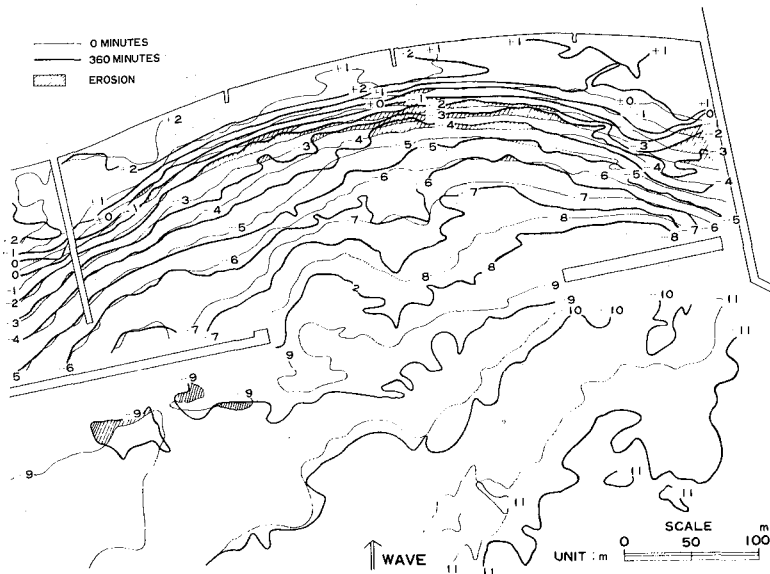

Fig. 6 Comparison of depth contour lines between before and after 6 hours wave action in the east part beach ($H = 2.4 \text{ m}$, $T = 8 \text{ sec}$)

Fig. 7 Changes of the levels of bottom between before and after 6 hours wave action ($H = 2.4 \text{ m}$, $T = 8 \text{ sec}$)

just behind of the small breakwaters, though the areas around both tips of it are a little eroded.

Fig. 8 shows the change of bottom profile of the central part for each the above mentioned case. In every case except Case 4, the offshore side of shoreline is eroded by wave actions. This erosion is severer in the cases with a submerged breakwater than the case without any countermeasures. Therefore, Case 4 is recommended as the countermeasure against the recession of the center portion of the arched beach, but, at the site, the beach have been remained without any such a countermeasure at present. The reason is why such a structure is not welcomed from the view point of recreation and the model tests have a scale effect in their results. It will be again considered if such countermeasure is necessary or not after finishing scheduled beach filling.

The Change of Bottom Topography in The East Part of The Beach

In the site, the beach filling was conducted every autumn from 1973 to 1977 at the east end portion, the total volume of filled sand being 180,000 m³. Fig. 9 shows the changes of L.W.L. shoreline after the filling in September 1977, when 83,000 m³ of sand was supplied so as to shift the foreshore seawards. The supplied sand was 1.6 mm in median diameter and 2.6 in Task's sorting coefficient. The shoreline of L.W.L, which was of nearly straight line, has receded in center and advanced in the both ends with the time. But, the latest change from December 1973 to June 1979 is very small, especially in the center part. It means that the shape of the shoreline has reached the state of equilibrium in nearly one year. This equilibrated shoreline is nearly similar to that of the model test shown in Fig. 6.

Fig. 10 shows the changes of the beach profile at the center and the both sides of the beach. The profile of Section B at the center has changed mainly in the part above one meter deep, while these change appeared in the part above 3 m deep in the model test, as shown in the first section of Fig. 8. It seems to be because the most waves were less than 1.5 m in height at the site during the duration. The eroded sand in the center of the beach may have been transported along the foreshore to the both ends of the beach by the wave action. As the results, the foreshores of Section A and C have advanced and have become steeper than in the center portion. Despite such a bottom change, the total loss of filled material was only 2,500 m³ in volume the period from September 1977 to March 1979.

Model Test on The Beach Evolution in The West Part of The Beach

The west part is, as described above, planned to be made in front of the reclamation land. The typical plane shape of artificial beach, which have been tested using a movable model of 1/80 in horizontal and 1/50 in vertical scale, are shown in Fig. 11. The three beaches are perfectly separated each other in Case 1 and are connected through the tip of the groin each other in Case 2 and 3. For each case, the crest level of the offshore breakwaters and the submerged breakwaters are 3.2 m above and 3 m below L.W.L., respectively. Moreover, Case 3 has the

Fig. 8 Comparison of change of bottom profile along the central section

Fig. 9 Change of the shoreline of 10 m after the sand filling in Sep. 1977 at the site

Fig. 10 Change of beach profile of the east part of the beach at the site

Fig. 11 Typical layouts of the artificial beach tested for the west portion

small open part of ± 0 m deep in the center of the offshore breakwater. Fine sand of 0.29 mm in median dia. was used as sediments.

(a) Comparison between Cases 1 and 2

Fig. 12 shows the change of the water depth between before and after 6 hours run of waves of 5 cm in height and 0.85 s in period. The model waves correspond to the prototype waves of 2.5 m height and 6 s in period on the basis of Floude's law. The waves come from SSW and the bottom topography before the run is the same as that in Fig. 11. For both cases, each beach is eroded in the part directly facing the incident waves and accreted in its either side sheltered by the offshore breakwaters. However, the quantity of water depth changes and the recession of shoreline at the center are severer in Case 1 than in Case 2 and more sand was lost seaward of the breakwater in the former case than in the latter case.

Fig. 13 shows the pattern of the currents caused by the waves for these two cases. The currents are measured by following by eyes the movement of a plastic ball of 0.7 cm in dia., the inside of which is filled with water so as for the ball to be a little heavier than the water. In Case 1, there are strong currents going outwards out of the open mouth of the western two beaches, but, in Case 2, there is not such current except weak currents in the central compartment. In Case 2, most currents approaching toward the offshore tip of either groin from the center of the beach flow towards the next compartment through the gap between the groin and the offshore breakwater. This difference of the current pattern is the cause that the sand loss in Case 1 is larger than that in Case 2. The seaward currents transport out the sands suspended on the beach by wave action.

(b) Comparison between Cases 2 and 3

Case 2 has rather large accumulation of sand in the vicinity of the tip of groin, as seen in Fig. 12. This accumulation is likely to grow up gradually and obstruct the current flowing toward the next compartment through the gap. Case 3 is a arrangement devised to prevent such obstruction, having the small open part of ± 0 m in its crown level in the center of the breakwater as mentioned previously. Fig. 14 shows the effect of the small open part, this is, the change of water depth between before and after 6 hours run of the same wave as (a) mentioned above but in SSE direction. In Case 3 with the small open parts, the vicinity of the tip of the groins is scoured and the recession of the shoreline at the center is smaller than in the Case 2.

The comparison of depth contour lines of the central compartment in these two cases is shown in Fig. 15 with the wave height ratio of Case 3 against Case 2. It is seen from the figure that the small open part makes wave height behind the offshore breakwater 3 - 1.5 times as large as the case without it, giving rise to currents running from it towards the base of the groin. As the results, the area around the tip of the groins is scoured and the accumulating area behind the offshore breakwater shifts toward the center of the compartment. Therefore, the sand transported along the shoreline from the central area of the compartment toward the both side decreases in volume, which prevent the recession of the shoreline at the center area of the compartment.

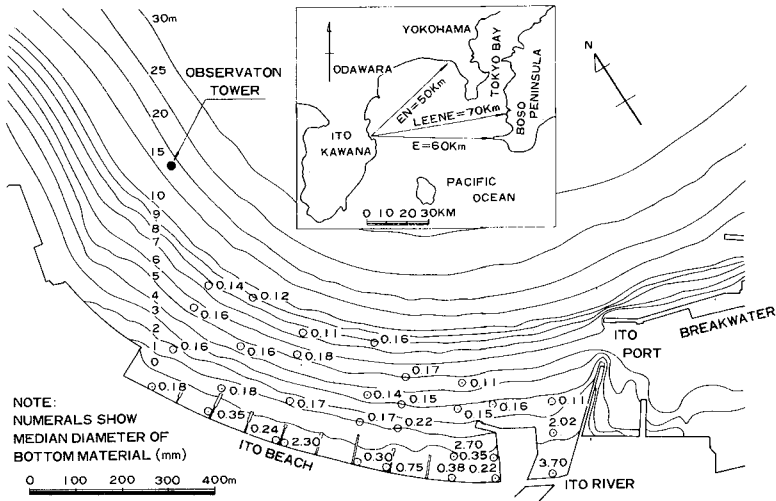

Fig. 16 Bathymetric map of Ito coast

ITO BEACH

Natural Condition of Ito Beach

Ito City is located at the east coast of Izu Peninsula which is about 100 km southwest from Tokyo as shown in Fig. 16. The figure shows bathymetric map of Ito Coast just before the beginning of the construction of the artificial beach, in 1973. The height of the backshore is 3 - 4 m above L.W.L. and the beach slope is nearly of 1/10 on the foreshore and 1/25 - 1/30 between 1 and 6 m. But the deeper part than 10 m deep has steeper slope of about 1/10. The median diameter of sea-bed material is 0.2 - 0.5 mm on the foreshore and 0.2 - 0.12 mm on the offshore until 6 m deep.

The beach is sheltered by the head land of Kawana against southerly waves, as estimated from Fig. 16. Therefore, northerly waves are predominant at the beach, but their height is almost 1.5 m in H1/3 except when typhoons pass near the beach in summer and autumn. Tidal current flowing in nearly parallel with the coast in the offshore forms reverse circulating currents in the nearshore the velocity of which is weak and the order of several $\text{cm}\cdot\text{s}^{-1}$. The mean range of spring tide is nearly 1.5 m.

Scheme of Artificial Beach Construction

The beach of nearly 900 m long, which is to the west of Ito port as shown in Fig. 16, is at present protected by 8 groins of 40 - 60 m long and has the sea wall of 4.8 m above L.W.L. in crest height. The road just behind the sea wall is very jammed by traffic in resort season. Ito City, which is a tourist resort with hot springs, has decided in 1973 with the aid of the central government to change the beach into a more beautiful and cleaner resort place after widening the road seaward by 7.5 m. Therefore, the authors have conducted the model experiment to make the plan of artificial beach.

Fig. 17 shows a plane view and a beach profile of the scheme of artificial beach which has been decided on the basis of the model experiment. A fishing basin of the east side and a slope way for fishery boats of the west side accommodate small fishery boats scattering on the beach at present. The present seawall is shifted seaward by 7.5 m as mentioned above, the green belt of 12.5 m wide is made, and artificial beach is arranged in front of the green belt. The beach is protected by three offshore breakwaters of 3.0 m above L.W.L. in crown height and three long groins, of which the two groins in the both side also work to protect the fishery boat area. The short wing parts parallel with the shore are attaching at the tip or its vicinity of each groin, which serves to stabilize sea-bed as shown later. The offshore breakwater are of rubble mound type covered with artificial brocks and the groin is of impermeable type of concrete blocks. Moreover, the tip part of each groin is protected with wave absorbers of artificial concrete blocks.

Model Test on Sea Water Exchange

Fig. 17 Scheme of the artificial beach at Ito

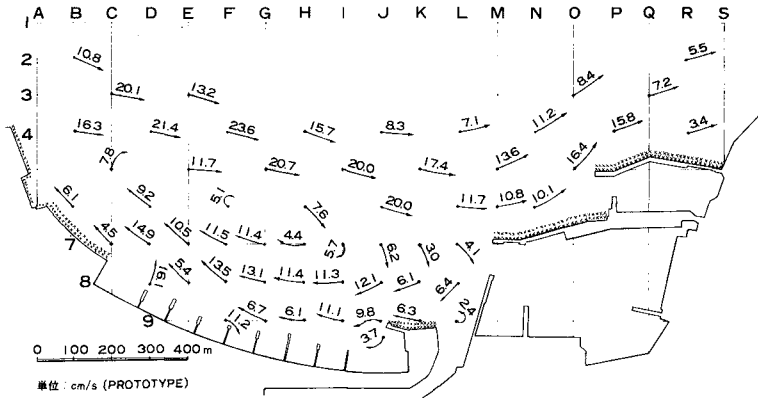

Fig. 18 A plane view of the model for sea-water exchange test

Fig. 18 shows a plane view of the model for the test on sea water exchange conducted in order to determine the above-mentioned scheme of Ito artificial beach. The model is of concrete mortar floor with the reduced scale of 1/200 in horizontal and 1/100 in vertical, in which the part deeper than 30 m deep below L.W.L. is made as the constant depth of 30 m deep. A tidal current generator, of which the main part is shown in the right upper part of the figure, produces cyclic currents flowing from right to left or from left to right in the test basin by means of a pump and rotating valves. The water level in the basin is periodically changed by a water-level-change equipment, which pumps up some suitable volume of water from the water-level-change basin to the high-level basin together with falling down some water by gravity from the latter basin into the former basin through a falling pipe. The water-level-change basin is separated by a lattice wall from the test basin so that the water is able to commute between these two basin freely. A wave generator is arranged in the water-level-change basin so as not to disturb currents in the test basin.

Fig. 19 shows the patterns of currents when both steady currents and waves are in force. The velocity of the steady currents corresponds to the maximum velocity of current at falling tide. The steady waves are 30 cm in height and 10 s in period which correspond to swells in summer. In the figure, numerals beside arrow marks of current direction show velocity in unit of $\text{cm}\cdot\text{s}^{-1}$. In (a) of the figure, there are reverse currents in the shallower area against the main currents flowing from left to right, and the currents of $10 \text{ cm}\cdot\text{s}^{-1}$ or so seen in the vicinity of the shoreline are caused by breaking waves. In (b) of the figure, there are comparatively strong currents flowing out from the open parts among offshore breakwaters and groins, though the current velocity inside the offshore breakwaters is nearly the same order as the existing state without offshore breakwaters and groins. The similar phenomenon appears also in the case of rising tide in which the main currents flow from right to left.

In order to check the influences of offshore breakwaters and groins on the sea water exchange between the onshore and offshore sides of these structures, fluorescent dye was discharged at 7 points on the M.W.L. shoreline only for 9 minutes at the time of the first H.W.L. and its dispersion was traced by taking the colour pictures from the ceiling under the condition that the sine curves of tide and current are generated to simulate the state of mean spring tide in addition to swells in summer. Discharged fluorescent dye is 700 cm^3 in volume and 500 ppm in density for each test. The current distribution at the M.W.L. of falling tide is the same as one shown in the above-mentioned Fig. 19. Fig. 21 shows the time changes of dye dispersion for the cases without and with the artificial beach, where each figure of 9 and 45 minutes corresponds to the first H.W.L. and the second H.W.L., respectively, as shown in Fig. 20. Currents flow from left to right in the offshore and from right to left in the nearshore during 9 minutes to 27 minutes. The dye discharged on the shore is transported offshoreward by current and diluted by mixing with the surrounding water. The case with the artificial beach is seen to be a little better than the case without it in offshoreward dispersion of fluorescent dye. It is because the offshore breakwaters serve as training walls against the

(a) Existing state

(b) State with the artificial beach

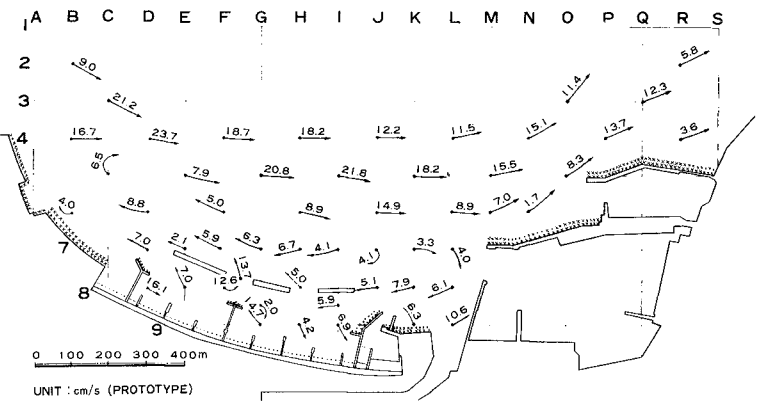

Fig. 19 Patterns of the fastest currents falling tide with summer swells

Fig. 20 Relation between tide and the time when dye-pictures were taken

current in their vicinity, as assumed from the current distribution in Fig. 19.

Model Test on Beach Evolution

For the model test on the evolution of artificial beach, in the model basin shown in Fig. 18, the area in the vicinity of the shore bounded with the dotted line was changed to the movable bed of fine sand of 0.17 mm in median diameter and the area deeper than 10 m deep was remolded to become constant depth of 10 m deep. Moreover, the wave generator was moved onto this part of constant depth and set to be parallel with the lattice wall. In this test, the water level was always M.W.L. and tidal currents was not generated.

Fig. 22 shows the changes of equi-depth lines due to wave action in the first proposed scheme. Model wave is 3 cm in height and 1 s in period which corresponds to the prototype wave of 3 m in height and 10 s in period by Floude's law. (a) and (b) in the figure corresponds respectively to before and after 3 hours of the run. As (b) is compared with (a), the foreshore near each groin of West and Center remarkably erodes and the area behind of each offshore breakwater remarkably accretes. Moreover, the mouth of the fishery basin in the eastside also shoals. As the countermeasures against such remarkable changes of the bottom topography, short wing breakwaters were attached at the tip or its vicinity of each groin and short jetty was added at the east side of the entrance of the fishery basin. Their effects are shown in Fig. 23, where the seawall is shifted seaward by 20 m in order to keep the space of the green belt and the widened road. Comparing this figure with Fig. 22, the changes of topography is much less remarkable. It means that the wing breakwater attached on the groin serves not only to prevent the erosion at the foot of the groin but also to restrain the accumulation behind the offshore-breakwater. The accumulation at the entrance of the fishery basin also has been moderated by the installation of the short jetty.

Change of Equi-Contour Lines at The Site

Construction of the West Offshore Breakwater has started in autumn of 1974, and its part of 120 m long has been completed until 1979. Fig. 24 shows the comparison of equi-contour lines between 1974 and 1979. Though the contour lines were in parallel with the shore-line in 1974, there are remarkable accumulation at the lee of the offshore breakwater in 1979. Especially the contour lines of ± 0 and 2 m deep advance toward the offshore breakwater and the slope between 2 and 4 m deep is steeper than 1974. These tendency of sea-bed change in the lee of the offshore breakwater can be observed in the model test shown in Fig. 22 and 23, though the value of contour lines which changed remarkably is a little different from the site. At the areas of the both side of the offshore breakwater, the area deeper than ± 0 m are scoured, especially the contour lines of 1 to 3 m deep receding landwards. But, the contour lines higher than ± 0 m deep do not recede on account of the existance of shore groins.

Fig. 25 Typical layouts of structures for the protection of an artificial beach

Conclusion

There are two types on the layout of the structures at artificial resort beach in Japan as shown in Fig. 25, one is the layout where a groin is installed behind an offshore breakwater as in Suma Beach and the other is the one where a groin is installed at the open part between offshore breakwaters as in Ito Beach. In the following description, the former layout is called A type and the latter one B type. The followings can be remarked from the above-mentioned tests:

- (1) In A type layout, the shoreline of each compartment between groins is likely to change to concave one with recession at its center and advancement at its either side. The bottom-slope just in front of the foreshore becomes flatter in the middle part and steeper in the either side part. In this case, placement of a submerged breakwater near the foreshore in the middle of the compartment is not effective to prevent the recession of the middle part.
- (2) In B type layout, the shoreline of each compartment tends to change to convex one with advancement at the center and recession at the either side. The bottom-slope of the middle part becomes steeper in the offshore far out of the foreshore though the part near the foreshore becomes flatter, and it of the either side becomes flatter in front of the foreshore.
- (3) In A type layout, the groin must not be connected with the offshore breakwater from the stand-point of the prevention against the loss of the beach sand outwards of the offshore breakwater and the stagnation of polluted water in the inside of the offshore breakwater. Moreover, lowering the crown level of a little part in the center of the offshore breakwater serves to moderate the erosion at the middle part of the beach as well as the accumulation at the either side part of it.
- (4) In B type layout, the groin should have a short wing breakwater at its tip. It serves to moderate the erosion near the groin as well as the accumulation behind the offshore breakwater.

ACKNOWLEDGEMENT

The authors express grateful thanks to the authorities of Kobe and Ito Cities for their presentation of many field data and to Messrs Hisao Kimura and Hideo Osanai in the same institute as the authors for their hearty cooperation in the model test.

CHAPTER 123

SEAWALLS IN DEEP SEAS

by

Shoshichiro Nagai¹, F. ASCE and Shohachi Kakuno²

ABSTRACT

Features in wave overtopping of two new types of seawalls designed to be built in considerably deep sea conditions are presented herein. One of those is the seawall of concrete caisson with a parapet wall and armor blocks on the top of the caisson, and another one is the seawall with a slitted box-type wave absorber.

The former type of seawall has successfully been constructed in the Japan Sea and the Seto Inland Sea and is also to be constructed at a site directly exposed to an open sea of the Pacific Ocean in 1980 and 1981. The latter type of seawall was proposed in 1977 after numerous experiments and has been under construction in the Port of Osaka since 1978.

The results of the experiments on the wave overtopping over the slit-type seawall were compared with the calculated results, obtained by an analysis in which the wave overtopping over a parapet wall was considered similar to the phenomenon of flow over sharp-edged weirs having time-dependent overflow-head. The calculated curves obtained are in good agreement with the experimental results.

The designs of these two types of seawall are also presented herein.

INTRODUCTION

In recent two decades in Japan, a special type of seawall, in front of which a 1 : 1.5 slope covered with concrete armor blocks is built, has been constructed to protect reclaimed lands and coastal areas from overtopping of waves during typhoons. The water depths at the sites have been several meters to about ten meters or a little more. The heights of the design waves were several meters and the

¹ Professor Emeritus, Director of Harbor and Coastal Engineering Laboratory, Osaka City University, Osaka, Japan

² Research Associate of Hydraulic Engineering, Faculty of Engineering, Osaka City University, Osaka, Japan

periods of them were 8 sec to 13 sec. Most of the seawalls, designed after experiments had been carried out at scales of 1/20 to 1/30, have been proved to be successful after attack of storm waves [1].

However, when the water depths where a seawall is built become so large as about 15 m to 25 m or more and the design waves are more than several meters in height and 13 sec to 15 sec in period, the section of the seawall mentioned above becomes very large; therefore its cost of construction becomes extremely high.

From such a reason, a new type of seawall was proposed in 1969 after numerous experiments had been carried out in the wave channel with a wind blower in our laboratory. This type of seawall is composed of a big concrete caisson with a parapet wall and concrete armors on the top. It has already been constructed at one place on the shore of the Japan Sea and one in the Seto Inland Sea, and has been under construction at a place on the shore of the Pacific Ocean since 1980.

In 1977 another type of seawall for deep seas was proposed. This type of seawall, called slit-type seawall, is composed of a concrete caisson and a slitted box-type wave absorber attached to it. It has been under construction in the Port of Osaka since 1978 [2].

CLASSIFICATION OF BEHAVIORS OF OVERTOPPING

As shown in Table 1, the behavior and quantity of overtopping waves over seawalls have been classified and judged in Japan the appropriateness of the seawalls by the relative overtopping quantity, q/q_0 , in which q denotes the quantity of overtopping over the unit length of a seawall for a wave period and q_0 is the volume of water transported shoreward over the unit length of the seawall by a shallow water wave for a wave period ($= HL/2\pi$, H : wave height, L : wave length) [1].

As known from Table 1, the limiting relative overtopping quantity for a seawall is $q/q_0 = 5 \times 10^{-3}$, that is, when $q/q_0 \leq 5 \times 10^{-3}$ the seawall can be effectively adoptable in the field.

TABLE 1.- Classification of Behaviors of Overtopping

Classification	Behavior of overtopping	q/q_0	Appropriateness
I	Only spray overtops (very well absorption of wave)	0 to 10^{-4}	Ade- quate for seawall
II	Lumps of water overtop (higher limit applicable to a seawall)	10^{-4} to 5×10^{-3}	
III	A substantial part of wave over- tops (imperfect absorption of wave)	5×10^{-3} to 10^{-2}	Inade- quate for seawall
IV	Large volume of wave overflows (poor absorption of wave)	10^{-2} to 10^{-1}	

SEAWALL OF CONCRETE CAISSON WITH A PARAPET WALL AND ARMOR BLOCKS ON THE TOP

The latest seawall of concrete caisson with a parapet wall and armor blocks on the top has been under construction since 1980 at a site, Gobo, directly exposed to an open sea of the Pacific Ocean, as shown in Fig. 1, to protect a reclaimed land of about 350,000 m² for a thermal power station from wave overtopping during typhoons. Fig. 2 shows the cross-section of the seawall. The water depth at the site is about 18 m below Datum Line (D.L.), and the design wave height and period are $H_{1/3} = 9$ m and $T_{1/3} = 13$ sec at the design sea level of 3.6 m above D.L.. The sea-bottom in front of the seawall has a slope of 1/100. N-shaped blocks are used as the concrete armors to be placed on the top of the caisson because they have much greater stability against wave attack than other specially-shaped concrete armors, in addition to their distinguished ability for absorbing wave energy [3].

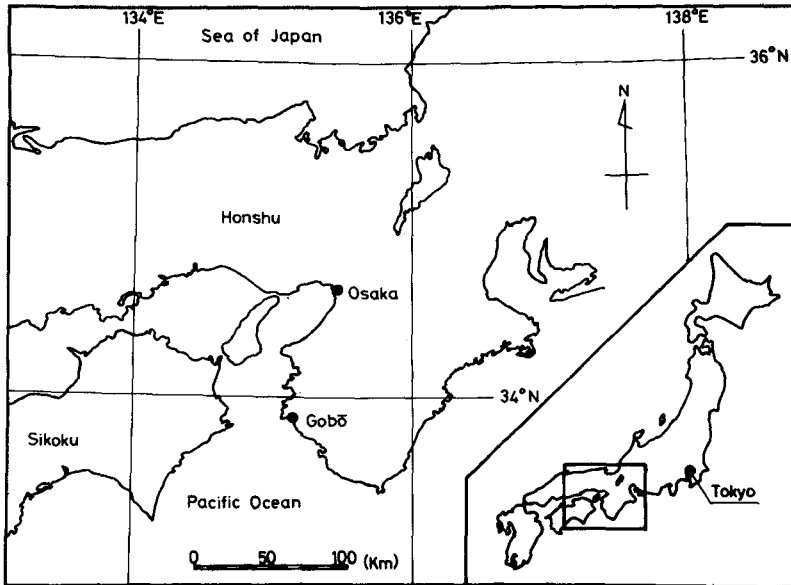

Fig. 1.- Location Map of Seawalls

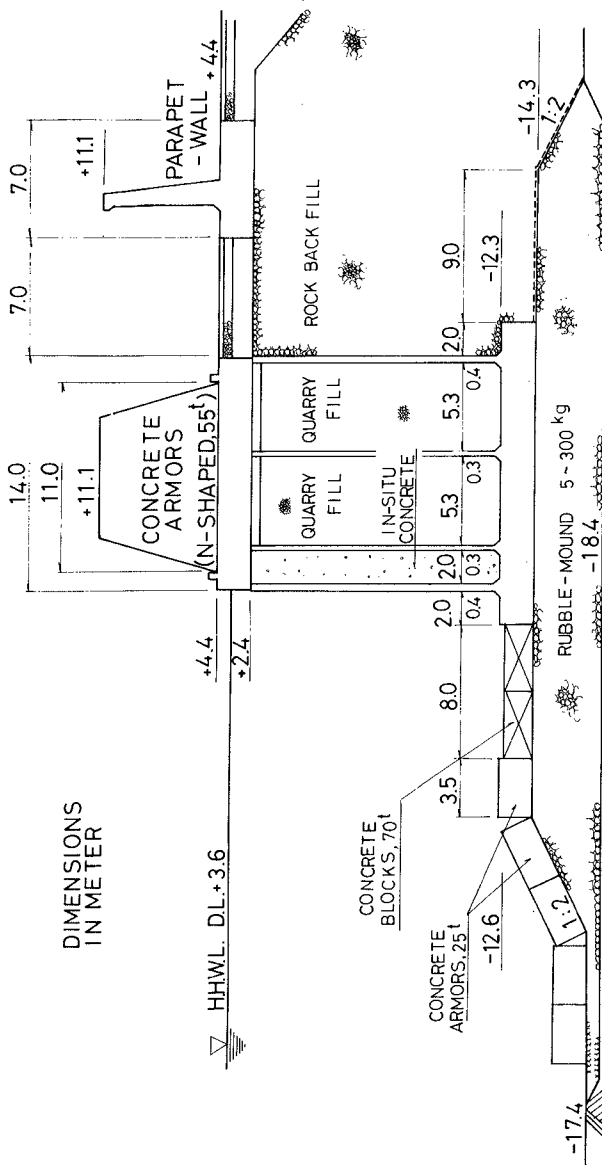

Fig. 2.- Seawall of Concrete Caisson with a Parapet Wall and Armor Blocks on the Top

Experimental Equipment and Procedures

In order to measure wave overtopping quantity over the seawall shown in Fig. 2 and to examine the stability of the concrete armors against wave attack, a great number of experiments were carried out at a scale of 1/35 using a wave channel with a wind blower, 100 m long, 1.2 m wide, and 2.0 m high, shown in Fig. 3.

The characteristics of the waves and winds used in the experiments are shown in Table 2.

Winds of velocities of 10 m/sec were blown in models over the waves in the wave channel to simulate the circumstances of the actual overtopping waves and sprays over the seawalls in the field.

Fig. 3.- Wave Channel (100 m long) with a Wind Blower

TABLE 2.- Characteristics of Waves and Winds in the Experiments

Wave characteristics (prototype)		Wind velocity (model)	Sea level (prototype)
Period T_p (sec)	Height H_p (m)	V_m (m/sec)	D.L. + (m)
13	8.7 to 12.4	10	3.6
10	8.5 to 12.6		
15	9.0 to 10.1		

As listed in Table 3, four conditions of the armor blocks were tested in the experiments. Fig. 4 shows the N-shaped block of 6 ton, and Fig. 5 shows the way of placing of the N-shaped blocks in two layers on the top of the caisson.

TABLE 3.- Conditions of the Armor Blocks
on the Top of the Caisson

Cross-section	Armor blocks	Weight (ton)	Placing	Width of placing (meter)	Top of armor blocks (meter)	Top of parapet wall (meter)
I	N-shaped	28	2 layers (5,4) rows	15.8	D.L. + 9.5	D.L. + 11.1
II		28	3 layers (5,4,3) rows	15.8	D.L. + 11.5	D.L. + 10.1
III		55	2 layers (3,2) rows	11.0	D.L. + 11.1	D.L. + 11.1
IV		55	2 layers (4,3) rows	14.8	D.L. + 11.1	D.L. + 10.1

Fig. 5.- N-Shaped Blocks in Two Layers

Experimental Results

Stability of the armor blocks was firstly examined using the cross-sections-I and -II with 28-ton N-shaped blocks in two or three layers. The results of the experiments for the waves used in the experiments showed that the N-shaped blocks of 28 tons were stable and the relative wave overtopping quantity, q/q_0 , for both sections was about 1×10^{-3} , smaller than the limiting quantity of 5×10^{-3} , if they were placed on the top of the caisson in two or three layers.

Fig. 6.- Detail of 55-Ton N-Shaped Block

Reinforced 55-ton N-shaped blocks, shown in Fig. 6, however, were decided to use in practice for more safety. Fig. 7 shows the results of q/q_0 as a function of wave height, H , for the seawalls with the 55-ton N-shaped blocks of the sections-III and -IV.

From Fig. 7 it may be stated that the overtopping quantities in the sections-III and -IV are almost same if the characteristics of the waves are same, and q/q_0 for the design wave of $T_{1/3} = 13$ sec and $H_{1/3} = 9$ m is about 1×10^{-3} in these two sections. Therefore, the seawalls with these sections are adoptable to the seas, as known from Table 1.

The section-III, shown in Fig. 2, was decided to adopt as the design section, because the width of placing of the armor blocks, 11.0 m, is smaller than the width of the caisson, 14.0 m.

Fig. 7.- q/q_0 as a Function of Wave Height

SLIT-TYPE SEAWALL

The slit-type seawall, shown schematically in Fig. 8, is composed of a concrete caisson founded on a rubble mound and a box-type wave absorber, attached to the caisson, with a slitted vertical front-wall and a slitted horizontal bottom-wall. Experimental results have already proved that this type of structure has features of low reflection and distinguished reduction in wave pressures [4, 5], and also has an ability of reduction in wave overtopping to a considerable extent if it is used as a seawall.

Experimental Equipment and Procedures

The experiments were carried out at a scale of 1/25 by using a wave channel with a wind blower, 50 m long, 1.0 m wide, and 1.75 m high.

The heights and periods of the waves used in the experiments are $H = 2.0$ m to 6.0 m, and $T = 6.0$ sec to 12.0 sec. The velocity of wind used is constant $V = 23$ m/sec in prototype through the experiments. The widths of wave chambers of the slitted box-type wave absorbers are $l = 3.75$ m and $l = 2.50$ m in prototype. The void ratios of the vertical front-wall and horizontal bottom-wall are constant $\lambda = 0.24$ and $\lambda' = 0.14$, respectively, through the experiments. The depths of water where the seawalls locate are $h = 12.2$ m, 13.2 m, 14.2 m, and 15.3 m. The rubble mound on which the caisson is founded has a top width of $B = 10.5$ m in prototype and a sea-side slope of 1 : 2.

Fig. 8.- Schematic Cross-Section of the Slit-Type Seawall

Fig. 9.- Relationship between q/q_0 and l/L .

0.05 of l/L for the minimum relative overtopping, $(q/q_0)_{\min}$, of the slit-type seawalls are less than half of 0.13 to 0.18 for the minimum reflection coefficient, $(K_R)_{\min}$, of the slit-type breakwater or quay-wall [4]. Because the horizontal velocities of the waves plunging into the wave chamber are attenuated by making the value of the relative chamber width to be 0.04 to 0.05.

The relations between q/q_0 and H_c/H in association with the characteristics of waves may be much of interest in the design of the seawalls. Figs. 10 through 13 show the relationships between q/q_0 and H_c/H when the values of l/L fall within the range of 0.04 to 0.05 for $(q/q_0)_{\min}$. From these figures it can be seen that the values of q/q_0 and H_c/H are in a certain relation regardless of the incident wave heights, and the values of q/q_0 become smaller than the limiting relative wave overtopping quantity of 5×10^{-3} , if H_c/H is taken to be larger than 1.0 and H_F/H , in which H_F denotes the height of the top of the vertical front-wall above the design sea level, is taken to be larger than or equal to 0.70.

Comparisons of wave overtopping quantities of the slit-type seawalls with those of other types showed that the slit-type seawalls give much smaller values of q/q_0 in most cases [2].

Experimental Results

The values of relative overtopping quantity, q/q_0 , for the slit-type seawall depend mainly upon the relative wave chamber width, l/L (wave chamber width/wave length). The minimum value of q/q_0 is obtained to be about 1×10^{-3} at the range of about 0.04 to 0.05 of l/L , if the relative parapet wall height $H_c/H = 1.0$, as shown in Fig. 9, in which H_c denotes the height of the top of the parapet wall above the design sea level. The range of about 0.04 to 0.05 of l/L where the minimum value of q/q_0 is obtained does not vary even though H_c/H becomes larger than 1.0. The values of 0.04 to

Calculations of Overtopping Quantities for the Slit-Type Seawall

When the water level inside the wave chamber of the slit-type seawall becomes higher than the top of the parapet wall, water flows over the parapet wall. The overflow was observed to occur calmly if $1/L$ was smaller than 0.06. This phenomenon implies that the analytical approach on wave overtopping over vertical seawalls [6] can also be useful for the analysis on the wave overtopping over the slit-type seawall with the values of 0.04 to 0.05 of $1/L$.

(1) Assumptions and analysis

The surface elevation inside the wave chamber is considered to be a perfect standing wave with the wave height of $2\gamma_T \cdot H$, in which γ_T is the transmission coefficient of the perforated (slitted) walls of the absorber and H denotes the incident wave height, because it is composed of the transmitted wave, η_T , through the perforated wall and the reflected wave, η_{TR} , from the solid back-wall, as previously described [4].

Therefore the time history of the surface elevation inside the wave chamber can be written

$$\eta(t) = \gamma_T \cdot H \cdot \sin(2\pi t/T) + \delta_0 \quad (1)$$

in which T is the period of the wave, $\eta(t)$, and is identical with that of incident waves, and δ_0 is the mean water surface elevation from the still water level at the solid-back wall, which can be observed in the experiments and could be subject to the characteristics of the incident waves, water depths, wave chamber widths, and the profiles of the rubble mounds.

Supposing that the parapet wall of the seawall is a sharp-edged weir, and that the overflow-head for it is $\eta(t) - H_C$, varying with time, one gets the overtopping quantity over the unit length of the seawall for a wave period as

$$q = 2 \int_{t_1}^{t_2} \frac{2}{3} \cdot C(t) \cdot \sqrt{2g} \{ \eta(t) - H_C \}^{3/2} dt \quad (2)$$

in which t_1 is the time when $\eta(t)$ equals H_C , t_2 is the time when $\eta(t) = \eta(t)_{\max} = \gamma_T \cdot H + \delta_0$, and $C(t)$, termed the coefficient of wave overtopping in this paper, is the coefficient corresponding to the discharge coefficient used in the expression for the discharge of the flow over weirs.

Supposing that the coefficient of overtopping is constant with time, i.e., $C(t) = C$, and substituting Eq.(1) into Eq.(2), one can get

$$q = \frac{4\sqrt{2}}{3} \cdot C \cdot (\gamma_T \cdot H)^{3/2} \int_{t_1}^{t_2} \left\{ \sin \frac{2\pi}{T} t - \frac{1}{\gamma_T} \left(\frac{H_C}{H} - \frac{\delta_0}{H} \right) \right\}^{3/2} dt \quad (3)$$

Dividing Eq.(3) by $q_0 = H \cdot L/2\pi$ to express Eq.(3) in the form of the relative overtopping quantity, and putting $t' = 2\pi t/T$ to express the integral term of Eq.(3) in non-dimensional form, one eventually obtains

$$q/q_0 = \frac{4\sqrt{2}}{3} \cdot C \cdot \gamma_T^{3/2} \cdot \frac{T\sqrt{gH}}{L} \int_{t_1'}^{t_2'} \left\{ \sin t' - \frac{1}{\gamma_T} \left(\frac{H_C}{H} - \frac{\delta_0}{H} \right) \right\}^{3/2} dt' \quad (4)$$

in which $t_1' = \arcsin \left(\frac{H_C}{H} - \frac{\delta_0}{H} \right) / \gamma_T$ and $t_2' = \pi/2$.

(2) Comparison with the experimental results

The full lines in Figs. 10 through 13 show the calculated results by Eq. (4). The value of $\gamma_T = 0.70$, which is the same value used in the calculations for the reflection coefficient of the box-type wave absorber [4], is used in the calculations. The values of C and δ_0/H in Eq. (4) are assumed to be $C = 0.12$ and $\delta_0/H = 0.50$ in order to fit the calculated results to the experimental results. The height of incident waves used in the calculations except the case of $T = 6.0$ sec is $H = 4.0$ m, which is the average value of the wave heights used in the experiments. For the case of $T = 6.0$ sec, $H = 3.0$ m is used to avoid the excessive wave steepness. The water depth used in the calculations is $h = 12.0$ m, which is about the same value as used in the experiments.

Figs. 10 through 13 show that the calculated curves obtained by the use of Eq. (4) with $C = 0.12$ and $\delta_0/H = 0.50$ are in good agreement with the experimental results. Most of the experimental results with the values of $H_F/H < 0.7$ in Figs. 10 through 13 are larger than the experimental results with the values of $H_F/H \geq 0.7$ and the calculated curves. The reason is that the upper portion of the wave crest just outside the front-wall plunges into the wave chamber over the top of the front-wall, and then it strongly hit the back-wall, to cause large sprays.

Fig. 14.- Effect of Wave Height

The calculated results also show that the effect of the incident wave heights on q/q_0 is not significant in the region of $H_C/H \geq 1.0$, as shown in Fig. 14.

Slit-Type Seawall in the Port of Osaka [2]

The slit-type seawall of 3,700 m length, the cross-section of which is shown in Fig. 15, has been under construction in the sea in the Port of Osaka, where the water depth is about 10 m to 12 m below the D.L., and the height and period of the design wave are $H_{1/3} = 3.3$ m and $T_{1/3} = 7.0$ sec.

Fig. 15.- Cross-Section of Seawall in the Port of Osaka

The width of the wave chamber was taken $l = 3.7$ m to make the relative chamber width, l/L , equal to 0.15 for waves with a period of 4 sec, which occur most frequently when small fishing boats are in operation in the sea. Then the reflection coefficient takes the minimum values, $(K_R)_{\min} = 0.10$ to 0.20. The void ratios of the front-wall and bottom-wall were taken to be $\lambda = 0.22$ and $\lambda' = 0.14$, respectively. The height of the top of the parapet wall was taken D.L. + 6.8 m to make the relative wave overtopping quantity $q/q_0 \approx 1 \times 10^{-3}$ for the design sea level of D.L. + 3.5 m and the design wave, by taking $H_c/H = 1.0$ and $l/L \approx 0.05$, as shown in Fig. 9, for the wave period of $T = 7.0$ sec, which is the period of storm waves during typhoons.

Fig. 16 shows the completed caisson of the seawall, and Figs. 17 and 18 show the upper part and lower part of the seawall taken from the inside of the wave chamber.

PROBABILISTIC DESIGN OF SEA DEFENCES

by W.T. Bakker¹⁾ and J.K. Vrijling²⁾

0. ABSTRACT.

Designs of dikes and dunes according to current Dutch guidelines, based on a deterministic approach, are not consistent with probabilistic philosophy. This statement is amplified in the present paper as a pilot investigation; a rough outline for a probabilistic method of dune and dike computation is given. Numerical comparison of probabilistic and deterministic methods is hampered due to the fact that the results according to the deterministic approach depend on engineering instinct in the choice of boundary conditions and because the probabilistic approach is not as yet operational. Illustrative computations show differences of a factor 1000 in failure probability, starting from dimensioning according to the same standards, following deterministic guidelines.

1. INTRODUCTION.

Sea defences are constructed to safeguard the population against storm surges. The rich tradition in the field of dikes in Holland shows however, that complete safety is unattainable. Realizing this, a method to assess the probability of failure (or safety) of a system of sea defences has to be developed. All possible causes of failure have to be analysed and consequences determined. For this aim, the "fault tree" is a good tool (figure 1).

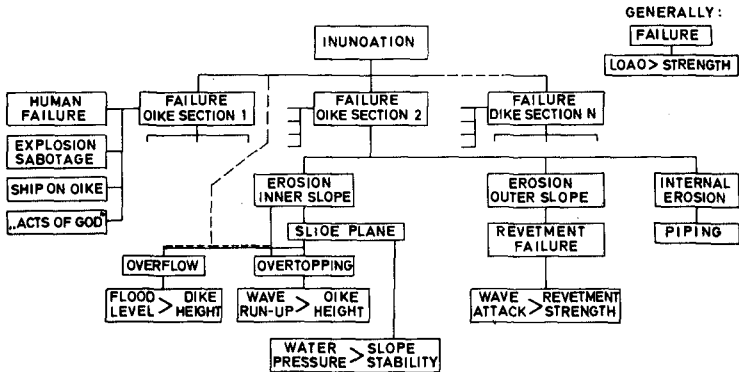

Fig. 1 Simplified fault tree for a dike circle, consisting of N sections.

1) Head of the Advisory Department Flushing, Rijkswaterstaat, Netherlands

2) Project Engineer, Delta Department, Rijkswaterstaat, Netherlands.

The fault tree combines four categories of events, that may cause the inundation of a polder:

- human failure; management faults;
- aggressive human action;
- "acts of God";
- technical failure of structural elements.

Although all four categories of events are equally important for the overall safety of the polder, the engineers responsibility is mainly limited to the technical and structural aspects. Therefore this paper deals only with technical failure of structural elements.

In the fault tree, all possible modes of failure of elements can eventually lead to the failure of a dike section and to inundation. This reflects good engineering practice, where attention should be given to all failure mechanisms of the construction under design. A common approach in the design of concrete or steel structures.

In dike and dune design, limit-state analysis is not yet established, although it has many useful features in clarifying technical problems as will be shown in this paper.

The ultimate limit-state (u.l.s.) of a failure mechanism describes the situation, wherein the acting loads are just balanced by the strength of the construction. The probability of occurrence of this u.l.s. for each technical failure mechanism can be found from a "convolution integral" (CIRIA, 1976).

Starting from a probability density function (p.d.f.) of the boundary condition one finds with a transferfunction the p.d.f. of the loads on the structural element, called $f_L(\lambda)$, being a function of the load λ . Combining the last-mentioned p.d.f. with the p.d.f. of the strength s of the structural section, called $f_S(s)$, gives the failure probability p_f of the element:

$$p_f = \int_0^{\infty} \int_0^{\lambda} f_S(s) ds f_L(\lambda) d\lambda \quad (1.1)$$

Fig. 2 The concept of the ultimate limit-state of a failure mechanism.

This concept is applicable in coastal engineering, when the narrow definitions of load and strength are widened to potential threat and resistance. The adapted concept of the ultimate limit-state of a failure mechanism is given in figure 2.

First, all basic variables that play a role in the theoretical relationships on which the design of a particular element is based, have to be specified. The main categories of basic variables are "resistance" and "potential threat". The category contains basic variables

that can be defined as threatening boundary conditions for the construction e.g. wind velocity extremes, water levels or a ship's mass.

The resistance of the construction is derived from the basic variables by means of theoretical models. The relations that are used to derive the potential threat from the boundary conditions are called transfer functions.

The safety margin between "potential threat" and "resistance" must guarantee a sufficiently low probability of failure.

Three different philosophies are currently available in construction practice:

1. deterministic philosophy;
2. quasi-probabilistic philosophy;
3. probabilistic philosophy.

The present dutch guidelines for dike and dune design follow a philosophy, that lies between the deterministic and the quasi-probabilistic approach. The ultimate potential threat is derived from extreme storm surge levels with a very low probability of exceedance (1% per century) and equated with the average resistance of the dike without any apparent safety margin. In this paper it will be shown that designs according these guidelines are not consistent with the probabilistic philosophy.

Beside the ultimate limit-state, there are situations, where the ever continuing presence of a load causes a deterioration of constructional resistance in time, without any imminent danger of failure (e.g. fatigue, creep).

However, this deterioration of constructional resistance can cause an unexpected failure in extreme conditions. The serviceability of the construction can also diminish without leading to collapse (e.g. settlements, deformation).

The serviceability limit-state is principally treated in the same way as the ultimate limit-state. However, attention is rather given to loading situations that occur very frequently during the lifetime of the construction than to extreme conditions.

A point of great practical importance is that a serviceability limit-state, i.e. a deterioration of constructional resistance in time, can be solved in two ways:

1. improving the resistance of the construction to guarantee sufficient strength during the service life;
2. the deterioration of constructional resistance can be controlled by inspection and maintenance procedures.

The second solution, however, introduces a certain non-technical risk, because constructional safety depends on the care of other people.

In some fields of dike and dune design the application of the limit-state conception as described above is cumbersome because a theoretical description is not available. This is especially true for erosion and scour problems, which govern the design of dunes and dikes. Neither transfer functions to transform waves and tide into forces on grains nor a theoretical model for the stability of grains are known.

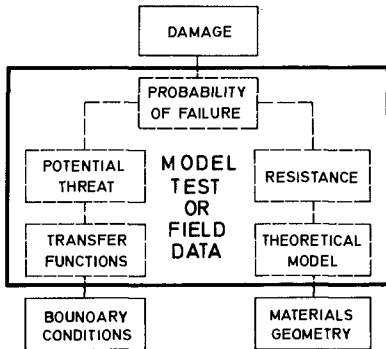

Fig. 3 The solution of a limit state by black box approach.

simplified dike designs according to the present dutch guidelines will be made. Afterwards the design will be checked with probabilistic methods.

As an example, two alternative designs situated in the mouth of the Eastern Scheldt, one facing Northwesterly storms and the other, a dike with a southeastern orientation (no wave attack), will be studied.

According to the guidelines (DELTA COMMITTEE, 1960) the starting point of the design of a dike that protects economically less important regions is a storm surge level with a frequency of exceedance of $2.5 \cdot 10^{-4}$ p.a. This storm surge level is determined by statistical extrapolation of empirical data at NAP +5.50 m. The design wave is also found by statistical extrapolation from wave data (vide cross in figure 6):

$$H_s = 5.00 \text{ m} \quad T_z = 7.7 \text{ sec.} \quad T_p = 12.0 \text{ sec.}$$

where:

H_s = significant wave height
 T_z^s = mean zero crossing period
 T_p = peak period of the wave spectrum

To calculate the wave run-up, a transfer function of the following form¹⁾ is applied (T.A.W., 1972):

1) In practical design calculations the wave run-up is evaluated with the formula $r_{2\%} = 8 H_s \tan \alpha$, which gives smaller values.- Theoretically, lastmentioned formula is only valid for a wave steepness $H/L \sim 0.05$. However, up'til now, this theoretical error has not caused serious problems due to run-up reducing phenomena.

To overcome this problem, a scheme to simulate all possible combinations of natural boundary conditions in a scale model of the construction and to correlate the damage done to the boundary conditions can be developed (figure 3). Of course, field data of boundary conditions, resistance parameters and damage are preferred as base for correlation, if they are available in sufficient amount.

2. CALCULATION OF DIKE HEIGHT ACCORDING TO THE PRESENT DUTCH GUIDE LINES.

As an illustration of the concepts developed in the foregoing paragraph three simplified dike designs according to the present dutch guidelines will be made. Afterwards the design will be checked with probabilistic methods.

simplified dike designs according to the present dutch guidelines will be made. Afterwards the design will be checked with probabilistic methods.

As an example, two alternative designs situated in the mouth of the Eastern Scheldt, one facing Northwesterly storms and the other, a dike with a southeastern orientation (no wave attack), will be studied.

According to the guidelines (DELTA COMMITTEE, 1960) the starting point of the design of a dike that protects economically less important regions is a storm surge level with a frequency of exceedance of $2.5 \cdot 10^{-4}$ p.a. This storm surge level is determined by statistical extrapolation of empirical data at NAP +5.50 m. The design wave is also found by statistical extrapolation from wave data (vide cross in figure 6):

$$H_s = 5.00 \text{ m} \quad T_z = 7.7 \text{ sec.} \quad T_p = 12.0 \text{ sec.}$$

where:

H_s = significant wave height
 T_z^s = mean zero crossing period
 T_p = peak period of the wave spectrum

To calculate the wave run-up, a transfer function of the following form¹⁾ is applied (T.A.W., 1972):

1) In practical design calculations the wave run-up is evaluated with the formula $r_{2\%} = 8 H_s \tan \alpha$, which gives smaller values.- Theoretically, lastmentioned formula is only valid for a wave steepness $H/L \sim 0.05$. However, up'til now, this theoretical error has not caused serious problems due to run-up reducing phenomena.

$$r_{2\%} = 0.7 T_p \sqrt{g H_s} \tan \alpha \quad (2.1)$$

where:

g = acceleration of gravity
 α = angle of the outer slope
 $r_{2\%}$ = wave run-up, that is exceeded
 by 2% of the waves

A minimum wave run-up of 0.50 m always has to be accounted for. Seiches and gust bump are estimated to have amplitudes of 0.24 and 0.25 m respectively. According to the guidelines, the amplitude of the gust bump B may be reduced if a combination with wave run-up occurs. The advised reduction R is:

$$R = \frac{B}{B + \xi \cdot r_{2\%}} \quad (2.2)$$

Now the minimum dike height can be calculated. However, three factors affect the height of the dike during its lifetime, i.e. secular change of the chartdatum (NAP), settlement of the dike and settlement of the deep soil. The first effect is estimated at 0.10 m per century (DELTA COMMITTEE, 1960). Soil-mechanical calculations have to provide an insight in the amount of settlement.

The dike height is now determined by the addition of all phenomena (table 2.1).

Table 2.1	transfer function	NW slope 1 : 6	NW slope 1 : 8	SE slope 1 : ?
storm surge level (NAP)		+ 5.50 m	+ 5.50 m	+ 5.50 m
wave run-up	$r_{2\%} = 0.7 T_p \sqrt{g H_s} \tan \alpha$	9.90 m	7.42 m	0.50 m
seiches	S	0.24 m	0.24 m	0.24 m
gust bump	$\frac{B}{B + \xi r_{2\%}} \cdot B$	0.03 m	0.04 m	0.18 m
design water level z (NAP)		+15.67 m	+13.20 m	+ 6.42 m
change of chart datum		0.15 m	0.15 m	0.15 m
settlement dike		0.10 m	0.10 m	0.10 m
settlement subsoil		0.50 m	0.50 m	0.50 m
dike height $\xi = \frac{1}{5}$ (NAP)		+16.42 m	+13.95 m	+ 7.17 m

2.1 Probabilistic calculation and evaluation of the dike height.

In the designs of the previous paragraph all parameters, except the storm surge level and the waves, have been thought of as specified constants. For an advanced analysis, all parameters should be specified as stochastic, which implies that their exact magnitude is not known with certainty.

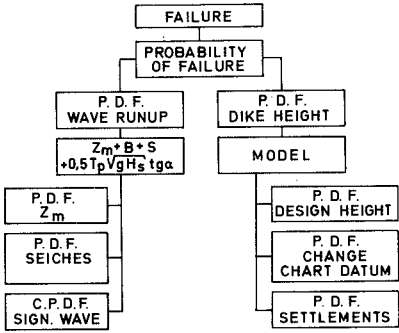

Fig. 4 Ultimate limit-state caused by wave run-up.

In figure 4 the ultimate limit-state caused by wave run-up is given in the schematical way developed in par. 1, whereby all relevant parameters are specified as probability density functions or distributions.

The distribution of the storm surge level z is based on the already mentioned set of empirical data. After a correction for the influence due to the Delta Works, the distribution has the form:

$$P_r (z > z) = \exp(-2.3 \frac{z-2.94}{0.696}) \quad (2.3)$$

$$z = [m]$$

Due to the extrapolation of the distribution to very low probabilities of exceedance, some uncertainty is introduced which is supposed to be normally distributed. The standard deviation is defined as a function of the storm surge level (DELTA COMMITTEE, 1960).

$$\sigma_z \geq 0.11 (z - 2.25) \quad \sigma_z = [m] \quad (2.4)$$

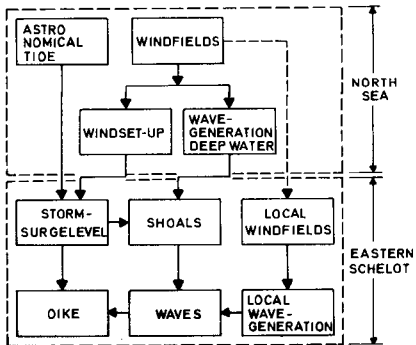

Fig. 5 Model to predict the sea state in the Eastern Scheldt.

A study of the sea states in the Eastern Scheldt has shown that the wave energy comes from two sources (VRIJLING and BRUINSMA, 1980).

1. Wave energy penetrates from the North Sea. This energy is reduced as a function of the water level by breaking on the shoals in front of the coast.
2. Local windfields generate wave energy in the area between the shoals and the dike.

This system analysis enabled the determination of the probability density function of the wave spectrum $S_{\eta\eta}$ as a function of the storm surge level z_m . Figure 6 shows the conditional probability density function of wave energy and storm surge level.

Now the joint probability density function of wave spectra and storm surge levels can be determined:

$$p(S_{\eta\eta} \cdot z) = p(z) \cdot p(S_{\eta\eta} | z = z)$$

Seiches in dutch coastal waters are irregular waves with a period of 10 to 50 minutes, that show no correlation with the storm surge level.

Assuming a Rayleigh distribution for the relative maxima and estimating the number of maxima during a storm at N, the probability density function of the highest maximum is (BATTJES 1972):

Fig. 6 Conditional probability density function of wave energy and storm surge level.

$$p(S_{max}) = \frac{S}{m_{0S}} \cdot N \cdot \exp\left(-\frac{S^2}{2 m_{0S}}\right) \cdot \exp\left(-N \exp\left(-\frac{S^2}{2 m_{0S}}\right)\right) \quad (2.5)$$

where:

$$m_{0S} = 0.08 \text{ m}$$

$$N = 12$$

This function can be approximated by a Gaussian distribution with the parameters:

$$\mu_S = 0.18 \text{ m}$$

$$\sigma_S = 0.04 \text{ m}$$

Gust bumps are single pronounced elevations of sea level. Lacking statistical data, a Gaussian distribution is assumed with the parameters:

$$\mu_b = 0.15 \text{ m}$$

$$\sigma_b = 0.05 \text{ m}$$

Now the natural boundary conditions are reduced to three dimensions by combining the uncertainty of the exceedance curve of storm surge level, the seiche and the gust bump in one variable h. Assuming statistical independence the result is

$$\mu_h = \mu_S + \mu_b = 0.33 \text{ m} \quad \sigma_h = \sqrt{\sigma_Z^2 + \sigma_S^2 + \sigma_b^2} \quad (2.6)$$

In the case studied here the transfer functions are trivial, except for the transformation from waves into wave run-up. A relation similar to (2.1) is used, which contains more spectral information (T.A.W., 1972):

$$r_{sign} = \frac{\gamma}{1.40} T_p \sqrt{g H_{sign}} \tan \alpha \quad \text{in which } \gamma = 0.48 + 0.37 \epsilon \quad (2.7)$$

where

$$\varepsilon = \frac{m_0 m_4 - m_2^2}{m_0 m_4} \quad \text{spectral width}$$

$$m_n = n - \text{th spectral moment}$$

Further it is assumed that the wave run-up r is Rayleigh-distributed.

$$P_r(\underline{r} > r) = \exp\left(-2\left(\frac{r}{r_{\text{sign}}}\right)^2\right) \quad (2.8)$$

Damage will only be done if the wave run-up exceeds the dike height several times during a storm. Based on the binomial distribution one finds for the probability distribution of wave run-up, which exceeds a given level at least m times in a storm containing N waves:

$$P(r_m) = 1 - \sum_{k=0}^{m-1} \frac{N!}{k!(N-k)!} \cdot P_r(\underline{r} > r)^k \cdot \{1 - P_r(\underline{r} > r)\}^{N-k} \quad (2.9)$$

This distribution is conditional on the occurrence of the sea state $S_{\eta\eta}$.

For numerical reasons the three-dimensional space $z, S_{\eta\eta}, h$ of natural boundary conditions is divided in small elements with dimensions $\Delta z, \Delta S_{\eta\eta}$ and Δh . The probability of occurrence $P_r(z, S_{\eta\eta}, h)$ of a combination of boundary conditions falling within these elements is:

$$P_r(z, S_{\eta\eta}, h) = p_r(z) \cdot p_r(S_{\eta\eta}|z) \cdot p_r(h|z) \quad (2.10)$$

where $p_r(z)$, $p_r(S_{\eta\eta}|z)$ and $p_r(h|z)$ denote the respective (conditional) probability densities times Δz , $\Delta S_{\eta\eta}$ and Δh respectively.

The potential threat, representative for this element now can be found by adding the storm surge level z and the seiche-gust bump combination h -giving together the still-water level z_m - and adding the wave m run-up r over and above that:

$$\tau = z + h + r \quad (2.11)$$

The probability of occurrence is evaluated as:

$$P_r(\tau) = P_r(z, S_{\eta\eta}, h) \cdot p(r_m | S_{\eta\eta}) \Delta z \quad (2.12)$$

Now the joint probability density function of still water levels and m -times exceeded wave run-up heights can be found by repeating the calculation for all possible combinations of boundary conditions.

The probability of exceedance of a specific potential threat can now be evaluated by integrating the two dimensional probability density function of still water levels and wave run-ups (figure 7).

$$P_r(\underline{r} > \tau) = \iint_{\underline{r} > \tau} p(z_m, r_m) dz_m dr_m \quad (2.13)$$

The probability of exceedance curve, which is numerically evaluated, appears to be of the form:

$$P_r(\tau > \tau) = \exp\{(8.36 - \tau) / 0.452\}$$

$$\tau = [m] \quad (2.14)$$

Having derived the probability of exceedance curve, it is interesting to compare the potential threat with a probability of exceedance of $2.5 \cdot 10^{-4}$ p.a. with the design level calculated according to the guidelines (table 2.2).

Fig. 7 Probability of wave run-up as part of the probability mountain.

	slope 1 : 6	slope 1 : 8	SE	
guidelines	NAP +15.67	NAP +13.20	NAP +6.42	heights in m
probabilistic	NAP +12.21	NAP +10.50	NAP +5.95	

An even more interesting experiment is to evaluate the probability of failure of the simplified dike designs of the preceding paragraph. Because the real failure mechanisms are not expressed in mathematical form, failure will be arbitrarily defined as the exceedance of the dike height by at least 12 wave run-ups during a storm.

On the side of the "resistance", the height of the dike also presents some uncertainty. When a storm occurs at some time in the future the effects, that are accounted for in the difference between the planned dike height and the design water level, are realized to some uncertain extent. In fact, the theory of the serviceability limit-state developed in ch. 1 applies.

heights in m levels: NAP	NW		SE	σ	cp table 2.1
	slope 1 : 6	slope 1 : 8	SE		
dike height	+16.42	+13.95	+ 7.17		
change of chartdatum	- 0.10	- 0.10	- 0.10	0.025	0.15
settlement dike	- 0.07	- 0.07	- 0.07	0.02	0.10
settlement subsoil	- 0.35	- 0.35	- 0.35	0.10	0.50
tolerance	-	-	-	0.10	-
	+15.90	+13.43	+ 6.65	0.14	0.75

This means, that the real dike height differs from the planned one unless a proper maintenance scheme is carried out. The real height can be approximated by normal distribution (table 2.3). Now the probability of failure caused by overtopping of the dike can be evaluated by integrating:

$$P_r(\text{failure}) = \int_0^{\infty} P_{\tau}(x) \cdot p_{\text{dike height}}(x) \cdot dx \quad (2.15)$$

$$= \int_0^{\infty} e^{-\frac{8.36-x}{0.452}} * \frac{1}{0.145\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{15.92-x}{0.145}\right)^2} dx$$

The probability of failure is given in table 2.4.

Table 2.4

	NW		SE
	slope 1 : 6	slope 1 : 8	
$P_r(\text{failure})$	$5.8 * 10^{-8}$	$2.2 * 10^{-7}$	$4.1 * 10^{-5}$

Fig. 8 Exceedance probability of wave run-up as function of revetment slope.

From the results (figure 8) it appears that the probability of overtopping of the dikes designed according the guidelines is not of the same order for various cases. Reducing the dike height by flattening the outer slope increased the chance of overtopping c.q. failure by a factor of nearly 4. The dike facing SE is even more unsafe. Here the potential threat, formed by the still water level without waves exceeding the dike height, will certainly cause inundation. So failure of this dike is at least 1000 times likelier than the dikes facing North West.

This illustrates that, under simplifying assumptions, designs according the present dutch guidelines are not able to be compared without further attention.

3. DUNE DESIGN.

At the same place, where in chapter 2 a dike has been designed, a dune will now be constructed.

3.1 Calculation of dune breadth according to the present Dutch Guideline.

The present Dutch "guideline for the Calculation of Dune Erosion during Storm Conditions" is based on the following assumptions (v.d. GRAAFF (1977) and VELLINGA (1978)):

1^o During a storm surge the coastal profile is reshaped, to a uniform profile, the "stormprofile", described by the formula:

$$y = 0.415 (\lambda x + 4.5)^{0.5} - 0.88 \quad (3.1)$$

in which:

y = depth in meters below the maximum surge level

x = distance in meters from the point of the profile lying at maximum surge level

λ = coefficient, lying between .8 and 1.25, dependent on the grain diameter; λ equals 1 when $D_m = 200\mu$

The profile is given in figure 11.

2^o The depth d_b to which the storm profile applies is equal to 1.28 times the height of the significant wave H_s at the breaking point. Thus defining the "width of spreading" B as the width of the stormprofile, over which the eroded sand from the dunes settles, one finds inversely from (3.1):

$$B = \frac{(2.41 d_b + 2.12)^2}{\lambda} - \frac{4.5}{\lambda} \quad (3.2)$$

3^o The inclination of the outer slope of the eroded dune is assumed to be 45°. The seaward side of the outer slope i.e. the "foot" of the dune-coincides with the origin of the x,y-coordinate system.

4^o During the storm surge, the coastal profile is reshaped, in such a way that the total area of the eroded sand equals the area of the settled sand.

5^o Losses of sand, either to the regions outside the breaker zone, or in landward direction or by a longshore gradient of the littoral drift are neglected.

With respect to necessary dune dimensions, one should take into account a very low beach level in the initial situation before the surge; after the surge a dune breadth of 10 m at surge level should remain.

Starting from the same data as in chapter 2.1, i.e. $H_s = 5.0$ m, a surge level of N.A.P. + 5.50 m and a beach level lying .30 m lower than the mean beach level, for a dune, which has to offer Delta protection during 10, 20 or 50 years respectively, one finds the dune dimensions given in table 3.1.

	MAINTENANCE PERIOD		
	10y	20y	50y
storm erosion	44.58	44.58	44.58
yearly erosion	3.75	7.50	18.75
minimum body	10.00	10.00	10.00
dune dimension	58.33	62.08	73.33

3.2 Probabilistic calculation and evaluation of the dune breadth.

3.2.1 General considerations.

The technical failure mechanisms, which can be distinguished for a dune, acting as sea defence, are principally the same as those for dikes: a. failure outer slope c. failure inner slope
b. submerging d. internal failure

With respect to d, internal failure, apart from failure by hydrologic overpressure, one should also take rabbit holes into consideration as these may occur in the most landward side the dunes.

In the following, the failure mechanism mentioned in b and c are combined by assuming that there will be inundation when the water level rises above a certain given level z_s . This water level will be lower than the dune height, because of wave set-up and wave run-up.

It will be assumed, that a certain "body" of dune should remain, of which the width is assumed to be known, in order to avoid internal failure (figure 9).

The most important failure mechanism for dunes is the "failure" of the outer slope. Therefore this mechanism will be considered in the first place.

Fig. 9 Definitions of load and strength.

Generally, failure occurs when the load on a construction is larger than the strength. The simultaneous probability of this occurrence is found by convolution of the probability density functions of load and strength. The following definitions of load and strength will be used (see also figure 9):

- The load e_s is defined as the dune erosion, caused by surges combined with waves.
- The strength R_t at time t is defined as the dune breadth, above a certain minimum, necessary to avoid failure mechanisms other than erosion of the outer slope.

Consider first the strength R_t , composed of three components.

$$R_t = R_0 + \epsilon_t + \epsilon_b \quad (3.3)$$

It depends upon:

- a. the initial conditions R_0 ;
- b. the effect ϵ_t of gradual erosion¹⁾ and, in the event, periodical supply;
- c. the effect on the erosion ϵ_b of the beach level at the moment of the occurrence of a severe storm.

Fig. 10 Location of the coastline in the course at time.

With respect to gradual erosion, it is assumed that the future trend can be found in principle by linear extrapolation of the trend in the past:

$$\epsilon_t = \underline{a} t + \underline{b} \quad (3.4)$$

Figure 10 gives an example: it shows the location of the coastline in a certain range, perpendicular to the coast, with respect to a reference pole; the "coastline" is defined as the mean between the high- and low-water line.

However, given this registration, the trend cannot be properly determined, and a uncertainty remains.

Therefore \underline{a} and \underline{b} are coefficients with a stochastic character. $E(\underline{a})$, $\sigma(\underline{a})$ and $\sigma(\underline{b})$ are found by linear regression from the registration in the course of time, of the coastline; $E(\underline{b})$ is assumed zero and determines the reference, from which ϵ_t is taken.

The dune erosion ϵ_s during storm conditions depends upon the beach level ζ at the moment of the storm. In the mathematical model, this may be simulated by assigning to the strength R_t a normally distributed stochastic component ϵ_b with mean zero and standard deviation $\sigma(\epsilon_b)$, which is related to the standard deviation of the beach level $\sigma(\zeta)$ in the following way:

$$\sigma(\epsilon_b) = \frac{\partial \epsilon_s}{\partial \zeta} \cdot \sigma(\zeta) \quad (3.5)$$

The used data and transfer functions are mentioned in table 3.2.

1) In this paper the dimensioning of an eroding dune will be considered, as this case is more intricate than an accreting dune.

Table 3.2 Data and transfer functions used for finding $E(\underline{R}_t)$ and $\sigma(\underline{R}_t)$.

$E(\underline{a})$		-0.375	m/y	
$\sigma(\underline{a})$		0.326	m/y	$\sigma(\underline{\epsilon})$ 0.30 m
$E(\underline{b})$		0		$\frac{\partial \underline{\epsilon}_s}{\partial \tau}$ 11.79
$\sigma(\underline{b})$		7.21	m	
$E(\underline{\epsilon}_t)$	$E(\underline{a}) \cdot t + E(\underline{b})$	-0.375 t	m	$\sigma(\underline{\epsilon}_b)$ 3.54 m
$\sigma(\underline{\epsilon}_t)$	$\sqrt{\sigma^2(\underline{a}) \cdot t^2 + \sigma^2(\underline{b})}$	$\sqrt{0.326^2 t^2 + 7.21^2}$	m	

From (3.3) and (3.4) one finds, assuming $\underline{\epsilon}_t$ and $\underline{\epsilon}_b$ statistically independent:

$$E(\underline{R}_t) = R_0 + E(\underline{a}) \cdot t$$

$$\sigma^2(\underline{R}_t) = \sigma^2(\underline{a}) \cdot t^2 + \sigma^2(\underline{b}) + \sigma^2(\underline{\epsilon}_b) \tag{3.6}$$

Further considerations concerning the strength depend upon the applied strategy and are given in chapter 3.2.2 and 3.2.3. Consider next the load.

Replacing in figure 5 the dike by a dune and using the same schedule as explained in chapter 2.1 for all possible combinations of still water level z_m and wave heights H_s the dune erosion ϵ_s can be numerically calculated using the assumptions 1° to 5°, given in chapter 3.1.

Thus, one finds the probability distribution for the dune erosion by surge (cf (2.14)):

$$P_r = (\epsilon_s > \epsilon_s) = \int_{\epsilon_s} \int p(z_m, H_s) d z_m d H_s \tag{3.7}$$

Starting from the initial profile, given in figure 11, the distribution found is shown in figure 12.

Fig. 11 Dune profile before and after storm surge.

Fig. 12 Exceedance probability of dune erosion during storm surge.

Table 3.3
(values in m)

	MAINTENANCE PERIOD		
	10y	20y	50y
$E(\underline{R}_t)$	$R_0 - 3.75$	$R_0 - 7.50$	$R_0 - 18.75$
$\sigma(\underline{R}_t)$	8.67	10.35	18.17

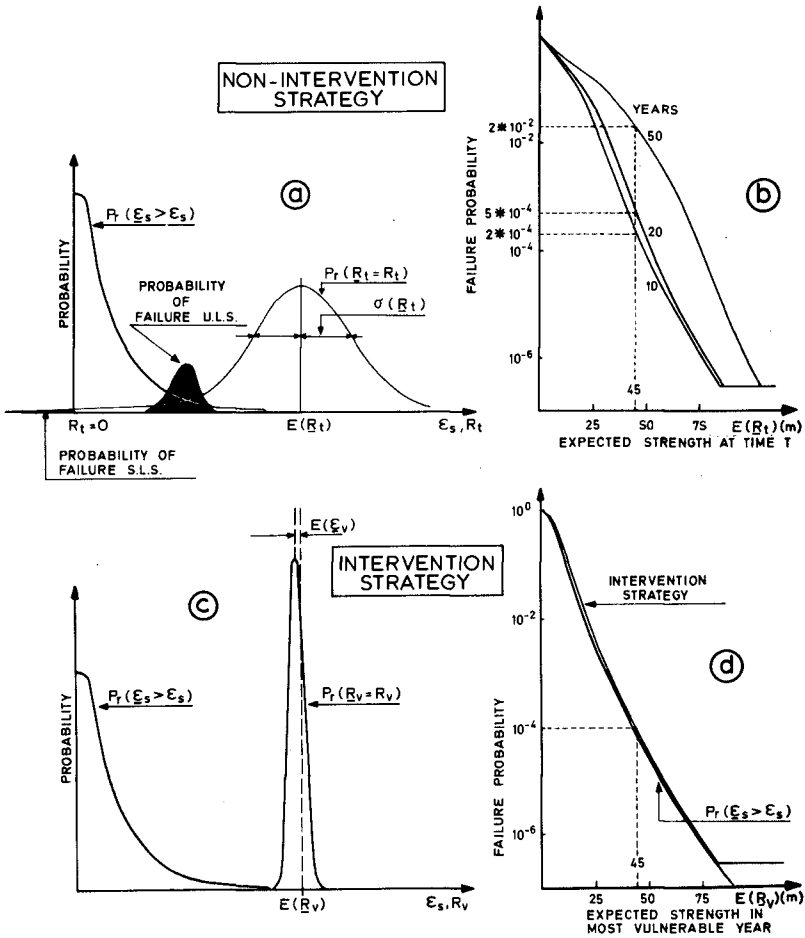

Fig. 13 Failure probability according to non-intervention and intervention theory.

3.2.2 Non-intervention strategy.

Now load and resistance will be combined.

In the numerical model, three examples have been elaborated starting from a period of non-intervention in the coastal processes of 10, 20 and 50 years respectively. Table 3.3 gives $E(R_t)$ and $\sigma(R_t)$ after these periods. Figure 13a shows an example of, on the one hand the probability density of the strength R_t , and, on the other hand the exceedance probability of the load ϵ_t . The figure shows two classes of failure: the ultimate limit-state, where the load surpasses the strength, and the serviceability limit-state, where the dune collapses, just because the gradual erosion is more than expected.

By convolution, one can calculate the total probability of failure as a function of the expected strength $E(R_t)$ at time t (figure 13b).

The upper part of the curves has a Gaussian character, determined mainly by the serviceability limit-state (gradual erosion more than expected). The middle part has a more or less negative-exponential character, determined by the ultimate limit-state. The lowest part, the horizontal line, is determined by the risk of submergence of the dunes.

The results are discussed in the evaluation.

3.2.3 Intervention strategy.

This strategy implies a sand supply to a seaward line 0 as soon as the dune foot surpasses a landward line L in landward direction (figure 14a,b). In the example treated, the line L has been chosen in such a way, that when the dune foot coincides with L, the strength necessary according to the deterministic approach was just available (i.e., that R_t equals 44.58 m, cf table 3.1). It has been assumed, that if in one year measures, that the eroding dune foot surpasses the limit L in landward direction, it takes another year for preparing and carrying out the dune replenishment. The distance OL depends upon the desired expectation of the return period of sand supply. Starting from the assumptions given in figure 14, one finds a probability density of the location of the dune foot in the course of many years as sketched in figure 14c, either by a numerical Monte Carlo simulation, or by analytical computations (BAKKER 1980). As it is the yearly probability of inundation that counts, the situation has to be considered in the year in which the dune is most vulnerable¹⁾. Figure 14c shows (interrupted line) the probability density of the location of the dune foot, under the condition, that it is measured in the year after the one, in which the landward surpassing of the line L was recorded and on the other hand before the supply to line 0 took place.

1) This means that in other years a "hidden safety" will be present. In this way, the average safety over, say 100 years of a dune will be higher than the one for a dike (with respect to this aspect).

Fig. 14 Probability density of dune foot location in the year that the dune is most vulnerable.

Figure 14d gives the same probability density, but now taking into account, that the rate of erosion a cannot be properly determined from the measurements, as stated in chapter 3.2.1. To this end, the computation of the last-mentioned probability density has been repeated for various values of the yearly expected erosion, assuming fixed values for the yearly variation of the erosion $\sigma(\epsilon_n)$ and for OL . After this, these probability density distributions are combined again, by giving each a weight, proportional to the occurrence.

probability -found from $E(a)$ and $\sigma(a)$, table 3.2- and adding. The result found does not depend very much on OL, when the expected return period is not too small. Analogous to figure 13a and 13b, figures 13c and 13d are constructed, where R_v , the strength in the year the dune is the most vulnerable, replaces R_t from (3.3):

$$R_v = R_L + \epsilon_v + \epsilon_b \quad (3.8)$$

in which R_L denotes the strength when the dune foot coincides with the line L; ϵ_v (of which the probability density is shown in figure 14d, indicates the gradual erosion with respect to L in the most vulnerable year and ϵ_b has the same meaning as in (3.3). In the example, $E(\epsilon_v)$ and $\sigma(\epsilon_v)$ are found to be 1.05 m and 1.31 m respectively.

Evidently, the standard deviation of R_v in figure 13c is much less than that of R_t in figure 13a. Consequently, as figure 13d shows, the failure probability according to the intervention strategy is nearly determined by the probability of erosion, $P_r(\epsilon_v > \epsilon_s)$, during storm surge. It shows that for equal values of $E(R_t)$ and $E(R_v)$, the intervention strategy (with the given reaction time of 1 year) gives more safety than the non-intervention strategy.

3.3 Evaluation of deterministic and probabilistic approach of dune breadth computation.

In chapter 3.1, a value of 44.58 m for the dune erosion during "super surge" with exceedance probability $2.5 \cdot 10^{-4}$ was found. Following the non-intervention strategy this value should be compared with the expected necessary strength $E(R_t)$ at time t, given in figures 13a,b.

Then, for $t = 10, 20$ and 50 years, figure 13b gives probabilities of failure of $2 \cdot 10^{-4}$, $5 \cdot 10^{-4}$ and $2 \cdot 10^{-2}$ p.a. respectively, when $E(R_t)$ equals 44.58 m.

Following the intervention theory, the wanted expectation of the strength $E(R_v)$ determines the location of line L (cq. (3.8)). When $E(R_v)$ equals 44.58 m, figure 13d gives the probability of failure in the year the dune is the most vulnerable as $8 \cdot 10^{-5}$ p.a.

Table 3.4

	MAINTENANCE PERIOD			
	10y	20y	50y	
dune breadth in m acc. to guideline	58.33	62.08	73.33	exceedance prob. $2.5 \cdot 10^{-4}$
failure probability for above-ment. dune	$2 \cdot 10^{-4}$ $8 \cdot 10^{-5}$	$5 \cdot 10^{-4}$ $8 \cdot 10^{-5}$	$2 \cdot 10^{-2}$ $8 \cdot 10^{-5}$	non-intervention intervention
dune breadth in m acc. prob. theory	57.75	65.50	89.0	non-intervention
failure prob. $2.5 \cdot 10^{-4}$	50.25	54.00	65.25	intervention

1) positive in seaward direction.

In table 3.4 these values have been summarized. Furthermore this table gives the dune width following the guide line as given in table 3.1.

Another comparison can be made in a way similar to that in table 2.1, i.e. instead of fixing the strength $E(R_t)$ and finding the failure probability, one fixes the failure probability and finds the necessary strength $E(R_t)$. Choosing a probability of $2.5 \cdot 10^{-4}$, as has been done for a dike (table 2.2), the results are summarized in table 3.4.

The intervention strategy results in smaller dune breadth for achieving the same safety as in the deterministic approach, because of the rather extreme choice of the wave boundary condition ($H_S = 5$ m where $z = +5.50$ m NAP, cf figure 6)¹⁾. As figure 13d shows, during storm surge the erosion ϵ_S with exceedance probability $2.5 \cdot 10^{-4}$ equals 36.5 m instead of 44.58 m, as found from the deterministic approach (table 3.1); this illustrates the fact that the wave height $H_S = 5$ m is too high to be representative. Apart from this fact, it shows, that in the case non-intervention strategy is applied, the deterministic method gives values too low, especially for long return periods.

4. DISCUSSION.

The theory, developed in this paper is far from operational. Further developments are in preparation in working groups of the Dutch Technical Advisory Committee on Water Defences. Questions which remain to be solved are:

- a. The failure probability of a sea defence system, surrounding a protected area²⁾ should be less than the probability of a (super) surge, which the system in any case should be able to withstand³⁾. Standards will have to be made for the allowable risk to areas to be protected.
- b. In the paper, only the probability of failure of the sea defence system in one cross-section is considered. Considering n cross-sections in a sea defence circle, the risk will be multiplied by a factor n , unless failure of one section implies failure of another. The length of the circle will affect the dimensions.
- c. The assumption of failure of a dike by 12 wave run-ups is quite unsatisfactory: here soil mechanics and hydraulics (overflow discharge) will have to come into the picture.

1) It may be pointed out, that this wave height was originally a boundary condition for the storm surge barrier. Thus it is clear, that a "safe" value has been chosen. For dimensioning of dunes in the same region a less pessimistic estimate is usual. This illustrates that the accuracy and the result of a deterministic approach depends upon (subjective) "engineers instinct".

2) This will be called a "sea defence circle".

3) DELTACOMMITTEE (1960): to withstand: each surge 10^{-4} p.a.; failure probability: $8 \cdot 10^{-6}$ p.a.; storm surge barrier project group (1979): failure probability storm surge barrier 10^{-7} p.a.

- d. With respect to dunes, the expectation and the variation of the width of spreading B (chapter 3.1 and 2^o) should replace eq (3.3). The failure mechanisms b, c and d (chapter 3.2.1) should be considered in more detail.

Considering the method as a whole, it may be pointed out that inaccuracy or uncertainty is translated into extra dimensions of the sea defence system. This gives an operational tool for steering coastal research, as the benefit of this research can be rated and weighted against the costs.

5. CONCLUSIONS.

- a. The probabilistic method is more consistent than the deterministic method.
- . Failure probability may differ considerably for various constructions, when using the same deterministic standards.
- b. The probabilistic approach offers more opportunity for taking "hidden safeties" into account,
- . the uncertainty in structural strength, including the effect of various strategies of maintenance;
 - . a better comparison is found for the safety of dunes and dikes.
- c. The method gives a general approach to the goal pursued: safety for the hinterland.
- . it gives a better insight in the relationships between the various failure mechanisms and better evaluation of the failure mechanisms itself;
 - . one is obliged to trace non-technical failure mechanisms.
- d. The financial value of accuracy and maintenance can be determined. This gives a tool for steering coastal research.

6. ACKNOWLEDGEMENT.

This paper is based upon a report of a preliminary working group of the Dutch Technical Advisory Committee on Water Defences (1979). The authors wish to thank the other contributors of this working group. Also the effect of discussions in other groups is gratefully acknowledged.

SYNOPSIS

The title of the paper contains two important key words - CONSTRUCTION and ISLAND. The techniques for safe and economical construction of an island breakwater located some distance from the shore in exposed waters are radically different from the techniques required for conventional breakwaters with one end attached to the land. The differences in construction technique are so profound as to change the preferred basic design selection from rubble mound to caissons.

The paper discusses:-

1. The circumstances in which island breakwaters will become increasingly necessary for unloading of bulk ships.
2. Reasons why prefabricated caisson breakwaters are preferable for construction in an offshore situation.
3. The economy to be gained by using the caissons as the structural support for ship unloading machinery.
4. A consequent necessity to develop a caisson breakwater configuration with adequate design criteria to ensure total safety of the equipment supported on it.
5. A research program aimed at deriving these criteria.

INTRODUCTION

The concepts discussed in this paper are based on the experience of Connell Eddie & Associates in the planning of two bulk unloading terminals, one in the Mediterranean and one in Western Australia. Both require deep water for large ships, and located 1500-2000 metres offshore outside existing sheltered ports.

FIG. 1a

FIG. 1

There is adequate experience world wide, and particularly in Australia to confirm that large bulkships can be loaded at exposed offshore terminals without requiring the protection of a breakwater.

There is no experience of unloading large bulk carriers other than in sheltered harbours. However the consensus of opinion is that unloading operations at an unprotected offshore berth would be rendered impossible in sea conditions much less severe than those which cause the cessation of loading operations.

The differences arise because loading equipment need never be in contact with the ship or its cargo, the bulk material being loaded through a telescopic chute suspended above the ship's hold. Therefore pitching, rolling and heaving of the ship have negligible effect on the loading operation. However, unloading equipment (grabs, screws, bucket chains etc) are immersed in the bulk cargo and hence movement of the ship can endanger the unloading equipment.

In the current world energy crisis situation, a rapidly escalating world trade in bulk coal can be expected, using ever larger vessels. Unloading of these vessels at existing ports causes high capital dredging costs and environmental problems, such as urban aesthetics involving coal stockpiles and power stations.

LIMITING OPERATIONAL CONDITIONS FOR BULK TERMINALS

In planning an offshore bulk terminal (i.e. one which is not in a sheltered harbour), the most important issue is whether a breakwater is necessary.

FIGS 1 & 1a show typical arrangements of protected and unprotected terminals respectively. In typical circumstances, such terminals are about 2km offshore.

The protected terminal is at right angles to the dominant wave direction, whilst the unprotected terminal is oriented in the same direction as the dominant waves. In both cases the waves arriving at the ship are travelling in the direction of the longitudinal axis of the ship and hence cause minimum disturbance to the ship.

In the case of the unprotected terminal, waves varying from the dominant direction will cause significantly increased ship disturbance. In the breakwater case, a change in wave direction has little effect because, (subject to adequate breakwater length) the diffracted waves are still travelling parallel to the breakwater when they arrive at the ship position.

Thus a breakwater has two effects which reduce the disturbance of the ship

- . Attenuation of wave height;
- . Virtual elimination of increased ship disturbance due to variation in wave direction.

FIG. 2.

Experience at a number of Australian loading terminals has provided good information on the limiting wave conditions which cause loading operations to cease. For unloading terminals there is no information available world-wide, but enquiries made of a number of operators and equipment manufacturers suggest the figures in TABLE 1.

TABLE 1

Wave direction relative to ship heading	Limiting Wave Height (metres)	
	Loading	Unloading
0°	2.5	1
45°	1	0.5

There are of course many other factors affecting the limiting conditions for safe operation (e.g. wave period, wind, ship size and inertia characteristics).

A full analysis would include all these factors, but the authors believe that a good first approximation to the berth availability equates with the amount of time each year that the waves fall into the categories shown in TABLE 1.

At offshore loading terminals so far constructed in Australia (1980) sufficient berth availability has been obtained without using a breakwater. Availability is normally required in the range 90-95%, but in some circumstances (e.g. low annual throughput tonnage) much less may be quite satisfactory. In periods of unavailability, the berth is shut down and if there is a ship in port it is taken off and anchored in deep water awaiting favourable weather. This type of off-shore terminal operation differs from the usual concept of all-weather port operations and must be understood in the context of this paper.

The planner of an unloading terminal is much less likely to find adequate berth availability if the berth is unprotected by a breakwater. FIGS 2, 3 & 3a show a typical wave climate such as the authors found at a proposed terminal site in the Mediterranean. If no breakwater is provided, the availability of an unloading terminal would correspond to the wave conditions shown in the last column of TABLE 1. Thus FIG 2 suggests an availability of 65%. However, FIG 2 represents the average of 13 years wave recordings and the authors wish to draw attention to the dangers of basing terminal planning on average statistics.

FIG. 3

FIG 3 shows the same figures broken down into winter and summer for each of the 13 years separately. This shows that in a bad winter (such as 1961) availability would be only 42%. FIG 3a shows the 1961 winter figures broken down into wave directions, and again using the criteria of TABLE 1, it can be seen that the availability is reduced to 30%.

In these circumstances, a high annual throughput installation would not be feasible with a single unprotected berth. Even a two-berth installation, whilst providing in theory sufficient unloading time, would be subject to long shut-down periods of both berths simultaneously. Accordingly, the authors believe that a single berth protected by a breakwater is the preferred solution.

The layout shown in FIG 1 is consequently the subject of this paper. It will be seen from FIG 3 that if the breakwater is capable of attenuating 4 metre incident waves to 1 metre at the berth, there will be 90% availability even in the worst recorded winter period. (As stated earlier, the variation of incident wave direction does not significantly affect a breakwater protected terminal).

Such an installation would be operated in the same way as the existing unprotected loading terminals in Australia - i.e. when the sea conditions prevent operations, a ship in berth would be taken off and anchored in deep water to await favourable weather.

DESIGN & CONSTRUCTION CONSIDERATIONS

New style offshore terminals satisfying the aforementioned availability requirements give rise to design and construction problems which necessitate further research.

The proposed offshore terminal differs from traditional concepts in two important ways.

1. The breakwater is not required to provide a safe anchorage on its lee side for 100% of the time, but only when the incident waves are 4 metres high or less. Operation of the terminal is not required when waves greater than 4 metres are allowed to overtop. This concept is termed a "limited availability breakwater".
2. The breakwater is an island structure, and this raises construction problems which have a profound effect on the design concept.

The required island breakwater is in fact connected to the shore by a piled trestle. For operational purposes, this trestle carries one or more conveyor belts and a roadway. Thus it may be argued that this trestle can be built first and used for access by trucks to construct a conventional rubble mound breakwater by end-over-end tipping.

FIGURES SHOW PERCENTAGE OF TOTAL TIME WAVES ARE WITHIN STATED HEIGHT AND DIRECTION RANGE WORST RECORDED WINTER PERIOD.

FIG. 3a

However, in practice this is un-economic for two reasons. Firstly it requires an unacceptably long time to construct the trestle and breakwater sequentially. Secondly the roadway on the trestle would have to be strengthened significantly above the standard required for operation of the berth.

The fundamental economics of construction dictate that the break-water must be constructed as an offshore operation, without use of the trestle for construction access. An offshore operation is defined by the authors as an operation in exposed waters with no access during construction other than by boats or helicopters. This requires the use of floating construction equipment and daily use of barges, tugs and other vessels for the transfer of men and equipment. These activities cannot generally be carried out safely when the waves exceed about 1 metre. Thus it can be seen that in a typical situation such as shown in FIGS 2 and 3, there may be an average of 35% downtime, with a maximum of 58% in a bad winter and a minimum of 16% in a good summer. These figures are not untypical of previous experience in the construction of offshore loading terminals (Ref.1).

Weather down-time in an offshore operation is very costly because it shuts down the entire construction establishment, which after each shut-down requires some time to restart. Furthermore, the wide variability of shut-down time from 16% to 58% makes effective planning of the operation very difficult.

In offshore operations such as construction of the North Sea oil platforms, these problems are so obvious that there is no economic alternative to total onshore pre-fabrication of the structure followed by very rapid offshore installation. The whole purpose of this concept is to reduce the required offshore working time to a minimum by making maximum use of onshore pre-fabrication.

The type of offshore terminal shown in FIG 1 shares the same problems. Instead of being 100km or more from the shore like an oil platform, it is only 2km. Therefore whilst it becomes feasible to adopt "conventional" construction such as would be used for the same structure if it were in sheltered waters, the authors believe that maximum onshore pre-fabrication is economically essential. In the context of a break-water this means caissons. The "conventional" alternative of a rubble mound requires the piecemeal offshore construction of both the break-water and a complete separate berth structure.

A number of eminent authorities have pointed out the disadvantages of caisson breakwaters (Ref. 2). It is the primary purpose of this paper to draw attention to the construction advantages of pre-fabricated caissons for the particular case of a detached bulk unloading terminal, and the consequent necessity to develop design criteria which adequately overcome the various objections to caissons. In the authors' opinion, the disadvantages of caisson breakwaters apply almost entirely to vertical wall fully reflecting structures. Caissons do not need to be fully reflecting or to have vertical walls.

FIG 4 (a)

Previously published work has suggested the concept shown in FIG 5 for the type of terminal shown in FIG 1. The Danish Hydraulic Institute (Ref 5) have recognised the advantages of an overtopping breakwater but suggested that a high reflecting wall, as shown in FIG 5, is necessary in cases where equipment is mounted on the caisson.

However, the maximum design wave load on the caisson depicted in FIG 5 can be shown to be 2 or 3 times that on a sloping face overtopping caisson, and furthermore it suffers all the other disadvantages of vertical wall structures, such as scour at the base.

Accordingly, the authors have developed the concept shown in FIGS 4a & 4b. This meets all the operational availability requirements discussed earlier. Incident waves up to 4 metres high are diffracted round the ends but do not overtop, creating safe conditions for unloading. Waves higher than 4 metres pass over the caissons but under the elevated plant deck. Under these circumstances the berth is shut down and ships taken off to await favourable weather.

The concept is based on the type of breakwater developed by the Danish Hydraulic Institute (Ref 5) but goes a step further by mounting the berth structure on an elevated deck. This retains all the advantages of a sloping face overtopping caisson without endangering the equipment.

The Danish Hydraulic Institute's published work (Ref 5) also draws attention to the fact that much of the advantage of a sloping face breakwater is lost when the tide level falls below the bottom of the sloping section.

The authors consider that from the construction point of view it is not essential to extend the vertical wall up to still water level. Accordingly, it is proposed to include in the research program the concept shown in FIG 6, with the slope extended below low tide level. Such a caisson would require temporary buoyancy tanks to assist flotation and installation. Its potential advantages are further reduction of the maximum wave load on the caisson, and reduced scour.

The paper so far has discussed operational and constructional requirements and demonstrated that these factors combine to create a need for research to establish suitable design criteria for the concept shown in FIGS 4 & 6.

The next part of the paper discusses the requirements of the research program proposed by the authors.

PROPOSED RESEARCH AND DEVELOPMENT

The proposed island breakwater concept (see FIGS 4 & 6) has to meet three principal design criteria:

- (i) its geometry must ensure that the wave climate at the berth behind the breakwater provides the required percentage time availability for unloading, i.e. it must have the specified attenuation factor.

FIG 4 (b)

- (ii) the breakwater must have an adequate factor of safety against a stability failure commensurate with the risk to personnel and unloading equipment.
- (iii) the breakwater geometry should minimise the "up throw" of overtopping waves in order to limit the require deck elevation.

These three criteria require opposing solutions with respect to the breakwater's height and seaward wall geometry, and hence a compromise design must be selected. In general terms a profile which minimises the loads on the structure will also create more overtopping.

Breakwater Stability

The basic requirement of the breakwater stability design comprise:

- (a) provision of the required factors of safety against sliding and overturning of the breakwater when subjected to the maximum design wave.
- (b) prevention of scour at the base such that the foundations are not progressively undermined.

The authors consider that ideally the factor of safety against an overturning failure or base failure, which would have catastrophic consequences for the installation, should be significantly higher than that against sliding. A slide of a few centimetres need not be classed as irreparable damage as it can be rectified by adjustments to the rails carrying the ship unloading equipment. It is of interest to note that most of the documented caisson breakwater failures have in fact involved slides (Ref 3).

Effect of Breakwater Profile with Respect to Stability

If a vertical wall caisson is first considered the wave forces can, as expected, be significantly decreased by allowing the higher waves to overtop instead of totally reflecting them. The graphs in FIG 7 were derived using the MICHE-RUNDGREN theory with the approximations discussed in Refs. 3 & 4. Both the horizontal force and the overturning moment are lower for the overtopping structure. More importantly, the rate of increase of moment with respect to wave height, is significantly reduced. Hence, the overtopping breakwater is considerably less sensitive to an unforeseen increase in the design wave height.

These points are also demonstrated by previous model test results (Ref 5) particularly as the wave conditions approach breaking.

It is possible to further reduce the wave forces and scour erosion of the overtopping breakwater by providing an inclined face to the seaward wall.

FULLY REFLECTING VERTICAL WALL
BREAKWATER

FIG. 5

Model tests (Ref 6) show that the pressure distribution acting on an overtopping inclined face breakwater are of the form shown in FIG 8. This diagram demonstrates another advantage of allowing waves to overtop, namely the stabilising effect of the downward component of the water pressure acting on the inclined face. Besides increasing the friction resistance to sliding this downward component can also be used to counteract some of the overall overturning moment.

Furthermore, model tests have shown that the shock pressures as well as the overall horizontal wave force can be reduced by inclining the seaward wall (Ref 5).

The model test results in Ref 6 indicate that by inclining the front face, the uplift force is also reduced, with further stability benefit.

The inclined wall breakwater has a further advantage in relation to scour effects. Waves breaking against a vertical wall are deflected both upward and downward and the latter effect results in high water velocities at the seabed which can lead to foundation erosion (Ref 4). The downward effect is substantially reduced by an inclined seaward face.

PROPOSED MODEL TEST PROGRAM

It can be seen that the attenuation and stability criteria require opposing solutions with respect to the breakwater's profile. Hence a model test programme is proposed to investigate optimum profiles.

A summary of recent relevant literature (Ref 5) suggests the following criteria may be pertinent to the test program:

- (i) physical models are valuable in deriving design criteria for stability of structures and wave forces on structures.
- (ii) the design of a shock-sensitive structure requires that the inertia of the structure and the stiffness of the foundation be taken into consideration in a dynamic analysis. Further, it is common that the natural period of a caisson-type breakwater on its soil foundation is about an order of magnitude smaller than the mean wave period, thus suggesting that the characteristics of the individual wave are all-important.
- (iii) acceptable values of shock forces may be expected on physical models of caissons providing air entrainment is unimportant in both model and prototype. Further, the shock forces are sensitive phenomena such that a large scatter in results is likely unless repetitive tests are carried out - 1000 waves minimum and preferably 3000-5000 waves have been suggested. Even with a random or model-reproduced natural wave train generation, due care should be taken in accepting one single random field record due to the large scatter in force reproductibility.

PROPOSED ALTERNATIVE
BREAKWATER

FIG. 6

- (iv) the maximum force on a vertical-faced structure increases with wave height up to the stage where the wave breaks on the face and begins to overtop. For higher waves the maximum force remains approximately constant or reduces.
- (v) sloping face structures cause less reflection than vertical faces because of energy loss and likely overspill.
- (vi) there are problems with model tests of reflecting structures due to re-reflections within the wave tank.
- (vii) wave height and water level with respect to the structure are the most important independent variables for structural stability analysis.
- (viii) for the same wave height, the longer the period the larger is the force.
- (ix) it is commonly considered erroneous to design structures on the basis of tests with regular waves of design height.

A wave tank 60 metres long and 1.83 m x 1.83 m in section will be used to contain physical models of scale 1:50 to study waves of height up to 5m and periods up to 30 sec. in water up to 50m deep. A larger model (scale 1:20) will be used for confirmatory pressure distribution studies, with waves up to 2m high. In view of the criterion (ii) above applying, and despite criterion (ix), regular waves are considered satisfactory for these tests, recognising re-reflections as a problem.

Additional to the physical tests, it is planned to examine the fully overtopping phenomenon by means of numerical techniques for wave force determination. This will provide valuable guidance as to the type of profile likely to produce the best results in the physical models.

The cross-section configuration of the caisson will likely be similar to that in FIGURES 4 & 6. However the length and angle of sloping front face, level and length of top face of caisson, freeboard height above caisson to plant deck are all variables to be examined. A free-draining wave-absorbing stilling basing set into the top face of the caisson may also be examined, as a possible way of lowering the caisson profile whilst still preventing overtopping.

It is too early to report the findings of these various studies in this paper. Instead, comment is invited on, especially, the usefulness and pitfalls associated with the numerical modelling envisaged.

This paper does not consider the very important issue of foundation strength and stability. Apart from considerations of sliding, shearing, overturning, and uplift pressure distribution, the foundation will be subject to erosion forces, the severity of which will depend on wave climate, water depth, and foundation configuration and composition.

NON-BREAKING WAVE FORCES USING MICHE - RUNDGREN FORMULAE (12 SECOND PERIOD WAVE)

TYPICAL WAVE PRESSURE
DISTRIBUTION FOR OVERTOPPING
BREAKWATER

NOTE:

The forces shown are those additional to the hydrostatic and gravity loads.

FIG. 8.

CONCLUSIONS

- . The construction of bulk unloading terminals in deep water will require the use of detached island breakwaters.
- . For construction reasons related to the delay risks when working in an offshore situation, pre-fabricated caisson breakwaters are preferable in this situation.
- . Significant cost savings can be achieved if the caissons forming the breakwater are also used as the structural support for the ship unloading equipment.
- . Significant further cost savings can be achieved if the highest 5% to 10% of waves are allowed to overtop the caisson.
- . Sloping face caissons supporting an elevated plant deck above the crest of the highest overtopping waves offer the most attractive solution.
- . Further research is required to define wave loads and other parameters with an adequate degree of assurance for safety of the equipment. The paper makes recommendations for the required research.

THE DESIGN AND CONSTRUCTION OF THE NEW
OIL PORT IN DALIAN, C.P.R.

Xin, Zhu-zhuang,

Qiu, Da-hong, Li, Yu-cheng and others
(Dalian Institute of Technology)

Abstract

The construction of New Oil Port in Dalian, C.P.R., was started from the end 1974 and completed in autumn 1976. In this paper a summary of the essential considerations in design and construction of this oil port, such as the planning of the pier, the determination of exciting forces (namely wave forces, forces due to earthquake, mooring line forces and berthing forces due to the impact of tanker on the fenders) on structures, the design of the large cylindrical caisson with a diameter of 9m and a height up to 19.7m and the construction of connecting bridges by two types, is presented.

General description

The New oil port is situated in Dalian, Liao-Ning, People's Republic of China, it is a terminal of the Da-Ching Oil Field. The design capacity of the export of crude oil is 15,000,000 tons per year.

Fig(1) is the general plan of the New Oil Port. The jetty is of cylinder-pier type and is located about one kilometer from the shore line. The direction of the axis of the jetty runs $N150^{\circ}$, which gives an efficiency of 85-90% utilization of the berth every year. The depth of the water alongside the jetty is 17.85 meters at low water level, which is sufficient for the berthing of 100,000 tonnage oil tanker.

The jetty is 421.3 meters long, consisting of an operating platform, two berthing piers and six mooring piers, as shown in fig(5). Fig(2) is its general view.

There are four spans of steel pipeline bridge between the operating platform and the piers No.6,7,8,9 and four spans of steel foot bridge between the operating platform and the piers No.4,3,2,1. The span lengths of these bridges are 24.2 meters, 2-30.7 meters and 51.5 meters respectively. The distances between the piers are determined mainly according to the adequate angles of mooring lines and the requirement of the berthing of the tankers. In this design, the arrangement of the piers is fitting for the berthing of 30,000 tonnage up to 100,000 tonnage oil tankers.

The water depth alongside the jetty at low water level is determined mainly according to the following considerations: (1) the berthing tanker will not touch the sea bed under the wave action of the operating condition, (2) the increase of the draft of the tanker when it navigates out of the port, (3) the reserved depth for deposition and

other factors.

Under the wave action, the draft of the berthing tanker will be increased due to the heave, roll and pitch motion of it .

The results of the 1:60 scale model tests are shown in table (1) for the beam sea and in table(2) for the oblique sea with an angle of 30° between the wave direction and the longitudinal axis of the tanker.

From the results shown in tab.(1), the increase of the draft under the beam sea does not exceed 0.94m. in the general case, and in the case of long period swell with the wave height less than 1.0m., its extreme value does not exceed 2.58m.

Under the action of oblique sea, in the test the amplitude of the motion of heave and roll decreased rapidly, but a pitch motion was produced. Although the amplitude of the pitch motion was not very large, due to the fact that the length of the ship was much longer than its width, the small pitch motion still caused a significant increase in the draft of the tanker. From the results shown in tab.(2), the increase in draft , generally did not exceed 1.17m. at high water level (HWL) and 0.57m. at low water level (LWL), and in

the case of long period swell, its extreme value did not exceed 2.54m. at HWL and 1.09m. at LWL.

The elevations of all the pier tops are +10.0m, and those of the top deck and low deck of the operating platform are +12.0m and +10.0m. respectively. The determination of these elevations is mainly due to the following considerations: (1) no overtopping of waves will occur, (2) no strong wave action on the pipeline bridge will occur, (3) the inclination angles of the mooring lines are adequate, (4) the operating range of the oil loading arm is sufficient for

different tonnage berthing tankers.

The jetty is connected to the shore by a 111.75m.long mole consisted of rubble mounds and 9 spans of steel bridge. Each span of the bridge is 100 meters long. The bridges are supported on the cylinder piers, which are spaced 106m. apart center to center. The axis of the connecting bridge runs out in the east direction, and makes an angle of 120° with the axis of the jetty. Fig (3) is the general view of the connecting bridge.

The construction of the piers

The piers are all of gravity type using the reinforced concrete cylinder caissons as the underwater structure. The soft top layer of the sea bottom was dredged and stones weighing 15 to 100 kg. for rubble mounds were deposited in the dredged cavities up to the design level, then the cylinder caissons were rested upon these rubble mounds. The largest cylinder caissons used are 9.0m. in diameter and 19.7m. high, the bottom of the caissons is octagonal in shape. The thickness of the wall of the cylinder is 30cm. and that of the bottom is 100cm. The superstructures of the piers over the caissons were three layers of solid or hollow precast reinforced concrete blocks, which were interlocked with each other by filling concrete in the concrete in the connecting holes with reinforcement in it. As an example, the construction of the operating platform is shown in fig (4).

The forces acting on the piers

The forces acting on the piers consist of the following forces: (1) wave forces, (2) forces due to earthquake, (3) mooring line forces, and (4) berthing forces due to the impact of tanker on the fenders.

The wave force exerted on single pier is calculated by Morison equation. In order to estimate the influence of the

pier group, a 1:60 model test were made in the laboratory. According to the test results, a coefficient was used to modify the calculated result for single pier. For the operating platform this coefficient is 0.9-1.1, and for the berthing pier, 1.0-1.4.

The mooring line force of the berthing tanker is caused mainly by the wind, current and wave action on the tanker. For the offshore jetty, the dominant condition is the wave action. This action is very complex, because it not only depends on the scale and the direction of the wave, but also on the loading condition of the tanker, the characteristics of the mooring lines and fenders, and the arrangement of mooring lines when in berthing. Model tests of the 100,000 tonnage tanker with 1:60 scale were made for measuring mooring line forces and impact force and energy of the berthing tanker on the fenders. The mooring line arrangement in the test is shown in fig(5). The test data are tabulated in table(3).

From analysis of the test data, the following informations can be drawn:

(1) The maximum mooring forces are produced by the beam sea, if the wave direction is at an angle with the longitudinal axis of the tanker, the mooring forces will be reduced rapidly. The maximum mooring forces will occur at the ballast loading condition. For the beam sea from the outside of the berth, the mooring line forces of a tanker in full loading condition are increased as the wave height and wave period increase. As for the tanker in ballast loading condition, the mooring line forces will be maximum when the wave period coincides with the natural roll period of the tanker. For the oblique sea and head sea, the mooring line forces are also increased as the wave height and wave per-

iod increase. For the beam sea however, the mooring line forces inside of berth will be greater than that outside of the berth due to the tendency of pushing the tanker away from the berth.

(2) When nylon breast lines are used, the mooring lines work normally for all test conditions, only for long period beam sea when the wave height reach 1.4-1.6m., the mooring lines will be broken occasionally. When the steel breast lines are used, the mooring line will be broken in most cases during test, it can work in normal condition when wave height is less than 1.5m. and wave period less than 4 sec. for beam seas and wave height less than 2.4m. and wave period less than 5.3 sec. for oblique and head seas.

According to the test results, the mooring line breaking force is used as the control force of the mooring line in design. This is mainly dependent upon the arrangement and the size of the mooring line selected. In design for the 100,000 tonnage tanker the 10" nylon line was selected and the arrangement of the mooring line is shown in fig (5).

The impact force of the tankers on the berthing piers is mainly due to the following two causes: (1) the kinematic energy produced by the approaching velocity of the tanker during berthing, (2) the kinematic energy produced by the motion of the berthing tanker due to wind, current, especially the wave action. For offshore jetties in the open sea, the latter is the controlling case for determining the impact energy in design.

The model test results of the impact energy of 100,000 tonnage tanker due to wave action are shown in table 4. From these test data we can see that the wave condition has great influence on the impact energy of the tanker.

Therefore in the design we must first determine reasonably the wave condition for safe loading operation of the berth. This is a complex problem because it depends upon many factors such as the management of the loading operation of the berth, the design criterion of the jetty, the requirement of the loading capacity of the berth per year and others. In this design, the wave condition for safe loading operation is tabulated in table (5).

From the test results and the analysis of the moored ship, we can get a semi-empirical formula for calculating the impact energy of the tanker.

$$E/H^2 = \alpha_1 \alpha_2 \alpha_3 \alpha_4 (1.4-2.7 \frac{D}{B}) \frac{LoA}{260} T^{2.5} (t-m/m^2)$$

Where: H, T—wave height (m.) and wave period (sec.) :

D, B, LoA—draft, breadth and total length of the moored tanker;

α_1 —the coefficient due to eccentric impact of the tanker,

$\alpha_1 = \frac{1}{1 + (L/r)^2}$, L is the distance between the fender and the center of gravity of the tanker on the cross section, r is the radius of gyration of the cross section of the tanker;

α_2 — the coefficient due to the change of the water level, for the case of tidal range less than 4.0 m. and small reserved depth for safety for the berth, $\alpha_2 = 1.0$;

α_3 — the coefficient due to the loading condition of the tanker and the influence of the elasticity of the mooring line, for the case of full loading, $\alpha_3 \cong 1.0$, for the case of ballast loading : $\alpha_3 = 1.0$ for all nylon mooring lines, $\alpha_3 = 1.5$ for steel spring lines with nylon lines for others, and

$\alpha_3=2.2$ for steel breast lines with nylon lines for others;

α_4 — the coefficient due to different wave direction,
 $\alpha_4 = 0.05 + 0.95 \sin^4 \alpha$, α is the angle between the wave direction and the longitudinal axis of the tanker;
 for beam sea from inside of the berth, $\alpha_4 \leq 0.6$.

The formula is applicable for the condition of wave period equal to or less than 7sec..

It is necessary to determine the dynamic characteristic of the piers for calculating the earthquake reaction. For this purpose, the natural frequency and the damping ratio of the completed connecting bridge piers No.1,2,3 and the jetty pier No.8 under construction, shown in table 6, were measured in site. The coefficient of the rigidity of foundation K calculated from the measured data was used to design the dynamic model test of the completed jetty pier No.8. The test results of the first mode of vibration of the dynamic model test were very close to the calculated values, as shown in table (7). The sketch for calculation is shown in fig(6).

Using the dynamic characteristic of the pier obtained from the test, we can calculate the deformation process of the pier during berthing and the earthquake force and its distribution along the pier.

The design of the large cassion

The construction of the reinforced concrete cassion is shown in fig. (7). The wall of the cassion is a cylindrical shell which is rigidly connected on the base plate of the cassion. In design, the following items are considered: (1) the strength and the stability of the cylindrical wall against crack, under the action of the external and internal pressure, (2) the stability of the cylindrical shell under the combined action of axial force and be-

nding moment,(3) the local strength of the shell due to the impact of the construction ships.

The cassion was built in two stages. In the first stage, the cassion was built up to a height of 12m. on land, and then slipped into sea on the slipway. In the second stage, it was built up to the full height of 19.7m. along the wharf under floating condition. Because the draft of the cassion floating vertically in state is larger than the water depth of the navigation channel, the cassion was towed by the tug at inclined position. The process of sinking down the cassion during the rising of tide and the reaction acted on the edge of the base of the cassion during sinking were checked in a 1:30 scale model test. The test results agreed closely with the calculated values.

The construction of the bridges

The all-welded Vierendeel trusses in parabolic shape are used in the construction of the connecting bridge. This is because the main loads of the bridge are uniformly distributed dead loads which occupy almost 84% of the total loads, and the moving loads are also essentially uniformly distributed.

The all-welded steel plate-girders strengthened by struts are used in the construction of the pipeline bridge along the jetty, because the total height of the bridge is limited in a small range of 4 meters. The result of using this type of structure is satisfactory in economy and service.

The span of the vierendeel truss is 100 meters, which is divided into 12 panels. The ten intermediate panels are 9 meters in length each, and the two end panels are 5 meters in length each. The distance between the trusses is

7.6m. and the total width of the bridge is 12m. The height of truss at mid-span is 12.5m., which gives a rise-span ration of $1/8$. The joints of the truss are strengthened, and the wedge-shape plate girders with an integral box section are used to strengthen the end panels. The sketch of the connecting bridge is shown in fig.(8).

The height of the plate-girder of the pipeline bridge is 2.0 meters. There is an elbow at each end of the girder to support the strengthening strut. Vertical members are spaced at 6.4m. apart to connect the plate girder and the strut. The distance between main girders is 5 m. center to center, and the width of the bridge is 9.0m. at the lower deck for carrying pipes and 5.0m. at the top deck. The sketch of the pipeline bridge is shown in fig.(9).

For checking the reliability of the design, several tests were made during construction.

For the Vierendeel truss, a photo-elastic model test and a 1:3 structural model test for the joint have been carried out and an overload (total load 840 t.) test for the whole bridge and a test for the non-uniform settlement of the supports were made on the assembly ground on the shore. The dynamic characteristics of the Vierendeel truss under different loading condition have also been measured, the results are shown in table (8).

Photo-elastic model tests of 1:100 scale for the whole span of the pipeline and 1:20 scale for the elbow part of the girder were made during design. The deflections of the bridge in prototype under the service loading condition were measured, the value agreed closely with the theoretical value with a deviation of about 5%.

The members of the bridges were fabricated in workshops and then assembled into a complete unit on the assembly ground, which was specially constructed for the assembly work of the

bridges. After a whole span of the bridge has been assembled, the pipes, traffic deck, and all accessories were installed on it, and then it was pulled on the shipway to the end of a mole. The assembled span was hoisted on the floating crane which was navigated by towing tugs to the bridge site and the span was finally erected on the piers.

SITING AND DESIGN CRITERIA OF DOCK STRUCTURES IN THE
MARSHALL ISLANDS

by

R.M. Noble¹, K.C. Leslie² and D. O'Day³ABSTRACT

In the summer of 1978, a siting/design investigation for dock structures (Marshall Islands Dock Project) was conducted at 15 atolls within the Marshall Islands group (see Figure 1). The Marshall Islands are within the U.S. Trust Territory of the Pacific Islands (TTPI), located in the North Pacific. The Marshall Islands Dock Project is part of the Capital Improvements Program currently underway in the Marshalls. The program, aimed towards making the Marshall Islands more self-sufficient in preparation for their independence in 1981, includes the construction of low cost dock structures for use by the design vessels described in this paper to load/unload agricultural products, supplies, and passengers. This study did not include the feasibility of this approach versus other alternative loading/unloading approaches.

This investigation included site selection, development of design criteria, and the design and alignment schemes for 12 new dock structures. In addition, design criteria and plans were developed for the upgrading of three existing dock structures. The site selection was performed using a multi-disciplinary approach which considered environmental, sociological, and archaeological impacts, in addition to the usual technical site selection. This paper only discusses the technical considerations to site selection.

Overall responsibility for the project was assumed by the Pacific Ocean Division of the U.S. Army Corps of Engineers on behalf of the Government of the Trust Territory of the Pacific Islands. Our work was performed for Alfred A. Yee & Associates, Inc., the structural engineer and prime contractor for the project, and in collaboration with R. M. Towill Corporation.

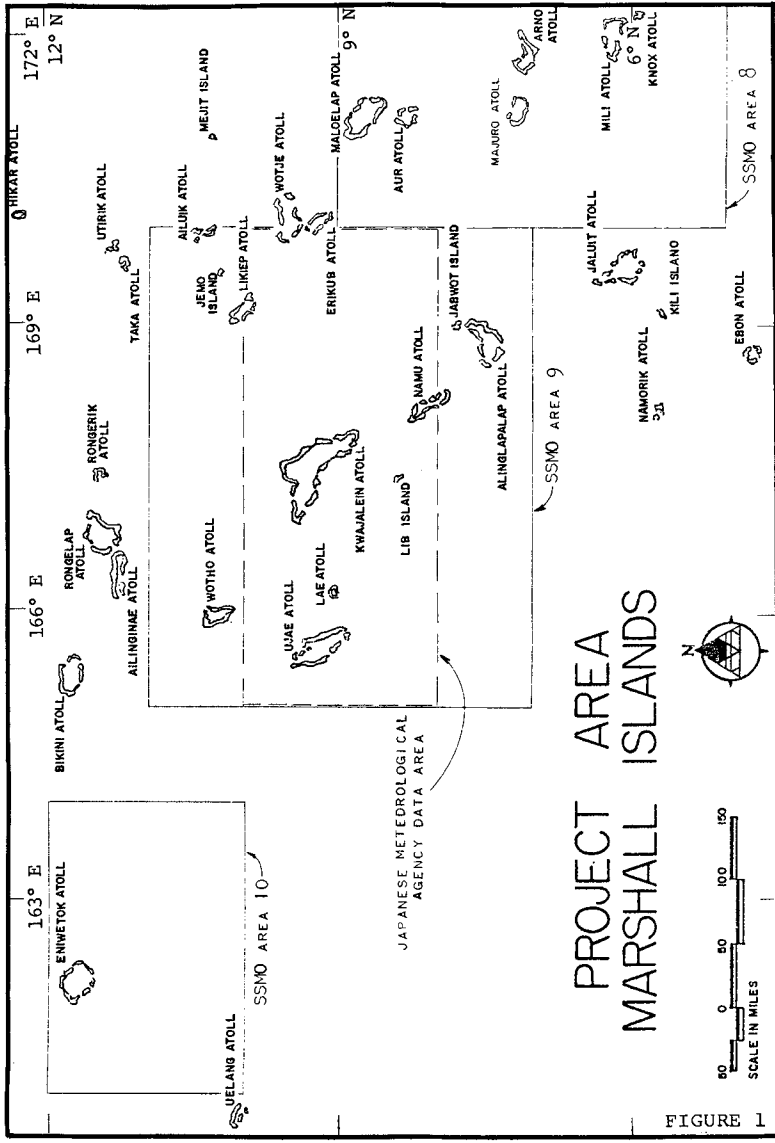

FIGURE 1

INTRODUCTION

The Marshall Islands group is composed of two roughly parallel, northwest-trending island chains approximately 500 miles long in the North Pacific. There are about 25 atolls and several islands in the Marshall Islands chain. The atolls are typically comprised of a number of elongated low lying islands and coral reef segments that enclose a lagoon.

This project involved the recommendation of sites and alignment schemes and development of design data for new docks in 12 island atolls, and recommended alignment schemes and developed design data for the upgrading of existing pier structures at three island atolls (Wotje, Jaluit and Ebeye). It is hoped that by providing centrally located dock facilities in the primary outer atolls, inter-atoll vessels could be put on a fixed schedule and copra production in the outer atolls could be increased. (Copra, the dried meat from coconuts, is a major, yet underdeveloped resource in the Marshall Islands.) In addition, one of the upgraded docks, Ebeye, was to serve for larger international vessels. The specifications of the design vessels (inter-island and international) are presented below.

	<u>M/V Eigamoiya</u> (Namu Pal Line, Melbourne, Australia)	<u>Micro Chief</u> (TTPI)
Length (feet)	368.5	185

Use	International containerized cargo	Inter-island cargo

* Estimated

The Marshall Islands Dock Project was different than most full scale siting/design investigations due to time and budget constraints and the remoteness of the Marshall Islands. A team of individuals were asked to perform a 3-day site investigation at each atoll to select sites, develop design criteria and determine dock alignment schemes. In U.S. coastal waters, a site selection and design investigation for a project such as this would involve a site-specific data gathering effort lasting many months.

OBJECTIVES

The following objectives were undertaken to complete the assigned task within the allotted time.

- Prefield program--Existing regional data including wind and wave information and atoll bathymetric charts and aerial photographs were reviewed and assessed in order to select candidate sites for each of the atolls. Design wind and waves for return periods up to 100 years were developed from the compiled regional wind and wave information.
- Field program--During the field program, which generally lasted 3 days per atoll, the following was performed:
 - Reconnaissance of candidate sites--Usually more than one site had been pre-selected for evaluation on each island. Each was briefly examined for its coastal characteristics;
 - Meetings with residents--Meetings were held with the local officials and the probable users of the facility;
 - Site selection--Based on previously-collected data, candidate site inspections, and local input, tentative site selections and alignment determinations were made considering all major factors;
 - Site investigations--Site-specific data were then gathered for use in the design phase. A recording current meter was deployed for approximately 2 days at each site, and general reconnaissance was undertaken onshore and offshore. Limited soil sampling and jet probing were performed using SCUBA diving equipment. Wind, wave, and tidal information was collected, and on- and offshore site processes, such as littoral transport and flooding potential, were evaluated.
 - Field report preparation--Preliminary reports including the data gathered in the field were prepared with tentative alignments and preliminary design recommendations.
- Formulation of recommendations--Upon returning from the Marshall Islands, field bathymetric/topographic data were reduced and maps drawn, current meter data records were interpreted, limited soils laboratory testing was completed on bottom samples, a number of

meetings between the project participants were held, final alignments were selected, and design recommendations were formulated.

- Report preparation--A final report documenting our efforts and including the results of the literature search, field and laboratory data, and discussions and recommendations was prepared for submittal.

BASELINE DATA

The Marshall Islands, lying approximately between 4 degrees and 12 degrees north, are within the northeasterly trade wind belt. The trade winds dominate the regional wind regime in the area. They blow strongest (average wind speed of 10 to 18 knots) and most steadily from December to March, but weaker (average wind speed of 5 to 10 knots) and less steady from July to November. Maximum trade wind speeds are in the 30 knot range. A representative wind rose for the Marshall Islands is presented on Figure 2. These data are based upon eight years of observational wind data contained in the Summary of Synoptic Meteorological Observations (SSMO, 1971).

Typhoons are uncommon in the Marshall Islands, but do occur. The winds, sometimes in excess of 100 knots, and accompanying battering waves, can alter an atoll island so radically that it is not recognizable (National Ocean Survey, 1976). The typhoon season in the Marshall Islands usually extends from July to October, although typhoons have been reported throughout the year. Approach direction of the typhoons is generally east to southeast. Violent gales, sometimes severe enough to endanger shipping and cause widespread destruction on an island, occasionally occur from August through November (National Weather Records Center, 1943). The most frequent approach directions are southeast to southwest. Thunderstorms are fairly common, except during the winter months when they are relatively infrequent. Most of the thunderstorms come from the northeast, east or southwest, but a few originate in the north, south, or southwest.

Return period estimates of surface wind speeds based on observational wind data (SSMO, 1971) are presented on Figure 3. Extreme wind speeds associated with typhoons are apparently not represented in the data base. Consequently, the extreme winds for a 100 year return period (non-typhoon condition) are on the order of 40 knots and reflect primarily the trade wind condition.

FIGURE 2

FIGURE 3

The predominant wave approach directions within the Marshall Islands area are northeast to east, which is a consequence of the persistent northeast trade winds. Wave data based upon wave observations made aboard ship over an eight- to ten-year period and compiled in SSMO (1971) and Japanese Meteorological Agency (1971-1978) are presented on Figure 4. These data indicated that less than two percent of the waves observed in the Marshall Islands area have heights exceeding 12 feet. The maximum wave height observed in either of the two data bases was a long period, 22-foot-high wave, directed from the northeast. Return period estimates of wave heights based on observational wave data (SSMO, 1971 and Japanese Meteorological Agency, 1971-78) are shown on Figure 5.

The protection afforded by the encircling islands and reef segments forming the atoll rim shelter the lagoon from incoming oceanic waves. Wave heights were calculated within the lagoons along critical approach directions using a 20-knot wind speed and the wind speed associated with a 50-year return period. The wave heights calculated using the 50-year return period wind speed ranged from 3.0 to 7.8 feet, depending primarily upon fetch length and degree of exposure, and were in close agreement with the maximum wave height observed by atoll residents.

Currents within the lagoons of the Marshall Islands atolls are generally wind dominated. The wind generated currents have speeds generally less than 0.5 knots. Tidal current speeds as great as 5 to 10 knots have been reported in some of the passes of the atolls.

Seiching was observed in several of the lagoons where a reference, such as the face of an existing pier, was available. It is likely that the seiching occurs as a result of lagoon excitation produced by incoming wave trains passing through the channels and passes.

The Marshall Islands are, in essence, coral atolls. Fringing reefs, sometimes rising above sea level to form islands, encircle the atoll, creating a protected lagoon. Deep drilling studies indicate the coral atolls are underlain at depth by basaltic bedrock (Emery and others, 1954). It is generally accepted that the volcanic masses once reached a near- or above-sea level elevation, and that during subsidence, upward growth of the coral has kept pace with the subsidence, thus preserving the near-sea level feature.

The reefs forming the atoll rim have adjusted to the prevailing wind, wave and current forces. Emery and others (1954) investigated the marginal reefs of Bikini and nearby atolls, and were able to correlate reef type with prevailing

oceanographic conditions. In general, the windward reefs, the more vigorous of the reefs investigated, had characteristic well-developed algal growth (Lithothamnion ridge) that appeared to be a consequence of an adjustment to strong, steady surf. The leeward reefs generally lacked this prominent ridge, were slower growing, wide, and had steeper seaward slopes. The reefs on the southern shore are adapted to weak surf conditions, as this is the lee shore, but are subject to severe damage during periods of southern storms (Emery and others, 1954). Large blocks of coral torn from the reef edge during storms litter the reef flat.

Between the reef segments are passes or channels that link the lagoon to the open ocean. The passes are characteristically deeper, and have flatter sea floor bottoms than the channels. Tidal currents maintain these passageways.

Shallow lagoons lie within the encircling reefs. The maximum depth of the lagoons is generally less than 200 feet. Beach or near-beach deposits are often present around the outside margin of the lagoon. Coral knolls and pinnacles rising near- or above-sea level are common features within the lagoons.

SITE INVESTIGATION

The site investigation team consisted of six professionals from Dames & Moore, Alfred A. Yee & Associates, Inc. and R. M. Towill Corp. Represented were experts in coastal/ocean engineering, geotechnical engineering, environmental/oceanographical sciences, surveying and structural/construction engineering. Also traveling with this team were one or two representatives of the U.S. Army Corps of Engineers and one or two representatives of the TTPI.

Key siting criteria were established for use in both pre-site and final site selection. Due to the short duration (average of 3 days per atoll) site visits, it was extremely critical to rapidly perform final site selection at each atoll where a docking facility was to be established. Therefore, all pertinent data, including navigational charts and aerial photographs, were thoroughly reviewed in advance of the site investigations to pre-select the most desirable sites. Siting criteria considered were as follows:

- Exposure
- Navigation
- Water depths near shore
- Bottom conditions
- Location/access within atoll
- Available landside area
- Environmental considerations

Of prime consideration in pre-site selection were: site exposure to or protection from oceanographic/meteorological conditions such as waves, winds, surge, currents, sediment transport, etc.; navigational approach to the site, sufficient water depths along approach, potential navigational hazards, transit through inlet passes for lagoon sites, vessel exposure to currents, waves, winds, etc.; and, proximity of deep water nearshore for more economical dock facilities.

Whenever possible, lagoon sites were selected over open ocean sites due to their usual better protection from wave conditions which resulted in lower design conditions, safer navigational approach, and longer duration of operational time during the year.

Just prior to the site investigations, a quick reconnaissance was performed to assess pre-selected sites. In addition, meetings were held with the local Marshallese to confirm preferred site locations. Preliminary diving and land surveys were then performed to select a final site and a possible alternative. This involved consideration of such added factors as: offshore bottom conditions from design, construction and environmental viewpoints; available landside area for storage and dock facilities; and, the site location relative to the atoll's population, copra production, and roads.

The means for performing physical site investigations were kept as simple as possible due to time, budget, weight, and maintenance constraints. On several occasions, we were left on atolls where we were totally self-sufficient by transporting all living supplies and field equipment (approximately 3,000 pounds) across several hundred feet of coral reef to a camp location. Field equipment consisted of such items as SCUBA gear, tanks, compressor, boat, outboard engines, gasoline, survey instruments, current meters, jet probe and pump, fathometer, weights, floats, etc. Field equipment had to be dependable as we could only handle a limited number of spares and selected maintenance equipment.

Site surveys consisted of both onshore surveys and offshore diver reconnaissance surveys. Offshore surveys consisted of a bathymetric survey, installation of an in situ current meter, jet probing into bottom sediments along the proposed pier alignment, mapping of bottom conditions including extent of coral, mapping of existing structures, and an environmental inventory. Onshore surveys consisted of a topographic survey, shoreline conditions, site exposure, onshore geologic structure, available land area and access, socioeconomic considerations, availability of construction materials, etc.

RECOMMENDATIONS

Site field data were reduced and assessed along with the analysis of available historical data to develop appropriate design criteria for the design and construction of dock structures. Design criteria consisted of the following:

- Water levels--deck height
- Wave/wind conditions--pier alignment
- Wind/impact loads
- Wave uplift forces
- Setback
- Pier support

A pile-supported trestle/pier structure with mooring dolphins was recommended. Gravity structures, such as landfills or permanent cofferdams, were ruled out for economic and environmental reasons. The basic pier design adopted consists of a 16-foot-wide approach trestle terminating at a 24- by 80-foot loading/unloading platform at the pier head. A dolphin off each end of the pier head was recommended to provide proper mooring, while minimizing the length of the pier head required to handle cargo and passengers. Preliminary vertical pile loads were estimated at 20 tons per trestle pile and 40 tons per pier head pile. The approach trestle was recommended for extension landward of the intertidal zone beyond the upper limits of wave uprush. This was recommended to reduce environmental and construction concerns if a landfill causeway had crossed the beach area to connect with the trestle. A pier deck height of +10 to +12 feet (chart datum) was recommended to account for the effects of tide, storm surge, wave, and wave runoff.

The following recommendations were of major importance in the final design and construction of dock facilities:

- Minimize
 - Dock lengths
 - Dredging
 - Maintenance
- Standardize
 - Dock configurations
 - Construction materials
 - Construction techniques
- Maximize
 - Precast concrete

It is recommended that standardized concrete modular units be prefabricated elsewhere and then transported to the sites. By use of a construction barge with a crane and pile driver and use of standard construction techniques, docks

would be assembled on location with minimum on-site construction. The above are recommended due to the remoteness of the sites, the unavailability of supplies and laborers, and to keep construction costs to a minimum. Concrete is recommended from a corrosion maintenance standpoint.

Due to the high cost of mobilization to the sites, additional field work to gather supplementary data was not economically feasible. Therefore, it is expected that some changes to the designs may be required in the field.

Coast Protection Against
the Action of Waves and Currents

Leren P. Mikhailov Cand.Sc.(Eng.)
Director of Hydroproject Institute

Sergei M.Uspenskii Eng., Chief of
Reservoir & Environmental Protection
Department Hydroproject Institute

According to the information available in the USSR, now in the world there are more than 13000 reservoirs with storage capacity over 1 million m³ in service and under construction. The largest ones are illustrated in Table 1. In some countries these storage reservoirs constitute rather a great per cent relative to all the reservoirs of the given country. (Table 2).

Lately, such reservoirs have substantially grown in number in many countries of the world, especially in the USSR and USA, what is seen from the chart (Fig.1).

In this connection, one can conclude on the great area of some reservoirs (reaching sometimes thousands of square kilometers), on their importance in the balance of the controlled runoff, making up in some countries over 95 per cent and on the intensive increase of their storage capacity beginning from the fifties of the present century. The above said is one of the reasons of greater interest in the action of waves and currents of the shore line showing up most intensively on the largest storage reservoirs.

The length of the shore line of the USSR reservoirs is over 40000 km. The length of the erosion shores of storage reservoirs at the hydroelectric projects on the Volga and Dnieper River make up more than 30 per cent of the total shoreline of these reservoirs, while that of the reservoirs on the Kama River - 35 per cent. Most intensively the erosion is going on in the first decades of the operation of the reservoirs. The action of waves on the shore results in formation of the underwater slope with a gradient at which the wave energy is dissipated on the shoal, and the shore erosion slows gradually down until it ceases completely. However, it is rather difficult now to determine the period of the shore formation attenuation process in view of the fact that the problem of distribution of wave energy between all the phenomena taking place here is not properly studied yet and it is not also clear what width and gradient of the shoal can fully baffle the wave energy and how much time it will take for such a shoal to get formed. The observation carried out on the natural water bodies well prove it. On the Seligher Lake (2) the shores of some large

islands have retreated during the last thirty years by 50-80 m with the shoal width varying from 64 m to 210 m. The signs of recent erosion of the shores have been discovered on the Kish-Lake with the shoal width being 80 m. In view of the variability of wave regime and, especially, level fluctuation in the reservoirs, it is believed that the wave erosion of the shores can proceed for rather a long period of time.

In proper studies the action of waves and currents on the shoreline of the reservoirs is explained by the availability of a number of circumstances, complicating the studies, as compared to the sea and lake conditions. First of all, it is the geological and geomorphological factors and, especially, considerable water level fluctuations which influence the waves and currents formation. These factors are most effectual in the first decades of the reservoirs operation. In this period the length of the longshore currents owing to a sinuous shoreline is not great. As the shoreline simplification proceeds, the currents become stronger and lengthy. One of the causes of a more complex relation of the wave growth vs. the duration and fetch length is the size of water bodies and their volume, which are less as compared with the sea ones. The height of waves on the reservoirs is less than on the sea and is usually not more than 3m. As a rule the waves here steeper than on the sea. Owing to a less volume of water in the reservoir, the wind waves here attenuate very quickly, contrary to the sea condition, where the swell remains long. The water circulation in the zone of waves disruption is caused by the setup of the longshore currents and of compensating currents (countercurrents or rip currents, being a particular case of the first ones). All this governs the complexity and variability of the hydraulic regime of the littoral zone in which the protection works are located. When working the problem of building the protection works the economic analysis is usually made which includes the study and comparison of the following alternatives:

- absence of protection works, and as a consequence necessity arises to relocate or remove the national economy projects; there are land losses caused by shore transformation and flooding;
- provision of protection works after five-ten and even more years of the reservoirs operation. In view of the transformation and flooding of the shores during this period it becomes necessary to take into account the protection measures to be undertaken and the conditions of construction of the coast engineering works with account for the developed underwater and above-water shore slopes;
- construction of the protection works during the period of creating the reservoirs.

The above analysis makes it possible either to discard the protection works or choose the constructive solutions,

which from the viewpoint of their designation can be divided into two large categories:

- shore erosion protection works and
- shore flooding protection works

The first category of works include the shore protection walls made of stone, concrete, reinforced concrete; shore revetments made of rock, concrete, reinforced concrete, asphalt-concrete and cement-earth mixture; groins, breakwaters, sand inwash, planting and different combination of the above protection works. Depending upon the hydrogeological conditions and usage of the littoral area, the construction of drainage can be required. The length of the protected shoreline of the storage reservoirs at the hydro projects on the Dnieper River is over 400 km.

The second category of works include the works which protect the shores against erosion and flooding. very often it is a complex of protection works, including levees, pump stations and drainage arrangements. Such protection works can afford a considerable saving, especially, in case of protecting the towns against floods.

So, vast areas of valuable arable lands near many storage reservoirs in the USSR have been protected against flooding.

Only near the reservoirs on the Dnieper River over 200000 hectares of lands have been protected what gave a 30 per cent saving in land easement. On the Lower Kama and Cheboksary storage reservoirs which are being constructed now, the work is under way also to protect about 50000 hectares of lands. Rock and concrete are widely used in protection works.

If rock is available, it is possible to use riprap. Its advantage is easy and simple placement procedure and repair and suitability for all types of underlying soils. The job is easily mechanized and can be carried on at any time of the year.

The merits of the protection of continuous and cellular precast and cast-in-situ concrete slabs are the following; strength watertightness, possibility of wide mechanization (and for precast slabs-possibility of prefabrication) and carrying the job in winter.

Among the demerits are the necessity of importing such materials as cement, reinforcing steel and aggregates; rigidity and low roughness of structures and for precast slabs - thorough slope levelling; difficulties in concreting the joints and in repair. The analysis of malfunction of such types of protection has shown that the underestimation of one or another factor such as the upper limit of water level fluctuation, wave action, ground water seepage velocities and deformation properties of the underlying soil had a great effect.

The analysis of the state of the structures in service affords a valuable information that can be used in their designing.

The most interesting is the analysis of the behaviour of the works under the extreme conditions which allow for revealing the reliability and disadvantages of the construction.

Fig.3a) Upstream slope of the Kamensk dike during the rock toe repair

Fig.3b) Shore protection in the town of Kakhovka after the storm.

Such conditions appeared on a number of storage reservoirs on the Dnieper River where a storm of rare frequency was recorded in October, 1969. With the wind velocity of about 35-40 m/s in the area of the Kamensk dike on the Kakhovka reservoir the wave reached 2.5 m in height. The upstream slope of the dike is made $m=3$ and protected with a riprap layer 0.55-0.7 m thick, placed over an inverted filter 0.7 m thick.

To protect the downstream cut-off the sand inwash 0.5-2.0 m was provided, that appeared to be a very reliable means of protection. The transformation of the inwashed fill during the storm followed the pattern: erosion - in the water edge zone and soil accretion at the outer side of the inwashed fill (Fig.2). The visual observations proved that the disruption of high waves had taken place on the outer side of the inwash at a distance of 90-120 m from the water edge. No evidence of the dike slopes damage was traced. The inwashed fill had undergone inconsiderable transformation (Fig.2), while the Znamensk dike on the same reservoir had been damaged. The upstream dike slope is $m=3.0$, the downstream slope is $m=2.5$. The upstream slope is protected with stones weighing 40-180 kg and placed over a double-layer inverted filter 60 cm thick. To prevent the underwashing of the cut-off, silty sand was sluiced in one place, while the rock banquette was built in the other place. The crest of the sluiced sand fill was 3-3.5 m below the Norm. HWL, that is why its effect in the waves extinction was insignificant. The slope protection was damaged locally with scours which appeared two meters above and below the Norm. HWL and reached 84-480 m². Here, the filter material had been washed out and stone had subsided. So, about 864 m² of slope protection and 2400 m³ of rock banquette had been destroyed (Fig.3)a)b). In so far as the sluiced sand fill its lowered top elevation (3-3.5 m below Norm. HWL) did not promote the extinction of waves, the Znamensk dike slope protection was damaged. The comparison of behaviour of structural elements of practically the similar design illustrated how effective in wave energy dissipation the sluiced sand fill was. The cause of damage of the Znamensk dike slopes was the unjustified lowering of the sluiced fill crest by 3-3.5 m, below the Norm. HWL.

The cost analysis of the coastal engineering projects showed that the most expensive structures are the dike of economical section with concrete protected slopes; their cost makes up 70-80 per cent of the total cost of the coastal engineering, and the cost of slope protection is about 40 per cent of the dike construction cost (5). That is why, one of the most important trends in searching the rational design solutions is finding out of the ways to reduce the cost of the slope protection or to eliminate it. The latter, to some extent, be met by the dikes with gentle slopes.

On the reservoirs at the hydroprojects on the Dnieper River the length of such dikes is about 200 km; 120 km of the dikes are with a "beach" upstream slope (1:25-1:50) and downstream slope (1:4).

The dikes of this type have been built to protect the shallows and shores against the waves not more than 1.5 m in height. The height of dikes is 6-7 m and soil particles $d_{50} = 0.18-0.25$ mm (6).

When the dike is over 7-8 m in height and wave is over 1.5 m in height the smooth slopes are economically inefficient. Under such conditions the "beach" slopes are protected against the currents and waves with the help of rockfill groins and underwater intermittent breakwaters.

The advantages of the dikes with gentle slopes are the following:

- good stability of the dike body;
- elimination in many cases of drainages in the dike body and on the protected area;
- safety of the dikes founded on the easily compressible soils;
- elimination of imported materials (concrete and rock);

However, a demerit of the dikes in question is rather a great area they occupy.

The construction of the above dikes affords a saving of 8-10 per cent as compared with the other dike types; the running costs are only 10-15 per cent higher than these of the economical section dike and for some of them they are practically the same (6).

Quite promising are the shore protection works of economical design worked out by the Institute of Hydromechanics, AS Uk SSR, using the method of "natural analogues". The essence of the method consists in simulation of the natural process of transformation of the erosion shore into the stable accretion one under the dynamic action of waves and currents.

The designation of the protection structures using the principle of "natural analogues" is that they direct the energy of the wave flow to the transformation of unstable shore (intensively transformed by waves and alongshore currents) into the dynamically stable ones. Owing to this, on cessation of the unidirectional shore transformation, the protection works which had been used to control the wave energy, become its permanent elements and maintain the shore in the dynamically stable condition. Thus, the protected shore become a hydraulic structure functioning as an "artificial analogue" of the self-protection element of the shore that had transformed to the dynamically stable one.

The protection structures employed lately in coastal engineering are the intermittent protection of the shore and double-groins (tombolo).

The intermittent protection of the shore makes it possible to stop the development of the shore and transform it into the bay-shaped shore, dynamically stable at any wave (Fig. 4) and it can be used in the cases, when the

shore retreat deep into the territory is permissible. When it is not permissible (Fig.4, b), the double-groins shall be used.

The relationship between the size of protection and the dynamically stable shore shape depending on the zone of the alongshore drift (transit and sediment pick-up zones) is illustrated in Fig. 4, where T-the coefficient of the dynamically stable slope for the design waves and normal wave approach to the shore (7). Under the action of waves every adjacent couple of double-groins and the length of the protected shore enclosed between them from "bays". In time, the shore profile in plan changes in accordance with the shape of the waves getting into the water area and curved due to diffraction and refraction. So, the frontal approach of waves to the water wedge is provided lengthwise the whole perimeter of the bay irrespective of the direction of initial wave what ensures the development of the bay shape with dynamically stable surface of the underwater shore slope. Being completely transformed the bays take the form of semicircumferences, with the radius $L = \frac{1}{2}S + \frac{2}{3}S$ (Fig.4) (8). The construction of the above protection works makes it possible:

- to transform the eroding shore into the stable bay-shaped one by a directed harnessing of the energy of waves eroding it, thus eliminating the possibility of development of the unique alongshore wave flow, as one of the causes of the shore erosion;
- to cut down the requirements in building materials (concrete, rock) considering the intermittent protection, as compared with the conventional breakwaters;
- to facilitate the execution of work, since it can be done ashore and during the reservoir operation.

The economic analysis proves that the intermittent protection works in some cases are 1.5-3 times cheaper than the continuous riprap protection (3).

Provided the rock is available, the reservoir coasts are protected by riprap of graded and ungraded rock placed in two layers: the upper layer consists of large-size material, the lower layer-of rock with fraction size decreasing towards the protected surface. Based on the results of the study of the riprap behaviour and in order to facilitate the work execution the double-layer riprap protection has been substituted now by a single-layer riprap protection, i.e. by a mixture of all fractions which form two layers. However, it didn't eliminate the work on leveling the slope before placing the riprap to protect it and the construction of the rock toe (cut-off) at the base of the slope revetment. When the reservoir was filled, the work was much more complicated and the cost grew up.

Provision on a number of storage reservoirs of the transforming banquettes of rock muck designed on the principle of "natural analogues" allowed for eliminating the mentioned shortcomings of the employed revetments of rock muck.

Fig.4. Types of shore protection works

I. Intermittent protection (water edge recession deep into the shore is permissible)

II. Double - groin (water edge recession deep into the shore is not permissible)

a) shore profile after the construction of shore protection works

b) profile of the shore after its transformation to the dynamically stable bay-shaped shore.

III. Protective rock banquettes

1.-Shore to be protected; 2-intermittent protection works; 3-double-groins; 4-water edge; 5-water erosion prediction line.

The natural analogue of the above construction was the shoals at the erosion shores with their body composed of highly desintegrated rocks.

Immediately after its completion, the banquette is a prism filled of rock muck lengthwise the shore to be protected at the level of water edge with natural (for this material) angles of repose for the upstream and downstream slopes (Fig.4).

Under the action of waves and alongshore currents a part of the shoal in front of the structures is washed out and the front end of the banquette gets deformed. The rock muck in this case rolls down onto the coast shoal at the banquette base and spreads to form a train of V-shaped cross section. At the same time the rock muck brought by waves to the train body is segregated as if in the inverted filter, thus making the protection stable to the wave hydrodynamic loads and preventing the beach shoal from being eroded.

The applied methods of calculations (8) enable one to choose the main dimensions and construction work quantities for the structures of different service life. Among the above tasks to be solved when designing the banquette are the substantiation of the design parameters of wind waves; calculation of movement of the load under the wave action within the length of the protection structure and on the adjacent shore sections; choosing of the grain size distribution of the rock muck to be used for the banquette according to the wave parameters and characteristics of soil composing the beach shoal.

This structure, depending upon its designation and proposed lifetime, can be considered as the temporary, permanent or, constructed in several stages.

The operation of the similar type structures on the Kakhovka reservoir and designing of the shore protection on the Volgograd reservoir attests that the use of a rock muck banquette to protect the shore against erosion is 18-38 per cent cheaper than the conventional type of protection - riprap protection; a combination of concrete re-vestment and riprap and others (9).

Besides, the design of the rock banquette makes it possible to mechanize practically all construction operations, to employ the unskilled labour and, what is most important, to carry all the work under conditions of the filled reservoir. The same advantages are characteristic of the structures isolating the shallows and simulating the natural accumulation forms, such as spurs, bay-bars and bars.

The approach to such structures differs from the traditional one, i.e. when the alignment of the structures is chosen on the principle of their longitudinal axis orientation along the most elevated points of the reservoir bed. However, this principle is unacceptable, if such

structures are considered as the artificial analogues of the natural accumulation form. In this case their shape in plan shall follow the natural accumulation forms stable to the action of waves and currents which could develop under the natural conditions with a required amount of sediment available and under the action of prevailing winds. Such works, creating the natural "analogues" (spurs, doublegroins, bars) by the directed utilization of the energy of waves and alongshore currents, provide the isolation of shallows and comparatively cheap protection of shores against erosion.

The coastal engineering works make possible at the same time, the rational development of the natural resources and are of importance for nature conservation, namely:

- protection of arable lands, mineral deposits, historical and architectural monumental against underflooding, flooding and banks collapse;
- improvement of sanitary and hygienic conditions of the water bodies by slowing down the intensity of water "bloom" and by reducing the shallow areas;
- selection of the hydroelectric project site and Norm. HWL that guarantees the most rational utilization of natural resources by all the users.

In the USSR the coastal engineering works protecting the shores and agricultural lands against flooding and erosion find expanding application. The protection works are being erected on the reservoirs under construction as well as on the existing reservoirs. Carrying out of these works in an even increasing scale is dictated by the considerations of nature conservation stated in the USSR Constitution and in other legislative documents.

Conclusions

1. Intensive increase of the number of large storage reservoirs, a considerable share in control of the total runoff, great length of erosion shores and complex action of waves and currents on the reservoir shores prove the urgency of the problem of elaborating the economical designs of the protection works;

2. The most expensive elements of protection works are revetments. One of the progressive trends in studies aimed at working out the structural solutions which enable one either to reduce the quantities of work involved or to eliminate the protection is the "method of natural analogues";

3. The protection works allow the rational utilization of natural resources and at the same time they conserve the nature, namely, they conserve the land resources, prevent the shore erosion, improve the sanitary and hygienic conditions in the reservoirs etc.

FOREWORD

The Seventeenth International Conference on Coastal Engineering was extremely important in many ways to those who attended the conference and to those who will benefit from use of these *Proceedings*. The Seventeenth Conference marked the 30 year point in the history of the coastal engineering conference series and a change in leadership. Since the first conference was held in Long Beach, California in October 1950, Dean Morrrough P. O'Brien and Professor Joe W. Johnson have provided the continuity, direction, and motivation that have made the International Coastal Engineering Conferences so successful. For thirty years Dean O'Brien has served as Chairman and Professor Johnson as Secretary of first the Council on Wave Research and now the Coastal Engineering Research Council. Because of the importance of their contributions to the coastal engineering conferences the Council decided that these *Proceedings* will be dedicated to these two leaders. A summary of the accomplishments of each in coastal engineering is presented here.

MORROUGH P. O'BRIEN

His distinguished career in coastal engineering has been much too full to cover adequately in this space; only a sketch of his accomplishments are included here. M. P. O'Brien retired as Dean of the College of Engineering at the University of California, Berkeley, in 1959. His tenure at Berkeley included an impressive record of teaching, research and university administration. During this interval, through his students and research, he established the reputation of "The Father of Coastal Engineering." After leaving his post at Berkeley he has been very active in industrial and governmental research and development projects. At his present age, 78, Dean O'Brien is still an extremely active professional in coastal engineering.

Dean O'Brien graduated from Massachusetts Institute of Technology in 1925 and pursued graduate work at Purdue University. In 1927 he was awarded the ASCE John R. Freeman Scholarship which allowed him to attend the Technische Hochschule, Danzig, and the Royal College of Engineering, Stockholm, to study hydraulic structures and machinery. He has received honorary degrees from Northwestern University, D.Sc.; Purdue University, D.Eng.; and University of California, Berkeley, LL.D.

He joined the Mechanical Engineering Department at the University of California becoming Department Chairman in 1936 and Dean of the College in 1943. During his tenure as Dean he was instrumental in the development of graduate education and research and in the modernization of the undergraduate program.

In 1929, Dean O'Brien organized and initiated a program of research on shoreline processes and coastal engineering for a board appointed by the Chief of Engineers of the Army; subsequently, Congress established this work on a permanent basis under the U.S. Beach Erosion Board. Dean O'Brien has served as a member of this board and its successor, the Coastal Engineering Research Board from 1938 to 1980. He has maintained an active interest in ocean waves and shoreline phenomena. During the war years, this interest led to work on the design of landing craft, on forecasting surf conditions,

and on intelligence studies of landing beaches. Following the war he served as Chairman of the ad hoc committee on Amphibious Operations of the National Research Council which reviewed the plans for modernization of the Marine Corps. Consulting engagements in the field of coastal engineering included restoration of the beach at Santa Barbara, regulation of the estuary of the Columbia River, Dos Bocas Harbor in the Gulf of Campache and other similar coastal projects.

Dean O'Brien's research on hydraulic machinery led to many practical applications by industry. Most of the jet pumps sold in the United States follow the designs of O'Brien and Gosline. Application of the theory of airfoils to the design of propeller pumps and fans by O'Brien and Folsom provided the basis for extensive production of low-head, high-capacity pumps for irrigation and drainage. Consulting engagements on hydraulic machinery during this period included Byron Jackson, Food Machinery, Fairbanks-Morse, Becker Pump, Navy Department, Corps of Engineers, and many other governmental agencies. His experience with turbo-machinery led to his appointment in 1949 as a consulting engineer by the Aircraft Gas Turbine Division of the General Electric Company, an association which has continued to the present. He is now a consultant to the Technical Systems and Materials Sector of General Electric, dealing with both technical and management problems of jet engines, missiles and space vehicles, ordnance, and electronic systems.

During the war years, Dean O'Brien directed the University of California's program of engineers' science and management war training for technical and professional personnel in the aircraft and shipbuilding industries. During the four years of its existence, this program included 1800 instructors and 46,000 students. Concurrently, he served as dean of the college and as consultant in the research section of the Bureau of Ships on problems of submarine propeller noise, and on amphibious operations. In 1946, he participated in Operation Crossroads at Bikini as a consultant on the measurement of waves generated by the bomb tests; most of the photographs of the Baker tests, which appeared in the press, were taken by the tower and aerial cameras which Dean O'Brien and his associates operated for wave measurements.

Twice, he has taken full-time leave from academic duties to engage in engineering practice; once, 1947 to 1949, to serve as director of research and engineering with the Air Reduction Company and, again in 1953, to join General Electric Company's Aircraft Nuclear Propulsion Project. He has held membership on many influential boards and commissions, among them the Coastal Engineering Research Board, formerly the Beach Erosion Board; the National Science Foundation's panel of engineering consultants; the Army Scientific Advisory Panel; the Atomic Energy Commission's personnel security board; the Maritime Research Advisory Committee and the Advisory Board on Education of the National Academy of Sciences, National Research Council; and the board of directors, McGraw-Hill Publishing Company. In 1958 President Eisenhower appointed him a member of the Board of the National Science Foundation. During 1958-1959, he was a visiting institute professor at the Massachusetts Institute of Technology, and a visiting research fellow at Harvard University.

Among awards he has received are the Army-Navy Certificate of Appreciation; the Distinguished Civilian Award, Department of the Army (twice); and the Bliss Medal of the Society of American Military Engineers. In 1968 he received the ASEE's Lamme Award, and in 1969 a building at the University of California's Berkeley Campus was named after Dean O'Brien.

He has written more than 100 published articles on technical subjects and engineering education, and is co-author of "Applied Fluid Mechanics," published by McGraw-Hill in 1937. The bibliography is his own selection of the papers which he most enjoyed

writing. He is a registered professional engineer in the states of California and New York, and a chartered Mechanical Engineer in Great Britain. In 1969 he was elected to the National Academy of Engineering. He is an Honorary Member of both the ASCE and ASME.

JOE W. JOHNSON

Professor Johnson has had a long and very distinguished career in coastal engineering. His reputation extends around the world, reaching forth from his consulting, his research and especially his students. In 1975 he retired as Professor of Civil Engineering from the University of California, Berkeley. Professor Johnson is also well known for his excellent handling of the *Proceedings* of all sixteen prior coastal engineering conferences. Since his retirement from the University of California he has been extremely active in his consulting practice and professional duties.

Professor Johnson graduated from the University of California, Berkeley, in 1931 with a B.S. in Civil Engineering and in 1934 with an M.S. degree. Following a brief stay at the Waterways Experiment Station he devoted eight years to studying sediment transport with the Soil Conservation Service. He then returned to the University of California and enjoyed a very fruitful career of teaching, research and public service.

He has been consultant to many international projects involving shoreline development including: an ore port in Vitoria, Brazil; harbor development along the coast of Venezuela; port development in Northwest Australia; port development in Damietta, Egypt; sedimentation at Bahia Blanca, Argentina; Hay Point Coal Port, Australia; and wave action and sedimentation in Brazil. His associations with coastal engineering projects in the United States are equally extensive; a brief list follows of his involvement: Rio Grande Valley, wind tides in Lake Okeechobee, wave analysis of Marina del Rey, San Francisco Bay Area Rapid Transit, Turkey Point Power Plant in Florida and beach erosion at the Zion Atomic Power Plant.

In addition Professor Johnson has been a member, since 1974, of the Shoreline Erosion Advisory Panel created by the U.S. Congress. His expertise in coastal engineering has been quite instrumental in the success of this research and development program. He also has been selected as the chairman of the U.S. Delegation to the U.S.-Japan Cooperative Seminar on Coastal Engineering held in Japan. Professor Johnson has been appointed to numerous other boards and committees. He was the Secretary of the Council on Wave Research during its existence from 1950 to 1964, and then of the subsequent organization, The Coastal Engineering Research Council of the ASCE. He has been very active in the AGU holding key positions and has been a major driving force behind the American Shore and Beach Preservation Association as Vice President and Editor of *Shore and Beach*.

In 1976, Professor Johnson was elected to membership in the National Academy of Engineering and in 1979, he received the distinguished honor of Honorary Member of the ASCE. He is also the recipient of the Guggenheim Fellowship, The Outstanding Civilian Service Medal for his service in the field of coastal engineering and the Berkeley Citation. A selected listing of his over ninety publications are given below. Professor Johnson has been and still is a very active and important part of international coastal engineering.

Selected Bibliography

- The Transportation of Sediment by Streams: Bed Load, *Inter. Union Geod. and Geophys.*, 1939.
- Transportation of Sediment by Flowing Water, *Soil Conserv.*, vol. 6, 1941.

- A Distinction Between Bed Load and Suspended Load in Natural Streams (with Einstein and Anderson), *Trans. Amer. Geo. Union*, 1940.
- “War-time research on waves and surf.” *The Military Engineer*, June 1947.
- “Refraction of surface waves by currents.” *Trans. Amer. Geo. Union*, 1947.
- “The force exerted by surface waves on piles,” (with J. R. Morison, M. P. O’Brien, and S. A. Schaaf), vol. 189, 1950.
- “The Damping Action of Submerged Breakwaters,” (with R. A. Fuchs and J. R. Morison), *Trans. Amer. Geo. Union*, vol. 32, 1951.
- “The March 1962 Storm on the Atlantic Coast of the United States,” (with M. P. O’Brien), Proc. Eighth Conference on Coastal Engineering, 1963.
- “Ship Waves in Shoaling Water,” Proceedings Eleventh Conference on Coastal Engineering, 1968.
- “Lessons in Coastal Engineering,” Symposium on Coastal Engineering, Stellenbosch, South Africa, 1970.
- “Closure of Tidal Entrances,” Proc. Fourteenth Conference on Coastal Engineering, 1974.
- “Littoral Processes at Some California Shoreline Harbors,” *Shore and Beach*, vol. 43, no. 1, April 1975.

The omissions from the accomplishments of Dean O’Brien and Professor Johnson are solely the responsibility of the writer; however, the magnitude of their contributions to coastal engineering has forced the writer to condense their many activities. Indeed a detailed listing of their individual efforts would fill a volume.

While listening to the discussions of the mechanics of sand waves by Professor Arthur Brebner, Professor Longuet-Higgins was able to tie some of Brebner’s findings with the theoretical work he (Longuet-Higgins) had done on water waves of maximum steepness. Since Professor Longuet-Higgins’ Keynote address begins the *Proceedings*, it was felt proper to end them with a brief summary explaining the application of his limiting wave theory to sand bed-forms. His discussion can be found on page 3107.

Billy L. Edge, Secretary
 Coastal Engineering Research Council
 American Society of Civil Engineers

ACKNOWLEDGMENTS

ORGANIZING COMMITTEE

Mr. J. G. Betty, Chairman,
Macdonald Wagner & Priddle Pty. Ltd.
Mr. G. Evans,
Department of Public Works of N.S.W.
Professor D. N. Foster,
The University of New South Wales.
Mr. W. J. Kerle,
Department of Public Works of N.S.W.
Mr. N. Lawson,
Maritime Services Board of New South Wales.
Mr. W. M. Lewis,
Esso Australia Ltd.

LADIES COMMITTEE

Mrs. D. E. Betty,
Wahroonga, N.S.W.
Miss K. Winter,
Maritime Services Board of New South Wales.
Miss J. Shaw,
The University of New South Wales.

SUPPORT

The Institution of Engineers, Australia, in collaboration with the Coastal Engineering Research Council of the American Society of Civil Engineers, acknowledges the support and encouragement given by the following organizations:

Department of Public Works, N.S.W.
Esso Australia Ltd.
Macdonald, Wagner & Priddle Pty. Ltd.
Maritime Services Board of New South Wales
New South Wales State Government
The Sydney County Council
The Exhibiting Companies
The University of New South Wales.

INTERSTATE CORRESPONDING COMMITTEE MEMBERS

Mr. R. Culver, Dept. of Mechanical Engineering, The University of Adelaide,
South Australia 5000.
Dr. J. Hinwood, Dept. of Mechanical Engineering, Monash University, Clayton,
Melbourne, Victoria, 3168.
Mr. B. McGrath, Dept. of Harbours and Marine, G.P.O. Box 2195, Brisbane,
Queensland, 4001.
Professor R. Silvester, Dept. of Civil Engineering, University of Western Australia,
Perth, 6009.

Morrrough P. O'Brien

Joe W. Johnson

THE UNSOLVED PROBLEM OF BREAKING WAVES

by

M. S. Longuet-Higgins
Institute of Oceanographic Sciences
Wormley, Surrey, England

PART I

THEORETICAL AND OBSERVED WAVE CHARACTERISTICS

Chapter 1	
SOME IMPLICATIONS OF RECENT ADVANCES IN WAVE THEORIES	
J. R. Chaplin and K. Anastasiou	31
Chapter 2	
ACCURATE NUMERICAL SOLUTIONS FOR NONLINEAR WAVES	
J. D. Fenton and M. M. Rienecker	50
Chapter 3	
MASS TRANSPORT IN PROGRESSIVE WAVES OF PERMANENT TYPE	
Yoshito Tsuchiya, Takashi Yasuda and Takao Yamashita	70
Chapter 4	
RAY CURVATURE AND REFRACTION OF WAVE PACKETS	
J. Ernest Breeding, Jr.	82
Chapter 5	
VERIFICATION OF A WAVE REFRACTION MODEL	
G. Henderson and N. B. Weber	101
Chapter 6	
WAVE SHOALING CALCULATED FROM COKELET'S THEORY	
T. Sakai and J. A. Battjes	121
Chapter 7	
A SURVEY OF "RANDOM" WAVE GENERATION TECHNIQUES	
J. Ploeg and E. R. Funke	135
Chapter 8	
THE MEASUREMENT OF INCIDENT AND REFLECTED SPECTRA USING A LEAST SQUARES METHOD	
E. P. D. Mansard and E. R. Funke	154
Chapter 9	
ORBITAL VELOCITIES IN IRREGULAR WAVES	
F. C. Vis	173

Chapter 10	
INVESTIGATIONS ON IRREGULAR WAVES IN HYDRAULIC MODELS	
Karl-Friedrich Daemrich, Wolf-Dietrich Eggert and Soren Kohlhase	186
Chapter 11	
METHOD OF ANALYSIS OF RANDOM WAVE EXPERIMENTS WITH REFLECTING COASTAL STRUCTURES	
Pierre Gaillard, Michel Gauthier and Forrest Holly	204
Chapter 12	
WAVE HEIGHT DISTRIBUTION AROUND PERMEABLE BREAKWATERS	
Shintaro Hotta	221
Chapter 13	
NON-RESONANT WAVE AGITATION IN SMALL CRAFT HARBOURS	
J. W. Kamphuis and D. A. Y. Smith	241
Chapter 14	
EXPERIMENTAL INVESTIGATIONS OF PERIODIC WAVES NEAR BREAKING	
J. Buhr Hansen	260
Chapter 15	
AN HEURISTIC MODEL OF WAVE HEIGHT DISTRIBUTION IN SURF ZONE	
Masaru Mizuguchi	278
Chapter 16	
RESONANCES OF COASTAL WATERS BETWEEN PERTH AND GERALDTON (WESTERN AUSTRALIA)	
H. Allison, A. Grassia and R. Litchfield	290
Chapter 17	
A CLOSELY RESPONDING, VERSATILE WAVE TUNNEL	
C. H. Hulsbergen and J. J. Bosman	310
Chapter 18	
CONDITIONAL SIMULATIONS OF OCEAN WAVE PROPERTIES	
Leon E. Borgman	318
Chapter 19	
WIND WAVES TRANSMISSION THROUGH POROUS BREAKWATER	
Stanislaw R. Massel and Piotr Butowski	333
Chapter 20	
FIELD MEASUREMENTS OF WIND WAVE KINEMATICS	
J. A. Battjes and J. van Heteren	347
Chapter 21	
HF RADAR MAPPING OF EXTENSIVE OCEAN WINDFIELDS	
P. E. Dexter and R. C. Casey	363
Chapter 22	
SOURCES OF MEASURED WAVE DATA	
Laurence Draper	372
Chapter 23	
VISUALLY OBSERVED WAVE DATA AT PT. MUGU, CALIF.	
Christine Schneider and Richard Weggel	381
Chapter 24	
WAVE HINDCASTS AND MEASUREMENTS - BASS STRAIT	
M. N. Silbert, T. P. Barnett, D. J. H. Peters and R. C. Hamilton	395

Chapter 25		
REALTIME WAVE ANALYSIS, NEWCASTLE, AUSTRALIA		
N. V. Lawson and P. H. Oull	412
Chapter 26		
FLORIDA COASTAL DATA NETWORK		
Gary Howell	421
Chapter 27		
A MEASUREMENT OF SLOPE, CURVATURE, AND DIRECTIONAL SPECTRA OF WIND WAVES IN LAKE MICHIGAN		
Paul C. Liu	432
Chapter 28		
WAVE ATTENUATION AND WAVE SET-UP ON A COASTAL REEF		
Franciscus Gerritsen	444
Chapter 29		
LONGSHORE CURRENT FLOWS IN A WAVE BASIN		
P. J. Visser	462
Chapter 30		
DYNAMIC CHARACTERISTICS IN THE NEAR SHORE AREA		
Kiyoshi Horikawa and Masahiko Isobe	480
Chapter 31		
VELOCITY FIELD IN A STEADY BREAKER		
J. A. Battjes and T. Sakai	499
Chapter 32		
THE FLUID MECHANICS OF WAVES APPROACHING BREAKING		
D. H. Peregrine, E. D. Cokelet and P. Melver	512
Chapter 33		
A SIMILARITY MODEL IN THE SURF ZONE		
Hsiang Wang and Wei-Chong	529
Chapter 34		
VELOCITY AND PRESSURE FIELD IN SPILLING BREAKERS		
M. J. F. Stive	547
Chapter 35		
DIRECTIONAL WAVE SPECTRA AND WAVE KINEMATICS IN HURRICANES CARMEN AND ELOISE		
G. Z. Forristall, E. G. Ward and V. J. Cardone	567
Chapter 36		
PREDICTION OF THE SEVEREST SIGNIFICANT WAVE HEIGHT		
Michel K. Ochi and Joseph E. Whalen	587
Chapter 37		
PREDICTION OF DOMINANT WAVE PROPERTIES AHEAD OF HURRICANES		
Omar H. Shemdin	600
Chapter 38		
LONG PERIOD DISTURBANCES DUE TO WAVE GROUPS		
E. C. Bowers	610
Chapter 39		
TWO-DIMENSIONAL SURF BEAT		
Reinhard E. Flick, Douglas L. Inman and Robert T. Guza	624

Chapter 40		
LONG WAVES GENERATED BY COMPLEX BOTTOM MOTIONS		
J. L. Hammack and F. Raichlen		639
Chapter 41		
TSUNAMIS ALONG WEST COAST OF LUZON, PHILIPPINES		
R. L. Wiegel		652
Chapter 42		
TSUNAMI PRONE FRICTION FACTORS FROM WIND MEASUREMENTS		
Charles L. Bretschneider		672
Chapter 43		
RUN-UP OF TSUNAMIS BY LINEAR AND NONLINEAR THEORIES		
Chiaki Goto and Nobuo Shuto		695
Chapter 44		
ON THE CORRECTION OF LAND-BASED WIND MEASUREMENTS FOR OCEANOGRAPHIC APPLICATIONS		
S. A. Hsu		708
Chapter 45		
NUMERICAL MODELLING OF TROPICAL CYCLONE STORM SURGE		
Rodney J. Sobey, Bruce A. Harper, and George M. Mitchell		725
Chapter 46		
A NUMERICAL MODEL OF STORM WAVES IN SHALLOW WATER		
A. Hauguel		746
Chapter 47		
THE GENERATION OF LONG WAVES IN THE LABORATORY		
Derek Goring and Fredric Raichlen		763
Chapter 48		
CORRECT REPRODUCTION OF LONG GROUP INDUCED WAVES		
N. -E. O. Hansen, S. E. Sand, H. Lundgren, T. Sorensen and H. Gravesen		784
Chapter 49		
AN ELECTROMAGNETIC ANALOGY FOR LONG WATER WAVES		
G. W. Jackson and D. L. Wilkinson		801
Chapter 50		
INTERACTIONS OF WAVES WITH SUBMARINE TRENCHES		
Jiin J. Lee, Robert M. Ayer and Wen L. Chiang		812
Chapter 51		
TRANSIENT FINITE-DIFFERENCE TSUNAMI CALCULATIONS		
Ove Skovgaard and Ivar G. Jonsson		823
Chapter 52		
AN INVESTIGATION OF WAVE SHELTERING BY ISLANDS		
S. V. Hsiao, J. E. Vesecky and O. H. Shemdin		840
Chapter 53		
THE DISSIPATION OF WAVE ENERGY BY TURBULENCE		
Yu Kuang-ming		850

PART II
COASTAL SEDIMENT PROBLEMS

Chapter 54	
BEACH CUSPS AT POINT REYES AND DRAKES BAY BEACHES, CALIFORNIA	
Robert G. Dean and E. M. Maurmeyer	863
Chapter 55	
BARRON RIVER DELTA INVESTIGATION	
D. A. Robinson, D. J. Cook and J. G. Barff	885
Chapter 56	
SOFT DESIGNS FOR COASTAL PROTECTION AT SEABROOK ISLAND, S.C.	
Miles O. Hayes, Timothy W. Kana and John H. Barwis	897
Chapter 57	
GEOLOGICAL CONTROLS ON PROCESS-RESPONSE, S.E. AUSTRALIA	
P. S. Roy and A. W. Stephens	913
Chapter 58	
BEACH EROSION-ACCRETION AT TWO TIME SCALES	
B. G. Thom and G. M. Bowman	934
Chapter 59	
PHYSICAL PROCESSES AND SEDIMENT FLUX THROUGH REEF-LAGOON SYSTEMS	
Harry H. Roberts	946
Chapter 60	
INSHORE-NEARSHORE MORPHODYNAMICS-A PREDICTIVE MODEL	
John Chappell	963
Chapter 61	
BEACH CUT IN RELATION TO SURF ZONE MORPHODYNAMICS	
L. D. Wright	978
Chapter 62	
BREAKER TYPE AND PHASE SHIFTS ON NATURAL BEACHES	
Peter J. Cowell	997
Chapter 63	
BEACH RESPONSE TO VARIATIONS IN BREAKER HEIGHT	
A. D. Short	1016
Chapter 64	
THE DYNAMIC SWEEPED PRISM	
David M. Chapman	1036
Chapter 65	
A LABORATORY STUDY OF OFFSHORE TRANSPORT OF SEDIMENT AND A MODEL FOR ERODING BEACHES	
Tsuguo Sunamura	1051
Chapter 66	
NEARSHORE CURRENTS ON A PARTIALLY ROCKY SHORE	
T. O. Sasaki, H. Igarashi and S. Harikai	1071

Chapter 67	
TOPOGRAPHIC CONTROL OF RUN-UP VARIABILITY	
Mark P. Bradshaw	1091
Chapter 68	
BEACH PROFILES AND ON-OFFSHORE SEDIMENT TRANSPORT	
Akira Watanabe, Yoshihiko Riho and Kiyoshi Horikawa	1106
Chapter 69	
SECONDARY SAND TRANSPORT MECHANISMS	
A. W. Smith and A. D. Gordon	1122
Chapter 70	
SAND TRANSPORT BY WAVES	
Jan van de Graaff and Wiel M. K. Tilmans	1140
Chapter 71	
NEARSHORE SUSPENDED SEDIMENT LOAD DURING STORM AND POST-STORM CONDITIONS	
Timothy W. Kana and Larry G. Ward	1158
Chapter 72	
ONSHORE-OFFSHORE TRANSPORT AND BEACH PROFILE CHANGE	
Masataro Hattori and Ryoichi Kawamata	1175
Chapter 73	
ON-OFFSHORE SEDIMENT TRANSPORT RATE IN THE SURF ZONE	
Toru Sawaragi and Ichiro Deguchi	1195
Chapter 74	
FIELD MEASUREMENTS OF SAND MOTION IN THE SURF ZONE	
Douglas L. Inman, James A. Zampol, Thomas E. White, B. Walton Waldorf, Daniel M. Hanes and Kim A. Kastens	1215
Chapter 75	
AN APPROACH TO UNDERSTANDING COASTAL PROCESSES	
A. D. Gordon and D. B. Lord	1235
Chapter 76	
RELATIONSHIP BETWEEN ALONGSHORE WAVE ENERGY AND LITTORAL DRIFT IN THE MID-WEST COAST AT TAIWAN	
Ho-shong Hou, Chung-Pan Lee, and Lung-Hui Lin	1255
Chapter 77	
LONGSHORE WATER AND SEDIMENT MOVEMENT	
D. H. Swart and C. A. Fleming	1275
Chapter 78	
CRITERION FOR STABILITY OF SHORELINE PLANFORM	
John D. Wang and Bernard le Mehaute	1295
Chapter 79	
ZETA BAYS, POCKET BEACHES AND HEADLAND CONTROL	
R. Silvester, Y. Tsuchiya, and Y. Shibano	1306
Chapter 80	
BEACHES: PROFILES, PROCESSES AND PERMEABILITY	
Michael R. Gourlay	1320
Chapter 81	
SAND BED-FORM LENGTHS UNDER OSCILLATORY MOTION	
Arthur Brebner	1340

Chapter 82	
SEDIMENT TRANSPORT PROCESSES AND COASTAL VARIABILITY ON THE ALASKAN NORTH SLOPE	
E. H. Owens, J. R. Harper and D. Nummedal	1344
Chapter 83	
SEDIMENT DISPERSAL ON THE N. S. W. CONTINENTAL SHELF	
Ron Boyd	1364
Chapter 84	
FLUID MUD DYNAMICS AND SHORELINE STABILIZATION: LOUISIANA CHENIER PLAIN	
John T. Wells and Harry H. Roberts	1382
Chapter 85	
NEARSHORE SEDIMENT TRANSPORT STUDY EXPERIMENTS	
R. J. Seymour and C. G. Gable	1402
Chapter 86	
A SEDIMENT TRAPPING EXPERIMENT AT SANTA CRUZ, CA.	
R. J. Seymour, G. W. Domurat and D. M. Pirie	1416
Chapter 87	
WAVE FORCING OF BEACH GROUNDWATER	
Evans Waddell	1436
Chapter 88	
LONGSHORE TRANSPORT EVALUATIONS AT A DETACHED BREAKWATER	
R. O. Bruno, R. G. Dean, and C. G. Gable	1453
Chapter 89	
MIGRATION OF LONGSHORE BARS	
Hans H. Dette	1476
Chapter 90	
A PHASED-DREDGING PROGRAM FOR SANTA CRUZ HARBOR	
James R. Walker and Peter J. Williams	1493
Chapter 91	
DESIGN OF ENCLOSED HARBORS TO REDUCE SEDIMENTATION	
Craig H. Everts	1512
Chapter 92	
OPENING AND MAINTAINING TIDAL LAGOONS & ESTUARIES	
Scott A. Jenkins, Douglas L. Inman and James A. Bailard	1528
Chapter 93	
RESEARCH IN SOUTHERN QUEENSLAND INTO THE MANAGEMENT OF COASTAL SAND DUNES	
James B. McKenzie and David A. Barr	1548
Chapter 94	
WIND AND SEDIMENT MOVEMENT IN COASTAL DUNE AREAS	
John R. Hails and John Bennett	1565
Chapter 95	
SAND TRANSPORT UNDER THE ACTION OF WIND	
Ulrich Zanke	1576
Chapter 96	
A NUMERICAL MODEL FOR DUNE DYNAMICS	
J. Sundermann, H. -J. Vollmers and W. Puls	1584

Chapter 97	
ESTUARINE RESPONSE TO DREDGING IN THE TWEED RIVER, AUSTRALIA	
Bruce M. Druery	1599
Chapter 98	
NOOSA BEACH RESTORATION SCHEME	
R. J. Lloyd	1619
Chapter 99	
BEACH NOURISHMENT AS A MANAGEMENT TECHNIQUE	
David M. Chapman	1636
Chapter 100	
CAPRICORN COAST BEACHES	
D. C. Patterson and L. R. Ford	1649
Chapter 101	
THE BEACH IMPROVEMENT PROGRAMME: NEW SOUTH WALES	
Heale A. Philip and Phipp H. Waite	1669
Chapter 102	
EDDY CURRENTS AND SEDIMENT TRANSPORT OFF THE DAMIETTA NILE	
S. P. Murray, J. M. Coleman, H. H. Roberts and M. Salama	1680
Chapter 103	
A COMPARISON BETWEEN DREDGE INDUCED SEDIMENT RESUSPENSION AND THAT PRODUCED BY NATURAL STORM EVENTS	
W. Frank Bohlen and Marine Sciences Department., Univ. of Conn.	1700
Chapter 104	
SEDIMENTATION IN CHANNELS AND TRENCHES	
E. W. Bijker	1708
Chapter 105	
SEDIMENTATION IN DREDGED NAVIGATION CHANNELS	
Lars Mikkelsen, Preben Mortensen, and Torben Sorensen	1719
Chapter 106	
SOME ASPECTS OF COASTAL ENGINEERING RESEARCH WORKS IN CHINA	
Yen Kai	1735

PART III
COASTAL STRUCTURES AND RELATED PROBLEMS

Chapter 107	
SIMULTANEOUS WAVE AND CURRENT FORCES ON A PIPELINE	
David A. Knoll and John B. Herbich	1742
Chapter 108	
WAVE FORCES ON AN INCLINED CIRCULAR CYLINDRICAL PILE	
Toshiyuki Shigemura	1761
Chapter 109	
WAVE-INDUCED SEEPAGE EFFECTS ON A VERTICAL CYLINDER	
Thomas J. P. Durand and Peter L. Monkmeyer	1781

Chapter 110	
STABILITY ANALYSIS OF SEAFLOOR FOUNDATIONS	
Tokuo Yamamoto and Yasumasa Suzuki	1799
Chapter 111	
WAVE FORCES ON OFFSHORE PIPELINES	
N. Jothishankar and V. Sundar	1819
Chapter 112	
WAVE IMPACT PRESSURES ON COMPOSITE BREAKWATERS	
G. R. Mogridge and W. W. Jamieson	1829
Chapter 113	
CONSTRUCTION AND MODEL INVESTIGATION OF STORMWATER OUTFALL	
K. A. Heathcote and G. W. Britton	1849
Chapter 114	
FULL SCALE NEAR SURFACE WATER PARTICLE VELOCITIES AND PRESSURES ACTING ON AN INCLINED TUBULAR MEMBER	
Fritz Busching and Eckehard Martini	1869
Chapter 115	
ENERGY TRANSMISSION OVER BREAKWATER—A DESIGN CRITERION?	
P. Bade and H. Kaldenhoff	1885
Chapter 116	
THE DESIGN CONCEPT OF DUAL BREAKWATERS AND ITS APPLICATION TO TOWNSVILLE, AUSTRALIA	
W. Bremner, N. N. Foster, C. A. Miller and B. C. Wallace	1898
Chapter 117	
DESIGN OF AN OVERTOPPING BREAKWATER

HARBOUR DESIGN INCLUDING SEDIMENTOLOGICAL PROBLEMS USING MAINLY NUMERICAL TECHNIQS	
B. Latteux	2213
Chapter 134	
NEW JETTIES FOR TUNG-KANG FISHING HARBOUR, TAIWAN	
Chi-Fu Su	2230
Chapter 135	
MAJOR RECLAMATION SCHEME FOR MARINA CITY, SINGAPORE	
S. Y. Chew and J. Wei	2245
Chapter 136	
SHIP-BRIDGE-PIER PROTECTIVE SYSTEMS	
Akira Iwai, Hitoshi Nagasawa, Kazuki Oda and Kuniaki Shoji	2261
Chapter 137	
WAVE-WAVE INTERACTIONS, CURRENT-WAVE INTERACTIONS AND RESULTING EXTREME WAVES AND BREAKING WAVES	
Soren Peter Kjeldsen and Dag Myrhaug	2277
Chapter 138	
CAN WE DEVELOP NEW BREAKWATER ARMOUR FORMULAE?	
John Dorrington Mettam	2304

PART IV
COASTAL, ESTUARINE, AND ENVIRONMENTAL PROBLEMS

Chapter 139	
SEPARATION OF CLIMATIC FLUCTUATIONS AND IMPACTS OF ENGINEERING ACTIVITIES IN ESTUARIES	
G. Krause	2325
Chapter 140	
WAVE ENERGY DISTRIBUTION IN AN ESTUARY	
Volker Barthel	2340
Chapter 141	
HYDRAULIC RESEARCH IN THE OOSTERSCHELDE ESTUARY	
Anton W. Walther	2360
Chapter 142	
PORT OF BRISBANE SILTATION STUDY	
N. V. M. Odd and T. Baxter	2377
Chapter 143	
A 3-D MODEL FOR PENOBSCOT BAY, MAINE	
Bryan R. Pearce, Bruce R. Fidler and Adrian C. Humphreys	2397
Chapter 144	
THE USE OF ARRAY PROCESSORS FOR NUMERICAL MODELLING OF TIDAL ESTUARY DYNAMICS	
D. Prandle, E. R. Funke, N. L. Crookshank and R. Renner	2413
Chapter 145	
PARAMETER IDENTIFICATION IN ESTUARINE MODELING	
Wen-Sen Chu and William -G. Yeh	2433
Chapter 146	
AUTOMATIC CALIBRATION OF NUMERICAL TIDAL MODELS	
K. -P. Holz and U. Januszewski	2450
Chapter 147	
TIDAL INLET BEHAVIORAL ANALYSIS	
A. F. Nielsen and A. D. Gordon	2461
Chapter 148	
SEDIMENTATION PROCESSES IN TIDAL CHANNELS AND TIDAL BASINS CAUSED BY ARTIFICIAL CONSTRUCTIONS	
E. Renger and H. W. Partensky	2481
Chapter 149	
ARTIFICIAL ROUGHNESS IN PHYSICAL MODELS OF ESTUARIES FOR STORM SURGE INVESTIGATIONS	
D. Berndt, E. Giese, H. Schwarze, and H. -J. Vollmers	2495
Chapter 150	
COMMENTS ON TIDAL ENTRANCES ON SANDY COASTS	
Morrough P. O'Brien	2504
Chapter 151	
TIDAL PRISM-INLET AREA RELATIONS FOR SMALL TIDAL INLETS	
R. J. Bryne, R. A. Gammisch and G. R. Thomas	2517
Chapter 152	
A COASTAL INLET WITH FIXED BED AND MOBILE SIDES	
R. C. Nelson and A. J. Keats	2534

Chapter 153	
INLETS/ESTUARIES DISCHARGING INTO SHELTERED WATERS	
H. P. Riedel and M. R. Gourlay	2550
Chapter 154	
THE CORPS OF ENGINEER'S GENERAL INVESTIGATION OF	
TIDAL INLETS	
Robert M. Sorensen	2565
Chapter 155	
SATELLITE APPLICATIONS ON A COASTAL INLET STABILITY	
STUDY	
Yu-Hwa Wang	2581
Chapter 156	
BOUNDARY CONDITIONS FOR ANALYSIS OF FLOW IN TIDAL	
INLETS	
T. C. Gopalakrishnan and J. L. Machemehl	2595
Chapter 157	
MECHANISMS OPERATING AT A JETTIED RIVER ENTRANCE	
Bruce M. Druery and Alexander F. Nielsen	2607
Chapter 158	
STABILITY OF ESTUARY MOUTHS IN THE RHINE-MEUSE DELTA	
J. van de Kreeke and J. Haring	2627
Chapter 159	
BARDEN INLET, N.C.: A CASE STUDY OF INLET MIGRATION	
Limberios Vallianos	2640
Chapter 160	
STUDY ON VORTEX CURRENT IN STRAIT WITH REMOTE-SENSING	
Sotoaki Onishi and Tsukasa Nishimura	2655
Chapter 161	
DYNAMIC SIMILARITY OF TRANSPORT PHENOMENA	
M. S. Yalin and F. Gerritsen	2671
Chapter 162	
MOORING FORCES INDUCED BY PASSING SHIPS—MEASUREMENTS	
IN PROTOTYPE	
K. Haffke	2691
Chapter 163	
NUMERICAL MODELLING OF NEARSHORE CIRCULATION	
Bruce A. Ebersole and Robert A. Dalrymple	2710
Chapter 164

FLOATING BREAKWATER PERFORMANCE COMPARISON

Volker W. Harms

Lawrence Berkeley Laboratory
University of California
Berkeley, California 94720

ABSTRACT

Wave-transmission and mooring-force data of the Tethered-Float Breakwater and Pole-Tire Breakwater (PT-Breakwater) were compared, and the basic costs (without mooring system) of two equivalent breakwaters determined. It was found that, for short-fetch applications, the PT-Breakwater was an order of magnitude less costly than the Tethered-Float Breakwater. The PT-Breakwater is a more effective wave-energy filter than a Tethered-Float Breakwater of equal size. For open ocean conditions neither of these breakwaters has so far been proven to be economically feasible.

1. INTRODUCTION

An increasing demand for mooring space and the simultaneous depletion of suitable construction sites that are naturally sheltered from wave action creates a need for artificial low-cost protection of marinas and harbors [1]. Floating breakwaters are frequently chosen to provide this protection, particularly in locations where large water depths, poor foundation conditions or large seasonal water-level changes have to be considered [1]. Although the basic concept of using floating structures as wave-attenuation devices is certainly not new [4,11], the idea of utilizing automobile tires or tethered floats as major functional components is [16,12]. The Floating-Tire Breakwater and Tethered-Float Breakwater are two innovative breakwater concepts that have received considerable attention in recent years from researchers, users and the public press and, as a consequence, are increasingly considered in the solution of wave-protection problems. For short-fetch applications (fetch less than approximately 10 km), or semi-protected regions, both appear to be technically and economically feasible [3,6,9]. For large-fetch exposed locations this has not been demonstrated to date.

In the endeavor to meet a particular wave-protection problem with a functional cost-effective engineering design, the practicing engineer is generally faced with the important task of assessing the relative merits of several technically feasible solutions. Using the available data on

the tethered-float and floating-tire breakwaters, such an assessment is difficult to perform. It is our aim here to provide needed information on the relative cost, wave-attenuation performance and mooring forces associated with these structures. Additional factors such as breakwater size, useful life, aesthetics, maintenance and repair are certainly involved, but the two primary design factors to be considered here are the wave-attenuation performance and cost of the basic structure. For a specified degree of wave attenuation, the coastal engineer should be able to estimate and compare the cost of alternative structures able to provide this protection. Using presently available data, this cannot be done in the case of the tethered-float breakwater (TF-Breakwater) and floating tire breakwater.

The generic name of floating-tire breakwater is generally applied to three types of floating structures using pneumatic tires as construction components: the Wave-Maze Breakwater [8,10,16], the Goodyear Breakwater [3,5,7], and the Pole-Tire Breakwater [5,6]. For purposes of this report, the most recent entry into the field, the Pole-Tire Breakwater (PT-Breakwater) was chosen as a basis of comparison for the Tethered-Float breakwater (TF-Breakwater). This is particularly appropriate since the PT breakwater has exhibited very promising survival capabilities and wave-damping characteristics in waves up to 2 m in height during recent tests (1979) at the U.S. Army Corps of Engineers Coastal Engineering Research Center.

2. BASIC DESIGN FEATURES

Most breakwaters function primarily as wave reflectors. Although some of the intercepted wave energy is indeed dissipated upon the structure, the larger portion is generally redirected seaward again. The converse is true for the breakwaters considered here: they are predominantly dissipators of wave energy. Most of the incident wave energy is transformed into turbulence within and around the many components of these structures, while only a small portion is reflected. For the PT-Breakwater, ten times as much energy is typically dissipated as is reflected [5].

In the TF-Breakwater the basic energy dissipation units are oscillating spherical floats that are individually tethered to a rigid submerged frame. The frame, shown in Fig. 1, is ballasted to provide proper float submergence and transmits all wave-induced loads to the mooring system. A portion of the incident wave energy is converted into turbulence by the pendulum-like wave-induced oscillations of the tethered buoyant floats. The tethered float constitutes a tuned, selective wave-energy filter. Waves that are able to excite the float into high-amplitude oscillatory motions, out of phase with the wave water-particle motions, experience substantial levels of drag-related turbulent energy dissipation. Relatively long waves that cause the float to move in phase with the wave water-particle motions experience little decrease in energy, as do, on the other end of the spectrum, very short waves that are not able to set the float into motion at all. Some important design features of the TF-Breakwater are [14,15]:

- 1) Optimum tether length in deep water is approximately 10% of the peak energy wave length of the spectrum.

Plate 2. Assembly of PT-Breakwater.

CBB790-14041

- 2) Best performance in deep water is attained with floats totally submerged approximately one-quarter diameter beneath the surface. Some floats must pierce the surface in order to provide reserve buoyancy.
- 3) Ballast frames must be flexibly interconnected and frames must be kept small with respect to the peak energy wavelength. This is necessary in order that both frame and floats follow the sea surface and thus prevent emergence of floats in the wave trough (avoiding associated shock loadings during resubmergence).
- 4) A flexible terminator or boot must be provided at the base of the tether in order to reduce bending stresses and ensure reasonable life expectancy of the tether assembly.
- 5) Reasonable diameters of the TF-Breakwater will be of the same order as the significant wave height.

In the case of the PT-Breakwater the basic energy dissipation units and major structural components are discarded pneumatic tires (truck, automobile, earthmover, etc.). These are interconnected and, in conjunction with a rigid longitudinal member (telephone pole, steel or concrete pipe, etc.), form an integral part of the structure, as can be seen in Figs. 2 and 3 and Plates 1 and 2. The PT-Breakwater is essentially a dense mat composed of a large number of interconnected tires floating near the surface, with approximately 85% of the structure submerged. It functions predominantly as a wave-energy dissipator: most of the incident wave energy is transformed into turbulence in and around the many elements of the structure, with only a small portion being reflected. The breakwater is interconnected with conveyor belting [2], as shown schematically in Fig. 3.

3. LABORATORY DATA AND ANALYSIS

3.1 Experimental Conditions

Models of the TF and PT-Breakwaters were tested in the large wind wave tank (109 m × 4.5 m × 1.5 m) of the Hydraulic Laboratory at the Canada Centre for Inland Waters in Burlington, Ontario, shown in Fig. 4 and Plate 3. Additional full-scale tests of the PT Breakwaters were performed at the University of Delaware and the U.S. Army Coastal Engineering Center. Models of the TF Breakwater were constructed at two scales using 5 cm spherical styrofoam floats and 15 cm pressurized plastic balls. They were constructed according to guidelines given by Seymour [14,15]. Tires from a 1/8-scale model automobile were utilized in the construction of the PT-Breakwater models. Telephone poles were modeled from wooden hand-rail material.

In the test section shown in Fig. 4, the tank was subdivided into three channels (1 m, 1 m, and 2.5 m wide) so that two breakwaters as well as the undisturbed incident wave could be monitored simultaneously. For each breakwater the transmitted wave and mooring force on the seaward mooring line were recorded. Waves were generated with a programmable piston-type wave machine. Most experiments were performed with regular

XBL 799-2995

Fig. 4. Schematic diagram of wave tank at the Canada Centre for Inland Waters.

Plate 3. One-quarter scale model of TF-Breakwater in drained wave tank at Canada Centre for Inland Waters (model of Goodyear Breakwater in foreground).

waves, but machine-generated and wind-generated wave spectra were also investigated. In the case of irregular waves, the transmission coefficient $C_t = H_t/H$ and wave steepness H/L were evaluated using the peak-energy wave length and the average wave height as obtained from time-series analysis of the water surface elevation.

3.2 Dimensional Analysis

For the breakwater configuration shown in Fig. 1 we assume that the transmitted wave height H_t is an unknown function of the following variables:

$$H_t = f(H, L, d, \rho, \nu, g, D, \rho_s, \ell, B, \lambda, N) \quad (1)$$

Here H, H_t = incident and transmitted wave height; L = wave length; d = water depth; ρ = fluid density; ν = kinematic viscosity; g = gravitational acceleration; D = float diameter; ρ_s = float density; ℓ = tether length; B = beam dimension of breakwater; λ_s = length of breakwater; N = number of floats in breakwater. Note that the transmitted wave height H_t is assumed to depend only upon the total number of floats N , not their geometrical arrangement, as long as no interference between balls occurs. According to Buckingham's Pi Theorem, this is equivalent to the following non-dimensional relationship:

$$H_t/H = f[L/B, H/L, \ell/d, \ell/D, \rho_s/\rho, B/D, \lambda/D, \sqrt{B\lambda/ND^2}, D\sqrt{gH/\nu}] \quad (2)$$

Note that the last term is a Reynolds number and that the next to last term is simply a measure of the float spacing, e.g., with $G_1 = G_2$, $\frac{B}{\lambda} = nG_1$, $\lambda = mG_2$ in Fig. 1 and $N = nm$ = number of floats; it follows that $\sqrt{B\lambda/ND^2} = G_1/D$. We simplify this expression by:

- i) Keeping some terms the same in all models $\rho_s/\rho, \ell/D$;
- ii) Considering only quasi-two-dimensional tests,
i.e., no diffraction influences from ends λ/D ;
- iii) Assuming that some parameters are of second-order importance if they are sufficiently large ... $B/D, D\sqrt{gH/\nu}$

For such experiments:

$$C_t \approx f[L/B, H/L, \sqrt{B\lambda/ND^2}, \ell/d] \quad (3)$$

i.e., the transmission coefficient $C_t = H_t/H$ depends primarily upon the relative wave length L/B , the wave steepness H/L , the effective float spacing $\sqrt{B\lambda/ND^2}$ and the relative draft ℓ/d . For the mooring force we obtain, similarly:

$$F/\gamma B^2 = f[L/B, H/L, \sqrt{B\lambda/ND^2}, \ell/d] \quad (4)$$

For the PT-Breakwater, following procedures similar to those applied above, we may anticipate a relationship of the form

$$C_t = f[L/B, H/L, B/D, D/d] \quad (5)$$

$$F/\gamma B^2 = f[L/B, H/L, B/D, D/d] \quad (6)$$

where D now designates the tire diameter.

3.3 Wave-Attenuation Performance

In Fig. 5 the wave-height transmission ratio C_t has been plotted as a function of relative wave length L/B for three models of the TF-Breakwater. These models were constructed according to guidelines given by Seymour and are similar to structures tested in San Diego Bay, California [14,15]. An averaged wave-height transmission curve representing Seymour's predictive model [14] for several wave spectra with peak energies at $L/B = 0.6, 1.0$ and 1.7 has been included for comparison. Agreement in basic trends is evident, but measured C_t values are generally larger. Although Reynolds' numbers appear to be sufficiently high for proper modeling of float dynamics (and to maintain the turbulent character of the drag-related energy dissipation mechanism that governs at larger scales), it is possible that some Reynolds-number influences are being observed in the case of the small breakwaters. Seymour performed laboratory and field experiments on the TF-Breakwater and found his predictive model to be satisfactory [14]. For purposes of comparison it will be assumed that Seymour's predictive model describes the wave-transmission characteristics of the TF-Breakwater correctly.

In Fig. 6 the wave transmission curve for the PT-Breakwater is shown as a dashed line that increases monotonically as a function of L/B . This curve corresponds to $H/L = 0.04$ and is based upon extensive data, both model and full-scale. The data will not be included here because it is already well documented [5,6]. This performance curve was originally established using tires 8.4 cm in diameter, but has also been confirmed by full-scale experiments with truck and automobile tires 64 cm and 100 cm in diameter. A fundamental difference in the filtering characteristic of these structures is evident in Fig. 6: the TF-Breakwater is a tuned discrete filter that is most effective around $L/B = 0.7$, and becomes increasingly less effective at wave lengths other than this (either shorter or longer), whereas the PT-Breakwater is a monotonic filter that becomes increasingly more effective as the wave length decreases. It is apparent that the PT-Breakwater offers substantially more wave protection (lower C_t levels) than a TF-Breakwater of equal size.

3.4 Mooring Forces

The data presented here applies to a single-point mooring that provides an essentially horizontal restraining force on the seaward side of the breakwater, similar to the anchor line depicted in Fig. 1. Only the peak mooring force recorded during the experiment is reported (excluding wave-generator stop-start transients). Although accurate scaling of elastic properties and damping characteristics of the mooring system could not be assured, it was found that satisfactory agreement with full scale measurements existed for similar breakwaters tested in the past [5,6]. In tests with irregular waves the wave length corresponding to the spectrum energy peak is utilized in the wave length parameter L/B .

Mooring force data for the TF-Breakwater is plotted in Fig. 7 for large wave steepness ($H/L > 0.04$), and Fig. 8 for low wave steepness

($H/L < 0.04$). For comparison, the corresponding mooring force curve for the PT-Breakwater ($H/L = 0.06$, $D/d = 0.06$) has also been included in Fig. 7. It is evident that the peak mooring force for the PT-Breakwater is larger than that of a TF-Breakwater of equal size, but it should be recalled that such a PT-Breakwater is also more effective (Fig. 6). In previous studies [5] a useful empirical relationship for the peak mooring forces on a PT-Breakwater was determined to be

$$F/\gamma B^2 = 0.15(H/L)^2(L/B) \tanh(L/B) \quad (7)$$

This indicates that for a given wave length and structure the peak mooring force grows rapidly as a function of wave height. Mooring force measurements performed by Seymour with waves of very low steepness are also included in Fig. 8. It is apparent that these forces are significantly higher than those from this investigation. The two force measurements at a low wave steepness of $H/L = 0.02$, for example, are as high as those for $H/L = 0.06$ in the present study.

4. COST COMPARISON

The following material is intended to be of assistance to the coastal engineer in a preliminary assessment of relative costs associated with the TF- and PT-Breakwaters. The principle of "equal wave protection" has been utilized here in order to arrive at meaningful, comparable cost figures for the different structures. This implies that the size of each structure was first fixed so as to provide equal levels of wave protection from the same incident wave. The associated breakwater costs were then determined using these dimensions. The resulting cost figures may therefore be meaningfully compared as costs associated with two equivalent solutions to a particular wave protection problem. Cost estimates are given for major cost-contributing components of the structure, the mooring system, has not been included.

4.1. Equivalent Breakwaters

Figure 6 indicates that over practically the full spectrum of wave lengths L/B , the wave attenuation performance of the PT-Breakwater is superior to that of a TF-Breakwater of equal size. The only exception to this is a narrow band of essentially equal wave attenuation from $L/B = 0.65 - 0.85$. This narrow region would be of importance only in the case of monochromatic laboratory waves and not with regards to the broader wind-generated spectra encountered in actual design cases. In view of this disparity in wave attenuation performance, it is clear that one should not compare the cost of two breakwaters of equal size, for different "amounts of wave protection" would then be purchased with each structure. We therefore determine first how large a TF-Breakwater must be in order to provide approximately the same level of wave protection as a PT-Breakwater. In Fig. 9 a PT-Breakwater with beam B is compared to a TF-Breakwater with beam dimension $B_{TF} = 1.5B$, and from this conclude that approximate equivalence of wave protection has been attained. In the simple design procedure used here, the beam dimension of the TF-Breakwater is chosen so that the region of maximum effectiveness of the breakwater (the trough

XBL 799-2993

Fig. 5. Wave-height transmission data for TF Breakwater.

XBL 799-2994

Fig. 6. Wave transmission curves for TF and PT Breakwaters of equal size.

XBL 799-2998

Fig. 7. Peak mooring force data for the TF Breakwater and $H/L > 0.04$ (curves for TF and PT Breakwaters, $H/L \approx 0.06$).

Fig. 8. Peak mooring force data for the TF Breakwater and $H/L < 0.04$ (curve for $H/L \approx 0.06$).

XBL799-2999

Fig. 9. Wave transmission curves for PT Breakwater and larger TF Breakwater ($B_{TF} = 3/2 B$).

region at $L/B = 1$) corresponds to the design wave length or, equivalently, the peak energy wave length of the incident spectra. With this in mind, and recognizing that most short-fetch wave spectra are much broader than the cross-hatched region around the incident wave-energy peak at $L/B = 1$, it is reasonable to conclude that the two breakwaters are, for most practical purposes, equal in wave attenuation performance. The beam-size relationship to be used in the cost comparison is consequently $B_{TF} = 1.5B$, i.e., the TF-Breakwater requires a 50% larger planform area.

Considering the case of a design-wave period (or peak energy period) of $T = 3.0$ sec and a wave height of $H = 1.0$ m, and assuming deep-water conditions, one finds that $L = 14.0$ m and $H/L = 0.07$. This wave length should correspond to $L/B = (3/2)L/B_{TF} = 1.0$ in Fig. 9 in order to maximize the effectiveness of the TF-Breakwater. The beam dimension necessary to achieve this is consequently $B_{TF} = 3/2 L = 21.0$ m. To attain comparable performance with the PT-Breakwater requires a beam dimension of $B = 1.0 L = 14.0$ m. The corresponding peak mooring forces can be determined from Fig. 7 using $H/L = 0.06$ as an approximation. For both the TF-Breakwater ($L/B = 2/3$) and the PT-Breakwater ($L/B = 1.0$), the peak mooring forces turn out to be very nearly equal, $F = 780 \text{ Nm}^{-1}$.

4.2 Cost Estimates

The following cost comparison is based predominantly upon the cost of major structural components required for assembly of the breakwater. Construction labor costs are also included, but mooring system costs and expenditures for construction equipment that may be utilized during assembly and launching are not. In the absence of site-specific data on mooring and launching costs, the total component cost figures given here become useful first approximations of the installed cost, particularly in the case of the TF-Breakwater for which the neglected cost items (mooring system and launching) are generally only a small fraction of the total.

Cost data for the TF-Breakwater were obtained from a 1977 "Feasibility Study to Evaluate the Commercial Market for a Tethered Float Breakwater System" [Maritime Administration, U.S. Department of Commerce]. Cost figures for the PT-Breakwater reflect recent construction experience (1979) with two breakwaters at the State University of New York in Buffalo: these utilized telephone poles and steel pipes 12 m in length in conjunction with automobile and truck tires, respectively. The utilization of automobile tires is financially attractive particularly because they can generally be obtained in large quantities at no cost. In the US the cost associated with the disposal of a truck tire is typically US \$1 (landfill sites generally charge user fees and, to improve compaction, also demand that tire casings be cut up prior to disposal). Trucking and tire-recapping firms are consequently willing to not only supply tires, but deliver them to the breakwater construction site as well: in most cases they still save money. All cost figures were adjusted to 1980 levels by assuming annual price increases of 10%.

COMPONENT COST ESTIMATES: TETHERED FLOAT (TF) BREAKWATER

Module Dimensions : B = 21.0 m, λ = 3.80 m

Materials : Spherical floats (D = 38 cm, γ = 0.04 gm cm⁻³),
 Tethers and flexible tether terminals,
 Steel ballast frames with flexible couplings
 (3 frames 7.00 m × 3.00 m per module),
 Concrete ballast.

<i>Item</i>	<i>Quantity</i>	<i>Unit Cost (US \$)</i>	<i>Total (US \$)</i>	<i>Cost per meter (US \$)</i>
Float unit (float, tether, flex. terminals)	135	24.30*	3279.30	863.00
Ballast frame (incl. flexible couplings)	3	465.90*	1397.60	367.80
Concrete ballast	4.2 m ³	113.10*	475.20	125.00
Assembly (labor only)	14 hrs	6.00	84.00	22.10

Cost per meter of breakwater = \$1377.90
 (excluding mooring system)

*Source: Ref. (9)

COMPONENT COST ESTIMATES: POLE-TIRE (PT) BREAKWATER

Module Dimensions : B = 14.0 m, λ = 4.00 m

Materials : Automobile tires (typically 0 = 64 cm),
 Telephone poles (4 m spacing),
 Conveyor belting (3-ply, 14 cm wide, 5000 N cm⁻¹
 breaking strength),
 Nylon bolts, nuts, washers (13 mm or equivalent).

<i>Item</i>	<i>Quantity</i>	<i>Unit cost (US \$)</i>	<i>Total (US \$)</i>	<i>Cost per meter (US \$)</i>
Tires	403	none	none	none
Tying material (conveyor belting)	180 m	0.90	162.40	40.60
Nylon bolts, nuts, washers	105	0.55	57.80	14.40
Telephone poles	1	50.00 (salvage @ 15% new)	50.00	12.50
Assembly (labor only)	18 hrs	6.00	108.00	27.00

Cost per meter of breakwater = \$94.50
 (excluding mooring system)

Note: The use of steel pipe (41 cm diam, 6 mm wall) and truck tires will increase the cost by approximately \$130 per meter.

5. CONCLUSIONS

- 1) The Tethered-Float and Pole-Tire Breakwaters are technically feasible solutions to wave protection problems in short-fetch (say, less than 10 km) or semi-protected locations.
- 2) The Pole-Tire Breakwater is a more effective wave-energy filter than a Tethered-Float Breakwater of equal size.
- 3) In a typical short-fetch design case, a Tethered-Float and Pole-Tire Breakwater were found to compare as follows (for equal levels of wave protection):
 - a. The Pole-Tire Breakwater costs less than one-tenth as much as the Tethered-Float Breakwater.
 - b. Peak mooring forces are approximately the same.
 - c. The Pole-Tire Breakwater requires less space.

6. ACKNOWLEDGMENTS

This research was sponsored in part by the New York Sea Grant Institute under a grant from the Office of Sea Grants, National Oceanic and Atmospheric Administration, and in part by the Energy Technology/Solar Division of the U.S. Department of Energy under Contract No. W-7405-ENG-48. The writer would like to express his appreciation to T. M. Dick of the Hydraulics Research Division of the Canada Centre for Inland Waters (CCIW) for making the laboratory tests at CCIW possible. The valued assistance of Tom Bender, graduate student at State University of New York at Buffalo, is gratefully acknowledged.

CHAPTER 130

LITTORAL DRIFT OF SAND NEAR PORT OF OARAI

by

Kazumasa Mizumura

ABSTRACT

To study the main direction of littoral drift of sand near the Port of Oarai, field observations were made. Through the analyses of the results the following facts were obtained.

- (1) The relative changes of foreshore gradients alongshore were correlated with the characteristics of beaches.
- (2) By investigating sand grain sizes on the coast the predominant direction of littoral drift of sand could be illustrated.
- (3) The direction of littoral drift of sand was almost coincident with the main nearshore currents.

INTRODUCTION

Problems on coastal changes are important and have attracted many engineers. The most reliable work for the shore protection before the construction of ports and harbors is considered to be field observations. Stillmore, the success of hydraulic model tests is also dependent on the data analysis of field observation. To investigate the plan of extension at the Port of Oarai in regard to coastal changes, field observations were done before the start of the plan. Herein, the characteristics of the coast near the Port of Oarai are studied using the results of field observations. Therefore, beach profiles, littoral materials and nearshore currents were measured in July of 1977.

Since the predominant direction of littoral drift of sand was determined, the groin of 400m in length had been constructed in September of 1977.

Associate Professor, Dept. of Civil Engineering, Kanazawa Institute of Technology, Kanazawa, Japan

GENERAL

The Port of Oarai is located north of Tokyo, Japan and faced to the Pacific Ocean as illustrated in Fig.1. In the south of the port there is a sandy Kashimanada Coast which has an arcuate form and almost 70 km in length. To the east of the port there exist Oarai Headland and Oarai Coast. Contours along the Kashimanada Coast and the Oarai Coast are almost linear and parallel to the shoreline except near Oarai Headland as shown in Fig.1. Because there exist marine ridges in the offshore of Oarai Headland. Therefore, the incident wave energy converges to the headland and shows the shoreline of erosion. In the west of the Port of Oarai some breakwaters remain as represented in Fig.1. This was the old Port of Isohama and tried to construct about 60 years ago. But this was stopped during the construction of breakwaters because of the deposition of much sand. At the present, the sandy beach forms a good bathing place in summer. The arm of the south breakwater is expanded to the south and it causes erosion problems along the segment of the opposite coast to the breakwater. It can be observed that the position of erosions moves down to the south as the south breakwater expands.

WIND AND WAVES

Wind directions and velocities were measured at the position which is located 4.5 km in SE direction of the Port 1973 to 1975. The wind directions from ENE to N are predominant and occupy almost 40 % of the total. Wave conditions offshore were measured at the south point of 9 km from the port. ENE direction is predominant and reaches more than 50 % of the total as shown in Fig.2. The percentage of the periods from 9.0 sec to 13.0 sec attains almost 58 % of all available data as illustrated in Fig.3. Especially, 11 sec and 12 sec are predominant and about 14 %. The percentage of wave height more than 3.0 m is almost 4 % and less than 1.5 m amounts to 75 % as given in Fig.4. It can be seen that the coming wave height is low and seasonal changes are not found.

FORESHORES AND BEACH PROFILES

To study the characteristics of beaches near the port, beach profiles, specially foreshores were surveyed at 8 points as numbered in

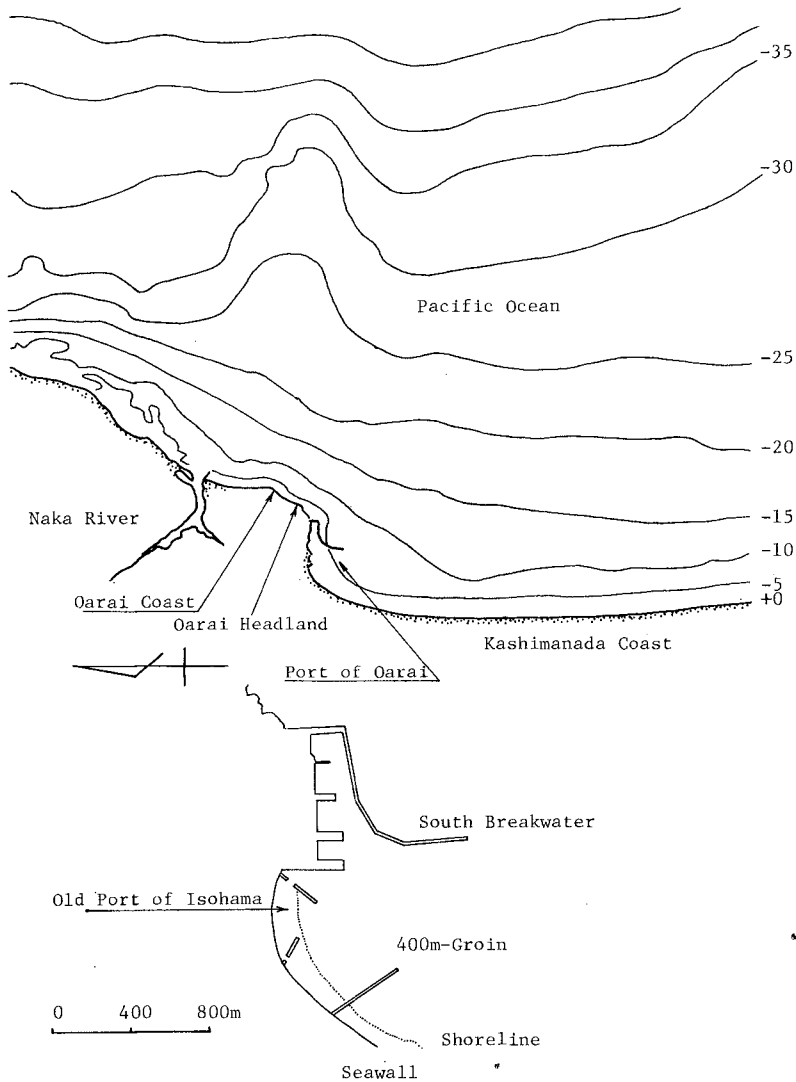

Fig. 1. - Study Area and Port of Oarai

Fig. 2. - Distribution of Wave Directions

Fig. 3. - Distribution of Wave Periods

Fig. 4. - Distribution of Wave Heights

Fig.5. These points correspond to the sampling points of bed materials on the beaches. The beaches in the sheltered zone by the south breakwater are very wide and sand grains are fine there. The slopes are milder than $1/100$. The zone between the sheltered zone by the south breakwater and the zone which is not influenced by coastal structures is for simplicity defined as the intermediate zone in this study. The shore in the intermediate zone recedes to the seawall partly and shows the shore of erosion by the existence of the system of small offshore breakwaters and groins for shore protection. The slopes are steeper than $1/30$. The southward beaches which are far from the south breakwater have no influence from any coastal structures and are called open beaches. The slopes are about $1/60$. The shape of beach profiles on each point are represented in Fig.6.

LITTORAL MATERIALS

Sand was sampled by dredges at 48 points as illustrated in Fig.5 and its physical properties such as specific gravities and size distributions were investigated. The specific gravities are almost constant and equal to 2.65. Fig.7 represents the relationship between sea bottom slopes and mean diameters of sand grains. This means that very fine sand exists on sea bed with milder slope and vice-versa. The grain diameters in breaking zones are large due to the wave sorting effect. Moreover, Fig. 8 shows "curves of equi-mean diameter" based on the sampled data at 48 points. On the southward beach which does not have any influence from coastal structures, the curves are almost parallel to each other and the shoreline. In the intermediate zone the intervals of the curves become narrow and the curves approach to the shoreline. If imaginary curves were drawn from the south to the north until near the port in parallel condition to the shoreline, it can be understood that the curves in this zone shift more landwards than they are drawn in the south. This suggests that the shifting is caused by sand movement and the predominant direction of littoral drift of sand is landward. In the sheltered zone by the south breakwater the pattern of the curves changes. That is, the curves are not parallel to the shoreline, but almost perpendicular to that. By considering the imaginary curves of the equi-mean diameters previously discussed, the real

Fig. 5. - Map of Field Observations

Fig. 6. - Beach Profiles

Fig. 7. - Relationship between Mean Diameters of Sand Grains and Bottom Slopes

Fig. 8. - Curves of Equi-Mean Diameters

curves drawn in the figure can be recognized to shift seawards. This shows that the shifting is caused by sand movement and the predominant direction of littoral drift of sand is seaward in this zone. The combination of the above two directions of littoral drift of sand gives the direction of that between the two zones. Namely, the transported sand from the offshore in the intermediate zone moves alongshore and deposited in the sheltered zone. The one part of the transported sand moves seawards and deposits in the port. The other part moves alongshore, reaches near the old Port of Isohama and deposits there.

NEARSHORE CURRENTS

The nearshore currents in the breaking zones of 17 points as illustrated in Fig.5 were measured by floats when the wave direction and the wave height were E or ENE and 0.5 m to 0.8 m, respectively. The measured average velocities of nearshore currents are represented in Fig.9.

Simple modeling of the measured flow pattern shows the existence of a circulatory current in the lee of the south breakwater. The cause of the circulatory current is explained as follows. The incident waves from the predominant direction ENE are diffracted by the south breakwater and this produces the difference of breaking wave heights along the shore. Moreover, this generates the difference of the mean water level along the shore by the radiation stresses. Therefore, the regular and stationary circular current is induced alongshore from high to low water levels. In the intermediate zone the component of the circulatory current flows landwards and erodes the shore. In the sheltered zone, the component of the circulatory current forms the longshore current and it transports sand alongshore into the port. This fact is also proven by the movement of fluorescent sands as illustrated in Fig.10a and b. The throwing points of the fluorescent sands are located on the beach in the sheltered zone as shown in Fig.5. All sands move definitely alongshore to the port.

COMPARISONS OF PAST SURVEYS AND AERIAL PHOTOS

The comparisons of each contour between June of 1977 and December of 1973 are represented in Fig.11. Solid lines and dotted lines show the contours in June of 1977 and December of 1973, respectively.

Therefore, erosion area is illustrated by the zone of hatching and

Fig. 9. - Measured Nearshore Currents

Fig.10b. - Movement of Tracers

Fig.11. - Comparison of Past Surveys

Fig.12. - Aerial Photo in Dec. of 1969

Fig.13. - Aerial Photo in Jan. of 1975

accretion area is shown dotted in the same figure. As previously discussed severe erosion occurs in the intermediate zone, the eroded sand is transported near the old Port of Isohama and forms accretion area.

The maximum advance of the shoreline in the accretion area is almost 120 m in 3.5 natural years. Moreover, aerial photos in December of 1969 and in January of 1975 are shown in Fig.12 and Fig.13, respectively. The comparison illustrates the remarkable accretion phenomena near the old Port of Isohama. Namely, in December of 1969 the shoreline had touched the old breakwaters, but in January of 1975 the shoreline moved more seawards and much sand accumulated around the old breakwaters.

SUMMARY AND CONCLUSIONS

The following conclusions are made for characteristics of the coast near the Port of Oarai under the field observations used in this study.

- (1) The foreshore gradient on the eroded beach is steep and that on the accreted beach is mild, relatively.
- (2) The sizes of sand grains are correlated with the sea bottom slopes.
- (3) The curves of equi-mean diameter obtained by size distributions of sand grains can indicate the predominant direction of littoral drift of sand.
- (4) There exists the circulatory current in the lee of the south breakwater and the direction of this current is coincident with that of littoral drift of sand.

LONG-TERM EXPERIENCE WITH THE USE OF SYNTHETIC
FILTER FABRICS IN COASTAL ENGINEERING

by

Georg HEERTEN ¹⁾

1)

Dr.-Ing., Scientific Assistant, Franzius-Institut of the
University of Hannover, Germany

ABSTRACT

Various types of synthetic filter fabrics are available for geotechnical applications. Especially in the field of coastal engineering a lot of experiences are generally known. Unfortunately technical recommendations and testing regulations for specific implementations of geotextiles are not generally available and some actual examples of damage of coastal structures urgently require investigations on long-term resistance. A research program oriented towards the development of guidelines for testing geotextiles, the development of filtration rules and the clarification of long-term resistance of fabrics was carried out. This paper deals with testing procedures associated with the estimation of the opening size and the permeability to water of fabrics. Results of investigations on long-term resistance are described and filtration rules for selecting a fabric according to the special requirements of the application are given.

INTRODUCTION

For more than 10 years the use of synthetic filter fabrics in various types is a standard in coastal engineering works at the North sea coast.

We can distinguish the following applications to filter fabrics:

- as a filter-layer in revetments of seadikes and shore lines

- as a filter- and separation-layer for the foundation of groins and breakwaters
- as a flexible filter-layer for the bottom protection against scouring for example at tidal- and stormsurge-barriers and when closing a dike
- as sand filled bags or tubes as construction elements of groins and embankments.

Designing coastal structures, a synthetic filter fabric almost is represented only by a "synthetic filter fabric" named line (Fig. 1). At first this designation seems to be

REVETMENT OF A SEADIKE WITHOUT FORELAND
(NORTHFRISIAN COAST)

Fig. 1

without problems but when selecting a suitable fabric for a special application the engineer has to recognize that there are a lot of conditions to be considered. He has to notice that various types of synthetic filter fabrics (woven, non-woven and combinations) are offered, produced of different polymers.

TYPES OF FABRICS

Of the variety of offered filter fabrics Fig. 2 only gives an impression by showing some of the most important kinds of woven and non-woven fabrics.

mesh netting

tape fabric

woven fabrics

fibre fabric

spun fabric

non-woven fabric

Fig. 2
Different kinds of geotextiles

The properties of fabrics are very different, influenced by the polymer properties and by the manufacturing process. For woven fabrics for example we have to distinguish the kinds of threads (multi-filament, mono-filament, tapethreads), the kind of weaving, the used polymer and the finish (e.g. PVC-coating). Non-woven fabrics also are produced by different polymers and we have to distinguish the method to obtain the cohesion of the fibres or filaments.

THE GIVEN SITUATION IN USING FILTER FABRICS

For dimensioning and selecting a fabric a comparison of product datas and the requirements of the buildings, given by dimensioning rules or other proved standard values, is necessary. If there are two or more fabrics performing the requirements - a comparability of the testing methods is provided - a selection can consider economical aspects.

Unfortunately there exists a lot of different testing methods used by the manufacturers to estimate the properties of the fabrics, so that the product datas of different fabrics are not comparable in many cases. Therefore an optimal selection of a fabric is very difficult and sometimes impossible.

It is an additional difficulty too, that there are no sufficient technical recommendations up to now to select a fabric according to the special requirements of the application. Therefore it doesn't wonder, that the present situation in the extensive use of woven and non-woven fabrics is characterized by a selection based on local experiences or on the costs per square meter.

Up to now there was no serious doubt about a sufficient long-term resistance of the synthetic fabrics covered by soil materials and protected against ultra-violet irradiation. But actual examples of damage of coastal structures urgently require investigations to estimate the long-term resistance of fabrics, especially in comparison to the time of use of the structures (30 to 50 years).

RESEARCH PROGRAM

The specified uncertainties in the use of synthetic filter fabrics lead to a special research program carried out at the FRANZIUS-INSTITUT FOR HYDRAULIC RESEARCH AND COASTAL ENGINEERING OF THE UNIVERSITY OF HANNOVER.

The investigation program consists of three parts:

1. extensive questionnaires were sent to the coastal engineering authorities to evaluate the experience in the use of the synthetic filter fabrics.

2. testing methods were development to estimate the filtration properties of fabrics.
3. various filter fabrics being in function for many years were diged out of coastal struktures.

From this investigations the following results can be presented:

TESTING METHODS

To estimate the filtration properties of fabrics the developed testing methods allowed the determination of the effective opening size and the permeability as a function of superimposed load. The testing methods can shortly be described as follows:

To estimate the effective opening size we used a wet sieving with a defined testing sand. In the test, the fabric has to operate as a sieve (Fig. 3). The complete testing equipment for the wet sieving shows Fig. 4.

Fig. 3

Placing of the fabric for sieving operation

A grain-size analysis of the retained and the passing material leads to the effective opening size as a essential filtration parameter by a fixed evaluation method (4).

For testing the permeability of the filter fabrics we used a permeability test with constant hydrostatic head, generated by two overflow reservoirs, as proposed by BOURDILLON (1).

Fig. 4
Testing equipment for the estimation
of the effective opening size of geotextiles

Fig. 5 shows the test lay out. In the permeability cell a sample of several layers of the fabric is placed and after measuring the flow, the difference in piezometric level, the water temperature and the settlement of the sample a DARCY-coefficient can be determined. Repeating this procedure for various superimposed loads the permeability as another essential filtration parameter can be given as a function of load conditions.

This two tests may be like a standard for testing the filtration properties of synthetic filter fabrics. Only in special cases or for testing woven fabrics an additional test can be carried out, testing the system of fabric and original soil material. In cases of testing non-woven fabrics in combination with soil material it has to be considered that the testing conditions in the laboratory are very different to natural conditions. This is a result of field investigations on coastal structures. It can be seen that in non-woven fabrics-diged out of coastal structures - the incorporation of soil material is a multiple in nature than in a comparatively short laboratory test.

FIELD INVESTIGATIONS

The field investigations on coastal structures mentioned before were the most important part of the research program.

EQUIPMENT FOR WATER PERMEABILITY TEST

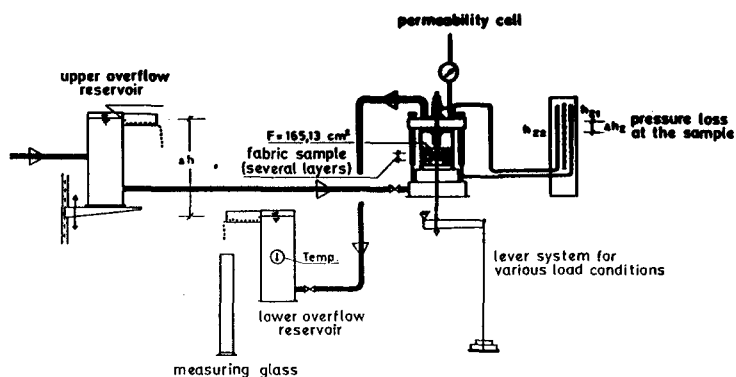

Fig. 5

At 13 locations at the Northsea coast of the German Bight sampling operations were carried out and samples of 39 fabrics were taken.

16 samples were diged out of revetments of seadikes and 23 samples of woven fabrics were taken from sandbags and sand filled tubes.

Fig. 6 shows the revetment of the seadike without foreland at the Dithmarscher Bight at the Northfrisian coast and Fig. 7 gives an impression of the sampling operation at this location and in Fig. 8 a non-woven fabric is shown after removing the cover layers of the revetment.

The photographs in Fig. 9 and Fig. 10 give an example of the application of sand filled tubes. First as small dams in land reclamation fields in the tidal flats in front of the seadikes (Fig. 9) and second as stabilizing elements in a beach feeding area (Fig. 10).

From the sandbags and sandfilled tubes two different samples were taken, one of the weathered upper side and one of the

Fig. 6

Fig. 7

Digging out a fabric

Fig. 8
Non-woven fabric after removing the cover layers

Fig. 9
Sand filled tube in a land reclamation field

Fig. 10
Sand filled tube in a beach feeding area

protected bottom side. By this it is possible to calculate the influence of weathering on the long-term resistance of the fabrics.

For fabric samples diged out of revetments the following individual investigations were carried out:

1. Condition and changing of the profile of the revetment
2. Condition of the fabric
3. Testing the tensile strength
4. Testing the filtration properties
5. Testing the fabric weight and soil content
6. Grain-size analysis and permeability test of the subsoil

For fabric samples of sand bags and sand filled tubes the research program is reduced to the following individual investigations:

1. Condition of the fabric
2. Testing the tensile strength
3. Estimation of effective opening size
4. Grain-size analysis of packed soil.

Essential results of the investigations of the seadike revetment are the registered extensive filling of the coarse-layers with sand and mud particles and the considerable incorporation of soil in the non-woven fabrics. Caused by the filling of the coarse-layers with sand and mud, shown by Fig. 11, the boundary layer of fabric and subsoil was protected against dynamic wave attack.

Fig. 11

Coarse layers filled up with sand and mud particles

This situation also gave a stability in revetment sections with fabrics of too large opening size according to actual knowledge.

The extensive incorporation of soil in the non-woven fabrics lead to the assumption as mentioned before to doubt about the similarity to nature of laboratory test with non-woven fabrics and soil. Fig. 12 gives an example of an non-woven fabric with an incorporation rate of about 9000 grams per squaremeter by a fabric weight of about 1000 grams per squaremeter.

Additional investigations lead to the perception that the sand and mud particles in the coarse-layers mostly came from the seaside of the construction and not from the bottom side. Some significant profile changes with a flater slope of the revetment were perhaps caused by soil-liquefaction under wave impact but certainly not by a washout through the filter-fabrics.

Fig. 12

Non-woven fabric filled up with sand and mud particles

RESULTS ON LONG-TERM RESISTANCE

A usual method to give some informations about the long-term resistance of synthetics is a comparison of tensile strength of the new and of the aged material. The strength testing procedure used corresponds to the conventional textile strip test like the German standard (DIN 53857).

In the following some examples of the results of the investigations about long-term resistance of the synthetic filter fabrics are presented.

In Fig. 13 the relative residual strength determined for different fabrics of nylon (PA 6.6) as a function of exposure time by unprotected weathering is shown. The minimum value of residual strength is about 20 percent after an exposure time of 20 years. By protection against ultra-violet irradiation, the residual strength decreased only to values of about 70 percent after an exposure time of 20 years (Fig. 14).

The next examples give an impression of the long-term resistance of all fabrics examined in the research program. For each of the basematerial of the fabrics average values of residual strength were determined.

Fig. 15 shows these average values for fabrics by unprotected weathering. It can be seen that the residual strength

FOR FABRICS OF VARIOUS TYPES AND POLYMERS
(protected against ultra-violet irradiation)

Fig. 16

of tape-fabrics with polyethylene or polypropylene as base material is higher than the residual strength of multi-filament fabrics of polyester, polyamide and polypropylene. Comparable results are given by protection against ultra-violet irradiation (Fig. 16), but nevertheless in general the decrease in residual strength is lower as seen in Fig. 15.

By the interpretation of these results we have to consider that the fibre fineness is of great influence in long-term resistance of fabrics. Therefore the good results of the tape-fabrics, produced of relative thick tape threads, doesn't surprise. - The fibre fineness of the tape-threads is about some hundred dtex whereas the fibre fineness of filaments is only 5 to 10 dtex.

In addition we have to consider that the results determined at samples of the salt-water region could be influenced by a lot of parameters like suspended load of the seawater, duration of tidal overflow, covering of the fabrics by mud, seaweed, mikro-organism or rubble and their temporary variation. The damage of fabrics could also be caused by wave-action, drifting-wood, ice, shipping or tourists. Most of the parameters only influenced the sections with unprotected weathering like the upper sides of the sandfilled tubes. Synthetic filter fabrics in revetments protected by several cover-layers are less endangered but there is to pay attention that there is no damage of the fabrics during construction time.

Finally we can say that the most important parameters influencing the long-term resistance of fabrics in the salt-water region of the northsea coast are the ultra-violet irradiation and the raw material and fibre fineness of the fabric. Ageing by biological and chemical damages is of lower importance. Attention has to be paid that there is no damage of fabrics during construction time.

This results show fair agreement with results of investigations carried out on the woven synthetic filter fabric being a construction element of protection against scouring at the Eider stromsurge barrier. The protection against scouring was damaged but the first supposition that the damage was caused by an insufficient long-term resistant of the woven fabric could not be confirmed.

In addition to the investigations on long-term resistance filtration rules have been development.

FILTRATION RULES

A new dimensioning method to select a fabric allows, to fulfil and calculate the requirements of sand-tightness as well as the requirements of the hydraulic permeability of

fabrics. Fig. 17 shows a flow diagram which explains the procedure to select a fabric according to the characteristics of the subsoil and the construction. In the first step we have to estimate the effective opening size D_w . D_w is given by filtration rules as a function of the particle distribution curve of the soil and the load conditions.

In the second step the hydraulic conditions have to be controlled. To prevent over-pressures in a revetment-construction the permeability of the filter fabric has to be higher than the permeability of the subsoil. Special investigations were carried out to consider the decrease of the permeability of woven fabrics by blocking and non-woven fabrics by clogging. Now, as a result of the investigations, it is possible to estimate a permeability-reduction factor as a function of fabric data and soil characteristic. Only for non-woven fabrics, when the effective opening size is small in relation to the diameter of soil particles, an additional restriction is given by $D_w < 0.5 \cdot d_{10}$ leading to a η_V value $\eta_V = 1.0$. The permeability of the fabric is sufficient when

$$\eta_V / G \cdot k_f \geq k.$$

The filtration rules to fulfil the sand-tightness are determined as follows:

Static load conditions and $u \geq 5$	$D_w < 10 \cdot d_{50}$ and $D_w \leq d_{90}$
Static load conditions and $u < 5$	$D < 2.5 \cdot d_{50}$ and $D_w \leq d_{90}$
Dynamic load conditions	$D_w < d_{50}$

Fig. 18 shows the diagram to estimate η_G . η_G is given as a function of the standard test permeability coefficient k_f and the soil parameter d_{10} .

η_V is given as a function of the fabric parameters k_f and P (Fig. 19). k_f is the standard test permeability coefficient and P is named porosity of the fabric. P is defined as a product of the

voids ratio n
fabric thickness d under a load of 2 kN/m^2
and effective opening size D_w .

At times the application of this diagram is limited by the particle distribution of the investigated soils at the sampling locations. The range of the particle distribution curves are shown in Fig. 20.

Further investigations will be carried out to complete the diagram with η_V as a function of the soil parameter d_{10} .

Particle distribution curves at the sampling locations

CONCLUSION

For applications in coastal engineering in the salt-water region of the Northsea coast the investigations on long-term resistance of fabrics lead to first satisfying results. The given filtration rules make it possible to select a geotextile according to the special requirements of the application given by the particle distribution curve and the DARCY-coefficient of the soil. Some additional investigations will be carried out at the FRANZIUS-INSTITUT in the near future.

SUMMARY

Sand bitumen was used in the core of a rubble mound breakwater to form an impermeable barrier, essentially to inhibit the recirculation of warm water exhausted from a power station outlet back into the intake pumps. The core had a secondary advantage in permitting the placing of bitumen grouting to the rock on the lee face of the breakwater to stabilise it against wave overtopping.

The paper describes the reasons which led to the adoption of this unique method on a very exposed coastline. It also outlines some of the measured properties of the sand bitumen and the methods used and experience gained in its mixing and placing.

The sand bitumen, which has not to our knowledge been used for this purpose and as a core material previously, is proving to be successful.

1. INTRODUCTION

In 1967, the Electricity Supply Commission of South Africa (ESCOM) decided upon the location of Africa's first nuclear power station at a coastal site adjacent to the Atlantic Ocean, some 35 kilometres to the north of Cape Town. The first phase of development of this project is for the construction of two reactors, each of 920 MW, which should be commissioned by 1984. Further development has been allowed for in the future immediately to the north of the station which could eventually increase its capacity.

The site was selected, inter alia, because of its proximity to unlimited supplies of cooling water coming from the Antarctic in the cold Benguela current. However, this section of coastline is extremely exposed and devoid of any naturally deep and protected

area from which to draw the water. The wave climate is severe with the deep water significant wave height exceeding 2 metres for about 38% of the time and maximum wave heights of 11 metres have been recorded. It is axiomatic that power station cooling water should not contain heavy concentrations of sediment and, on this coast, with its severe wave climate and 1 in 60 to 1 in 100 bed slopes, one of the problems relating to the abstraction of cooling water is that considerable quantities of sand are suspended in a very wide surf zone. The firm of Watermeyer, Halcrow and Partners, which is a joint partnership between Watermeyer, Legge, Piesold and Uhlmann and Sir William Halcrow and Partners was retained by ESCOM to advise on the best means of obtaining cooling water and, later, to undertake the detailed engineering design and supervision of construction of the scheme that was finally adopted.

Feasibility studies on a number of possible schemes, which included tunnels with offshore intakes, concluded that the most suitable and economic solution would be to situate the pump houses within a dredged basin, protected by rubble mound breakwaters.

The configuration and detailed design of this basin had to satisfy the parameters of:-

- (a) stability of the breakwaters under wave action;
- (b) limiting wave penetration and wave heights at the intakes;
- (c) controlling sediment build-up around and, in particular, in the basin; and
- (d) restricting recirculation of warm exhaust water.

Detailed site measurements of the local marine environment (1), were combined with physical model studies of the breakwaters and a mathematical modelling of sediment build-up (2) to examine items (a) to (c) above. These considerations essentially determined the final configuration.

As illustrated in Figure 1, the pump intakes are located along the original shoreline and are protected by the main (south) breakwater which is 933 m long and the north breakwater which is 578 m long. The basin entrance is in about 8 metres of water at high water.

In this first phase of station development the pump intakes will draw in a total of about 80 cumecs of seawater at ambient temperatures ranging between 8 and 16° C. This water will be heated through a range of about 10° C in its passage through the turbine condensers and will be discharged through a shallow outfall channel into the surf zone just to the south of the main breakwater (see Fig. 1).

Figure 1. CONFIGURATION OF INTAKE BASIN

It was feared that, in connection with (d) above, the warm outlet water could pass through the rubble mound of the south breakwater in significant quantities and re-enter the pump intakes during certain times of the year. Field observations using dye were made of the transmission of water through the breakwaters at Richard's Bay which confirmed these fears.

The flow through a rubble mound breakwater without an impermeable core was also studied theoretically. Because of turbulence, Darcy's formula was inappropriate and Hazen's formula for permeability was adopted. For the purposes of this calculation, wave set-up outside the basin was assumed whilst the cooling water pumps were drawing sea water from within. This produced low flows in the order of about 3 cumecs over 300 m of breakwater length. However, when it was assumed that the breakwater contained a network of very twisted rough pipes, the flow became significant e.g. for 500 kg and 1 000 kg rock over a 300 m length of breakwater the calculated equivalent flows through the structure were 28 and 55 cumecs respectively.

Similar recirculation problems were solved, following construction, at Fukushima nuclear power station in Japan by driving steel sheet piles parallel with and close to the breakwater inside the basin. This arrangement was examined for Koeberg, as well as several other alternative solutions involving grouting, sand bitumen, slicework and blockwork. Eventually it was decided to construct an impermeable core to the breakwater with a mixture of sand and bitumen. This construction material had been used previously in the United States and, more notably, in the Netherlands but, as far as is known, never before in this manner as a breakwater core material.

The sand bitumen core offers a further benefit at the seaward, more exposed end of the south breakwater. Normally the crest of the structure in this area would have to be heightened and/or the lee face reinforced with additional and possibly heavier armour units as a safeguard against wave overtopping. Fortunately, however, the sand bitumen core acts as a barrier against the transmission of air/water pressure through the rubble mound, and permits the use of relatively light rock on the lee face, grouted to act as a spillway for overtopping waves. Without the impermeable sand bitumen core, air and water pressure within the rubble mound caused by wave attack on the seaward face would almost certainly dislodge the grouted rock on the leeward face. The rock grouting was also carried out with a sand bitumen grout, but since the characteristics required were different, the constituents and mixing proportions differed from the sand bitumen core.

Breakwater construction commenced in October, 1977, and placing of the rubble mound and sand bitumen was completed in December, 1979. The construction has proved successful and the resistance to erosion of the sand bitumen core when exposed to the force of the waves at the scar end during construction was found to be surprisingly good - better in fact than the filter layers of rock on either side of it.

2. DESIGN CONSIDERATIONS

Two possible methods of constructing a barrier within the heart of the south breakwater to impede the passage of water through the rubble were examined in detail, namely:

- (i) the installation of large precast hollow concrete rectangular boxes with compatible curved front and rear faces placed in contact with each other on a bed of prepared rubble (i.e. a type of slicework construction).
- (ii) a sand bitumen core.

Solution (i) would have provided a relatively impermeable boundary only between the levels of - 1.0 m and + 2.0 m G.M.S.L. However, the rock above it would have been grouted and it was considered that this form of construction would provide an adequate barrier to the passage of heated exhaust water because the heated water will largely be confined to the surface layer.

Solution (ii), because the column of sand bitumen would be continuous, provided an impermeable barrier throughout the depth of the breakwater. It did, however, require the provision of filter layers to protect the core during the life of the breakwater.

The feasibility of construction of the breakwater utilising the hollow concrete box solution was tested in a 3D model, as it was suspected that the boxes might be unstable during the construction stage. It was envisaged that the core area would be partly protected from wave action, along the most exposed length of breakwater, by rock mounds on either side. Although tests showed the boxes to be vulnerable during periods of severe wave action, it was concluded that construction was feasible.

The comparative study showed that the sand bitumen core was clearly the better of the two solutions. No special method of placing was required (i.e. it could be placed in a similar manner to the rock). Its use, unprotected in temporary works in Europe,

had shown it to be a reasonably tough, resilient, material. It would provide a complete barrier between sea bed level and the underside of the concrete cap. And it was significantly cheaper than the precast concrete alternative when all factors were taken into account.

It was envisaged that the sand bitumen would be placed, from trays, in the form of a Christmas tree, the Contractor using the same plant to transport both the sand bitumen and rock. However, only minimum thicknesses for the sand bitumen core and its adjacent filter layers were specified, giving the Contractor freedom to choose his own method of placing (Figure 3). In the event, the Contractor chose to adopt a Christmas tree similar to that originally envisaged (Figure 4).

It was appreciated that, during storms, some large rocks might be washed into the core area. This could pose long-term stability problems because, if the bitumen on placing were to span a large void, this could gradually "pipe" through the sand bitumen, its size only marginally decreasing. Consequently, it was thought that, if necessary, after storms a sand bitumen mix with a higher bitumen content could be placed, at higher temperature, in order to provide a material of higher plasticity and minimise the likelihood of large voids in the core area. In the event, however, no increase in bitumen content for this purpose was required.

The presence of an impermeable core offers the advantage of permitting the lee face of the breakwater to be grouted. However, it also means that the transient pressure which would normally be transmitted through a rubble structure must be contained or dissipated within the seaward half of the structure. As may be seen on Figure 3, blow holes some 6 m apart, were provided through the cap on the seaward side of the core to dissipate these pressures.

Consideration was also given to the effect that the impermeable core might have in decreasing the wave energy absorption capacity when compared with a normal rubble mound breakwater. This might result in a need for heavier dolosse armour units than would otherwise be the case. Consequently, the stability of the breakwater with the impermeable core was extensively model tested both in a flume and in a 1:80 scale 3D model.

In making these tests, it was realised that the 3D model would tend to give conservative answers (i.e. less energy would be destroyed in the model than in the prototype) because of Reynolds scale effects. Another conservative factor was that, for site safety reasons, extreme environmental conditions were considered

in the breakwater design. However, even when applying an estimated "one-in-a-million" storm condition (including surge plus wave set-up plus run-up) the design wave remains depth limited, and the stability of the outer armour units was found to be acceptable.

The sizes of the dolosse armour units adopted on the south breakwater were 6 t, 15 t and 20 t and, on the north breakwater, 6 t and 15 t. In fixing dolos sizes, consideration was also given to available crane capacities, overall cost, and the requirement that the need for future maintenance of the breakwater should be minimized.

3. SAND BITUMEN PROPERTIES

3.1 Contract Requirements and Trial Mixes

The Contract Specification required sand, won locally from sand dunes on the site, to be mixed with 80/100 pen. straight run bitumen. The bitumen content could be fixed, subject to trial mixes, at between 3 and 6 percent by weight. The grading limits were specified to lie anywhere between 2 mm and 0.063 mm sieve sizes.

At the commencement of the Contract suitable dunes were located. Table 1 below shows a typical grading curve which indicates that the sand was fine and essentially single-sized.

Sieve Sizes (mm)	Percentage Passing
1,18	100
0,600	99
0,300	92
0,150	6
0,075	0

TABLE 1. Typical Grading of Local Dune Sand

Before construction commenced, trial mixes were undertaken with bitumen contents ranging from 3 to 6% in half percent increments as specified in the Contract Document. In the

absence of documented methods of judging their suitability, each of the mixes was appraised by both the Engineer and the Contractor on a somewhat subjective basis. It was observed that the mixes containing 3 and $3\frac{1}{2}\%$ bitumen had little inherent strength or cohesion and looked unstable. The 4% mix showed a remarkable improvement whilst the $4\frac{1}{2}\%$ mix was marginally better still. Further increases in bitumen content did not appear to improve the properties of the mix. In view of likely batching inaccuracies (see ASTM D1663-74) of $\pm \frac{1}{2}\%$ the bitumen content was set at $4\frac{1}{2}\%$ in the knowledge that if it dropped to 4% the resulting mix would be acceptable.

In practice, it was found that the tolerances on the batches provided by the Contractor were very much better than $\pm \frac{1}{2}\%$ and in a sample of 119 bitumen content tests (of many more taken) the standard deviation on the bitumen content was 0.128%.

3.2 Laboratory Testing

With the exception of routine bitumen content and sand grading tests, no other laboratory testing was required under the Contract.

Apart from the data published by van Asbeck (4), Visser (5) and Kerkhoven (6), very little data could be traced on the behaviour and testing of sand bitumen. It seemed important to carry out some objective tests on this unique material in order that:

- a record could be made of the physical state of the material during construction for future reference should deterioration ever occur;
- to give an indication of the properties of the materials that are actually in place in the breakwaters;
- to provide at least some data for others in the future.

Therefore the ensuing tests were undertaken, although it should be noted that the results are not necessarily definitive. They should be interpreted with care, as the material actually used in the breakwater was placed under a wide variety of physical conditions and was not compacted. Its properties in-situ may therefore be variable and the laboratory test results may not be truly representative of the actual sand bitumen core.

Finally, it should be pointed out that the characteristics of any bituminous mix are dependent upon numerous variables such as sand grading, temperature, bitumen content, bitumen grade, etc., and that these results are therefore not necessarily universally applicable.

3.2.1 Marshall Testing

Two samples with 4 $\frac{1}{2}$ % bitumen were tested by the Standard Marshall Method (ASTM D1559).

The results are given below.

	Sample No.	
	1	2
Briquette compacted by	10 blows each side	5 blows each side
Density of Mix tonnes/m ³	1,8	1,8
S.G. of Sand	2,6	2,6
Voids in Mineral Aggregate %	30,8	30,8
Stability kN	0,61	0,24
Flow mm	0,46	9,0

TABLE 2.

MARSHALL DATA

3.2.2 Durability Testing

This test was made in an attempt to obtain some quantitative index of the durability of the sand bitumen in service in the breakwater. The mix contained 4 $\frac{1}{2}$ % bitumen and the test was the "Wet-Dry Durability Test" adapted for sand bitumen. The procedure for testing is given in the South African Standard Methods of Testing Materials Method A19 which is almost identical to ASTM D558.57 and D559-57. Samples, compacted in a standard fashion, were subjected to repeated cycles of brushing with a wire brush and the

loss of weight recorded. Tests were carried out for five cycles of brushing on four sets of four samples. Figure 2 summaries the results obtained.

3.2.3 Permeability Tests

Three specimens of the 4½% content mix were tested by filling a 76 mm dia. ring 18,75 mm thick with sand bitumen at 120° C and allowing it to cool. Standard falling head permeameter tests were performed with water at 12° C.

The results are given in Table 3 below.

Test No.	Dry Density (kg/m ³)	Coefficient of Permeability (m/s)
1	1685	3.7 x 10 ⁻⁵
2	1681	3.7 x 10 ⁻⁵
3	1751	2.3 x 10 ⁻⁵

TABLE 3. RESULTS OF PERMEABILITY TESTS

3.2.4 Shear Strength Tests

Three undrained, unconsolidated triaxial tests were carried out on the 4½% mix. Samples were prepared by filling a 75 mm dia. x 150 mm deep mould with sand bitumen heated to 120° C and allowing it to cool to testing temperature. Tests were conducted at temperatures considered representative of the sea adjacent to the breakwaters.

A shear box test was also carried out in an attempt to assess the strength of the cold joint between adjoining layers. Here the lower layer was permitted to cool before the overlying layer was added.

Figure 2. RESULTS OF BRUSHING TESTS

Test Type	Test Temp.	Apparent Cohesion	Friction Angle
	° C	KPa	°
Triaxial UU	8	175	53°
"	12	90	46°
"	16	60	45.5°
Shear box	12	74	45°

TABLE 4. RESULTS OF SHEAR STRENGTH TESTS

4. APPLICATION

The Main Contractor for the construction of the breakwaters sensibly employed a specialist asphaltting firm as sub-contractor to produce the sand bitumen and bitumen grout mixes. This sub-contractor established a continuous drum mixer on the site which could reach an output of about 40 tonnes of material per hour.

The bitumen was added by nozzle at the entrance to the drum and the flow rate was regulated by a load cell on the sand supply conveyor. This proved extremely satisfactory.

Batching proceeded on a daily basis and the materials were generally mixed at about 115° to 130° C. The material was placed in storage bins to cool down to placing temperatures that could range between 40° and 95° C. In practice, it was found that the optimum temperature for placing material in the sea was about 60° C. At higher temperatures the mix held together poorly and the washout losses were high whilst at lower temperatures the transport lorries had difficulty in getting the material to tip out. It should be noted that the material retains its temperature for many days thus it is both possible and reasonable to specify the placing temperature. In the height of summer, it still had ample heat to be used after a week. In winter it had to be used within 4 days. Heating elements were built into the bin walls and these were occasionally used to heat up mixes which had fallen below the minimum specified temperature. This procedure was sometimes supplemented by mixing cold and freshly mixed hot batches with a front-end loader.

Sand bitumen was loaded from the bins into tipper trucks and transported to the breakwater. There it was tipped into the rock tray of the breakwater crane which then positioned the load according to a predetermined pattern and tipped it into the sea. Some 37 000 cu. metres of sand bitumen were placed in this manner in individual loads of about 7 tonnes.

Figure 3 shows a typical idealised cross-section through the breakwater with its sand bitumen core. The core itself is protected on either side by graded rock filters with the seaward face armoured with dolosse units. In practice, the Contractor could not, of course, construct this idealised cross-section and dumped the rock and sand bitumen in a succession of layers, resulting in the "Christmas Tree" cross-section. This is shown on Figure 4.

Although the sand bitumen is protected by the rock filters in its permanent state in the breakwater, it was exposed to wave attack at the scar end during construction. Under these conditions it proved highly resistant to wave attack and this is well illustrated in Figure 5 which shows sand bitumen being placed at about water level. As can be seen, the mix stands up well to the erosive force of the waves. No doubt its long-term erosion resistance is poor and it requires the filter armouring but this property was extremely useful during the short construction phase.

Very soon after placing, the cold sea hardened the outer shell of the sand bitumen which must have greatly improved its early erosion resistance. Many instances of this property were observed during construction, where wave action removed the rock on either side of the sand bitumen, leaving the core standing proud.

Another helpful aspect of this material was found to be its ability to envelop discrete boulders. As previously mentioned, it was foreseen at the design stage that boulders could be washed by the sea or accidentally dropped by the Contractor into the core area. Observations during construction of the breakwater and core samples obtained by drilling indicated that such boulders become totally surrounded by sand bitumen thus preserving the integrity of the core. These boreholes also indicated that at lower sections, the core area sometimes tended to become filled with sand before the sand bitumen was placed on top. In one instance a pocket of sand over 1 metre thick was located in a borehole between the underside of the core and the top of the small rock foundation blanket.

Two sets of prototype tests, using dye placed on the south of the breakwater during strong south to south east winds have indicated that little or no transmission of water is taking place through the core.

5. CONCLUSIONS

The use of sand bitumen in this instance as an acceptably impermeable core material has, so far, proved successful.

Its unit cost was higher on this occasion than the quarry run which would normally be used. However, it could find application as a general breakwater material in areas where rock is expensive. Because of high wave activity and sediment transport, the lower portion of the breakwater core became contaminated with sand before the bitumen could be placed.

On this project a net saving in the total cost of breakwater construction might be claimed as the presence of the sand bitumen core permitted grouting to the lee face, thus obviating the need for increasing its crest height and providing lee face armouring towards the seaward end. The extra cost of the sand bitumen and grout thus tends to be balanced by the savings in crest height armour units.

Care is necessary in the design of the armour layer as a breakwater with an impermeable core may not absorb as much wave energy as a conventional rubble mound and some of the wave energy within the breakwater may be reflected. The design should therefore be model tested.

6. ACKNOWLEDGEMENTS

The authors would like to thank ESCOM for their assistance in compiling this Paper and permission to publish it.

CHAPTER 133

HARBOUR DESIGN INCLUDING SEDIMENTOLOGICAL PROBLEMS USING MAINLY NUMERICAL TECHNIQS

by
B. LATTEUX⁺

ABSTRACT

For most of the needed studies for the design of Calais harbour enlargement works, the "Laboratoire National d'Hydraulique" chose to use numerical models. This approach includes the determination of currents around and inside the new outer-harbour, just as the evaluation of the project sedimentologic impact and of the long-term evolution of a bank named "le Riden de la Rade", edging the access channel.

Current studies were performed using four nested bidimensional computer models fitted on field data and supplying in each point the depth-averaged velocity and the total water height. These four models are based on an implicate finite difference fractionnal step method. Besides for the very near field model the method is especially elaborated to enable the detailed reproduction of eddies and flow separations.

The sedimentological numerical study is based upon current models results : the bed-load transport is computed from the depth-averaged velocity and the water height previously determined using an empirical formula, and the continuity equation applied to this load transport gives then the bed evolution. As soon as the ceptn variation is significant enough to react on the flow pattern, current fields are readjusted by a simple method based on flow continuity equation.

This numerical model, applied to the near field, has given an evaluation of the sedimentological impact of the harbour enlargement project :

- strong erosion in front of the new harbour due to current strengthening ;
- accretion on each side of this erosion area, especially in the channel ;
- bar formation at the harbour entrance.

1. INTRODUCTION

Due to the increase of the passengers traffic between Calais and the United Kingdom, Calais Harbour is going to be equiped with supplementary car-ferry berths ; this development required an enlargement of the outer-harbour which will enable in a second stage the harbour spreading towards East (fig. 1).

Electricité de France. Chatou. France.

Fig.1 - CALAIS HARBOUR : NEW OUTER-HARBOUR LAYOUT

Hydraulic and sedimentological studies required by this development have been performed using mainly computer models : wave refraction off the harbour and diffraction inside were thus numerically studied by the "Service Central Technique des Ponts et Chaussées" ; the determination of tidal currents around and inside the new outer-harbour, just as the evaluation of the project sedimentological impact on bed-load transport, both presented here, were carried out in the same way by the "Laboratoire National d'Hydraulique". Only breakwater structure adjusting and final tests of wave agitation inside the harbour have required physical modelling.

2. NOTATION

C = Chezy's bottom friction factor ;
 C_S = Strickler's bottom friction factor ;
 d_m = mean particle diameter ;
 g = gravitational acceleration ;
 h = water height ;
 K = dispersion coefficient reckoning velocities vertical heterogeneity in ;
 K_S = porosity coefficient ;
 t = time variable ;
 T = bed-load transport rate ;
 U, V = components of flow discharge per unit width ;
 v = depth-averaged velocity ;
 x, y = space variables ;
 Z_0 = bottom elevation related to the horizontal reference level ;
 λ = mean latitude in the model's field ;
 ω = water specific weight ;
 ω_s = particle specific weight ;
 τ = bottom shear stress ;
 τ_c = critical bottom shear stress ;
 Ω = angular rotational velocity of the Earth.

3. STUDY OF THE CURRENTS

3.1. Presentation

Tidal stream and level distribution have been computed on mean spring tide conditions by means of four nested bidimensional numerical models (fig. 2 and 3) fitted on field data :

- a global model of the Southern part of the North Sea (5 kilometers mesh-grid) ;
- a regional model of the Dover Strait (one kilometer mesh-grid) ;
- a local model of Calais region (250 meters mesh-grid) ;
- a very near field model representing outer and inner parts of the harbour (variable mesh down to 30 m).

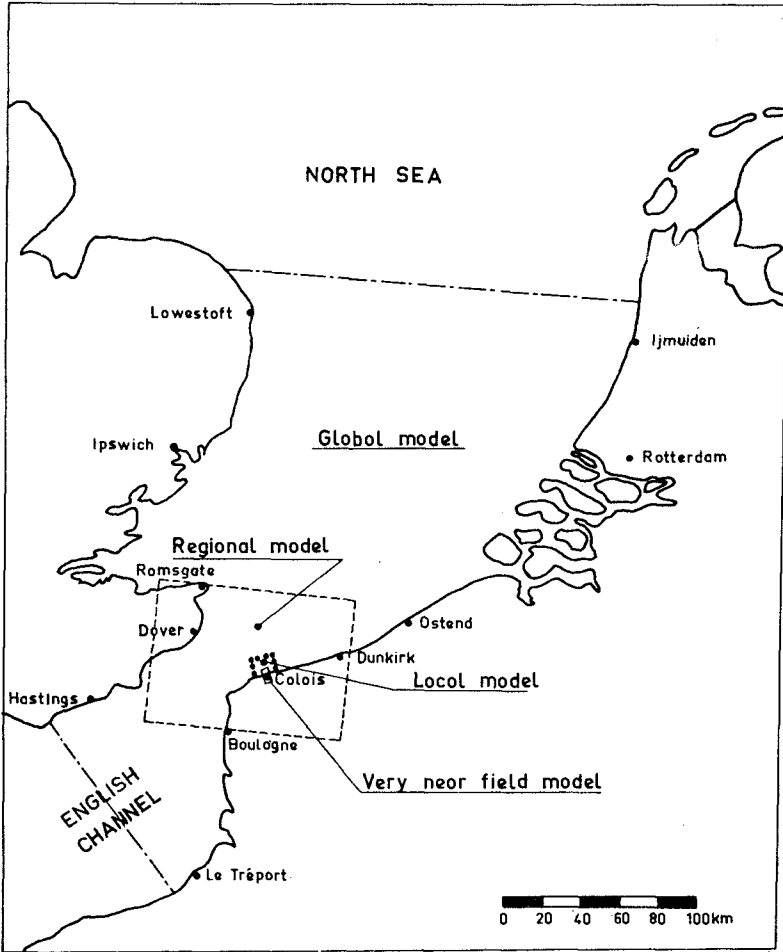

Fig.2 - AREA COVERED BY THE DIFFERENT NUMERICAL MODELS

Fig.3. AREA COVERED BY THE LOCAL AND VERY NEAR FIELD MODELS

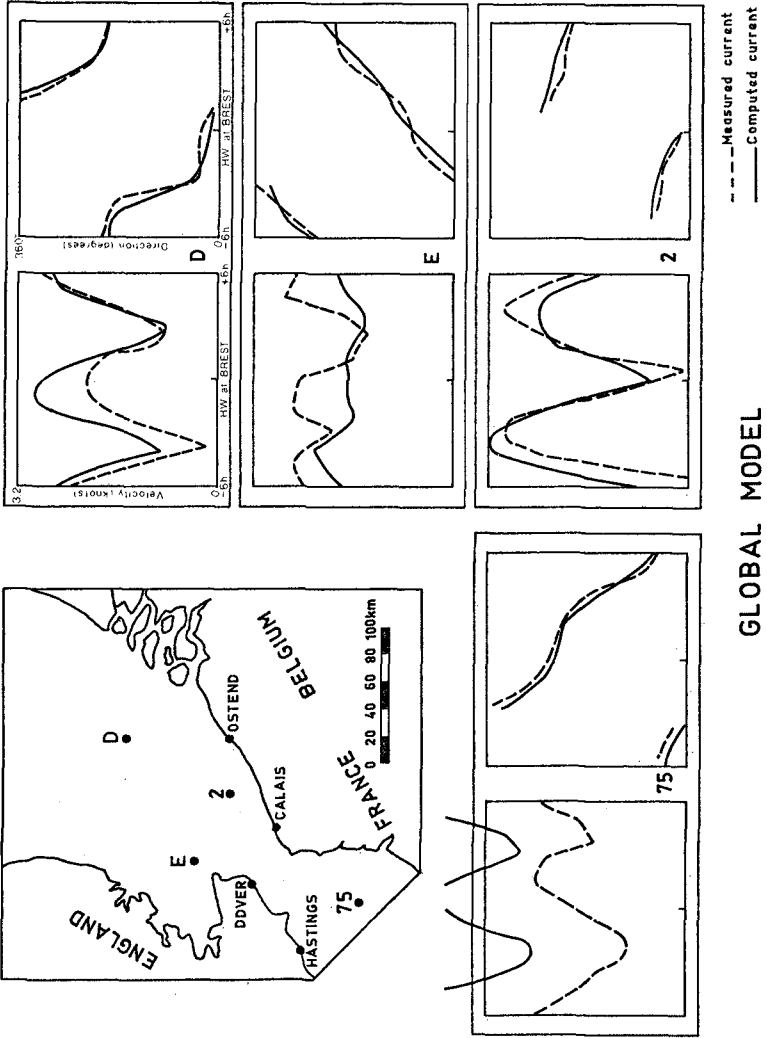

Fig. 4 - COMPARISON BETWEEN COMPUTED AND MEASURED CURRENTS

Only the last two models are directly within the goal of the study, allowing the evaluation of the project nautical conditions and serving as input to the sedimentological investigation ; the first two models, extending very far off the studied area, are only used to solve the problem of the boundary conditions : the few field measurements near Calais are not sufficient to give by interpolation adequate conditions ; limits must then be pushed away so far as computed current near the harbour depends on the well-known bed and coast topography and on the global boundary conditions rather than on the distribution of these conditions.

3.2. Model principle

The model is based upon the assumptions of an hydrostatic pressure, slight curvature of the bottom and the free surface and a vertical quasi-homogeneity of the current. Sun and moon attractive forces are neglected in the model's field (they are included only in the boundary conditions). The model computes then the depth-averaged velocity and the total water height using the classical Saint-Venant equations including bottom friction and Coriolis force :

$$\frac{\partial h}{\partial t} + \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} = 0 \quad (1)$$

$$\frac{\partial U}{\partial t} + \frac{\partial}{\partial x} (U^2/h) + \frac{\partial}{\partial y} (UV/h) + g h \frac{\partial h}{\partial x} = - g h \frac{\partial Z_b}{\partial x} - g \frac{U\sqrt{U^2 + V^2}}{C^2 h^2} + 2 \Omega V \sin \lambda + K \Delta U \quad (2)$$

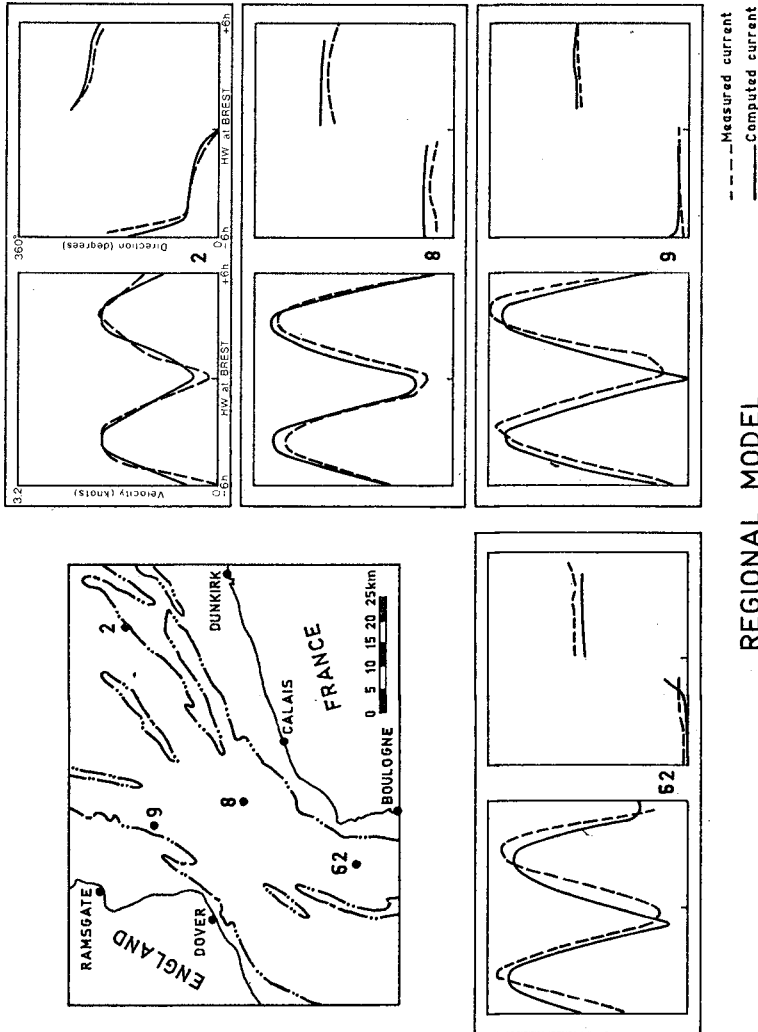

$$\frac{\partial V}{\partial t} + \frac{\partial}{\partial x} (UV/h) + \frac{\partial}{\partial y} (V^2/h) + g h \frac{\partial h}{\partial y} = - g h \frac{\partial Z_b}{\partial y} - g \frac{V\sqrt{U^2 + V^2}}{C^2 h^2} - 2 \Omega U \sin \lambda + K \Delta V \quad (3)$$

The solving method is an implicate finite difference fractional step scheme using an orthogonal grid. Boundary conditions (water height, flow discharge or tidal wave) are coming partly from field data, partly from the results of another global model in the case of the largest one. The finer models are successively feeded with boundary conditions interpolated from the results of the preceding one.

3.3. Results

3.3.1. Global model

This model includes the Southern part of the North Sea and the Eastern part of the English Channel from Great - Yarmouth - Ijmuiden to Hastings - Le Tréport with a 5 kilometers mesh. On

REGIONAL MODEL
Fig.5 -COMPARISON BETWEEN COMPUTED AND MEASURED CURRENTS

the northern boundary, crossing an amphidromic point, surface level and flow discharge were fixed basing on field data ; on the southern boundary were imposed both components of flow discharge, supplied by the results of another preexisting numerical model, covering the whole English Channel.

The complex tidal range distribution due to the superposition of two tidal waves, one coming from the English Channel, the other from the North Sea, is generally well reproduced except near the Dover Strait, too narrow compared with the mesh to be correctly described. Figure 4 shows the comparison between measured and computed current for some of the calibration points ; it reveals a rather good agreement concerning flow direction, even when his value is continually changing (points E and 75), and a less accurate simulation of the velocities.

3.3.2. Regional model

Dover Strait is considered in more details in the regional one kilometer mesh model. Boundary conditions, supplied by the global model, are the two components of flow discharge.

Tide law is rather improved ; as displayed on figure 5 for some calibration points, velocity, direction and phase of the tidal stream are accurately reproduced, except on narrow banks, badly described in the grid system, where velocities are often overrated.

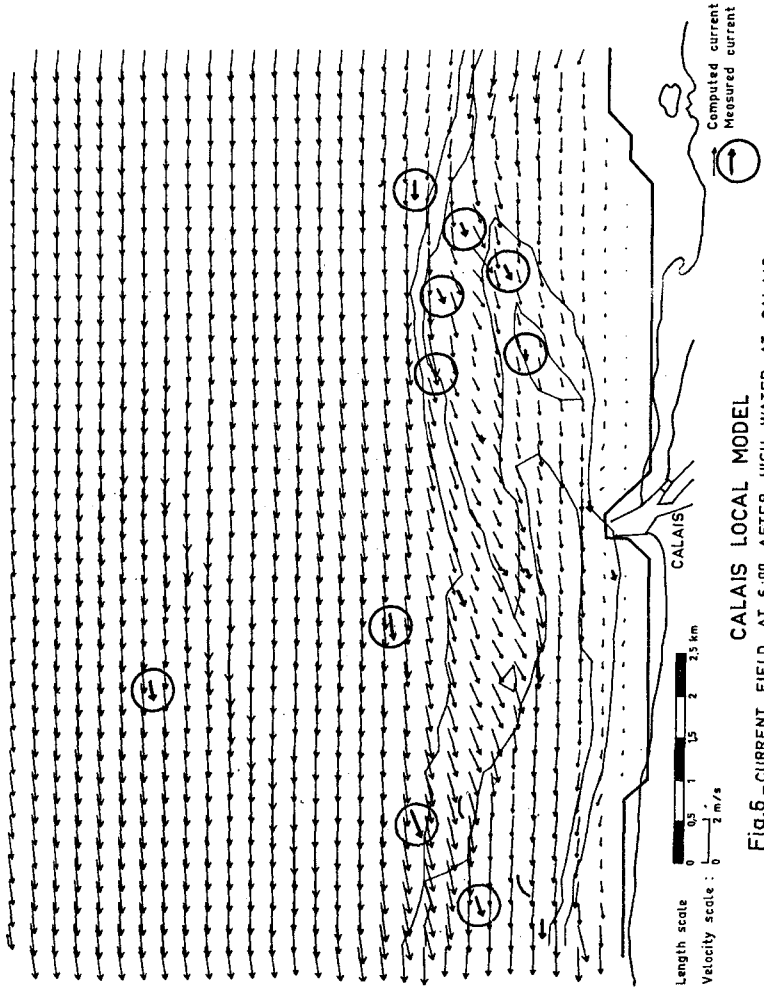

3.3.3. Local model

This 250 meters mesh model covers the whole "Riden de la Rade" (fig. 3), a sand bank edging the access channel to Calais Harbour, whose evolution has to be computed with and without the influence of the new outer-harbour.

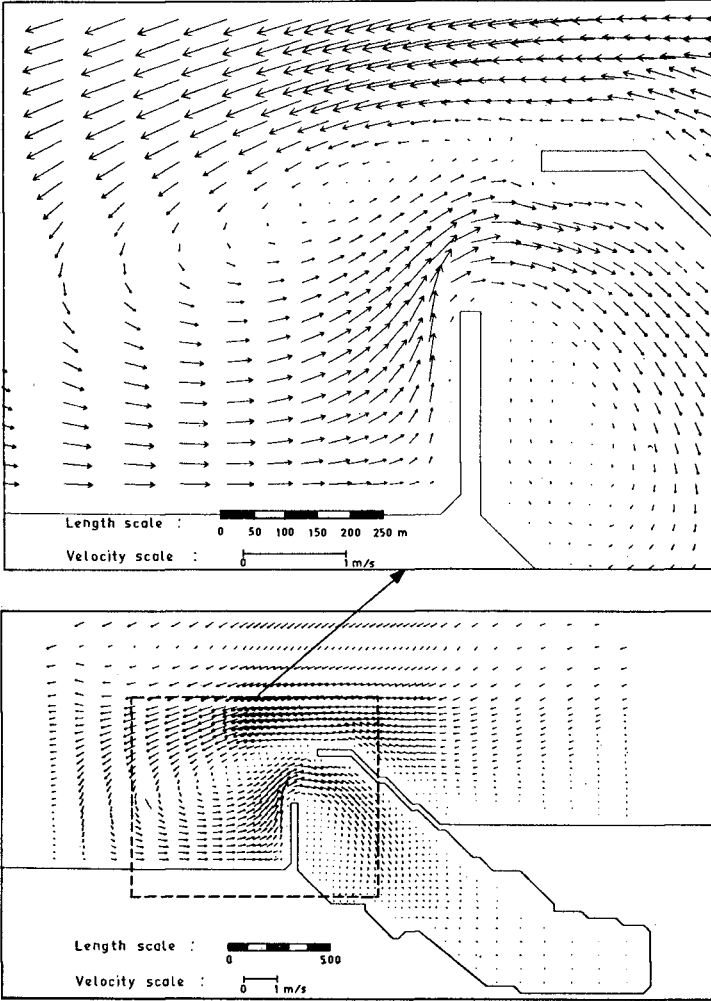

The flow pattern peculiarities involved by this bank are effectively achieved by the model in spite of the two-dimensional representation of the actually three-dimensional flow configuration. Figure 6 gives the computed stream distribution 6 hours after high water, compared with current measured in a few points : natural current deflection on the bank induced by the feeding of the southern channel, just as the ebb flow reducing in this channel are rather well reproduced.

3.3.4. Very near field model

The last model, representing the enlarged outer-harbour and its close vicinity, uses a variable mesh grid (down to 30 m), allowing an accurate representation of the harbour entrance and inner parts while having at the same time boundaries far enough to get there a flow pattern not disturbed by the harbour enlargement. The solving method is especially suited to enable the detailed reproduction of eddies and flow separations ; these flow configurations can be reproduced

CALAIS LOCAL MODEL
Fig.6 -CURRENT FIELD AT 6:00 AFTER HIGH WATER AT CALAIS

CALAIS HARBOUR VERY NEAR FIELD MODEL

Fig.7- CURRENT FIELD AT 3:00 BEFORE HIGH WATER

owing to the zero velocity assigned on solid boundaries, whose effect is carried inside the model field by the diffusion terms. Both components of flow discharge are imposed on eastern and western fluid boundaries ; on the northern one, rather near to the harbour, it has proved better to impose water level and tangential component of flow discharge, thus allowing contingent flow lines deflection by the new breakwater even on the boundary.

Flow pattern has been computed for two stages of the harbour development and for two different considerations of the west breakwater one being permeable. The model results show a significant flow strengthening and deflection northward of the harbour during flood, slighter during ebb, and the development of two eddies, the largest one occurring to the west of the harbour at the end of ebb (fig. 7). In the harbour entrance velocities do not exceed 30 cm/s ; inside, the flow is rather slow, slightly vortical at the end of filling.

These results yield an estimate of the nautical conditions, which seem rather better than the present ones, point out the most propitious time for the harbour access and give precious informations concerning the access handling.

4. SEDIMENTOLOGICAL STUDY

Current results are used to compute by means of a two-dimensional bed-load transport model the sedimentological effect of the harbour enlargement.

4.1. Model presentation

Besides assumptions considered for current determination, following ones are made :

- flow and bottom evolutions are slow ;
- bed-load transport has the same direction as the depth-averaged velocity.

Bed-load transport induced by tidal current is computed using Meyer-Peter's formula :

$$T = 8 K v \sqrt{\frac{g}{\bar{w}}} \frac{1}{\bar{w}_s - \bar{w}} (\tau - \tau_c)^{3/2} \quad \text{pour } \tau > \tau_c \quad (4)$$

$$T = 0 \quad \text{pour } \tau < \tau_c$$

Where τ is given by Strickler's law :

$$= \frac{\bar{w}}{C^2} \frac{v^2}{h^{1/3}} \quad (5)$$

and τ_c by Shield's law :

$$\tau_c = A (\omega_s - \bar{\omega}) d_m \quad (6)$$

where A is a coefficient between 0,02 and 0,06 (0,047 according to Meyer-Peter).

Continuity equation applied to the bed-load transport provides then the bed evolution :

$$\frac{\partial Z_b}{\partial t} + \text{div } \vec{T} = 0$$

Numerical solving is based upon an explicite finite difference method using an orthogonal grid. Boundary conditions have to be imposed only when flowing in ; sea bed is then kept fixed on the bound mesh.

In order to avoid a prohibitive number of computation steps, tide is filtered by expanding sedimentological time step with respect to hydraulic one (so a lengthened tide represents several tides, in the same way as it is made on scale models). At every step velocity is readjusted according to the new water depth assuming that the initial flow discharge remains the same at the same time of the tide.

This model has already been applied in a similar case, related to the sea bed evolution induced in the building of the new outer-harbour of Dunkirk, about 40 kilometers away from Calais : mathematical model results turned out to be close to those achieved on the physical movable bed model operated for the study, themselves well corroborated afterwards by the natural bed evolution.

4.2. Results

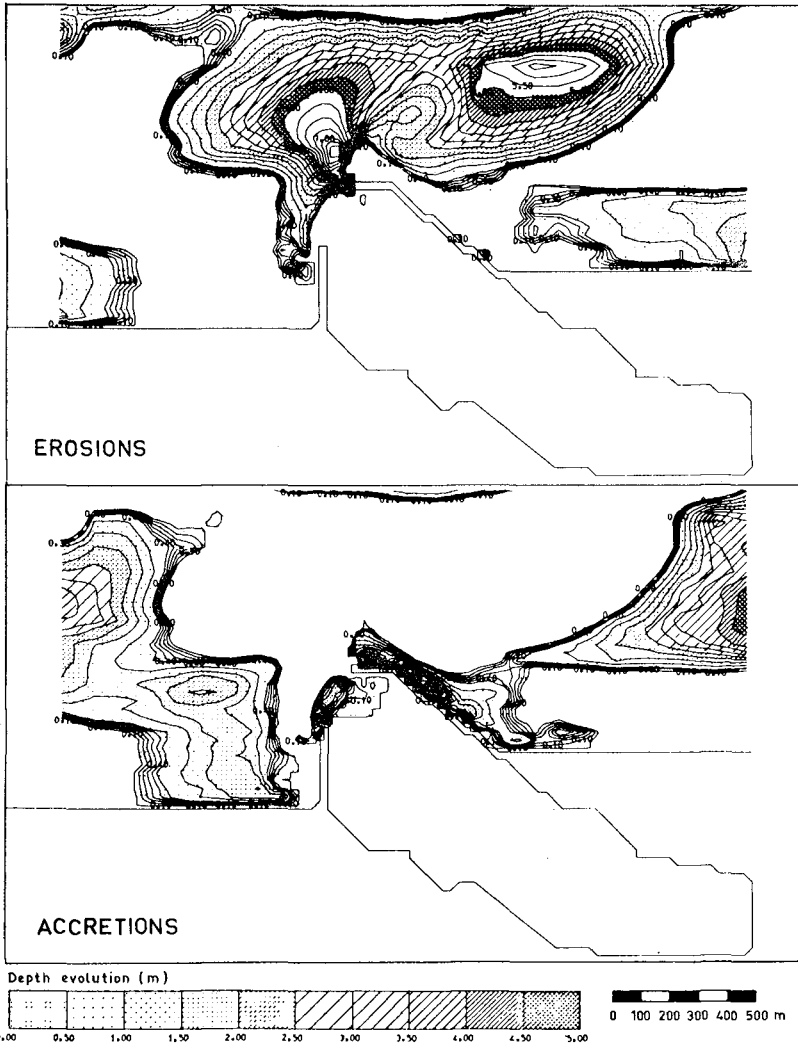

Based on the results of the very near field current model, the bed-load transport model, using the same grid as the current one, has supplied an evaluation of the sedimentological impact of the final enlargement project.

Figure 8 displays, in the initial state, the computed distribution of tidal-averaged sediment transport rate : it points out predominance of flood action, especially northward of the harbour where current strengthening inferred from the new breakwater building is then much more significant than during ebb ; in this area sediment transport rate reaches 1 500 m³/year/m width, i.e. ten times as much as on the eastern and western bounds. On each side of the harbour occurs a sediment transport "eddy" caused by unequal distribution of both ebb and flood current downstream the harbour, strengthened in the north and reduced in the south in the of the breakwaters. As time elapses maximum transport rates decrease gradually because of mutual adjustment of flow distribution and bottom topography.

CALAIS NEW OUTER-HARBOUR

Fig.8 - COMPUTED PATTERN OF NET SEDIMENT TRANSPORT
(INITIAL STATE)

CALAIS NEW OUTER-HARBOUR

Fig.9 - COMPUTED EVOLUTION AFTER 5456 TIDES (8 YEARS)

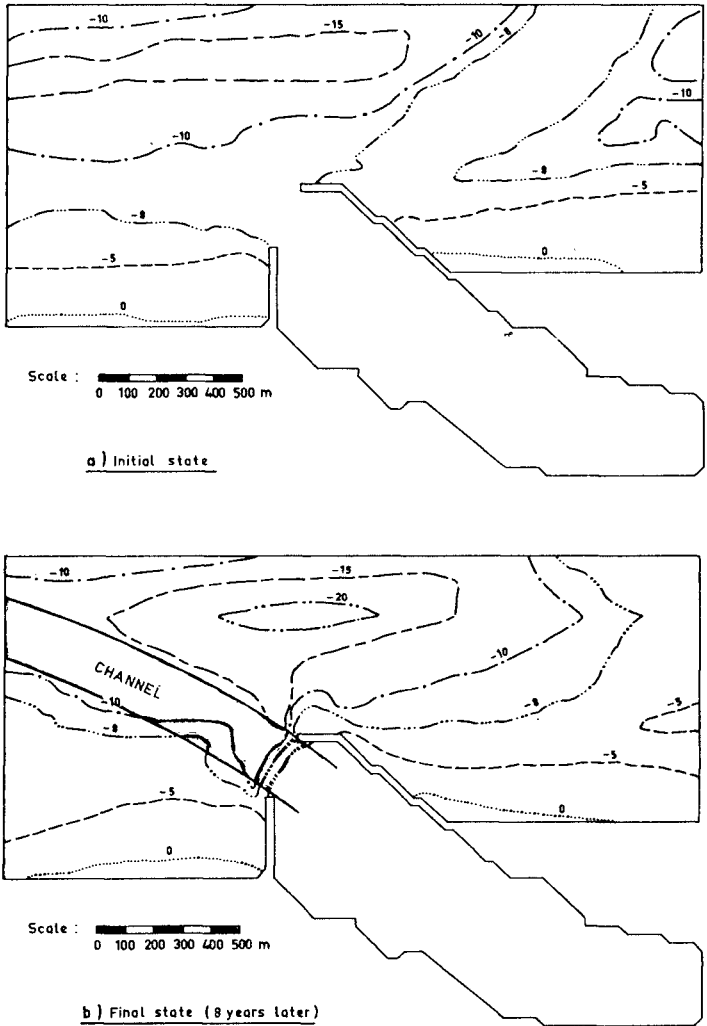

Fig.10- CALAIS - COMPUTED BED EVOLUTION NEAR THE NEW OUTER-HARBOUR

Figure 9 presents the bed evolution computed after 8 years of tidal current action ; it shows a large area of erosion from the north-west to the north-east of the harbour with deepening exceeding 8 m near to the new breakwater head ; slighter accretion occurs on each side, especially at the edge of the access channel ; in the harbour entrance the current velocity gradient brings out the development of a bar of rather limited size.

Figure 10 yields the comparison between present and final bottom topography, showing up the necessity of maintenance dredging in the harbour entrance and in the south of the outer channel.

The results of this bed-load transport study show that a bed protection has to be placed at the toe of the new breakwater ; they also give an estimate of the sand volume to be dredged to maintain the harbour access.

Bed evolution owing to suspended sediment, notably prevailing inside the harbour, will be separately examined using a method of balance calibrated from the present state data.

5. CONCLUSION

Among hydraulic studies needed by the enlargement of Calais Harbour, both stream distribution and sedimentological impact of the project have been dealt by means of numerical technics : current computer simulation, involving four bidimensional nested models, has enabled the detailed determination of nautical conditions in relation with the design of the new outer-harbour, pointing out the most propitious time for the harbour access and giving information for access handling ; current results have then been used to compute from a bidimensional bed-load transport model, validated on a similar study, the effect of the harbour extension on the bed evolution, yielding definitions of bed protection and forecast of channel dredging rates. This computer model will be used afterwards to study the evolution of a bank named "Riden de la Rade" (fig. 3) which could threaten in a very distant future the harbour access.

Physical modelling was required only for items needing little equipment and able to be quickly dealt with : final tests of wave agitation and breakwater structure adjusting.

This procedure of comprehensive numerical harbour design study is of moderate cost, of great flexibility and rather fast compared with scale modelling.

NEW JETTIES FOR TUNG-KANG FISHING HARBOR, TAIWAN

Chi-Fu Su
Manager
Engineering Department
Taiwan Fisheries Consultants, Inc.
Taipei, Taiwan

INTRODUCTION

Tung-Kang Fishing Harbor, which is about 16 km to the south of Kaohsiung Harbor, is a river harbor on the south-west coast of Taiwan. This harbor is located at the estuary of the Niu-Pu River, which meets the Tung-Kang River and the Kao-Ping River on the north side. (see Fig. 1) The original north and south jetties were constructed in 1959. Because the entrance is located at the meeting of the three rivers and the water depth at the entrance is shallower than that in the breaking zone, the entrance is easily choked with sand during the summer season when the south-west wind and waves are strong. Therefore, dredging is always necessary to maintain the required depth. On the other hand, because of the increasing number of fishing boats and deeper draft, the port cannot function effectively. Therefore, how to keep the required water depth at the entrance and to obtain a wider and stable water basin is an urgent problem with this harbor.

Based on the sounding of 1973, the littoral drift is mainly from the south. In the next year the construction of a 176 m long new south jetty was begun to protect the entrance and to facilitate the sedimentation study. In 1975, the Taiwan Fisheries Consultants was appointed to undertake the investigation and long-term planning work. This project includes littoral process study, planning, model test and design. Finally it is recommended that an adequate layout of south and north jetties can solve the problem of accretation of the harbor entrance.

The purpose of this paper is to describe some aspects with emphasis on how to prevent the shoaling of the entrance channel located at the meeting of the rivers.

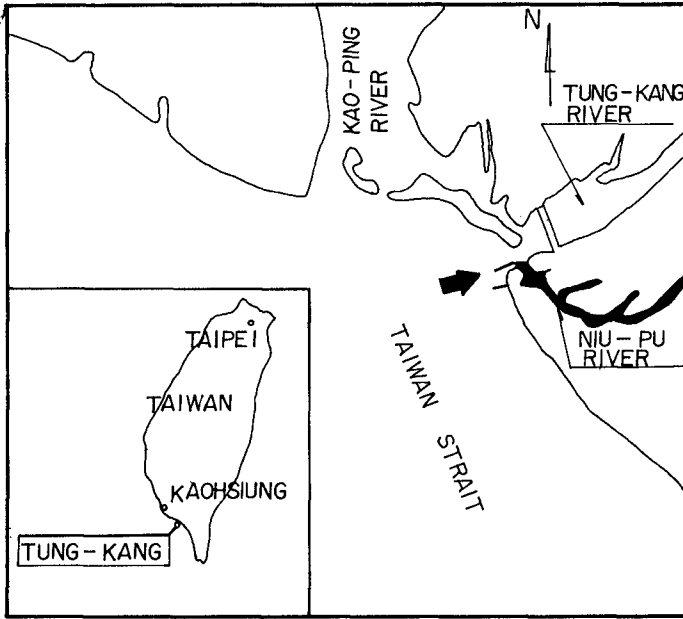

Fig-1 SITE LOCATION

LITTORAL ENVIRONMENTAL CONDITIONS

Wind

Because of the lack of site data, those observed at Kaohsiung are referable. The wind data from 1951 through 1970 were analyzed. (2) Winds from north-northwest occur in the greatest part of the time and prevail during the months of September through April. Higher velocities are associated with typhoon passing this area or tropical depression which occurs in the South China Sea mainly during June through September. The strongest longshore winds with speeds ranging from 5.4 to 13.8 m/sec occur during the summer season and predominantly from the southeast.

Waves

Based on the wave data measured in 12^m of water at Kaohsiung Harbor, the predominant wave height is 0.5-1.0^m, with wave period of 7-8^{sec} and from southwest. The higher waves occur during the summer season, especially in the typhoon period.

Tide

The spring tidal range is 1.3^m, the maximum water level was observed in 1969 at 2.7^m above low water level. This is due to the combination of spring tide and storm surge. The measured current speeds of both ebb and flood tide are below 0.5 m/sec.

Rivers

There are four rivers in the study area (see Fig. 1); except the three of them meeting at Tung-Kang Harbor, the Lin-Ben River is 10 km to the south of this harbor. The maximum measured discharge of the Kao-Ping River is 18,000^{cms}, 1,470 the Tung-Kang River and 2,950^{cms} the Lin-Ben River. The discharge in the Niu-Pu River is too small and negligible. The estimated annual sand volume transported by Kao-Ping River is 24 million cubic meters, 0.5 million cubic meters the Tung-Kang River and 1.5 million cubic meters the Lin-Ben River.

Topography off Tung-Kang Coast

Fig. 2 shows a deep marine canyon off this coast. Therefore most of the sediment discharged from rivers are trapped in it.

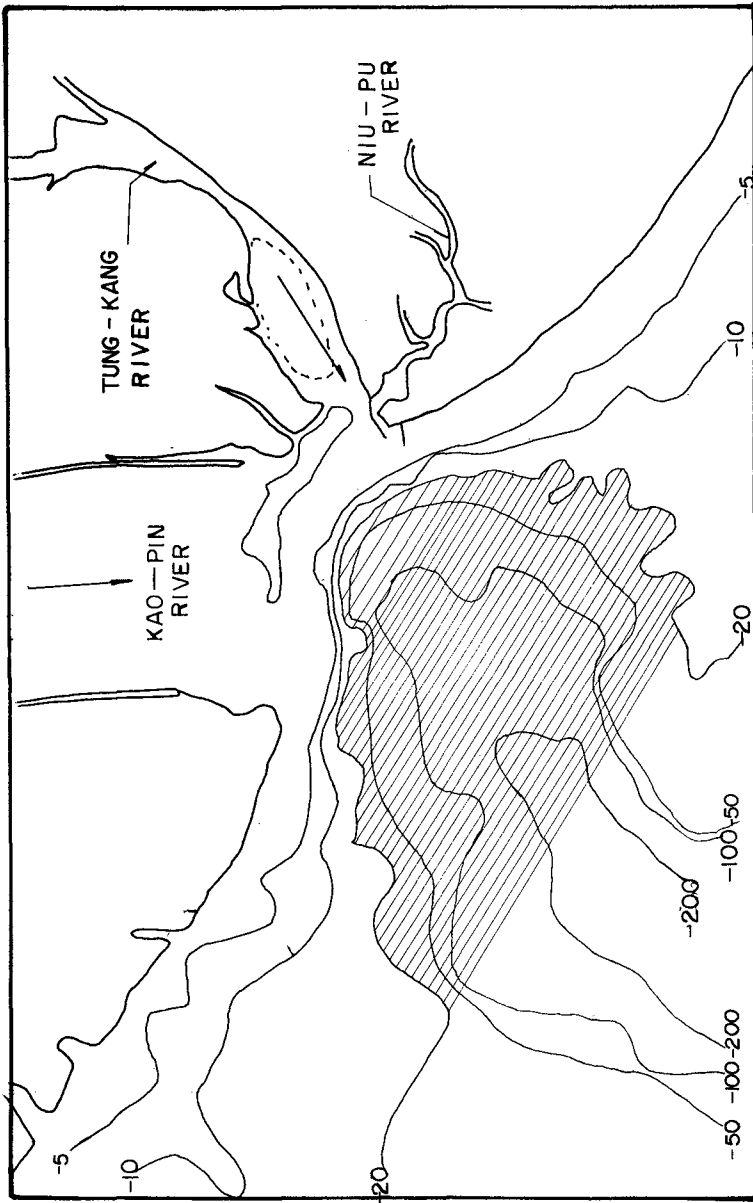

Fig-2 Marine , Canyon Of TUNG-KANG Coast

LITTORAL PROCESS

Bathymetry

From the bathymetric survey of September 1973, it was found that the littoral drift was mainly from the south. As shown in Fig. 3, the sand bars were formed at both heads of the original north and south jetties. In the next year the construction of a 176^m long new south jetty (see Fig. 7) was begun to protect the entrance and to facilitate the sedimentation study. For further study, three other soundings were conducted in May 1975, September 1975 and June 1976. The lengths of the newly constructed south jetty in these three soundings were 120^m, 176^m and 216^m, and the depths at the jetty head were 1.8^m (below low water level), 2^m and 4^m respectively. The results of the sounding were used for comparing changes of contour. So the sand sources and seasonal sea bottom change in the region between shoreline and some water depth contour could be interpreted. The influence of the newly constructed south jetty on the behavior of littoral drift was also evaluated.

Grain size Distribution

With the last two soundings littoral materials were also sampled for analyzing grain size and size distribution in the study area.

The median grain size was analyzed, from the size distribution overall the study area, the following results could be obtained. 1. The June 1976 data showed that the relatively coarse sands were distributed in the range from -2 to -3^m depths, while those of September 1975 were in -5 to -6^m depths. They were positioned in breaking zone, and during typhoon period the position moved seaward. 2. At the mouth of the Tung-Kang River, the median size D50 was up to 0.6^{mm} which was rather coarser than at the other place. From this we can know that they came from the Tung-Kang River or the Kao-Ping River. The finer sands were transported by wave current and the coarser ones remained behind. 3. At the entrance of the harbor, the sand was fine because of low wave energy there.

Dredging Record

To provide the required navigation channel, dredging work was conducted during the period from 1973 through 1975. The monthly dredging volume is listed in Table 1, which shows the annual volume to be around 100,000^{m³}.

Fig-3 SOUNDING OF SEPTEMBER 1973

Table 1. Records of Dredging Volume

Month	Volume	Year			
		1973	1974	1975	1976
1		3,400	6,300	13,442	7,600
2		9,100	9,450	5,600	7,400
3		9,270	11,600	10,000	-
4		7,250	9,200	11,000	-
5		10,410	8,400	13,300	-
6		11,415	6,800	6,300	-
7		3,970	8,000	9,200	
8		5,970	4,900	1,200	
9		14,580	11,400	9,750	
10		7,160	9,600	5,560	
11		8,200	8,240	9,600	
12		6,480	9,270	9,200	
total		97,250	103,610	104,152	

Seasonal Changes of Shore

They were analyzed by comparing the survey of May 1975, September 1975 and June 1976.

Summer Season: In the area immediately south of the new south jetty, the rip current induces by the jetty was obvious and deeply affected the foreshore and inshore topography. Along the shoreline accretion and erosion occurred at different positions relative to the new south jetty. Due to the action of waves arriving from WSW to SSW, accretion occurred in the area from the south jetty to a line approximately 200^m south. From the 200^m line to the line of 600^m south, the concentrating rip current made this area eroded evidently. While southwards the rate of erosion decreased

and accumulation occurred by the supply of the southerly sand. Inspecting the onshore-offshore change, the influence of rip current was down to the depths between -4^m and -6^m . Deeper than this, there was accumulation because of slower current and abundant supply of material.

The area north of the new south jetty was mainly affected by the sand from the Tung-Kang River and the Kao-Ping River. Two impounding zones could be found in the lee of the south jetty and in the zone immediately north of the north jetty respectively. In the former case, littoral material moved along the outer face of the jetty and deposited in the relatively calm water in the lee of the structure. While in the latter case, sand transported by the rivers accumulated in the zone between the north jetty adjacent to the Tung-Kang River, due to slower water flow and wave current on the reverse at the river mouth. The accumulated sand may be transported by diffraction waves to deposit at the entrance. Fortunately, most of the sand there is moved by northward longshore current to the deep marine canyon off the mouth of the Kao-Ping River. This is why the small scale Tung-Kang Fishing Harbor could be maintained by dredging about $100,000^m^3$ of sand every year, as shown in Table 1.

Winter season: During the winter months, the approaching waves shift to the west direction and more perpendicular to the shoreline. So both the impounding capacity of the new south jetty and the southerly littoral drift are decreased. Although the rip current becomes slower, the shortage of sand supply made the erosion area moved northward. While to the south of the 600^m line, the volume accumulated still increased and also moved northward due to the continuous supply of sand. Rapid erosion in the area north of north jetty is due to the decrease of sand from rivers during the winter months. The bar formed during the summer season was moved northward or transported seaward to the deep marine canyon by waves.

From the above analysis, the deep marine canyon is an effective sink to trap the large volume of sand transported from the Kao-Ping River. The orientation of the coast makes the direction of advancing wave toward the shore stable, and create a coast-longshore current from south to north, these two local conditions are very important for solving the entrance stabilization problem.

HYDRAULIC MODEL TEST

To prevent the sand from entering the entrance, both the newly constructed south jetty and the north jetty should be adequately extended. This was studied by using hydraulic model test conducted in the laboratory of Chung Hsing University⁽⁴⁾.

The south jetty is mainly to stop the southern longshore drift and let it bypass the entrance. The extended north jetty is not only to provide a deeper entrance channel but also to reflect the waves to transport the sand at the head to the north. Besides, some short groins connected to the south bank of the Tung-Kang River can change the flow direction so as to discharge the sand away from the entrance. Based on these principles, the jetties were arranged and verified by model test.

A distorted scale (1:75 vertical and 1:150 horizontal) movable-bed model in which fly-ash with median diameter $D_{50}=0.08\text{mm}$ and specific gravity $S_m=2.02$ was used as bed load. The wave generator was only 9m long. In order to have a larger scale model, the model was divided into two parts. (see Fig. 4) Part A included the area from the entrance to a point 1000m from the south of the new south jetty. The test was principally on the southern longshore drift. Part B included the area between the lines 300m to the south and 1000m to the north of the entrance. This part covered the estuary of the Tung-Kang River. The test was mainly on the sand from the river. The test was carried out with a number of cases with different layout of jetties.

In part A, five cases and thirteen runs were carried out with various wave conditions and durations. The results suggested a layout in which the south jetty was 410m including the shore connected portion of 350m long, then turning to the north-west and widening the north jetty so as to have a longer head for reflection waves. (see Fig. 5) In this case, no obvious accretion took place in the entrance channel; accretion occurred around the north jetty where the counterlines moved seaward. The current induced by the new south jetty transported sand in the south-west direction. This corroborate the field investigation results.

In part B, five cases and seven runs were carried out. Besides various wave conditions and durations, the discharge and sand from the Tung-Kang River was also simulated. The results suggested a layout in which

Fig-4 The Scope Of Part A & Part B Test

Fig-5 PART A TEST

Fig-6 PART B TEST

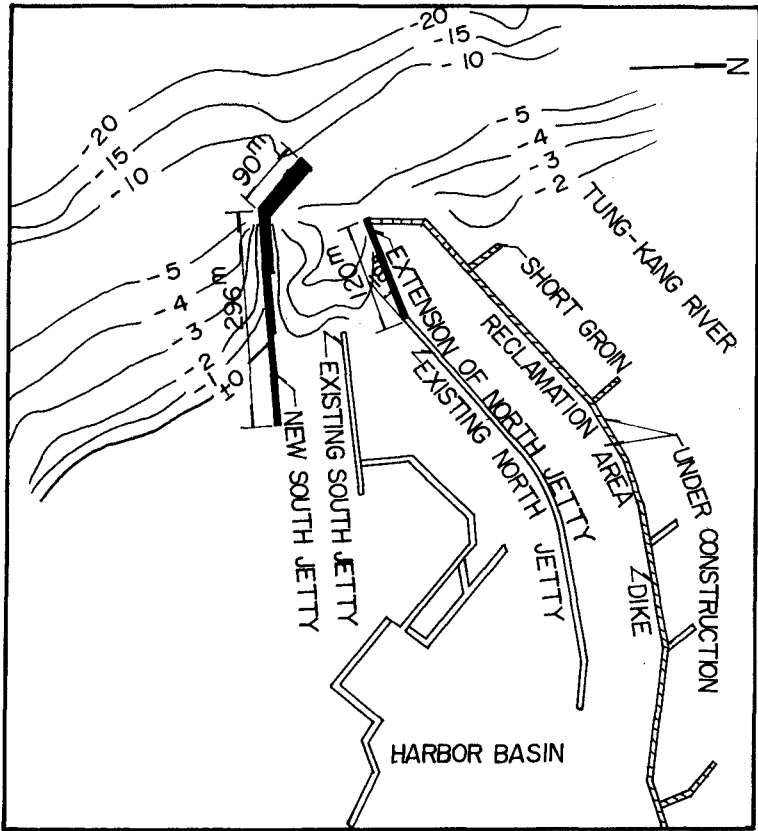

Fig-7 LAYOUT OF NEW JETTIES

the length of the new south jetty was 356m including the shore connected portion of 296m then turning to the north-west, and the north jetty was turned clockwise by 18° from the head of the existing north jetty and lengthened by 120m. (see Fig. 6) To reflect the waves at the head of north jetty so as to transport the sand apart, a reclamation area on the north side of the north jetty was suggested so as to have a wider head to reflect the incident waves. In this case, the southern longshore drift could by-pass the entrance without accretion because of the reflected waves from the north jetty head. The sand discharged from the Tung-Kang River was far away from the entrance due to the action of reflected waves and the effect of the reclamation area.

FINAL LAYOUT AND STRUCTURE TYPE

The final layout is as shown in Fig. 7. The new south jetty was lengthened by 30m so as to have a calmer basin. The first 176m section was rubble mound type armoured with holtripod. The other portion of 60m long was composite-caisson type. The width of caisson at head section is 15m, 8.5m high and 12m long. Composite-Caisson type was also adopted for north jetty. The construction work of the new south jetty and the extension of the north jetty was completed on 1979. The reclamation area, dike and short groins will be built in the following years.

CONCLUSIONS

- (1) A careful field investigation of littoral process is helpful to the study of a small scale harbor which is located at the meeting of rivers.
- (2) A prototype jetty (if possible) for aiding the study of longshore drift is very effective.
- (3) A physical hydraulic model is proved to be an important tool for the functional design of jetty system for entrance channel with complicated littoral drift phenomena.
- (4) An adequate arrangement of jetties can make the diffraction and reflection waves play important roles in the sand bypassing system.

CHAPTER 135

MAJOR RECLAMATION SCHEME FOR MARINA CITY, SINGAPORE

S.Y. CHEW
Manager, Building and Development Division,
Housing and Development Board, Singapore

and

J. WEI
Principal Civil Engineer, Building and Development Division,
Housing and Development Board, Singapore.

SUMMARY

One of the most ambitious coastal reclamation projects in the Republic of Singapore to reclaim 360 hectares is now in progress and, when completed in 1985 at an estimated cost of S\$385 million, will provide a major portion of the lands required for the development of Singapore's new city centre to be known as Marina City. This paper describes the various activities involved in the planning, design and construction of the project.

INTRODUCTION

The island republic of Singapore with a very small land area of only slightly over 600 square kilometres saw rapid industrial and housing development in the early 1960's. This prompted the government to embark upon an intensive reclamation programme to provide new lands to meet the urgent needs.

Following a small pilot scheme reclamation in 1963 the East Coast Reclamation Scheme was launched and the following phases were executed (Figure 1):-

- (i) Phase I reclamation of 405 hectares commenced in April 1966 and was completed in April 1970 at a cost of S\$45 million. (Unit cost approximately S\$11 per sq metre)
- (ii) Phase II continued westwards from Phase I to reclaim 53 hectares. Work commenced in April 1970 and was completed in May 1971 at a cost of S\$10 million. (Unit cost approximately S\$19 per sq metre)
- (iii) Phase III to reclaim 67 hectares commenced in March 1971 and was completed in December 1975. The project cost was S\$23 million. (Unit cost approximately S\$34 per sq metre)
- (iv) Phase IV reclaimed 486 hectares from May 1971 to February 1976 at a total project cost of S\$44 million. (Unit cost approximately S\$9 per sq metre)

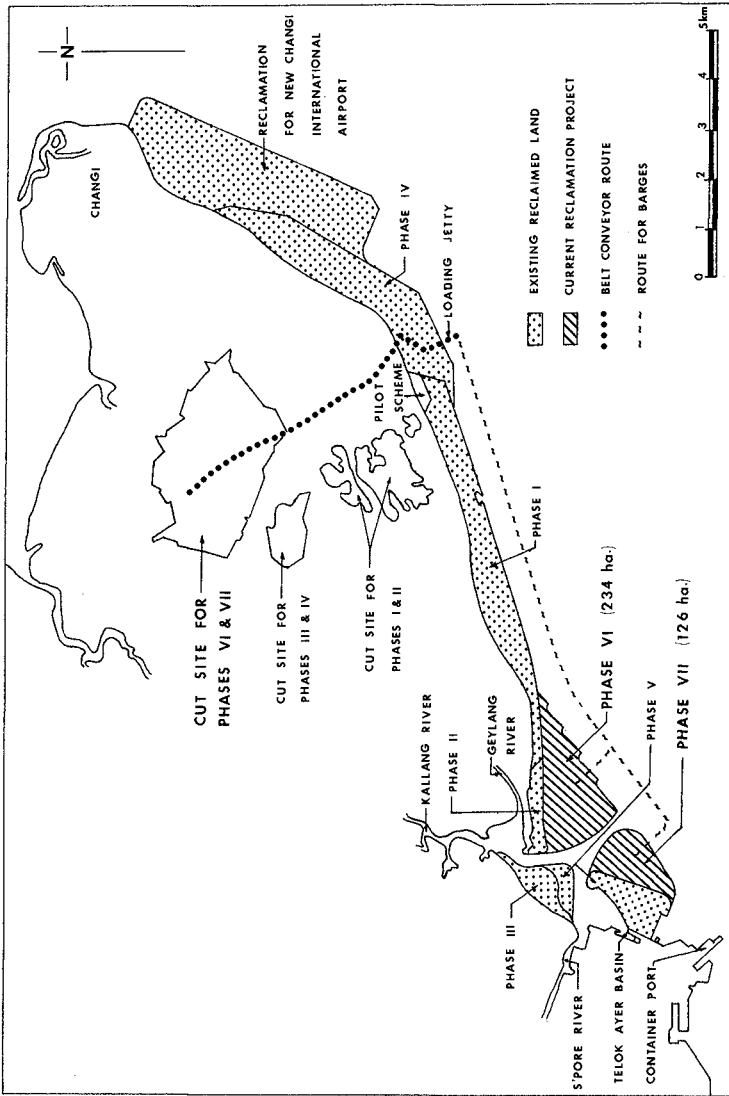

Figure 1 PLAN SHOWING THE LAYOUT OF VARIOUS PHASES OF EAST COAST RECLAMATION SCHEME, SINGAPORE.

(v) Phase V to reclaim 154 hectares commenced in April 1974 and was completed in December 1977 at a total project cost of S\$106 million. (Unit cost approximately S\$69 per sq metre)

Altogether, between 1966 and 1977 a total of 5 phases were completed, providing 1165 hectares of new land at a total cost of S\$228 million. The Housing and Development Board as agent for the Government carried out the planning, design and supervision of construction of these 5 phases of reclamation.

The proposed shifting of the international airport to Changi by 1982 has lifted planning constraints on areas adjacent to the existing city centre which are now under the flight path. Planners and architects were therefore able to plan a city of the future to meet the Republic's needs for the year 2000 and beyond. As a result, the concept of the Marina City was mooted and it became necessary to reclaim more land to meet the requirements of the proposed development. Thus Phases VI and VII of the East Coast Reclamation Scheme were initiated. When completed in 1985 these 2 phases together with some of the lands reclaimed under earlier phases will provide 660 hectares of new land for the Republic's city of the future.

Figures 1 & 2 show some of the main features of the project.

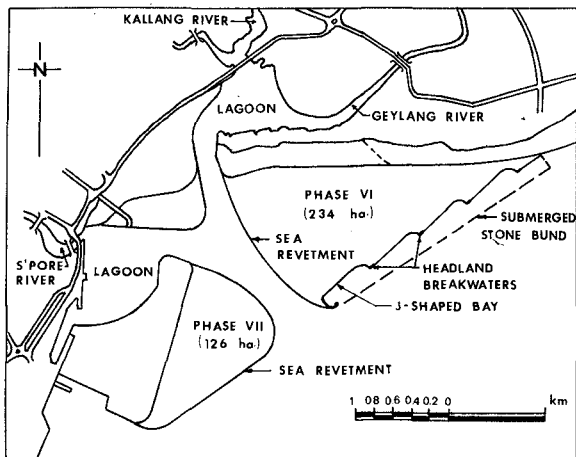

Figure 2 LAYOUT OF EAST COAST RECLAMATION SCHEME PHASES VI & VII

COASTAL PROCESS PARAMETERS

During the implementation of the earlier phases of the East Coast Reclamation Scheme various data such as waves, currents and tides were monitored (1) to enable studies to be carried out on the behaviour of the new coastline (2) as well as to provide information for the planning and design of the new reclamation projects.

From the field investigations it has been established that the southeast coast of Singapore is essentially a low energy coast throughout the year with waves coming from the southeast quadrant and a nett westward littoral drift is present. The area is considered as rather sheltered and winds from the north during the northeast monsoon (December to March) do not have a large influence except through refracted swell from the South China Sea. Higher waves are experienced during the northeast monsoon. Recordings showed a maximum wave height of 1.14 m with a zero-crossing period of 3 seconds and the highest probable maximum wave was 1.37 m.

It was found that the tides are essentially semi-diurnal of a mixed type and the current patterns appear to bear little relationship with the rise and fall of tide. Results of the field measurements also suggest that the tidal current is not a significant factor for distribution and transportation of bed material.

MODEL STUDIES

The data obtained from the investigations just mentioned as well as other data such as peak discharge values, distribution of direct run-off against time and water quality data of several rivers with outlets near the reclamation area were used in subsequent model studies to investigate the following:-

- (i) whether the proposed reclamation shapes or modifications thereof would limit the increase of water levels of the lagoons by no more than 5 cm above existing levels after reclamation (taking into account the coinciding of a 5-year flood with the high tide);
- (ii) whether adequate flushing of the lagoons would be possible;

(iii) the flow patterns resulting from the proposed reclamation on condition that this should not adversely affect the navigation of vessels leading to the Container Port, smaller craft to Telok Ayer Basin and Kallang Basin and movement of vessels in the general vicinity and

(iv) siltation aspects arising from the proposed shapes of reclamation.

The items (i) to (iv) above were carried out on the Singapore Tidal Model at Pōona (3). Horizontal and vertical scales of 1:700 and 1:120 respectively were used.

It was observed that of the different stages of flow viz. east-going ebb, east-going flood, west-going ebb and west-going flood, with and without freshet discharge, two flow conditions viz. east-going ebb and west-going ebb produced the bad flow conditions. Accordingly results of east-going ebb and west-going ebb when rivers carry their peak freshet discharge are considered.

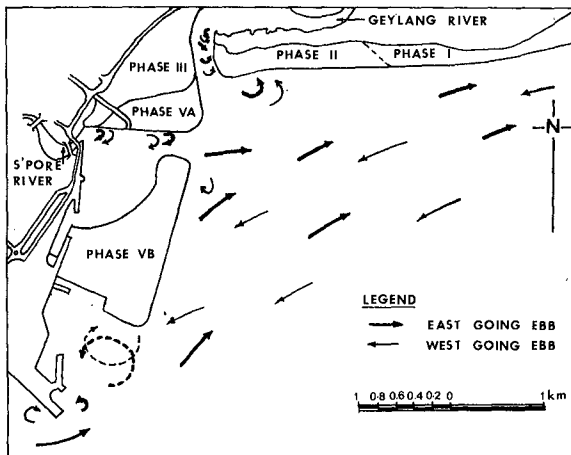

Figure 3 FLOW PATTERN FOR EXISTING CONDITION

Figure 3 shows the flow pattern for existing conditions, ie with the completed Phase V reclamation. Eddies were observed near the entrance to the new basin off the mouth of Singapore River and also near Kallang River mouth and south of Phase II. Eddies were also observed at the east and west of the Container Port for both east-going and west-going flows.

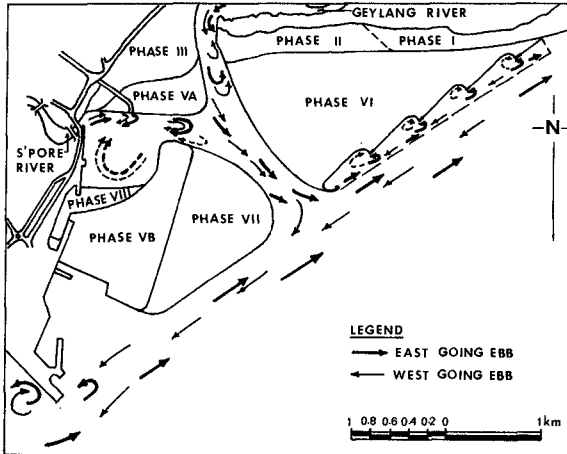

Figure 4 FLOW PATTERN WITH PHASES VI, VII & VIII

Figure 4 shows the flow pattern with Phases VI, VII & VIII. Phase VIII, incidently is not being implemented under the current project. It was observed that the flow pattern along the seaward faces of Phases VI and VII as well as in the channel between Phases VI and VII was good. However eddies were observed near the entrances to the new basin and Kallang Basin during the ebb phase of the tide. Eddies were also formed to the east and west of the Container Port during both east-going and west-going flows. The eddies in front of the Container Port which were observed for existing conditions (Figure 3) were not seen after simulating Phases VI, VII & VIII on the model.

With slight modifications introduced to the proposed reclamation profiles the flow pattern improved, as shown in Figure 5.

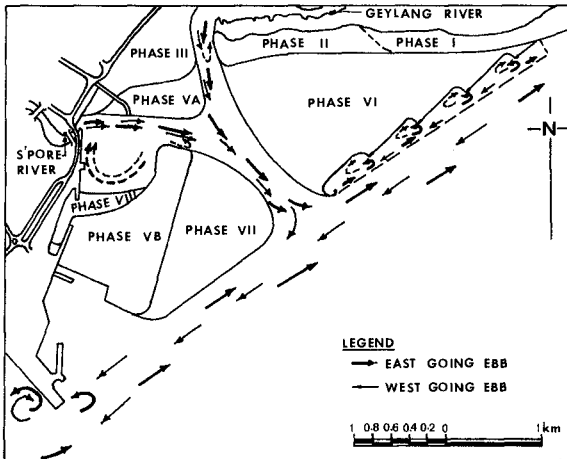

Figure 5 FLOW PATTERN WITH PHASES VI, VII & VIII
(with slight modifications)

From float track observation it was found that the average current velocity along the seaward face of Phase VII during east-going ebb was of the order of 0.36 to 0.38 m/sec. while that along the seaward face of Phase VI beyond the submerged stone bund was of the order of 0.42 to 0.47 m/sec. During west-going ebb the average current velocity along the seaward face of Phases VI & VII was of the order of 0.41 m/sec and that in the channel between Phases VI & VII was from 0.35 to 0.40 m/sec. The average current velocity between the submerged stone bund and the J-shaped bays of Phase VI varied from 0.17 to 0.23 m/sec.

It is however not practicable to modify the existing Phase V revetment because it had already been completed and the modification cost would be very high. In any case the flow pattern is no worse than that for the existing conditions, ie without Phases VI & VII.

To study the flushing characteristics of the lagoons, experiments were conducted on the tidal model by injecting fluorescent water soluble dye in the lagoons. A solution of fluorescent dye of known strength representing the pollutant was injected at a known uniform rate in the rivers and its dispersion under tidal activity with and without freshet discharge was studied over a period of 4 consecutive tides. It was observed that the strength of pollutant in the lagoons remained constant. Further experiments were conducted on the model by polluting only the lagoon water by fluorescent dye and its dispersion was studied with and without freshet discharge. It was observed that tidal activity equivalent to a 1-day duration for a tidal range of 3 m without freshet discharges from the rivers provided a dilution ratio of 5.5 in the new basin at Singapore River mouth and 23 in the Kallang Basin. With freshet discharge from rivers dilution ratios of 13.8 and 43.2 respectively were achieved at the end of a period equivalent to 1 day.

Results of the studies can be summarized as follows:-

- (i) Rise of water level in the lagoons caused by discharge (5-year flood) of various rivers coinciding with high tide would only be slightly over 3 cm. This was not measured on the tidal model because of the small vertical scale of the model. Instead the result was obtained by computation.
- (ii) Flushing characteristics of the lagoons would be satisfactory as indicated by no accumulation of pollutant in the model tests.
- (iii) Flow patterns would be satisfactory.
- (iv) Siltation characteristics would not change significantly with the construction of the proposed reclamation.

DESIGN OF SEABED STABILIZATION & REVETMENT

Because of the presence of thick soft marine clay strata at the reclamation site it is necessary to carry out seabed stabilization works in the form of dredged and sand filled trench, ie sand key.

Dimensions of sand key and ancillary components of stone bund and sea revetment were obtained by the method of slip circle analysis using the Bishop equation.

With known soil strength parameters obtained from offshore soil investigation and the trial dimensions for a given section as inputs for using a proprietary computer programme (Bishop method) numerous analyses were carried out to obtain a design with a minimum factor of safety of 1.30 against slip failure.

Final design sections adopted have factors of safety slightly over 1.30 and are founded on firm clay layer between upper and lower marine clay strata. An example of the results of one actual slip circle analysis is shown in Figure 6.

Figure 6 EXAMPLE OF SLIP CIRCLE ANALYSIS

Typical design sections for the stabilization works are shown in Figures 7 & 8.

Details of revetment are designed in accordance with the methods given in the Shore Protection Manual of the U.S. Army Corps of Engineers (4). The design wave height used is 1.7 m (25-year probable maximum height) (2) with a 5-second wave period.

Typical details of revetment are shown in Figure 9.

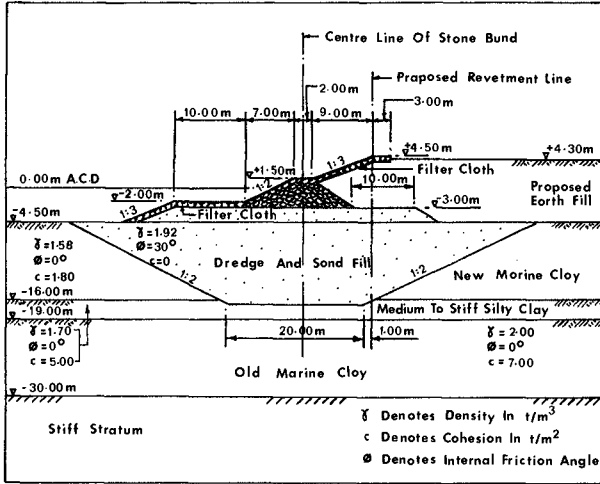

Figure 7 TYPICAL SECTION OF SEA REVETMENT

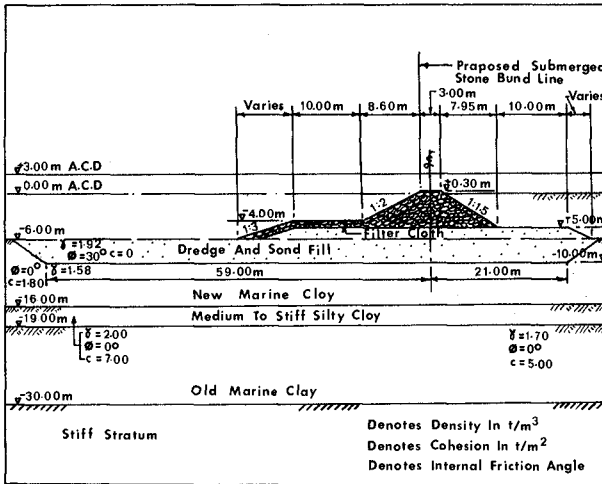

Figure 8 TYPICAL SECTION OF SUBMERGED STONE BUND

Figure 9 DETAILS OF STONE BUND AND REVETMENT

It can be seen that the sizes of the armouring units of granite blocks are generally somewhat bigger than those required by the design calculations. The reason for this is that the sizes adopted are those normally produced by local granite quarries and it would be uneconomical for contractors to break down the supplied sizes to the calculated sizes.

SHORE PROTECTION

For the whole of Phase VII and the western part of Phase VI shore protection in the form of sea revetment is adopted. However, in order to provide beaches for recreation, the southern edge of Phase VI is designed as an offshore platform with J-shaped bays between rip rap headland breakwaters. This method is based on a new concept (5) of protecting newly reclaimed shoreline by a series of shore-attached headland breakwaters (1), (2) and was first tried out successfully on earlier phases of the East Coast Reclamation further to the east (Plate 1).

Plate 1. Typical J-shaped bay between headland breakwaters
(Phase I reclamation).

Plate 2. Bucketwheel Excavator.

EXECUTION OF THE PROJECT

Execution of the current 2 phases of reclamation requires excavation of about 45 million cubic metres of earth from the Cut Site at Tampines (Figure 1). This excavation will pave the way for the development of Tampines New Town which will eventually house 225,000 people.

Excavation is being done by 2 large bucketwheel excavators (Plate 2) and the earth transported about 7 km by belt conveyors to a loading jetty (Plate 3) from which barges are loaded for transportation of the earth by sea over a distance of 12 km to the fill sites. The bucketwheel excavators and the entire conveyor system including the ship loader on the loading jetty are all electrically driven with a total power rating of about 10 MVA. Earthworks by this method has the advantage of very low noise and dust pollution as compared to the conventional method using traxcavators and tipper lorries.

Each bucketwheel excavator has a rated output of about 2,000 tonnes per hour while the conveyor system can handle up to about 5,000 tonnes per hour. Barges of various sizes ranging from 4,000 tonnes to 10,000 tonnes are used for the transporting operation.

The first stage of the construction involved dredging of the trench (Plate 4) for sand key to the design profiles followed by sand filling of the dredged trench. Depths of dredging are in the order of 16 m below A.C.D. (low low water level). A total of 4.5 million cu m and 5.5 million cu m of dredging and sand filling respectively are involved. At the same time the cut site and belt conveyor route preparations were carried out with construction of loading jetty, electrical system, overhead bridges and underpass across existing roads going on simultaneously.

Stone bund (Plate 5) was constructed over the sand filled trench to the design levels followed by temporary works of silt barricade. Two types of silt barricade, one using stone-filled gabions and the other using a floating screen are used to limit siltation in the adjacent port waters. Once a substantial portion of stone bund and silt barricade was completed the reclamation filling commenced, the timing being such that by then the cut site and conveyor system operations were ready.

Excavating, transporting and filling is now being carried out round-the-clock. At present about 60,000 tonnes per day are being executed. Initially direct dumping of fill material is possible until draught limitation necessitates unloading of the barges by reclaimer (Plate 6) and conveyor system on the newly reclaimed land.

Plate 3. Loading of fill material from the belt conveyor onto barges.

Plate 4. Dredging for sand key.

Plate 5. Stone bund at Phase VII reclamation site.

Plate 6. Reclaimer unloading fill material from barge into the sea to form reclaimed land.

The average median size of fill material from the cut site is 0.2 mm. After sorting by wave action it is expected that the average median size at mid-tide level will vary from 0.7 mm to 2 mm based on the results obtained in the earlier phases of reclamation(2).

Filling, grading and compaction to the final levels will be carried out by a combination of conveyor system and conventional equipment. The standard of compaction specified is a minimum dry density of 90% Modified AASHO Density at a level of 1 m below the finished level.

Other items of work such as construction of outlet drains, sea revetment, headlands and landscaping will form the last activities of the project.

CONCLUSION

The current Phases VI & VII of the East Coast Reclamation Scheme is one of the most prestigious and challenging projects ever carried out in Singapore.

Based on the current rate of progress it is anticipated that the Phase VII part of the reclamation will be completed by 1982 while the Phase VI part will be completed by 1984.

By early 1985 Singapore will have another 360 hectares of land on which will be built its city of the future.

SHIP-BRIDGE-PIER PROTECTIVE SYSTEMS

by

Akira Iwai¹, Hitoshi Nagasawa², Kazuki Oda³ and Kuniaki Shoji⁴

ABSTRACT

This paper describes the analytical and experimental studies on the behaviors of a ship subjected to a sheering flow induced around a rectangular solid-type marine structure, and also deals with ship-structure protective systems against ship impacts.

Large bridge piers, which are constructed in a narrow waterway with strong tidal currents, are treated herein as one of the typical solid-type marine structures.

INTRODUCTION

Owing to the recent increase of marine traffic and marine structures such as bridge piers in navigable waters, ship collision accidents with the structures have been increasing.

The collapse accidents of the Tasman Bridge of Australia in 1975, the Tjorn Bridge of Sweden in 1980 and the Sunshine-Skyway Bridge of America in 1980 were brought about by the very ship collision.

The national big projects for bridge construction aiming to link the Shikoku Island to the Main Land of Japan are put into practice at the present or under planning at different three routs by the Honshu-Shikoku Bridge Authority.

Most of their piers are being constructed or planning to be constructed in narrow straits with strong tidal currents where numerous marine accidents have occurred every year.

When a solid-type structure comparably large to a ship size is placed in strong tidal currents, sheering flows induced around the structures may cause serious navigational problems to the ships from the viewpoint of the safety maneuvering.

In this paper, bridge piers with a large rectangular cross section are treated as one of the marine structures, and the behaviors of ships navigating under the effects of sheering flows around the pier are predicted by means of an analytical method. And on the basis of the analytical results on the ship behaviors, the required minimum clearances between the ship courses and the pier to avoid collision accidents are proposed.

Moreover, the impact forces in the bow collision are estimated on the basis of the test results of the load-deformation characteristics of ship bows. And the load-penetration characteristics of proposed buffering devices are described.

SHIP BEHAVIORS NEAR THE PIER

Model experiments were carried out in a flow channel of Osaka City University, which is 35 m long, 4.0 m wide and 75 cm deep, to obtain the data of hydrodynamic exciting forces exerted on the ship due to sheering flows around the pier under conditions of reverse currents and zero ship speed.

One kind of ship model and three kinds of pier models were used. The length of the ship model was 100 cm. Though the length of the lateral side was maintained at 27 cm in all models, the length ratios of the longitudinal side to the lateral side, L_p/B_p , were varied 1.67, 2.00 and 2.33. The pier model of $L_p/B_p = 1.67$ was mainly used in the experiments. The length ratio of the lateral side of the pier model to the ship model, B_p/L_s , were varied 0.27 and 0.54.

The flow direction and the longitudinal axis of the ship model were kept normal to the lateral side of the pier model.

Hydrodynamic swaying forces and yawing moments on the ship model were measured by using dynamometers. And the hydrodynamic coefficients of swaying forces and yawing moments were obtained from Eqs. (1) and (2).

$$C_Y = Y_C / \frac{1}{2} \rho L_s d v^2 \quad (1)$$

$$C_N = N_C / \frac{1}{2} \rho L_s^2 d v^2 \quad (2)$$

where Y_C and N_C are respectively swaying forces and yawing moments, C_Y and C_N are coefficients of swaying forces and yawing moments; L_s and d are the length and the draft of the ship model; and v is the flow velocity; ρ is density of water.

Fig. 1 shows one example of the experimental results of the distribution of coefficients of swaying forces and yawing moments obtained from Eqs. (1) and (2) in case of $B_p/L_s = 0.27$ and $L_p/B_p = 1.67$. It may be said from Fig. 1 that both coefficients of swaying forces and yawing moments decrease exponentially with an increase of the dimensionless coordinates of the ship center x_0/B_p (or x_0/L_p) and y_0/B_p .

Fig. 1 Distribution of the hydrodynamic coefficients of swaying forces and yawing moments

For the purpose of the estimation of coefficients of swaying forces and yawing moments in numerical calculations of the ship motions, the following empirical equations were derived as functions of x_0/L_p and y_0/B_p on the basis of the whole experimental results.

$$C_Y = \begin{cases} \frac{0.266y_0/|y_0| (x_0/L_p - 1) \exp[-0.86(|y_0|/B_p - 1)]}{1 - (x_0/L_p - 1)^3} & ; x_0/L_p \leq 1.0, y_0/B_p \geq 0.5 \\ \frac{0.196y_0/|y_0| \cdot (x_0/L_p - 1) \exp[-0.86(|y_0|/B_p - 1)]}{1 + (x_0/L_p - 1)^4} & ; x_0/L_p > 1.0, y_0/B_p \geq 0.5 \end{cases} \quad (3)$$

$$C_N = \left\{ \begin{array}{l} \frac{0.110y_0/|y_0| \cdot (x_0/L_p - 1) \exp[-0.98(|y_0|/B_p - 1)]}{1 + 4(x_0/L_p)^2} ; x_0/L_p \leq 1.0, y_0/B_p \geq 0.5 \\ \frac{0.935y_0/|y_0| \cdot (4x_0/3a) \exp[-0.98(|y_0|/B_p - 1)]}{1 + (4x_0/3L_p)^5} ; x_0/L_p > 1.0, y_0/B_p \geq 0.5 \end{array} \right. \quad (4)$$

where x_0 and y_0 are the coordinates of the ship center in O-X₀Y₀ coordinate system shown in Fig. 1.

The solid lines in Fig. 1 denote the coefficients estimated from Eqs. (3) and (4).

Substituting these hydrodynamic forces and moments estimated from the empirical equations as nonlinear external disturbances into the equations of ship maneuvering motions expressed by simplified Eq. (5) and solving the equations of ship motions by numerical techniques, ship trajectories in the vicinity of the pier are obtained.

$$\left. \begin{array}{l} (m + m_x)\dot{u} = mvr \\ (m + m_y)\dot{v} = Y_{vV} + (-mu + Y_r)r + y\delta\dot{\delta} + Y_C \\ (I_{ZZ} + J_{ZZ})\dot{r} = N_{vV} + N_r r + N\delta\dot{\delta} + N_C \end{array} \right\} \quad (5)$$

where m = mass of the ship; m_x and m_y = respectively added masses in sway and yaw motion; I_{ZZ} and J_{ZZ} = moment of inertia and added moment of inertia of the ship about the vertical axis through the center of ship gravity; u , \dot{u} , v , \dot{v} = respectively components of the ship velocity and acceleration in X and Y axis direction (referred to Fig. 2); r and \dot{r} = angular velocity and acceleration about the vertical axis; Y_v , N_v , Y_r and N_r = hydrodynamic coefficients concerning damping forces and moments respectively; Y_δ and N_δ = hydrodynamic coefficients of swaying forces and yawing moments induced by steering; δ = rudder angle; Y_C and N_C = exciting swaying forces and yawing moments given by Eqs. (1) and (2).

It was assumed in the calculation that the ship comes up to the pier with an initial course parallel to the longitudinal side of the pier. Steering simulation was performed so as to give a rudder angle of 15 degrees to the occurrence of yaw angle deviation of 2 degrees from the initial straight course.

Fig. 2 Coordinate system

Values of added masses, added moment of inertias and other hydrodynamic coefficients concerning damping forces and moments used in the calculation are given in Table 1.

Table 1 Values of hydrodynamic coefficients used in the calculation of ship moments

Swaying motion		Yawing motion	
$\frac{m + m_x}{\frac{1}{2} \rho L_s^3}$	0.018	$\frac{I_{zz} + J_{zz}}{\frac{1}{2} \rho L_s^5}$	0.0015
$\frac{Y_v}{\frac{1}{2} \rho L_s^2 V}$	-0.01434	$\frac{N_v}{\frac{1}{2} \rho L_s^3 V}$	-0.00460
$\frac{Y_r - \mu u}{\frac{1}{2} \rho L_s^3 V}$	0.00456	$\frac{N_r}{\frac{1}{2} \rho L_s^4 V}$	-0.00296
$\frac{Y_\delta}{\frac{1}{2} \rho L_s^2 V^2}$	-0.00332	$\frac{N_\delta}{\frac{1}{2} \rho L_s^3 V^2}$	0.00165

where V is the ship velocity relative to currents.

Fig. 3 Examples of the calculated ship trajectories ($v_c/v_s = 0.75$)

Fig. 3 shows two examples of the ship trajectories calculated under the condition of $v_c/v_s = 0.75$ in the cases of $B_p/L_s = 0.27$ and 0.54 respectively. Herein, v_c is the current velocity and v_s is the ship velocity.

It can be said from Fig. 3 that the effect of sheering flow around the pier on the ship course keeping becomes larger with an increase in the length ratio of the lateral side of the pier to the ship, B_p/L_s .

REQUIRED SHIP COURSE CLEARANCE TO THE PIER

The maximum normalized sway deviation $\Delta y_m/L_s$ and yaw deviation $\Delta\phi_m$ from the initial straight course are shown in Fig. 4 (a) and (b) respectively for the case of $B_p/L_s = 0.27$ and $B_p/L_s = 0.54$ with respect to the normalized coordinate of the initial ship course, y_0/B_p . Herein, Δy_m and $\Delta\phi_m$ are the maximum sway and yaw deviation caused within a distance of one ship length away from the upstream side of the pier.

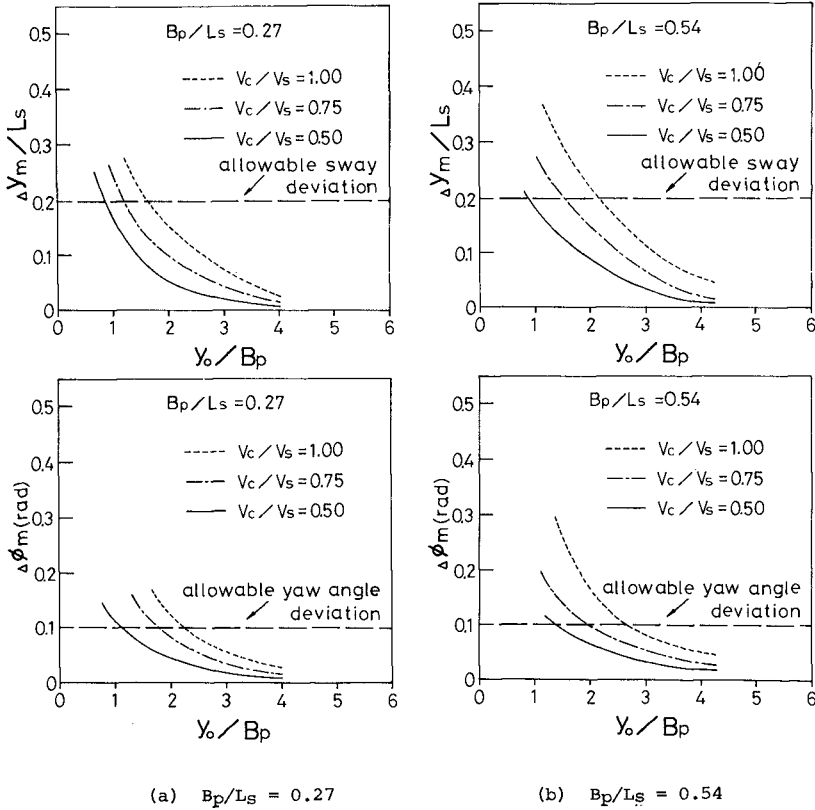

Fig. 4 Relationship between the maximum normalized sway deviation and the normalized coordinate of the initial ship course

If the allowable deviation of ship motions from the initial course are limited to 0.1 radian (about 5.7 degrees) in yaw angle and 0.2 time the ship length in sway displacement from the viewpoint of safety ship handling, the minimum required distance of the ship course from the pier center needed to avoid the collisions of the ship to ship as well as the ship to pier may be determined in the manner which is shown in Fig. 4 (a) and (b).

The minimum required distances from the pier center obtained in the manner mentioned above are shown in a solid line for the case of $B_p / L_s = 0.27$ and in a dotted line for the case of $B_p / L_s = 0.54$ in Fig. 5.

It may be said from Fig. 5 that the minimum required distance become larger with an increase in the velocity of tidal currents relative to the ship velocity.

Fig. 5 The minimum required distance of the ship course from the pier center

Fig. 5 is interpreted that for instance, when $V_c/V_s = 1.0$ in the case of $B_p/L_s = 0.54$, ships are recommended to navigate more than 2.6 times the length of lateral side of the pier away from the pier center in the distance. In other words, ships should pass near the pier having a clearance more than about 2.1 times the length of the lateral side from the longitudinal side.

COLLIDING FORMS OF THE SHIP

The behaviors of a drifting ship due to currents were experimentally observed in the vicinity of the pier by means of taking sequent pictures using a auto-driven camera.

Fig. 6 Classification of the main colliding forms of the ship

Through the examinations of the ship behaviors in both navigating and drifting near the pier obtained by means of the previous description, colliding forms of the ship against the pier may be classified mainly into three cases as shown in Fig. 6.

It may be said from the viewpoint of designing protective systems that the most serious case is the bow collision among these colliding forms.

LOAD-DEFORMATION CHARACTERISTICS OF THE SHIP BOW

Static collapse tests were conducted to examine the load-deformation characteristics using steel bow models which simulate the transversely framed structure of cargo-type ships of 500 G.T. and 4,000 G.T.

The models are made in a scale of 1:4 for 500 G.T. ship and in a scale of 1:8 for 4,000 G.T. ship.

For 500 G.T. ship, two kinds of bow models with a raked stem and with a vertical stem while only one kind of model with the vertical stem was used for 4,000 G.T. ship. The models with the vertical stem were used for the simplification of the tests. Fig. 7 shows a diagram of the one-fourth scale bow model of 500 G.T. ship with the raked stem.

Fig. 7. One-fourth scale bow model of 500 G.T. ship

Fig. 8 shows the test results of the load-deformation characteristics of the 500 G.T. type bow model with the vertical stem in comparison with the test results for the bow model with the raked stem. In Fig. 8, a solid line denotes the test results for the case of the vertical stem, and a broken line for the case of the raked stem.

It can be seen in Fig. 8 that there is little difference between the load-deformation curves for the bow models with the raked stem and with the vertical stem in the range of the deformation larger than the

length of the raked stem while the collapse loads near zero deformation show the great differences between them.

Fig. 8 Comparison between the load-deformation curves for two kinds of bow models of 500 G.T.

Fig. 9 also shows the characteristics of the load-deformation of one-eighth scale bow model of 4,000 G.T. with the vertical stem.

Fig. 9 Load-deformation curves of a one-eighth scale bow model of 4,000 G.T.

From these test results, it was found that the relationship between the load and the bow deformation is characterized by the buckling strength of a rectangular panel hull plate between the transverse frames (referred to Fig. 10) and the load-bow deformation curve can be simplified and represented as shown in Fig. 11.

Fig. 10 Definition diagram of the rectangular panel hull plate

Fig. 11 Simplified load-bow deformation curve

In Fig. 11, δ_f is a raked stem length which is equal to about a quarter of the depth in usual ships and P_{CR} is the component of a buckling load of the rectangular panel hull plate of the bow in the direction of the longitudinal ship axis which is expressed by Eq. (6)

$$P_{CR} = 2Dt \cos\theta \times \sigma_{CR} \tag{6}$$

where D = the depth of the ship; t = the thickness of the hull plate; θ = the entrance angle of the bow; and σ_{CR} = the buckling stress of the rectangular panel plate expressed by Eq. (7).

$$\sigma_{CR} = \kappa \left\{ \frac{\pi^2 E}{12(1 - \nu^2)} \right\} (t/b)^2 \tag{7}$$

where κ = buckling coefficient; E = Young's modulus; ν = Poisson's ratio; and b = the depth of the panel.

The dotted lines in Figs. 8 and 9 represent the calculated results by Eqs. (6) and (7) in comparison with the experimental results. Generally, it can be stated that the agreement between the calculated and the experimental results is satisfactory.

ESTIMATIONS OF THE IMPACT FORCES

Using the simplified load-deformation curve of the bow hull, ship impact forces can be estimated at the bow collision with a right angle against a vertical flat plane of a rigid bridge pier. The estimated results herein are graphically shown for the ship collision ranging from 500 G.T. to 4,000 G.T. in Fig. 12.

Fig. 12 Estimated impact forces at the bow collision

In Fig. 12, V_F is the speed of the striking ship resulting in the full collapse of the part of the raked stem. According to Fig. 12, V_F is equal to about 2.3 m/sec for every ship ranging from 500 G.T. to 4,000 G.T., and the maximum impact forces are estimated to be about 580 tons for the 500 G.T. ship and about 2,400 tons for the 4,000 G.T. ship.

Judging from the viewpoint of designing the ship-pier protection, it may be said that the striking ship speed should be less than the value of V_F using other detached-type fendering systems, or the impact forces should be reduced to the values less than the buckling loads of the bow hull plate by means of effective buffer devices installed on the pier. Herein, the ship-pier protective systems based on the latter idea were described.

PROPOSED BUFFER DEVICES AND THE FORCE-DEFORMATION CHARACTERISTICS

Four kinds of buffer devices were proposed which are coarse grid-type, dense grid-type, grid-composite-type filled up with hard polyurethane foam and composite-type filled up with hard polyurethane foam.

The schematic diagrams of the models of the proposed buffer devices are shown in Fig. 13 and the model dimensions of the coarse grid-type and the composite-type are shown in Fig. 14. The compressive strength of hard polyurethane foam used in the tests are 1.4 Kg/cm^2 .

Fig. 13 Schematic diagram of the models of the proposed buffer devices

Fig. 14 Model dimensions of the coarse grid-type and the composite-type

The comparisons between the force-bow penetration curves for the preceding four kinds of buffer devices are shown in Fig. 15. They were obtained from the static fracture tests performed by the use of a one-eleventh scale rigid bow model of 4,000 G.T. ship.

Fig. 15 Comparisons between the force-bow penetration curves for four kinds of buffer devices

It appears from Fig. 15 that the composite-type buffer device has almost linear characteristics in the relationship between the force and the ship penetration while other three kinds of buffer devices have somewhat complicate characteristics.

Every ship has a different bow collapse load because it depends on the size and the structure of the bow itself. The composite-type buffer device has the characteristic capable of absorbing the impact energies in relatively small reactive forces. Therefore, it can be stated from the viewpoint of practical designing that the composite-type is the most suitable buffer device among the proposed ones.

It was found from the further static fracture tests using a elastic bow model which simulates an actual bow that the linear superposition of the independent load-deformation characteristics of the bow itself and the buffer itself can be adapted for the estimation of the combined load-deformation characteristics in the ship-buffer collision.

The composed deformations of the bow and the respective buffer devices at the 4,000 G.T. ship collision were estimated in prototype values on the basis of the test results as shown in Fig. 16.

Fig. 16 shows that the composite-type has much larger deformation in comparison with the other three types. Fig. 17 shows the estimated results of the impact forces versus the penetration at the 4,000G.T. ship collision against the composite-type buffer device 4.0 m broad in which t and q represent the thickness of the steel plate of the

buffer and the compressive strength of hard polyurethan foam respectively.

Fig. 16 Composed deformations of the bow and the respective buffer devices at the 4,000 G.T. ship collision

Fig. 17 Impact forces versus the penetration at the 4,000 G.T. ship collision against the composite-type buffer device

SUMMARY AND CONCLUSIONS

In this paper, the behaviors of ships navigating under the effects of sheering flow around the solid-type bridge pier were predicted by means of the numerical analyses and the experiments in the flow channel.

Based on the previous predicted results, the minimum clearances between the ship course and the longitudinal side of the pier, which are required to avoid the ship-pier collision, were proposed.

The load-bow deformation characteristics for the ships ranging from 500 G.T. to 4,000 G.T. were examined by the bow collapse tests and were represented by the simplified equation.

Using the simplified load-bow deformation curve, the impact forces were estimated at the bow collision with a right angle against the vertical flat plane of the rigid bridge pier without any buffer devices.

The composite-type buffer device filled up with hard polyurethane foam was selected as the most suitable one among the proposed four kinds of buffer devices. And the impact forces at the 4,000 G.T. ship collision against the composite-type buffer device were estimated.

WAVE-WAVE INTERACTIONS, CURRENT-WAVE INTERACTIONS
AND RESULTING EXTREME WAVES AND BREAKING WAVES

by

SØREN PETER KJELDTSEN & DAG MYRHAUG
Senior Research Engineers

Norwegian Hydrodynamic Laboratories
Trondheim, Norway

ABSTRACT

The influence of an opposing current on highly non-linear transient breaking waves in deep water is described quantitatively from experiments. 3 new parameters that describe crest front steepness and wave asymmetry are introduced. Further, joint probability density distributions are obtained from an analysis of field data containing nearly 25000 storm waves. Thus, a tool is provided from which estimates for probabilities for occurrences of steep breaking waves in deep water, may be obtained.

1. INTRODUCTION

Detailed knowledge of the kinematics, dynamics and frequencies for occurrences of large breaking waves in deep water is important, and has many practical applications, due to the following reasons:

- 1) Experiments have now confirmed that transient, near breaking and breaking waves attain velocities up to 2.8 times the first order phase velocity. Local accelerations in the wave can attain values somewhat above 3 times the gravity acceleration (KJELDTSEN et al., 1980). Such results may be applied to evaluation of the operation and stability of ships under severe sea conditions. Further,

such results provide the basis for the estimation of wave drag and inertia forces from extreme breaking waves in deep water with many applications to the design and safety of offshore structures.

- 2) The large breaking waves give rise to the largest environmental pressures, both on fixed and floating structures, in the form of shock or impact impulses with a duration of some milliseconds.
- 3) The breaking waves give rise to the most effective mechanism for transfer of momentum from the wind to a mean surface current, (dominant compared with dissipation of non-breaking waves, LONGUET-HIGGINS, 1969). This implies that a detailed knowledge of ratios of breaking waves compared to the total number of waves has important practical applications for the evaluation of dispersion of pollution (e.g. hydrocarbons).

In order to evaluate safety at sea, a basic need is a prediction of the characteristics of extreme sea states. There is an extensive literature on the subject of the mysterious disappearances of ships, both large and small. A high percentage of these mysteries can be solved by even a cursory study of so-called 'freak waves' (a freak being 'capricious change'), which are more correctly termed extreme waves. In the following the term extreme waves will be used, since these are recurring events along the continental margins. Extreme waves occur in virtually all such areas during certain predictable times of the year, but the origin of these waves is not fully understood. It is believed that a shoaling mechanism, unique to a certain geographic location, as well as particular random phase relationship between waves, can account for the phenomenon. However, also an opposing shear current might change the wave conditions in an abrupt way, in particular in areas where the waves travel against a current gradient. Known areas of destructive waves are the Nova Scotia coast, the Bermuda rise, the water off Greenland, the coast of North West India, and the water off the South East African coasts, where the Agulhas current opposes the main dispersion direction of the waves. Also certain parts of the Norwegian Continental Shelf seem to contain areas where such extreme waves occur. In the

period 1970-1979, 26 Norwegian trawlers and freighters were lost due to capsizing in very rough seas. Reports from the Courts of Inquiry show that for 13 of these vessels surviving members of the crew confirmed a capsizing in extreme waves. In 13 other cases the vessels disappeared in very bad weather, the reasons being unknown, but capsizings in extreme waves were concluded to be the most probable. Altogether 72 lives were lost. (NEDRELID, 1978.)

In 1978 a new project, "SHIPS IN ROUGH SEAS", was initiated by a coordinating board with the Royal Norwegian Council for Scientific and Industrial Research, the Norwegian Fisheries Research Council and the Norwegian Maritime Directorate as sponsors. The aim is to use theoretical and experimental work and practical experience to improve the understanding of manoeuvring, rolling and capsizing, i.e. the response of ships to severe conditions in the form of extreme movements. Further, it is the aim of the project to try to establish new criteria for the stability of the vessels on the basis of knowledge of extreme environmental conditions and the motion properties of the vessel. This will be an improvement compared to the established stability criteria which consider movement of a ship in calm water or in regular waves. One of the main activities for this new project is:

To locate exposed areas in Norwegian waters where the probabilities for occurrences of extreme waves and breaking waves are most pronounced, and contribute to the development of forecast methods for such areas.

Results of a survey of areas on the Norwegian Continental Shelf with typical large scale refraction and current-wave interaction effects are shown in Fig. 1 (KJELDEN & MYRHAUG, 1978). Also, positions and estimated headings are shown for 24 of the lost vessels.

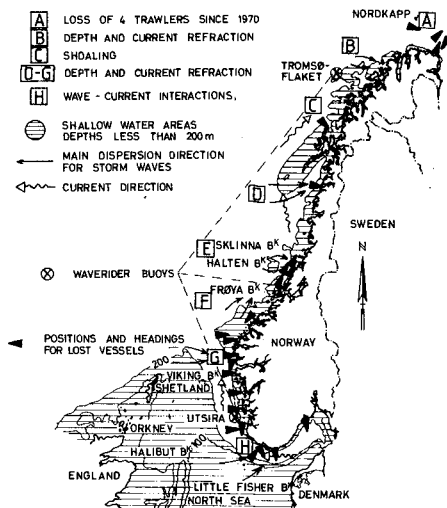

Fig. 1. Exposed areas on the Norwegian Continental Shelf, with positions and headings for lost Norwegian vessels. Foreign vessels lost in the same area are not shown.

An inquiry to all pilot offices in Norway has now indicated several local areas where probabilities for occurrences of extreme waves are believed to be higher than the average, under certain weather conditions. It is now remarkable that such 'Red Areas' agree very well with the mapping of earlier accidents, shown in Fig. 1. Altogether 19 local 'Red Areas' are now identified. (DAHLE, 1979.)

2. BASIC DEFINITIONS

A well defined quantitative description of transient highly asymmetric waves of finite amplitude approaching the point of breaking is needed. In general, finite amplitude storm waves at sea will not appear with a symmetric shape (as a high order Stokes wave), but will have a pronounced asymmetry, both with respect to a vertical and a horizontal axis. This is due to a sheltering effect, which gives rise

to pressure differentials over the upwind and leeward side of the crests. Further, the common wave steepness defined as $s = H/L$, where H is the total wave height and L is the wave length, does not represent a unique definition of steepness for extreme waves, as several asymmetric waves can exist with the same total steepness s , both with very different steepnesses of the wave crests.

The present study utilises the advantages that are contained in a zero-downcross analysis. This analysis uses the wave trough and the proceeding wave crest in the definition of a single wave, and defines the wave height as the difference between these water levels, Fig. 2. (The conventional zero-upcross analysis defines a single wave as a wave crest and the following wave trough, and *thus obtains a wave height behind and not ahead of a possible breaking wave.*) The zero-downcross analysis is therefore believed to be the only analysis which provides parameters that are a representation of the physical conditions with relevance to breaking waves, and thus, the only parameters which should be correlated with measurements of ship response or shock pressures.

Furthermore, careful observations show that the wave trough ahead of a breaking wave always appears with a certain and very characteristic shape, and finally the zero-downcross wave height is the only height corresponding to visual wave observations. It is thus only oceanographic wave data treated with the zero-downcross analysis that represents a reasonable basis for a comparison with the vast amount of existing wave observations, made from observers on ships and shore, collected and distributed by national meteorological institutions.

The present study provides a more accurate description of steepness and asymmetry in transient near breaking waves, when the three following parameters are introduced:

Crest front steepness:

$$\epsilon \equiv \frac{n'}{L'}$$

Vertical asymmetry factor:

$$\lambda \equiv \frac{L''}{L'}$$

Horizontal asymmetry factor:

$$\mu \equiv \frac{n''}{H} \quad (1)$$

The definitions are shown in Fig. 2. Here η' is the crest elevation measured from mean water level, while L' and L'' are horizontal distances defining the position of the wave crest relative to the zero-crossing points. It is generally accepted that use of the crest elevation for design applications provides a basic parameter more relevant to finite amplitude wave geometry than the wave height. Observations of breaking waves show that these waves can be characterized by a very steep crest front and high asymmetry factors. The ϵ -parameter is thus a mean front crest inclination.

Fig. 2. Basic definitions for asymmetric waves of finite height. (KJELDSEN & MYRHAUG, 1978.)

In this study the mean water level, MWL is defined as the still water level in a wave flume before the start of an experiment. For field data the mean water level is defined as the arithmetic mean of a 20 minutes recording period of surface fluctuations.

Thus, in our definition λ describes asymmetry with respect to the vertical axis in the crest, while μ describes asymmetry with respect to a horizontal axis in the mean water level. It is now possible to obtain the crest rear steepness directly as: $\delta \equiv \epsilon/\lambda = \eta'/L''$.

In the following deterministic experiments in the laboratory with extreme deep water waves will be described in section 4. A range of variation and maximum values of the parameters ϵ , μ and λ will be given, both for the case with interacting deep water waves, and for the case with interacting waves superposed upon an opposing shear current.

Then, in section 5 results from a statistical analysis of 25000 storm waves from Norwegian waters are given. This

analysis provides joint probability density distributions that relate the ϵ -parameter to a particular sea state. Thus, a tool from which estimates for probabilities for occurrences of steep and breaking waves in deep water might be obtained.

3. EXPERIMENTAL ARRANGEMENT

A new transient test technique is developed for generation of extreme storm waves in deep water. The waves appear as plunging breakers, deep water bores and spilling breakers, together with very steep near breaking waves, and are created from wave-wave interactions of several individual single wave components.

In deterministic laboratory experiments extreme waves are obtained at a specified time and location. At the Norwegian Hydrodynamic Laboratories this new technique is now developed to a level where on-line testing of fixed and floating structures under extreme deterministic conditions is possible and already undertaken. However, in this study only test series with extreme waves freely dispersing without interaction with structures will be discussed. The test arrangement is shown in Fig. 3.

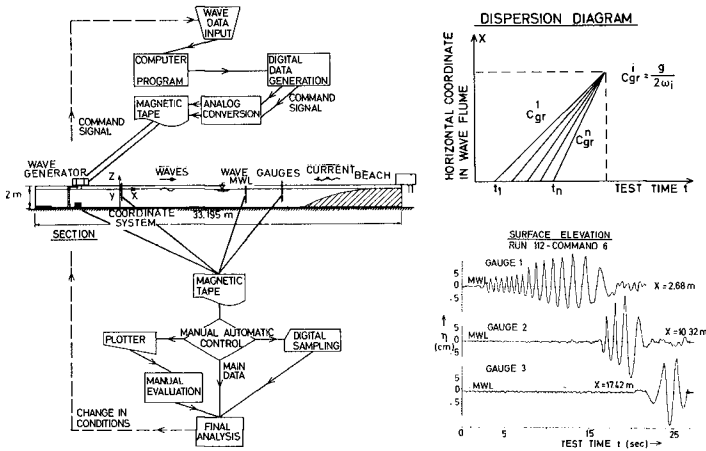

Fig. 3. Arrangement for wave-wave and current-wave interaction experiments.

Comprehensive series of experiments were performed in a 33 m long, 1 m wide and 1.60 m deep wave flume, equipped with a computer controlled hinged flap type wave generator at one end, and an energy absorbing parabolic beach at the other end. Further, it was possible to introduce a surface current at the beach with a discharge of $0.050 \text{ m}^3/\text{sec}$. The current opposes the dispersion direction of the waves and is extracted in front of the wave generator. The extreme breaking waves in deep water were obtained using several methods. One of them was to utilize the dispersion properties of gravity waves in a wave train. When the rate of change of the cyclic frequency for the wave train was kept constant, a transient event was obtained, where all available wave energy was concentrated at one nodal point in the flume, 12 m from the wave generator, Fig. 3. Surface elevations were measured with wave staffs, and fluctuating particle velocities with electromagnetic current meters.

Synoptic recordings of the surface form and breaker development were obtained with a high-speed movie camera operated with 300 frames/sec. synchronously with the wave staffs. The obtained synoptic wave profiles were then digitized with great accuracy in a motion analyzer.

In a model basin there are major difficulties in obtaining accurate measurements of breaking waves, or of the response of structures to breakers. One is that of generating highly non-linear finite amplitude water waves without scale effects in the flume (without correspondence to the ocean). Such sources of inaccuracy are:

- 1) Generation of higher harmonics which propagate with phase velocities other than the basic wave. Superposition of such harmonics on the basic wave gives rise to disturbances in the breaking process itself.
- 2) The wave-induced mass transport is not reproduced correctly in a wave flume. In the ocean, non-linear waves give rise to a drift velocity in the direction of propagation. In a wave flume this net drift is reflected by the beach and returns to the wave generator, and thus a circulation pattern is obtained, with the result that the kinematic profiles in the waves have no mean drift and therefore are not similar to the kinematic profiles in the ocean.

The new transient test technique avoids some of these difficulties, and takes advantage of the small time domain in which progressing waves occur with the correct drift velocity, before unwanted harmonic transients from the wave generator reach the section of observation.

4. EXPERIMENTAL RESULTS

A striking result of the experiments with breaking waves in deep water, is that the observed wave-wave interaction phenomena lead to the generation of breaking waves which can all be classified as (belonging to) three distinct types of wave forms, Fig. 4. It is obvious that many different forms of breaking waves can exist in deep water during advanced sea states. However, when only two-dimensional waves are considered, the number of wave forms decreases rapidly.

Fig. 4. Classification of breaking waves in deep water.

The first type is a deep water plunging breaker, which is a violently breaking wave, generated by interaction of several individual waves. The second type is a deep water bore. This breaker appears as a result of a highly non-linear wave-wave interaction phenomenon, in which one wave phase overtakes another. The overlying wave proceeds in a way which can be observed to be very similar to the travel of a tidal bore. The duration of the breaking is much longer than for a normal spilling breaker, and the asymmetry is very pronounced, with crest elevations which can approach 90% of the total wave heights. When the two wave phases finally meet, the whole front is nearly vertical and breaking.

The third breaker type, observed as results of wave-wave interaction experiments, is the spilling breaker, commonly known as "white capping". This breaker is a very symmetrical breaking wave. This study reports experimental evidence of all three. It is therefore a contribution to the classification of types of breaking waves in deep water, akin to the work by GALVIN (1968), in which breaking waves on beaches were classified.

Particular attention should be given to the results concerning the particle velocities in breaking waves. Fig. 5 gives a map of the horizontal velocity component at five levels for a situation with a plunging breaker, generated from a highly non-linear interaction of several waves in a wave train. In these experiments the rate of change of cyclic frequency was kept constant. The map is obtained as the mean of 26 plunging breakers, which all broke at the same nodal point under identical test conditions. Standard deviations for the measured surface elevations are plotted on the surface contour in order to demonstrate the accuracy of the experiments. The current meter was installed beneath the point where the wave profile became vertical, and the map gives the development in time of the particle velocity and the surface elevation at this position. The linear phase velocity c_{0B} corresponds to the measured wave period at the point of breaking. A considerable phase lag is found between the wave crest and the point where the maximum in the horizontal particle velocity appears. This effect is partly due to limitations in the dynamic response of the current meters. In deep water plunging breakers approximately one wave amplitude below mean water level, the measured particle velocities showed only minor deviations from linear theory.

Fig. 5 Non-dimensional plot of surface elevation and horizontal particle velocities in plunging breakers as functions of time

Fig. 6 Particle trajectories in the crest of a plunging breaker

Fig. 6 gives an example of the particle trajectories for a Stokes wave disturbed by a subharmonic with equal amplitude. Results are obtained from a high-speed film (300 frames/sec) with neutrally buoyant styropor particles as tracers. The map shows subsequent particle positions in the wave crest near the breaking zone. Particle velocities up to 3.76 m/sec, corresponding to 2.8 times phase velocity c_{OB} for a wave period $T_B = 0.85$ sec at the point of breaking, were recorded.

In a numerical model (VINJE & BREVIG, 1980), the development of the (breaking) wave profile, the particle velocities and the accelerations within the wave are simulated. The results are achieved up to the point where the overhanging crest hits the wave front. Comparison of the plunging breakers generated in the wave flume and calculated numerically, shows good agreement with respect to

the wave geometry. The measured and calculated velocities also agree well at depths larger than approximately one wave amplitude below the mean water level. In the wave crest near the plunging jet, the measured velocities are, however, 1.5 times as large as the calculated velocities. This may be due to the difference in the method of generating the plunging breakers in the two cases (KJELDSEN, VINJE, MYRHAUG, BREVIG, 1980).

It is a common observation at sea, that steep waves have a tendency to break, sometimes as plunging breakers when they disperse into an area with an opposing surface shear current with a vertical velocity gradient. However, experiments with this particular phenomenon have never been attempted. Therefore, in the following, particular attention will be given to two experiments; one is a case with wave-wave interactions which create a deep water plunging breaker in still water. The other experiment is performed with the same deterministic command signal to the wave generator, but now the wave-wave interaction takes place on a weak steady shear current, which opposes the dispersion direction of the waves. Fig. 7 shows the profile of the current as it was obtained from a film recording, using styropor particles as tracers.

Fig. 7. Current profile before start of transient wave experiment. Total depth is $K_{OB}z = 7.02$. Mean current velocity is $\bar{v} = 0.03$ m/sec.

Fig. 8 shows the time developments of two deep water plunging breakers. T_B is the period of the breaking waves obtained from wave staffs at the position of breaking. Relative time $t/T_B = 0$ indicates the moment when the wave front becomes vertical. To the left is shown the development with no shear current present. A small jet develops and plunges down in the front of the wave at

Fig. 8. Comparison of developments of deep water plunging breakers in still water and in water with an opposing shear current.

time 0.05. At time 0.11 air has been entrained and development of the breaking on the front increases. Here a large eddie that curls down on the front face of the wave appears, and more and more air is entrained.

To the right is shown the development when a steady shear current is present. The mean current velocity is only 2% of the linear phase velocity computed for the breaking wave. However, the result is remarkable. A much more violent plunging breaker with a very strong jet in the wave crest appears. It shoots forward with a very characteristic shape at time 0.11 and hits the front of the breaking wave at time 0.22. Thus, the duration of the breaking is much longer, and displays the breaking of a much more violent wave.

Fig. 9 shows the development of the two breakers displayed by the ϵ parameter. Data is obtained from a frame to frame analysis of the film with time steps 10 millisecond. At the time the wave fronts become vertical both breakers have ϵ values near 0.70. For the case with the shear current ϵ increases during the breaking to a value near 0.83, returning to values near 0.70. For the breaker development in still water, on the other hand, 0.73 is the maximum value, and ϵ then decreases when breaking takes place.

Fig. 9. Amplification of crest front steepness by a shear current.

Also the μ -parameter displays the development in a similar way, Fig. 10. When the wave fronts become vertical, both breakers show ratios of crest elevation to the wave heights as high as 0.75-0.80. For the case with a shear current the values of the μ -parameter then increases to nearly 0.90. For the case with no current, the μ -value slowly decreases when the breaker develops.

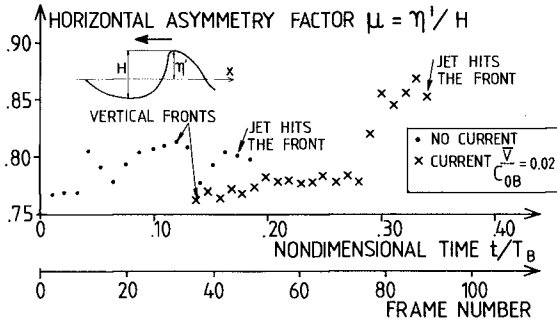

Fig. 10. Amplification of horizontal asymmetry factor by a shear current.

The amplification on the plunging breaker can be described as the relative increase in the ϵ and μ parameters:

$$\Delta\epsilon = \frac{\overset{\text{current}}{\epsilon_{\max}} - \epsilon_{\max}}{\epsilon_{\max}} = \underline{13\%} \quad \Delta\mu = \frac{\overset{\text{current}}{\mu_{\max}} - \mu_{\max}}{\mu_{\max}} = \underline{6\%} \quad (2)$$

Here ϵ_{\max} is the maximum value for a wave-wave interaction experiment, while $\overset{\text{current}}{\epsilon_{\max}}$ is the maximum value for a wave-wave interaction experiment with a shear current superimposed. Similar symbols are used for the μ -parameter. It is striking that a weak current (only 2% of the phase velocity) is able to create such drastic changes in the wave dynamics. The steepening of linear waves in the same shear current is very modest. This means that when a very asymmetric highly non-linear wave is triggered by even a weak energy flux, remarkable non-linear effects can be obtained.

Neither analytical nor numerical models are yet able to describe the phenomenon observed here. Such a high degree of amplification of breakers might lead to serious problems for mariners in smaller vessels in cases where high and steep waves approach even a weak current with a modest gradient. The phenomenon observed in deep water is a parallel to the well-known development of a plunging breaker on a beach, where return flow from the preceding wave can be observed to trigger the development of the following wave, in such a way that it might break as a plunging breaker. (KJELDSSEN & OLSEN, 1968.)

5. RESULTS FROM FIELD DATA

Storm Model

No single mathematical model for extreme wave statistics has gained universal acceptance. NOLTE (1973) used storm models which contained the most probable maximum wave height during a storm as a stochastic parameter. ARHAN et al. (1979) used a similar model based on significant wave height. MO, VIK & HOUMB (1978) used a model where consecutive values of $H_{1/3}$ exceed a threshold level, under the condition that also a higher level later is exceeded within a given time.

In the present study a storm model is given by the probability distribution:

$$S(H^*) = \sum_{i=1}^N \theta(H_{1/3}^i - H^*)/N \quad (3)$$

where the Heaviside unit function is defined by:

$$\theta(x-\xi) = \begin{cases} 1 & \text{for } x \geq \xi \\ 0 & \text{for } x < \xi \end{cases} \quad (4)$$

Here $H_{1/3}^i$ is the significant wave height for the i^{th} storm, N is the total number of storms and H^* is a wave height threshold level. This threshold level is taken as a definition of 'a gale' for the model. In this study only sea state 6, 7, 8 and 9 will be of importance, and a gale will therefore be defined as an event where the significant wave height exceeds 4 m.

With the assumption that storms are statistical independent events, no grouping correction is required. In this way the present model is superior to other methods. Only waves with zero-downcross wave heights exceeding 5 m were found to be significant for evaluation of stability and safety (from capsizing) for the vessels under consideration in the project "SHIPS IN ROUGH SEAS". From available field measurements on the Norwegian continental shelf, nearly 25000 single storm waves with heights exceeding 5 m were analyzed statistically. (KJELDSEN & MYRHAUG, 1978.) Approximately 8% of the most severe sea states in 26 gales were then selected for a closer study, and joint probability density distributions as well as marginal density distributions for relevant parameters were obtained. (KJELDSEN & MYRHAUG, 1979a.) The field data were sampled in the period 1974-78 with 3 wave rider buoys, located at Tromsøflaket, Halten and Utsira, Fig. 1. 20 minutes of recording was obtained every 3 hours, starting 20 minutes before 0 time GMT. The properties of the obtained probability density distributions show that data obtained from the 3 locations can be regarded as belonging to the same statistical population. This means that common statistical distributions can be obtained, which are representative for the wave dynamics in the whole area. (KJELDSEN & MYRHAUG, 1979b.) R.m.s.-values are used for normalisation, and dimensionless plots of probability density distributions are then obtained. The resulting data base provides a coupling to sea state, wind velocity and wave spectral parameters.

Probability density distributions of crest front steepness and asymmetry factors for waves with $H > 5$ m

Fig. 11 shows the probability density distributions of the crest front steepness ϵ , the vertical asymmetry factor λ , and the horizontal asymmetry factor μ , respectively, for 1754 storm waves with wave heights exceeding 5 m. For all distributions correlation coefficients are obtained using the Pearson χ^2 -test.

Fig. 11. Probability density distributions for ϵ , μ and λ .

The histogram of the crest front steepness ϵ is compared with the Rayleigh distribution:

$$p(x) = 2x \cdot \exp(-x^2) \tag{5}$$

where in this case $x = \epsilon/\epsilon_{rms}$ is the normalized crest front steepness. ϵ_{rms} is calculated for wave heights exceeding 5 m. A good correlation with a correlation coefficient of 0.99 is obtained. A two-parameter Weibull distribution is also fitted to the histogram of the crest front steepness. According to the two-parameter Weibull distribution, the cumulative probability is given by:

$$P(x \leq x_c) = 1 - \exp\left(-\left(\frac{x}{B}\right)^\gamma\right) \tag{6}$$

where x_c is a specific value. The result is given in Table 1. (The Rayleigh distribution corresponds to $\gamma = 2$ and $B = 1$.) The distribution of the vertical asymmetry factor λ also shows a good correlation with the Rayleigh distribution with a correlation coefficient of 0.94. The Weibull parameters are given in Table 1. The horizontal asymmetry factor shows a very good correlation with the Gaussian distribution given by

TABLE 1. WEIBULL PARAMETERS FOR MARGINAL DISTRIBUTIONS

1.8-2.0	3.22	1.38	.95	3.61	1.44	.98	5.54	1.29	.87
2.0-2.2	3.24	1.37	.94	3.52	1.41	.97	5.55	1.39	.83
2.2-2.4	5.17	1.99	.91	4.80	1.78	.93	5.65	1.33	.83
2.4-2.6	5.32	1.70	.88	5.62	1.90	.87	5.51	1.63	.76

$$p(\mu^*) = \frac{1}{\sqrt{2\pi}} \cdot \exp(-\frac{1}{2} \mu^{*2}) \quad (7)$$

where $\mu^* = (\mu - \bar{\mu})/\sigma_{\mu}$. Here $\bar{\mu}$ is the mean value of μ and σ_{μ}^2 is the variance of μ in the respective registration period calculated for wave heights exceeding 5 m. A correlation coefficient of 0.999 was obtained.

Joint probability density distribution of crest front steepness and wave height

Fig. 12 shows the joint probability density distribution of crest front steepness and wave height combined for all three locations, representing 6353 storm waves.

Fig. 12. Joint probability density distribution of ϵ and H .

The marginal distributions of the wave height and the crest front steepness are given in Fig. 15, showing good correlations to the Rayleigh distribution. Correlation coefficients of 0.98 were obtained for both distributions. Weibull parameters and correlation coefficients for the marginal distributions are included in Table 1. Further, the Weibull distribution given in (6), was fitted to the conditional distribution of the crest front steepness.

Weibull parameters and correlation coefficients corresponding to the best fit for each wave height interval are given in Table 2. If the crest front steepness and the wave height were uncorrelated, then the conditional distribution of the crest front steepness for given wave heights would be a Rayleigh distribution. However, the degree of correlation between ϵ and H is given in Table 2.

Joint probability density distribution of total wave steepness and wave height

Fig. 13 shows the joint probability density distribution of total wave steepness and wave height combined for all three locations. The marginal distribution of total wave steepness is given in Fig. 15, and corresponds well to the Rayleigh distribution with a correlation coefficient of 0.92. Weibull parameters are given in Table 1. The Weibull parameters for the conditional distribution of the total wave steepness for each wave height interval are given in Table 2. A marginal distribution of s that follows the Rayleigh distribution is in agreement with earlier results (BATTJES, 1976), but in our study use of the rms-value is recommended for normalisation. The s - H distribution shows a similar general shape as the ϵ - H distribution, and is included here in order to obtain a comparison of different types of steep waves.

Fig. 13. Joint probability density distribution of s and H .

Joint probability density distribution of wave height and wave period

Fig. 14 shows the joint probability density distribution of wave height and wave period combined for all three locations. The wave period was normalized with the parameter $\zeta^2 = (\overline{T^4})^{1/2}$, related to the rms-value of the wave period squared. The marginal distribution of the wave period is given in Fig. 15. The histogram is compared with the Rayleigh distribution of the wave period squared, i.e.

$$p\left(\frac{t}{\zeta}\right) = 4\left(\frac{t}{\zeta}\right)^3 \cdot \exp\left(-\left(\frac{t}{\zeta}\right)^4\right) \tag{8}$$

and shows a good correlation with a correlation coefficient of 0.98. Weibull parameters are given in Table 1. (The distribution of the wave period in (8) corresponds to $\gamma = 4$ and $B = 1$. The Weibull distribution is also fitted to the conditional distribution of the wave period for each wave height interval, Table 2. The joint probability density distribution of wave height and wave period shows asymmetry with respect to wave periods for lower waves and symmetry for higher waves, having the same general behaviour as the joint distribution given by CAVANIE et al. (1976).

Fig. 14. Joint probability density distribution of H and T.

Assuming a narrow band spectrum, LONGUET-HIGGINS (1975) found a theoretical joint distribution of H and T with an axis of symmetry at the mean period of the spectrum. This describes the observed joint distribution for high waves. A detailed comparison of LONGUET-HIGGINS and CAVANIE et al.'s theory is given by GODA (1978).

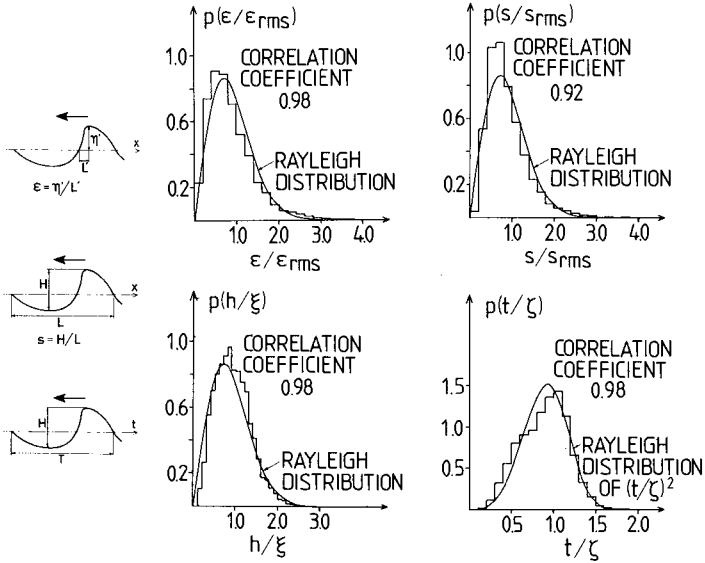

Fig. 15. Marginal distributions of ϵ , s , H and T .

6. DISCUSSION OF RESULTS

An analysis of 6353 storm waves showed that asymmetric waves with heights $H > 5$ m and vertical asymmetry factor $\lambda > 2$ appeared more frequently in wave groups than asymmetric waves with $H > 5$ m and horizontal asymmetry factor $\mu > 0.67$. (KJELDEN & MYRHAUG, 1979a.)

Fig. 11 shows that the horizontal asymmetry factor follows a Gaussian distribution for $H > 5$ m. An application of this result is that for waves with a given specific wave height (h), 16% of these waves will have crest heights that exceed:

$$\eta' = (\bar{\mu} + \sigma_{\mu})h \quad (9)$$

while 2.5% of the waves with the specific wave height, h , will have crest heights that exceed:

$$\eta' = (\bar{\mu} + 2\sigma_{\mu})h \quad (10)$$

This result has obvious important applications for the evaluation of both safety and design.

A very rough sea state can only be satisfactorily described as an event that contains both high values for the wave heights and high values for steepness and asymmetry parameters. High values of steepnesses combined with low values of wave heights describe a choppy sea, but this is not disastrous. Low values of steepnesses combined with high values of wave heights describe a heavy swell. *It is therefore the joint probability density distributions for high values of both steepnesses and wave heights that describe a very rough sea, and not the percentage of breaking waves itself.* Thus, the term *extreme waves* used earlier, describes a condition with high values of both wave height and crest front steepness.

When estimates of probabilities of occurrences of breaking waves are made, then the joint distribution of wave height and wave period is commonly used. A breaking criteria is then formulated in terms of the total wave steepness s . However, the parameter s does not define a steep asymmetric wave uniquely. Several asymmetric waves can exist, with the same total wave steepness s , but with very different crest front steepnesses, see Fig. 16.

Fig. 16. *The total wave steepness s does not define an asymmetric wave uniquely.*

Thus, the joint probability density distributions of s and H or of H and T are not suited, when estimates for probabilities for occurrences of breaking waves are made.

This study has shown that the crest front steepness is the most relevant parameter describing the mean inclination of the wave profile ahead of the crest, while the zero-downcross wave height is obtained ahead of a breaking wave. Therefore, when estimating probabilities for occurrences of breaking waves, the use of the joint distribution of crest front steepness and zero-downcross wave height is recommended.

7. CONCLUSIONS

- 1) The experiments show that all two-dimensional breaking waves generated by wave-wave or current-wave interactions in deep water can be classified as belonging to one of three distinct types, namely deep water plunging breakers, deep water bores, and deep water spilling breakers.
- 2) The difference in phases between a basic wave and a disturbance is crucial for the creation of a deep water plunging breaker.
- 3) A weak opposing shear current with a mean velocity of only 2% of the linear phase velocity for the breaking wave, was able to amplify a deep water plunging breaker violently. Thus, the relative increase in the μ -parameter became 6%, while the relative increase in the ε -parameter became 13%.
- 4) Recommendations for analyzing of steep asymmetric waves are to use:
 - zero-downcross analysis defining the wave height as the height ahead of the wave crest, giving a parameter relevant for the description of the development of the breaking process, and for the response of ships and structures.
 - the crest front steepness ε , the vertical asymmetry factor λ and the horizontal asymmetry factor μ in order to describe the zero-downcross wave uniquely.

- 5) Field data from the Norwegian Sea shows that the probability density distributions of the crest front steepness ϵ , and the vertical asymmetry factor λ follows the Rayleigh distribution. The horizontal asymmetry factor μ follows the Gaussian distribution. It was found that for waves with wave heights beyond 5 m, a high vertical asymmetry factor λ was obtained more frequently than a high horizontal asymmetry factor μ . Maximum values obtained in the field data and the laboratory experiments were $\lambda = 7.7$, $\epsilon = 0.83$ and $\mu = 0.92$. A high μ -value indicates that the crest height is very near the total wave height. *In other words, the wave is nearly entirely above mean water level.* This latter result is obviously important both for evaluations of safety and design.
- 6) Joint probability density distributions of the following zero-downcross wave parameters are given:
- . *Crest front steepness and wave height*
 - . *Total wave steepness and wave height*
 - . *Wave height and wave period*

Conditional distributions for given wave heights are presented as two parameter Weibull distributions. The joint distribution of H and T shows asymmetry with respect to wave periods for lower waves, and symmetry for higher waves, in the same general pattern as the one given by CAVANIÉ et al. (1976). Since s does not define steep asymmetric waves uniquely, neither the joint distribution of s and H nor the joint distribution of H and T should be used to estimate probabilities of occurrences of breaking waves.

- 7) Severeness of a particular sea state, containing estimates for the probabilities of occurrences of breaking waves, should be evaluated from the given joint probability density distribution of crest front steepnesses and wave heights *for individual zero-downcross waves*. This method will be superior to a method using mean parameters such as a mean wave period and a significant wave height.

8. ACKNOWLEDGEMENTS

Experiments with current-wave interactions were performed as a part of the project "Shock Pressures from Breaking Waves" sponsored by the Royal Norwegian Council for Scientific and Industrial Research (NTNF).

Other experiments and analysis of field data were performed as a part of the project "Ships in Rough Seas" sponsored by the Royal Norwegian Council for Scientific and Industrial Research (NTNF), the Norwegian Maritime Directorate and the Norwegian Fisheries Research Council (NFFR).

CAN WE DEVELOP NEW BREAKWATERARMOUR FORMULAE ?

John Dorrington Mettam*

Introduction

The purpose of this paper is to draw attention to the limitations of present empirical methods for the design of rubble mound breakwaters, particularly those using concrete armour units. Although it is unlikely that analytical techniques could become an adequate substitute for model testing, they should contribute significantly to a major advance in our understanding of breakwater behaviour. This is now long overdue and the art of breakwater design should be capable of substantial development.

Hudson's Formula

$$W_r = \frac{\gamma_c \cdot H^3}{K_D \left(\frac{\gamma_c}{\gamma_w} - 1 \right)^3 \cot \alpha} \quad (1)$$

During the last quarter of a century, most engineers and research workers have used Hudson's formula (ref: 1) for comparing different types of breakwater armour and for other purposes such as the design of simple breakwaters and the interpretation and correction of hydraulic model tests. Other formulae, such as Iribarren's formula have also been used to a lesser extent.

As new types of armour unit have been developed, their effectiveness has generally been measured by quoting the value of K_D in Hudson's formula in relation to their behaviour in model tests. However, Hudson's formula was originally developed to represent the behaviour of natural rock-type materials which retain their stability under wave action principally by their own weight and without any significant interlock with adjacent units.

In representing the behaviour of armour units of this basic type, Hudson's formula has been a very convenient tool even though in a single formula it over simplifies a very complex situation.

* Partner in the firm of Bertlin and Partners, Consulting Engineers of Redhill, Surrey, U. K.

The development of new types of artificial armour units, which to varying degrees do not behave in the same way as rock, has highlighted the limitations of Hudson's formula. The best-known such unit is the dolos which relies principally upon its interlock with a number of surrounding and underlying units to prevent displacement. For this reason dolos units may be less than a third of the weight of the natural rocks required to resist similar conditions. The unsuitability of the Hudson formula for dolos units has long been apparent (refs: 2, 3 & 4) e. g. it is necessary to quote different K_D values according to slope for these units. This has made it very difficult to interpret the results of different model tests.

It is also important to consider whether there are any other factors influencing stability which were not found to be of significance when Hudson's formula was developed for gravity-type armouring and which become of increased importance with units in which interlock is a major or predominant feature. There are indications from recent model testing (ref: 5 & 6) that contact friction between armour units could be one such important factor and that wave steepness may well be another.

What is now becoming very clear is that breakwater designers must appreciate the circumstances under which Hudson's and Iribarren's formulae were developed and the conditions for which they were designed. To use these formulae out of their original context is likely to be misleading and even dangerous. The application of Hudson K_D values to dolos and other interlocking units is convenient in comparing their weight-for-weight effectiveness against more traditional forms of breakwater armour; however, we must not be deceived into thinking that Hudson's formula therefore represents their behaviour or that such comparisons are valid.

Although most engineers would only advocate use of Hudson's formula for direct design purposes in the simplest cases, and would prefer to rely upon specific model tests for any important breakwaters, they would nevertheless in most cases have recourse to Hudson's formula for correcting hydraulic model test results for errors in modelling such as in water and material densities.

However, the fact that certain variables such as contact friction (or natural angle of repose) are not included in the formula does not imply that they are necessarily insignificant nor that they may be ignored with impunity when constructing and operating hydraulic models.

Before considering what other phenomena may be important to breakwater stability and then suggesting how breakwater design techniques might be developed, it is worth studying in some detail the development and derivation of Iribarren's formula.

Development and Derivation of Iribarren's Formula

The formula was first published in 1938 (ref: 7) in the form:

$$P = \frac{N A^3 d}{(f \cos \alpha - \sin \alpha)^3 (d - 1)^3} \quad (2)$$

It followed an earlier formula by Castro in 1933 (ref: 9).

A number of modifications have been suggested to the original formula. Some of these are expressed below using symbols defined in the legend

$$W_r = \frac{K' \gamma_c \mu^3 H^3}{(\mu \cos \alpha - \sin \alpha)^3 (S_r - 1)^3} \quad (3)$$

after Hudson (ref: 1)

$$W_r = \frac{\gamma_c \mu^3 H^2 L_p}{K_o \left(\frac{\gamma_c}{\gamma_w} - 1 \right)^3 (\mu \cos \alpha - \sin \alpha)^3} \quad (4)$$

after Gravesen et al (ref: 6)

The derivation of the term $(\mu \cos \alpha - \sin \alpha)$ shown in figures 1 and 2, is very simple but is worth mentioning to clarify thinking.

This derivation represents the stability of an isolated block tending to slide down a slope (α) with a coefficient of friction between the slope and block of $\mu = \tan \phi$ where ϕ is the angle of repose. Compared with $\cot \alpha$ in Hudson's formula it has the merit that $(\mu \cos \alpha - \sin \alpha)$ tends to zero as α approaches the angle of repose ϕ ; the weight of armour required therefore tends to the infinite.

Let us now remind ourselves of the derivation of the other main components of Iribarren's formula.

Disturbing force

$$\text{Water velocity} \quad V \propto \sqrt{gH}$$

$$\text{Drag force} \quad \propto M.V.A_{\text{area}}$$

$$\text{or } \gamma_w V V \left(\frac{W}{\gamma_c} \right)^{2/3} \text{ or } \gamma_w g H \left(\frac{W}{\gamma_c} \right)^{2/3} \quad (5)$$

FIG. 1.

For simple shapes μ = coefficient of friction

FIG. 2.

Force required for movement

Sliding down - $W_g (\mu \cos \alpha - \sin \alpha)$

Sliding up - $W_g (\mu \cos \alpha + \sin \alpha)$

If submerged x $\frac{(\gamma_c - \gamma_w)}{\gamma_c}$

Stabilising force (resisting down-rush)

$$\frac{Wg}{\gamma_c} (\gamma_c - \gamma_w) (\mu \cos \alpha - \sin \alpha) \quad (6)$$

Equating these and re-arranging

$$\gamma_w g H \left(\frac{W}{\gamma_c} \right)^{2/3} \propto \frac{Wg}{\gamma_c} (\gamma_c - \gamma_w) (\mu \cos \alpha - \sin \alpha) \quad (7)$$

$$W^{1/3} \propto \frac{\gamma_w H \gamma_c^{1/3}}{(\gamma_c - \gamma_w) (\mu \cos \alpha - \sin \alpha)}$$

$$\text{or } W \propto \frac{\gamma_c H^3}{\left(\frac{\gamma_c}{\gamma_w} - 1 \right)^3 (\mu \cos \alpha - \sin \alpha)^3} \quad (8)$$

It will be seen that the derivation of the modified form of the formula clearly represents the stability of the slope in resisting drag forces caused by wave down-rush. The formula does not represent the effects of impact forces on the armour units, nor does it consider stability of units subject to uprush (Hedar drew attention to this in 1960).

Some further points may be worth mentioning.

It will be seen that the third power relationship between W and most of the other factors arises from the basic fact that the main stabilising forces must be proportional to the volume of the units whilst the main disturbing forces must be proportional to the exposed area.

If W were not proportional to H^3 it would not, of course, be possible to use hydraulic models for testing breakwaters. This involves an assumption that the pressures of water on the armour units are proportional to the height of approaching waves and that the velocity of water within the armour layer is proportional to \sqrt{H} . An examination of the limitations of this assumption would be a fruitful area for further research and with the great advances of recent years in mathematical analysis of waves, this may perhaps be an area for mathematical research.

In the case of wave uprush it should also be considered whether impact forces obey the same relationship and over what range of conditions.

If the function $\left(\frac{\gamma_c}{\gamma_w} - 1 \right)^3$ is now considered it will be seen that it comes partly from the disturbing force and partly from the stabilising. The function does, however, appear to be fundamentally appropriate to the third power as in the Hudson and Iribarren formulae.

In 1972 Zwamborn (ref: 2 and 3) advanced the view that some other power may be more correct in the case of dolosse. One might rather question whether dolosse used in tests with different specific gravities may also have had some other differences such as different co-efficients of friction as this could provide an explanation of the effects reported by Zwamborn.

Factors which might affect Slope Stability

In considering the possibility of improving on present techniques of designing rubble mound slopes and the need to develop new tools for new types of armour unit and new applications, we must take a fundamental look at breakwater behaviour. Although the stabilising and disturbing forces must be related to the factors included in Hudson's and Iribarren's formulae, we can identify a number of other phenomena which may be of differing relative importance for different types of armour and in different circumstances but which do not appear in these formulae. These would include:-

- (a) Wave uprush.
- (b) Effect of surface slope angle and porosity on the wave behaviour.
- (c) Effect of bed depth and slope on the wave behaviour.
- (d) Incident wave steepness.
- (e) Dynamic and static stresses in armour units.

Development of New Formulae

If one starts to break the problem into its constituent parts it soon becomes clear that the single K_D factor of Hudson or the comparable factor in any of the versions of Iribarren cannot be expected to behave as a constant even for a particular armour unit. If we separate K_D into a number of functions (not factors) related to each element of the problem, each of these functions is necessarily a complex combination of many different variables.

Figs: 3 and 4 illustrate the problem and indicate functions f_1, f_2, \dots, f_7 . The different elements which can be expected to enter into each function are tabulated in Tables 1 and 2.

In addition to functions f_1 to f_7 which relate to different aspects of stabilising and disturbing forces, one more function, f_8 has been added to represent the damage condition at which the formula is being applied.

STABILITY FUNCTIONS

FIG. 3

DISTURBANCE FUNCTIONS

FIG. 4

TABLE 1 - Stability Functions

Function	Adjusting	Possible Factors
f_1	Effect of W as stabiliser (downrush)	1. Unit type 2. Interlock achieved 3. Surface friction
f'_1	Same as for uprush	Similar
f_2	Effect of interlock (downrush)	1. Unit type 2. Method of placing 3. Surface friction 4. Extent to which disturbing force acts on adjacent units
f'_2	Ditto (uprush)	Similar but 4 may be very different
S	Factor of safety	Possibly made up from S_1 . related to block type/size S_2 . related to quality of wave data

TABLE 2 - Disturbance Functions

Function	Adjusting	Possible Factors
f_3	H approaching	H/d Period T (or steepness) Bed slope Reflections, α
f_4	V Velocity at face of armour	Type of breakwater, bed slope, wave steepness, resonance effects, α , porosity, crest detail
f_5	Drag coefficient	Shape of arms of unit Shape of voids
f_6	Uprush velocity in armour	Slope type of unit, porosity, roughness, armour underlayers
f_7	Downrush velocity	As for f_6 , plus wave period or resonance effects crest detail
f_8	Degree of damage	Storm duration Wave spectrum Wave grouping

If we write the Iribarren formula in a form which keeps the stabilising and disturbing forces separate and insert the various functions $f_1 \dots \dots \dots f_8$ and a factor of safety S these become clearer.

$$\frac{Wg}{\gamma_c} (\gamma_c - \gamma_w) (\mu \cos \alpha - \sin \alpha) \propto \gamma_w g H \left(\frac{W}{\gamma_c}\right)^{2/3} \tag{7}$$

$$f_1 W (\gamma_c - \gamma_w) f_2 (\mu \cos \alpha - \sin \alpha) = S f_3 f_4 H f_5 f_6 f_7 f_8 \frac{W^{2/3}}{\gamma_c^{2/3}} \tag{9}$$

We may also consider the up-rush case as below:-

$$f'_1 W (\gamma_c - \gamma_w) f'_2 (\mu \cos \alpha + \sin \alpha) = S f_3 f_4 H f_5 f_6 f_8 \frac{W^{2/3}}{\gamma_c^{2/3}} \tag{10}$$

In equations 7, 9 and 10 the functions $(\mu \cos \alpha \pm \sin \alpha)$ are included to emphasise the point that up-rush and down-rush are different effects. It must, however, be admitted that these functions of μ and α may not be correct and that it may be better to consider f_2 and f'_2 separately.

Looking at equations 9 and 10 together with Tables 1 and 2, there will be many whose immediate reaction will be to despair of ever finding a solution. Indeed, in the sense of finding a single formula for all conditions, we may expect this to prove impossible.

In the same way that a structural engineer does not expect to use a single formula to analyse bending, shear, bond and torsion, we cannot expect to develop a single formula to represent all the phenomena involved in wave action on armoured slopes. We must therefore expect the development of a range of interrelated design formulae. In the meantime we must recognise the uses and the limitations of Hudson's and Iribarren's formulae.

Further Research

It is advocated that research into this subject should be carried out in a coordinated manner so that:-

- (i) The new formulae can be developed as rapidly as possible.
- (ii) Costs of the necessary model testing can be minimized and the greatest benefit obtained.
- (iii) Testing methods and procedures may be standardized.

In addition to development of the formulae, it will be necessary to carry out statistical studies. Even if we identify and correct the empirical coefficients for all the phenomena and influences which are identified, we shall not be able to correct for all the random elements involved. We may therefore expect a certain scatter in our test results and in the performance of prototypes. It will be necessary to have some sort of quantification of the risk element involved in using the formulae.

To commence development of new formulae it is advocated that research should be directed at determining the effect of each of the many parameters (such as slope, water depth and wave steepness) on the stability of the armour layer - not by just adding for each parameter one new function which attempts to represent all the effects of varying that parameter, but rather by considering separately the many different effects. As we use hydraulic models for design of breakwaters it is natural to use them to test the effect of varying the different factors which should be taken into account in any stability formula. This method has serious weaknesses, in particular:-

- (1) It can be extremely difficult to vary one factor while keeping all others constant.
- (2) The results of flume tests, in the form of numbers of units moving or displaced, necessarily show an enormous scatter. This must to a large extent be because of the human element involved in their measurement; the counting of units relies very largely on the judgement of those conducting the tests. The results are not as accurate as the numbers might imply.
- (3) The inherent soundness and stability of the model is likely to vary each time the model is rebuilt for new tests. Results are likely to vary randomly from test to test.

As indicated in Tables 1 and 2, changing one factor such as face slope can have a number of quite unrelated effects on different aspects of the disturbing and the stabilising forces.

This paper has indicated that the path ahead will not be easy but that it is important that we should at least attempt it. The means of progress will be an integrated programme of both theoretical research and model testing.

In planning such research it is suggested that effort should be directed chiefly to the problems of armouring rubble mound breakwaters in deep water. The work may well cast light also on the behaviour of breakwaters in the depths where breaking of waves limits the severity of wave attack but

this is an area where experience gives engineers a better basis for design (even though not as yet a rational analysis).

Having posed the general problem in broad terms, it may be helpful to discuss in more detail three aspects which have not always received sufficient attention. These are the importance of contact friction, the wave shape characteristics and structural strength.

Importance of Contact Friction

When natural rock armouring is represented in scale model testing, natural stone of suitable shape and size is used, preferably from the quarry from which the armour will be obtained. Its contact friction is similar in value to the rock it models. Similarly, early tests of concrete armour units were carried out using model units of cement mortar which again gave reasonable representation of contact friction. New techniques have recently been developed for moulding model armour units from other materials (ref: 10 and 11). These techniques are quicker and cheaper and are more reliable in terms of dimensional accuracy and specific gravity of the units. However, these model units often have very different contact friction values to the concrete armour which they represent and laboratory tests (ref: 5 and 6) show that this difference has a major influence on slope stability. This is hardly surprising as a change in contact friction alters the direction of the forces acting between units at the limiting condition when movement occurs; it must therefore alter the natural angle of repose of the units and this has been shown to be so. Methods to measure the natural angle of repose of an armour slope are described by Iribarren (ref: 8), Hedar (ref: 12) and Gravesen (ref: 6).

Fig. 5 shows the relationship between angle of repose and angle of contact friction for dolos units with extrapolation carried out for maximum and minimum repose angles. The curve is based on the values obtained for concrete mortar and DHP*plastic units (ref. 6). Tests on model dolosse from two other laboratories (Types A and B) have given lower values of contact friction although measurement of their natural angles of repose was not possible owing to the few samples available. (The values of contact friction were similar to those reported by Gravesen for porcelain and glazed porcelain). Angles of repose for types "A" and "B" have been estimated by reference to possible extrapolations of values on the curve of Fig. 5.

Taking Iribarren's Modified Formula (3) and rearranging it we get:-

$$\left(\frac{\mu \cos \alpha - \sin \alpha}{\mu} \right) = H^3 \frac{\sqrt{K' \gamma_c}}{\sqrt{W_r (S_r - 1)^3}} \quad (11)$$

* DHI Danish Hydraulic Institute

RELATIONSHIP BETWEEN ANGLE OF REPOSE AND ANGLE OF CONTACT FRICTION FOR DOLOS UNITS

FIG. 5

If, for a given type and weight of armour, we consider the effect of contact friction and face slope angle we may consider C to be a constant where:-

$$C = \sqrt[3]{\frac{K' \gamma_c}{Wr}} \quad (12)$$

and plot curves of H, C against ϕ (where $\phi = \tan^{-1} \mu$) for different slope angles; this is done in Fig: 6. The angles of repose of the various types of dolos mentioned have been plotted onto Fig: 6 and it can be seen that the influence of the natural angle of repose of armour units on their stability under wave attack is significant. It is not claimed that the results shown are precise, further tests are required, but it is fair to conclude that this effect is too important to be ignored as it has been by the majority of laboratories until now.

In view of the wide variety of materials being used for model armour units for test purposes, it is essential that contact friction should be represented correctly at least until we know how to correct for errors in modelling contact friction. It seems unlikely that mathematical analysis will assist us in this and it will be necessary to devise modelling techniques which enable contact friction to be varied without varying any other factors, such as specific gravity or hydraulic drag forces.

Wave Characteristics

Applying a significant wave height parameter to the Hudson equation does not seem suitable to a structure which has to withstand a spectrum including some waves which are considerably greater than this height. Care in selection of wave height was suggested by Hudson (ref: 1) with limits $H_{\frac{1}{5}} < H < H_{\frac{1}{100}}$ recommended by Morais (ref: 13).

Wave steepness is an important factor in terms of the disturbing force acting on the armour units. The steeper waves plunge whereas the flatter ones surge onto the breakwater.

Losada et al (ref: 14) carrying out tests on height-period interactions defined joint values of (H min, T) and (H, T min) which caused initiation of damage on breakwaters. (H min, T) therefore gives an optimum value of T for initiation of damage pertinent to each set of breakwater characteristics and also an optimum value of T for any wave height greater than H min, which causes the greatest amount of damage for that particular wave height.

Brunn (ref: 15) explained these optimum values of T as the occurrence of resonance between the wave period and the down-rush period. Peak forces perpendicular to the slope are set up by the collapsing-plunging wave repeatedly breaking, with the previous wave down-rush being in the same low position.

RELATIONSHIP BETWEEN ANGLE OF REPOSE
AND SIGNIFICANT WAVE HEIGHT

FIG. 6

Considering the rate at which energy is transmitted (wave power) towards a breakwater; it is directly proportional to wave period.

$$\text{Wave power} \quad P = \frac{g^2 H^2 T}{32\pi} \quad \text{/Sec.} \quad (13)$$

However, it has been found that as the wave period increases there is an increase in wave reflection (ref: 2) and a corresponding decrease in near surface orbital velocities. An optimum wave period for maximum damage is therefore anticipated.

The wave form itself is influenced by depth limiting factors such as refraction, shoaling, bed friction, bed permeability and wave breaking. On interception with the breakwater the wave characteristics are modified by both the armour slope and the porosity of the breakwater cover layers. Consideration of these influences is therefore necessary prior to determination of H in a stability equation and for determination of the wave field in model tests.

It is envisaged that mathematical analysis could now contribute significantly to our understanding of the nature of many of these effects.

Structural Strength

With the recently developed interlocking units, which rely on linkage with adjacent units rather than on their own weight, there are greater possibilities of movement and oscillation of units under wave action. These oscillations result in impacts, and it is necessary for the units to be sufficiently sturdy to resist these impacts. This has been recognized since the initial development of such units as has the possibility that structural strength problems might increase with size of unit (assuming a consequent increase in wave height). Considerably more full scale testing of armour units is required to increase our understanding of the strength of large concrete units. It is not possible yet to measure the amplitudes, velocities and acceleration of the oscillations of the armour units or to predict the amount of movement which will cause breakage. However, model tests using breakable armour units with inserts of material with reduced strength have been used in hydraulic flume tests (ref: 11). The results were interesting and indicate that this could prove to be a valuable method for determining the strength requirements of interlocking armour units. It will however be necessary to find a modelling material (not just an insert) with correct strength characteristics as well as correct specific gravity and surface friction.

Until such techniques have been developed it would be advisable to include in our formula a specific factor of safety against the conditions under which model testing shows the degree of movement likely to result in breakage.

Conclusions

We may conclude in summary that:-

- (i) Research into breakwater design and behaviour is now urgently needed to reduce reliance upon existing formulae which are no longer suitable for modern armour units.
- (ii) An integrated programme of theoretical analysis and model testing will be required.
- (iii) Future design methods will include more carefully controlled hydraulic model testing and the use of a range of new formulae.
- (iv) Until the new techniques have been developed, tested and proved, we must recognize the limitations of the present formulae and be very careful indeed not to use them out of their intended context.

Separation of climatic fluctuations and impacts of
engineering activities in estuaries

G. Krause

Institute of Marine Research
Bremerhaven, Federal Republic of Germany

Abstract

Using salinity as an example of dissolved substances in estuarine waters it is shown how the long term trend of concentrations can be split up into a man-made and a climatic contribution. The understanding of long term mixing processes and adequate sampling techniques are essential for this purpose. The physical state of the estuary can be described in terms of 3 basic variables, the river discharge, the filtered water level and the filtered salinity. The river discharge represents the climatic fluctuations in the catchment area, and the filtered water level is a record of the large scale weather pattern over the adjacent ocean basin. Salinity trends which cannot be attributed to these two variables must originate from man-made actions, such as dredging or other engineering activities which change the geometry of an estuary.

Two models are used for the trend analysis, the simplest possible mixing equation (which always holds for a sufficiently long time scale), and a salt flux consideration.

1. Introduction

In many cases environmental impacts of coastal engineering activities in estuaries are not easily assessed because it is necessary to separate the man-made changes from climatic fluctuations. Moreover, variables such as water level current velocity and salinity depend not only on tidal conditions and river discharge, but also on external forces like wind set-up, atmospheric pressure gradients, presence of shelf waves and changes of the large scale water circulation of the adjacent ocean basin.

Therefore, methods have to be developed that allow to eliminate all of these natural effects from measured data prior to any trend analysis which aims at assessing human impacts. For the variable salinity suitable methods will be described for a well-mixed estuary. They are derived from a case study using observations of a typical tidal estuary of the North Sea.

2. Area description and observations

Fig. 1 The river Weser estuary. The tidal range extends up to Hemelingen. The river discharge is measured at Intschede, all other data were obtained from a jetty at Blexen

Fig. 1 shows a map of the river Weser estuary. The mean tidal elevation is 3.40 meters, there are strong tidal currents up to several knots, and a weak stratification of salinity occurs only for two or three hours around slack waters.

The Weser river is an important shipping channel which connects the old Hanse town Bremen with the North Sea. Dredging of the channel has been carried out ever since the introduction of effective techniques.

Fig. 2 5 year averaged salinity and river discharge together with major dredging operations A, B and C during which the river was deepened from 5 down to 7 meters

Fig. 2 displays the development of salinity near the mouth of the river (Blexen) together with the river discharge covering the period from 1887 to 1940.

People were alarmed by the increase of salinity which followed the first extensive period of dredging, but it is seen that salinity just reflects the influence of the variable river discharge whereas effects of dredging are not obvious from the data.

However, there is biological and other evidence that salinity must have changed especially after deepening the river further upstream. Obviously, the large fluctuations of the river discharge mask the effects of dredging. It could also be the case that salinity sampling was not adequately carried out with respect to the problems to be studied. The old data set of fig. 2 just served as an in-

roduction into the problem of a long term trend analysis. The intention of this paper is to outline a method how man-made changes and natural fluctuations of salinity can be separated.

For this purpose another data set will be used which is represented in fig. 3. It was measured at a rather high sampling rate ($\Delta t = 1$ hour), and it covers 368 days of salinity, water level and river discharge observations.

Fig. 3 The data set (river discharge, salinity, water level) used for this investigation. Time scale is one year, sampling interval is one hour

3. Fundamentals of trend analysis of salinity

3.1 Scale considerations

The duration of a tidal cycle can be considered as a basic estuarine time scale. Mixing of river and sea water appears as a very complicated process within this scale. It involves turbulence, density effects, bottom friction, river discharge and many others amongst which are the water depth and other geometrical properties of the channel.

In order to predict salinity changes as a result of dredging the complicated mixing process is usually modelled, and respective parameters are systematically changed.

This usual engineering approach will not be adopted here. Man-made changes to salinity distributions in estuaries occur not only by single operations but also by many minor actions in the course of years or decades, and on these very long time scales one cannot consider all the details of mixing which take place within a single tidal cycle.

If a long term observer looks upon salinity in an estuary, the time averaged salinity \bar{S} can only be a function of the averaged volume ratio of fresh water to sea water \bar{q} , and the salinity of the adjacent ocean water S_0 , i.e.

$$\bar{S} = S(S_0, \bar{q}) \quad (1)$$

The volume ratio \bar{q} depends on the position within the estuary, on the geometrical dimensions, and on the amount of fresh water which is given by

$$F = Q + (P - E) \quad (2)$$

where Q is the river discharge, P is precipitation and E stands for evaporation. Restricting the discussion to one fixed position, assuming a channel-like estuary, neglecting $(P-E)$ compared with Q , and assuming salinity of the ocean water to be constant, then eq. (1) reduces to

$$\bar{S} = f(Q, \bar{h}) \quad (3)$$

where \bar{h} is the mean water depth. Eq. (3) indicates that the averaged salinity is a function of climatic fluctuations in the catchment area, and that it is also dependent on all external processes that change the mean water level. Such processes can be wind set-up, seiching, presence of shelf waves or atmospheric pressure gradients. Eventually, the mean water depth depends on the dredging operations in the area.

No particular mixing process has been assumed. If data are sufficiently averaged it does not matter how river and sea water is mixed, whether this is due to tidal or other currents or whether there exists a stratification or not for some periods of time. The basic question is only over what period of time the averaging procedure has to be extended so that the above arguments will hold. This can only be answered with the aid of observations, and the data set of fig. 3 serves for this purpose.

3.2 Selecting the time scale

The result of the previous discussion can also be put this way: Whenever the mean water level changes sea water is moved into or out of the estuary in addition to the tides. Given enough time this additional water mass will be mixed completely with the estuarine water.

fig. 4

If m_1 denotes the mass of water in a control volume and m_2 an additional water mass, then the equation

$$m_1 S_1 + m_2 S_2 = (m_1 + m_2) S \quad (4)$$

must hold after complete mixing. S_1 , S_2 and S are the respective salinities. Relating the masses to respective water levels (fig. 4) yields for small changes

$$\Delta S = \frac{S_2}{h} \Delta h \quad (5)$$

Near the mouth of the river S_2 can be considered constant (ocean salinity), it varies very much less than the salinity in the estuary. Therefore, one should expect a linear relationship between mean salinity and mean water level fluctuations. This can serve as a criterion for finding the characteristic time after which complete mixing has taken place.

With the frequently sampled time series available, the most obvious averaging procedure is filtering by a low pass filter.

For the river Weser estuary it was found (KRAUSE 1979) that mean data of salinity and water level satisfy eq. (5) after being filtered with a pass band between 35 h and 3000 h. The filtered time series are shown in fig. 5.

Fig. 5 Filtered salinity and water level

Fig. 6 shows an enlarged section of the filtered time series, and in fig. 7 the same data are plotted against each other.

Fig. 6 Filtered salinity and water level during September/October

Fig. 7 The data fig. 6 plotted against each other. B: begin, E: end

This picture appears confusing at the first glance, but this results only from the variable river discharge. For short times of almost constant discharge there holds a linear relationship which cannot be better fulfilled as indicated by fig. 8.

$$S_F = AH_F + B$$

A	B	R	Q (m^3s^{-1})
3.16	8.89	1.00	157
3.18	8.36	0.99	146
2.92	9.74	1.00	130

$$\Delta S = 3.02 H_F$$

Fig. 8 Regression lines through successive data points of fig. 7 (3 examples). R is the correlation coefficient and the last column is the river discharge. S_F denotes filtered salinity, H_F filtered water level and $\Delta S = H \cdot H_F$

It was assumed that the empirical relationship in fig. 8 holds throughout the record.

The physical significance of this result is that in the Weser river a time of about 3 tidal cycles (35 h) is sufficient to mix an additional water mass, associated with a change of the mean sea level, completely with the water already present at the observation site.

3.3 Rejection of external forces

The filtered sea level fluctuations in fig. 5 are closely related to the large scale weather patterns over North Sea and North Atlantic Ocean. However, it is not necessary to elaborate on the mechanism of this response. Whenever the filtered water level changes, water is moved into or out of the estuary. The filtered water level is simply a record of external forces on the estuary. The associated salinity fluctuations can be computed using the empirical relationship given in fig. 8. The result is displayed in fig. 9, and it is seen that the fluctuations are of considerable magnitude.

Fig. 9 Salinity fluctuations as a result of external forces on the estuary

They do not contribute to a man-made trend, they only contaminate the data. Therefore, they are subtracted from the filtered salinity time series of fig. 5. The result, presented in fig. 10 is a rather smooth curve which is almost the mirror image of the river discharge.

Fig. 10 Reduced salinity and river discharge

3.4 Rejection of climatic fluctuations in the catchment area

Under the assumptions of stationary conditions, constant bathymetry, constant salinity of the adjacent ocean basin and mixing processes being independent of the river discharge Q , the mean in- and outgoing salt fluxes through a cross section of the estuary would be in balance and be constant.

The outgoing salt flux is

$$f_{\text{out}} = \rho U_0 \bar{S} \quad (6)$$

where \bar{S} is salinity averaged over the cross section and over time, ρ denotes density and

$$U_0 = \frac{Q}{A} \quad (7)$$

is the outgoing velocity according to river discharge Q and cross sectional area A .

Under the above assumptions one has

$$f_{\text{out}} = - f_{\text{in}} \quad (8)$$

both being constant. Therefore, the total outgoing flux (mass per second) must also be constant, i. e.

$$\Sigma QS = \text{const} \quad (9)$$

and the ingoing flux needs not to be known. As indicated by eq. (7) a dredging operation which changes the cross sectional area A would change the constant in eq. (9).

To a first approximation eq. (9) can be used to eliminate the variable river discharge which expresses the climatic fluctuations in the catchment area of the river. The flux according to eq. (9) has been calculated, and the result is displayed in fig. 11. It is seen that most of the time the assumption of stationary conditions is violated. When a flood wave enters the estuary the flux increases, and salt is washed out of the estuary. Nevertheless, there are also times of almost constant discharge, which enables the observer to determine the constant in eq. (9). In the present case the constant is 1200 kg s^{-1} .

Fig. 11 River discharge and total outgoing salt flux

Observations taken at times of variable discharge cannot be used for the trend analysis under study. Fig. 12 gives some insight into the complicated response of salinity due to variable river discharge, and it supports the above argument.

Fig. 12 River discharge - salinity diagram. The solid curve corresponds to a constant flux of 1200 kg s^{-1} which had been determined from fig. 11

3.5 Results

The decisive processes which govern the subtidal variability of salinity in an estuary originate from the adjacent ocean basin and from climatic fluctuations in the catchment area. Resulting fluctuations mask the man-made changes. However, it is possible to recover the very weak signal of human impacts by regarding the other fluctuations as "noise" which contaminates all data gathered.

The salinity fluctuations as a result of external forcing are very well understood. On time scales beyond 3 tidal cycles in case of the Weser, they are linearly related to the filtered (mean) sea level, and corresponding salinity fluctuations are easily removed from observed salinities.

The response of salinity to the variable river discharge involves the previous history of the salinity distribution and depends also on magnitude and time history of the discharge. Only salinity data gathered during periods of almost constant river discharge are reliable for assessing man-made trends.

It is obvious that results derived for salinity will also hold respectively for other dissolved substances, pollutants, turbidity, current velocity and for sediment transport processes. Attention to the difficulties in estimating mean flow conditions in estuaries has been pointed out by WEISBERG (1976).

4. Applications

4.1 Monitoring strategies

With respect to the long-term development of salinity or other variables it is important to realize that in spite of the predominance of tidal variability, a tidal estuary is a meteorologically governed area of the sea. This prescribes the sampling rate to be adopted by monitoring schemes.

In order to demonstrate this more clearly, the salinity data set of fig. 3 (again as an example) can be resampled according to various schemes.

If one assumes an observer who could take a sample at every high water the result would be the trace in fig. 13. In case of pollutants such frequent sampling is beyond any hope of achievement.

Fig. 13 Results of various monitoring schemes. Trace: Sampling at each high water, dots: sampling on monthly intervals.

Sampling on monthly cruises gives rise to serious errors in trend calculations as indicated in fig. 13. Data of such schemes e.g. depend on the starting time.

A suitable monitoring strategy can only be based on the 3 basic variables water level, salinity and river discharge. They are easy to measure continuously and they characterize the physical state of the estuary. One can apply the reduction procedures outlined before, and this can also be carried out on-line. Based on the results (i.e. stable or unstable conditions due to variable river discharge, mean sea level fluctuations etc.) other measurements can be assessed or perhaps be corrected. One can also adopt a flexible approach. A costly field investigation is only carried out when the conditions are right.

4.2 Assessment of available data sets

The results of chapter 3 enable the assessment of existing data of an estuarine environment also in cases where no salinity measurements have been carried out. It is necessary to know the time history of mean sea level and river discharge to have an indication of the usefulness of data with respect to trend analyses.

4.3 Calibration of mathematical models

Numerical models designed to predict salinities or other variables rely on a data set for calibration that only depends on processes which have been modelled. As has been demonstrated before, estuaries are seldom in a stationary state and field data depend on the previous history. Therefore, great care is necessary to measure a suitable data set that ensures the general validity of the model parameters.

5. Conclusions

- (i) The basic element for a long term trend analysis of estuarine variables is the fact that an estuary is a meteorologically governed area of the sea in spite of the predominance of tidal variability.
- (ii) The long term trend of the concentration of a conservatively dissolved substance depends only on the large scale weather patterns over the adjacent ocean and the catchment area of the river.

- (iii) Whereas other authors (e.g. ELLIOT and WANG, 1978; SMITH, 1978; WANG, 1979) have studied the influence of atmospheric forcing on estuaries in detail, this is not necessary for a long term trend analysis. The filtered (mean) sea level is the record of all external forcing mechanisms.
- (iv) In well-mixed estuaries only a few tidal cycles have to elapse until the simplest possible mixing equation describes adequately the response of salinity to external forces which change the filtered water level. Filtered water level fluctuations are natural "experiments" by which the time scale can be determined.
- (v) Filtered salinity, filtered water level and river discharge are the basic variables which describe the physical state of an estuary. They can be used to design monitoring schemes and to assess available data, mathematical tidal models and impacts of engineering activities on estuaries which are masked by large climatic fluctuations.

Wave Energy Distribution in an Estuary

by
Volker Barthel *

Abstract

A field investigation program on waves in the Weser Estuary, German Bight of the North Sea, was started to learn about the complex wave climate in this region. The comparison of results in the various locations shows that most of the wave energy is transferred from deep water across the reef region to the wadden area. The comparison of spectra in the different sites and the parametrization of these multi-peak-spectra gives another feasibility to describe estuarine waves.

Introduction

Waves coming from deep water and entering an estuary generate a very complex wave climate. In addition to the influence of wind and shoaling water (refraction, diffraction etc.) nonlinear wave-to-wave-interactions occur. Therefore it is very difficult to find a reasonable prediction method as a basis for the design of all structures and for shipping purposes in the region in question. A field investigation which for economical reasons has to be restricted to a few locations in a strongly divided area of an estuary normally can only give a limited view. But with a sophisticated choice of the sites the comparison of the results can give valuable references of the behaviour of waves in this area.

In 1976 a field investigation program on waves was started in the Weser Estuary (German Bight of the North Sea) (Fig. 1).

* Dipl.-Ing., Federal Waterways Administration,
Wasser- und Schifffahrtsamt Bremerhaven, F.R.Germany

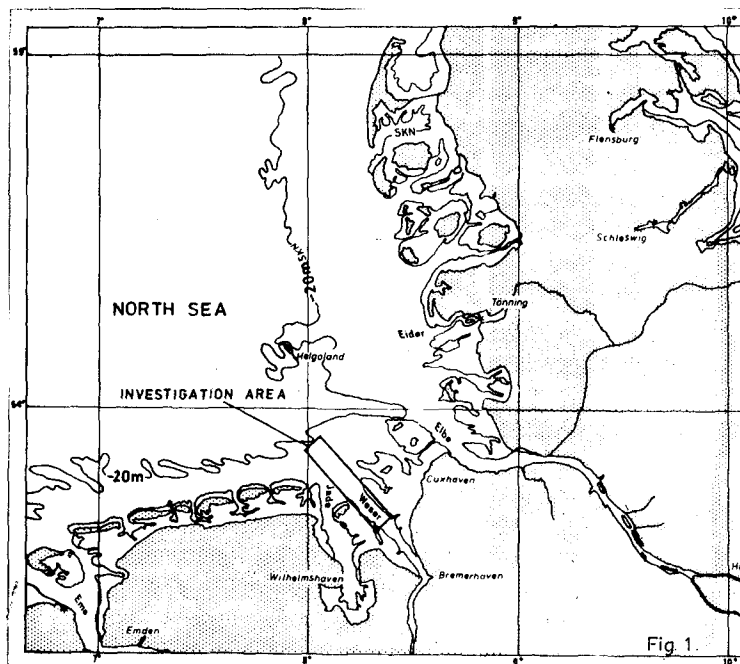

Fig 1

The measurements were carried out by the German Federal Waterways Administration which is part of the Federal Ministry of Transportation. They were supported by the German Coastal Engineering Board (KFKI).

Fig. 2 gives a better view of the investigation area with the single sites. The location ST lies at a water depth of about 20 m below MLW and is to registrate the waves coming from the open sea. RSW lies on the edge of the deep shipping channel "Neue Weser".

The water depth is 10 m below MLW. RSO lies behind the bar "Roter Grund", where the water depth is 7 - 8 m below MLW. Finally the location TPW on the edge of the shipping channel is to record the change in wave height and period in the interior estuary in front of the wadden area. On most of these locations waverider buoys were installed, the radio-signals of which were received and recorded on a light-house in the near-by wadden area.

Though a lot of records with nearly all wind directions and - velocities could be gathered the following analysis was only worked out for a series of records with strong winds from WNW during a minor storm surge. Previous measurements had shown that already slight changes in wind-direction in this area very promptly exercise an influence on wave parameters.

Three of the main ideas of this program were:

- a) to find a reasonable site for a permanent measuring station, which could lead to predictions for the whole estuary,

- b) to find out whether long waves could penetrate the estuary causing a possible danger for deep-drawing ships
- c) to express multi-peak-spectra by parameters, which can be correlated with different influence factors.

Loss of Wave Height or Energy on the Reef

Fig. 3 shows the significant wave height H_s ($H_{1/3}$) versus the wind-velocity as an example for the location RSW. The distinctions between ebb - or flood - currents were not regarded in this case. The results of a lot of measurements as far as this correlation is concerned made it possible to complete the plot of the variations of

Fig. 3 H_s versus $\frac{u^2}{g}$ (m) - Loc. RSW; WIND SW - NNW

wave heights and periods on all locations though the technical equipment allowed a 20 - minutes - record every 80 minutes only. Fig. 4 shows the variations of wave parameters of 4 locations on April 27th and 30th, 1979. While in the left part only minor wind-velocities occur they rise up to 20 m/s on April 30th. In accordance with this and the mean waterdepth over the reef between RSO and ST the significant and maximum wave height H_s and H_{max} and the peak-period T_{f0} react. The first task was to find interdependencies between the wave parameters of the different regions of the estuary. In this study the significant wave height H_s was looked at in detail. The waves coming from the open sea and entering the estuary at location ST are hardly affected by the sea bottom if they aren't too high under severe storm conditions.

VARIATIONS OF WAVE HEIGHT H_s , WIND AND TIDE

FIG. 4

VARIATIONS OF WAVE HEIGHT H_{max} AND PEAK PERIOD FIG. 4

First influences are to be expected in the reef region and were to be recorded at the locations RSW and RSO. We expected to find a considerable loss of wave-energy and therefore wave - height in the reef region.

Fig. 5: ΔH_S versus H_S

Fig. 5 shows the difference of the significant wave height ΔH_S between ST and RSW respectively ST and RSO as a function of H_S at ST. With no reference to the water depth on the reef this is an accumulation of single points, which can be delimited by curves. These boundary lines weren't transgressed after the evaluation of a lot of additional records with the same wind-direction either. Though the slope of the curve ST - RSO is a little bit steeper the difference between RSW and RSO is smaller than expected.

Regarding the further course of waves into the inner estuary we found out a fairly good dependency between RSW resp. TPW.

Fig. 6 shows that the damping of wave height resp. the loss of wave energy between RSW and TPW decreases with increasing H_S at RSW.

Fig. 6: Damping of wave height RSW - TPW and RSO - TPW

That seems to be an indication for the direct connection between both locations in the deep channel, which becomes better with increasing wave height. That is not so evident with RSO and TPW where the slope is nearly linear.

A certain correlation with the inclusion of the waterdepth over the reef resp. the water level in this area was only to be found between ST and TPW directly.* The scattering of values may be due to the oscillating tide currents, the influence of which is to be recognized at TPW predominantly. Tidal currents in this region can have a velocity up to 2.0 m/s. The following table gives a view of some of the results of the measurements:

Table of significant wave height H_s and water depth d over the reef

1 ST	2 RSW	3 RSO	4 TPW	Depth d
2.42	2.20	1.92	0.90	5.75
2.81	2.31	2.12	0.95	5.20
2.89	2.80	2.43	1.12	5.30
2.65	2.57	2.84	1.37	6.40
3.17	2.92	3.38	1.54	7.40
3.94	3.31	3.77	1.80	8.30
3.80	3.20	3.41	1.79	8.50
3.47	3.27	3.39	1.76	8.60
3.35	2.80	3.00	1.51	8.10
3.66	2.49	2.29	1.32	6.80
3.64	2.62	2.47	1.12	5.90
2.56	2.40	2.27	0.78	5.30
3.12	2.55	2.59	0.96	5.30

H_s and d in (m)

Results of the correlation:

$$\frac{H_{s1}}{H_{s2}} = 1.07 \frac{H_s}{d} + 0.66 \quad (R_{xy} = 0.59)$$

$$\frac{H_{s1}}{H_{s3}} = 2.17 \frac{H_s}{d} + 0.17 \quad (R_{xy} = 0.69)$$

$$\frac{H_{s1}}{H_{s4}} = 5.45 \frac{H_{s1}}{d} - 0.15 \quad (R_{xy} = 0.88)$$

*Fig. 7

The three equations at the bottom of the table show once more that there is a poor correlation between ST, RSW and RSO - in other words: water depth over the reef or the reef itself doesn't play an important part for the decrease of height or energy. To summarize the results of the investigations concerning loss of energy resp. damping of wave height Fig. 8 shows the mean proportional

Fig. 8: Mean proportional decrease of wave height H_s and H_{max}

decrease of wave height H_s and H_{max} . It is shown that waves having travelled across the reef or via the deep channel still have 86 - 87% of the original height. Only when having arrived at TPW there was another decrease of 38 - 45 %. (The lower part of the graph shows a skeleton diagram of the bottom profiles in the different routes.) This means that the maximum part of wave energy isn't lost in the reef region, as one could have expected especially for higher waves. More than 40 % are lost on the way between the reef region and the wadden area. That is an important conclusion for planning and design of all structures.

Discussion of Spectra

Normally the records were evaluated statistically and with the Fast-Fourier-Transformation of COOLEY and TUKEY a power spectrum was calculated. The comparison of a series of plotted energy spectra in Fig. 9, 10 and 11 gives an indication of the alteration of waves more obviously:

Fig. 9: Energy spectra in the Weser Estuary

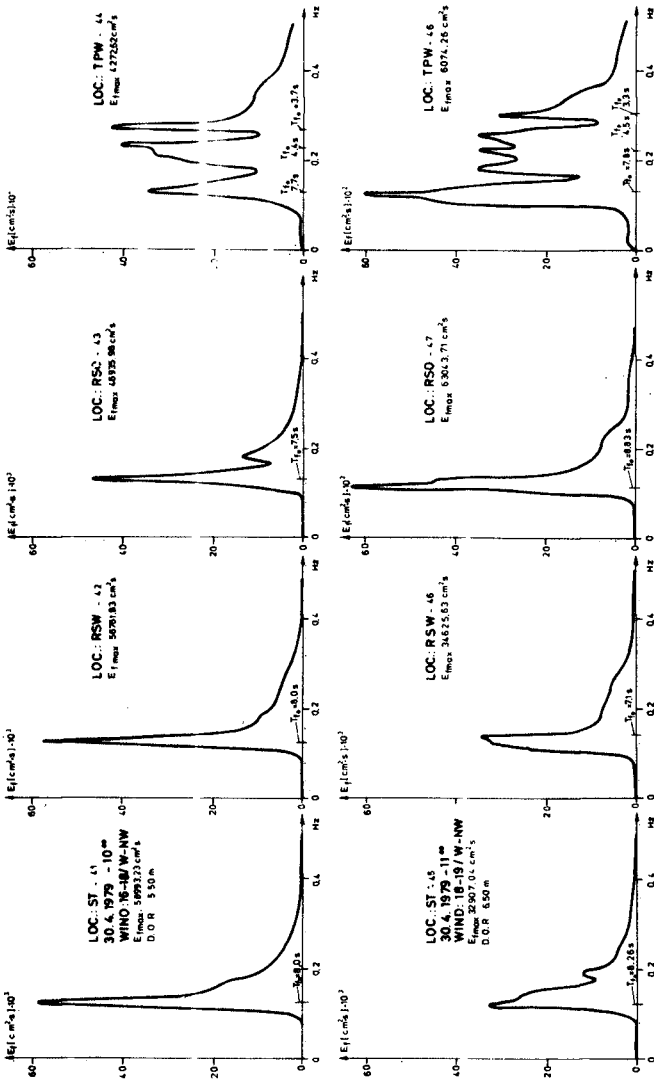

Fig. 10: Energy spectra in the Weser Estuary

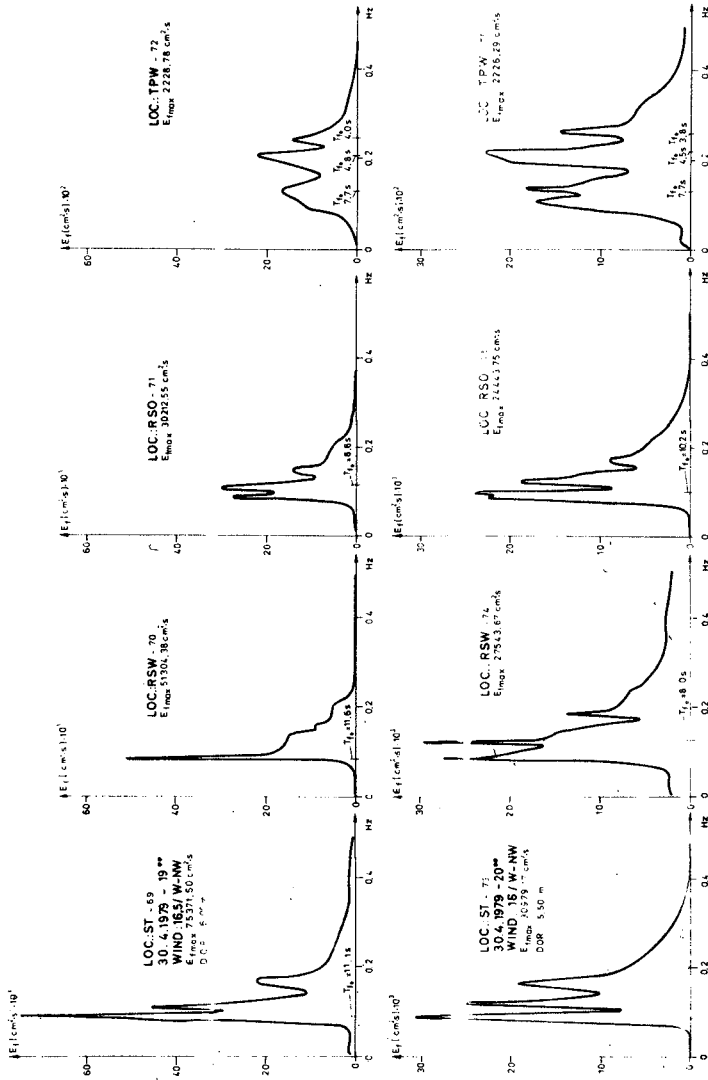

Fig. 11: Energy spectra in the Weser Estuary

Fig. 9: On loc. ST the spectrum shows energy shares of higher frequencies with a peak at 7.3 s. With low wind-velocities a max. height of 2.5 m arises. Waves with longer periods penetrate the estuary and are to be found with a small increase of the peak-period T_{fo} . The spectral shape varies strongly and shows the presence of more than one wave system. The spectra of April 30th, 7.00, show a normal shape at ST and energy shares of the locally arisen sea at RSW and RSO. At TPW the maximum of energy density lies in the region of higher frequencies, but the penetrating long-period-waves with $T_{fo} = 8.3$ s can be recognized clearly.

Fig. 10 shows two additional series of energy spectra with higher wind-velocities, still increasing. This time one can see a typical spectral shape at loc. TPW. This - as we called it - 3-peak-spectrum shows the complexity and variety of waves in an estuary. This shape could be detected again and again at this location. Among others it points out that waves with longer periods penetrate the estuary without remarkable alteration of period or length. This is important knowledge for ships with only a small underkeel-clearance, which enter the narrow channels of an estuary. The two additional systems at this location can be explained by locally arisen sea and reflexion or refraction.

Fig. 11 shows another two series of energy spectra with decreasing wind-velocity and the 3-peak-shape at loc. TPW again. There is a lot of additional information in this graph, which can be extracted either by further discussion or computer analysis. Though the frequencies of the long-period-waves don't change very much while penetrating the estuary the energy contents within certain frequency ranges can shift.

Fig. 12 shows the proportional shares of the spectral energy $m_o = \int E(f)df$ for three frequency ranges. The situation is presented for a) minor wind-velocity (increasing), b) high wind velocity (still increasing) and c) high wind-velocity (decreasing). It can be recognized that with minor wind velocities the spectral energy is concentrated within the frequencies 0,1 - 0,25 $1/s$ with a decreasing tendency into the inner estuary. Increasing wind-velocities generate longer waves with an increasing share into the inner estuary. With decreasing high wind-velocities this development has a downward movement with a high percentage of waves with periods 4 - 10 s in the interior estuary.

Parametrization of Spectra in Estuaries

The above mentioned analysis or discussion is very largescale as far as the evaluation of energy-shares and the description of spectral shape is concerned. But there is of course a possibility to have that done by a computer. To express the alteration of energy spectra or to describe them in a simple way we have the possibility of parametrization.

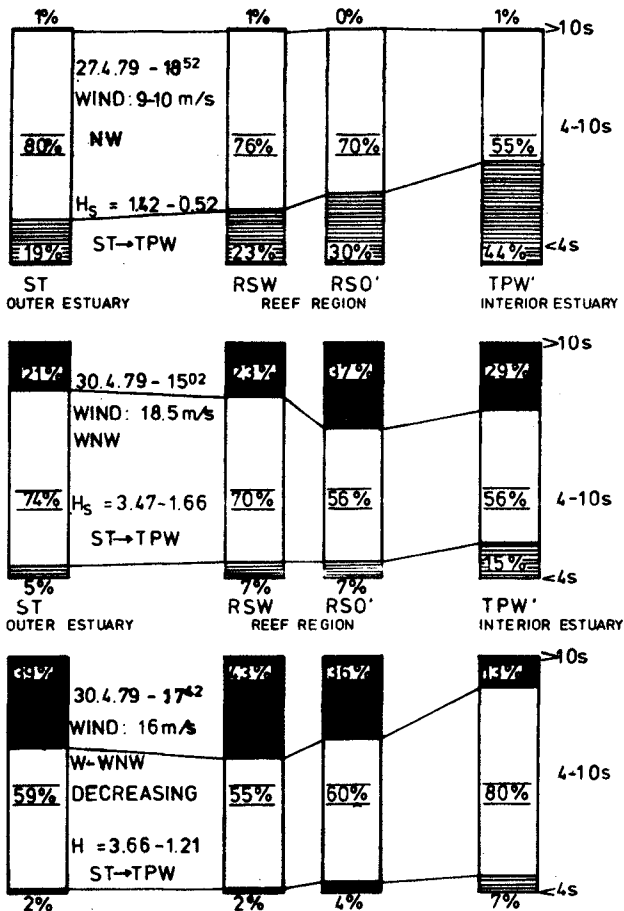

Fig. 12: Proportional energy shares for three frequency ranges.

Examples for that are given by the BRETSCHNEIDER-Spectrum, the PIERSON-MOSKOWITZ-Spectrum or the JONSWAP-Spectrum, which is expressed by the equation:

$$S(f) = \alpha g^2 (2\pi)^{-4} \cdot f^{-5} \cdot \exp\left(-\frac{5}{4}\left(\frac{f}{f_0}\right)^{-4}\right) \cdot \exp\left(-\frac{(f-f_0)^2}{2\delta^2 f_0^2}\right)$$

Several attempts to express an estuary-spectrum in the JONSWAP-form were very unsuccessful because there was no possibility to register more than one peak. So we tried to divide a two-peak-spectrum into two parts, to approximate the measured (Hamming-smoothed) partial spectra to the JONSWAP-form and to superpose them again. One gets a 10-parameter-spectrum then:

$$\begin{aligned}
 f_K(p) &= \text{SPECTRAL FUNKTION} \\
 S(f)_p &= \text{PARAMETRIZED SPECTRUM} \\
 S(f)_H &= \text{"HAMMING" - SMOOTHED SPECTRUM} \\
 f_K(p) &= S(f)_p - S(f)_H \rightarrow \text{CONSTRAINT MINIMUM SEARCH}
 \end{aligned}$$

$$\text{MIN. } \sum (f_K(p))^2$$

$$\text{MIN. } \sum f_K(p+\Delta p)$$

TWO - PEAK - SPECTRUM

$$S(f) = S_1(f_{01}; \alpha_1; \gamma_1; \xi_{ab1}) + S_2(f_{02}; \alpha_2; \gamma_2; \xi_{ab2})$$

Fig. 13 shows the results of a first attempt for three spectra.

1. APPROXIMATION - 10 PARAMETER-SPEKTRA

Fig. 13:
First Approximation-10-Parameter-
Spectra

But this solution wasn't sufficient yet because of the shifting of the peak-frequencies f_{01} and f_{02} during the calculation resp. the approximation process.

Because of the inadequacies we defined the peak frequencies and gave them a fixed value after looking at the Hamming-smoothed spectrum. So we got a spectrum with 8 parameters which can describe a two-peak-spectrum in a sufficient way.

Fig. 14 shows 3 examples with a fairly good correspondence between measured and calculated spectra.

Fig. 14:
8-Parameter-Spectra in the
Weser-Estuary
(the continuous line shows the
superposed spectrum whereas
the dotted line gives the
measured (Hamming-smoothed)
spectrum)

It is possible either to combine JONSWAP- and PM-Spectra in case of the parameter $\chi < 1$ or to superpose more than two partial spectra if necessary.

Conclusions

The evaluation of a lot of wave records in the Weser Estuary gives a basis for a sufficient prediction system. With a permanent reference location it would be possible to predict wave heights and periods for the various regions of the estuary. The comparison of the height of waves in the exterior and interior estuary and the energy loss on the way prove that there is hardly any shelter by the submerged bars in the reef region so that the high waves can get to the wadden area. This fact has to be taken into account for nautical purposes too.

The wave-energy loss together with the tidal currents in this region cause a high amount of sand transport. Fig. 16 gives an idea of the morphological changes in the area of TPW and TPO. The erosion rate within one year per km² is 260.000 m³ resp. 120.000 m³ (Fig. 16).

The parametrization of estuary-wave-spectra has to be developed and tested for another series of more difficult cases. The description of a complicated multi-peak-spectrum by a couple of parameters and their correlation with the factors of influence is another step for the analysis of the complex wave climate in an estuary.

CHAPTER 141

Hydraulic research in the Oosterschelde Estuary.

A.W. Walther

Head of Hydraulics Division, Delta Department of the
Ministry of Transport and Waterways, The Netherlands.

In 1974 a major policy change was made to the Delta plan (fig. 1) to close the Oosterschelde (East Scheldt). For ecological reasons it was decided to replace the originally planned barrier dam with a storm surge barrier. This could be opened to allow normal tidal movement or closed during storm surges.

Figure 1: Delta Plan, Netherlands.

Instead of completing the dam in 1978, the new structure (fig. 2) would be finished in 1985. The vertical tidal movement in the estuary would be reduced to about 80 per cent of the original tidal range, while under storm surge conditions the storm surge barrier (with a cross-sectional area of about 15,000 sq.m.) could be closed, thus serving both ecology and safety at the same time. This new concept

Figure 2: Storm Surge Barrier.

required a large number of new investigations in coastal engineering and soil mechanical fields.

In the "Driemaandelijks Bericht Deltawerken", an illustrated quarterly Dutch magazine with English abstracts (1), both the design of the barrier and the investigations are described.

The soil mechanical research was reported in the "International Symposium on Soil Mechanics Research and Foundation Design for the Oosterschelde Storm Surge Barrier" in 1978 (2).

The results of the hydraulic research will be presented during a symposium in August 1980 (3).

This paper gives a general description of some of the hydraulic investigations.

In the design stage of the storm surge barrier a probabilistic approach of the hydraulic loading conditions of the structure was made. The barrier must survive a force with a frequency of exceedance of 2.5×10^{-4} per annum. The starting point in the determination of this force is formed by the three-dimensional probability density function of storm surge levels, wave energy and basin levels. Basically there are two ways of extrapolating the measured data of these parameters and their correlation into regions of low probability of occurrence, where measured data are not available viz. statistical extrapolation or extrapolation by means of mathematical models based on physical laws and checked with measured data. A combination of these methods has been used in finding the probability density function of storm surge levels and the conditional probability density functions of wavespectra and basin levels, from which the three-dimensional probability function is derived.

The probability density function of the storm surge level is based on 40 years of historical data; extremes are predicted by statistical extrapolation. The knowledge of the physical laws governing this phenomenon has been used to see whether predicted extremes could be reached.

The conditional probability density function of basin levels depends at least partly on the closing strategy of the barrier during storm surges. A simple model was developed based on the fact that a storm is formed by a random combination of wind set up and astronomical tide. From this model the conditional probability density function of basin levels (conditional on storm surge level) could be derived for different closing strategies. The basin level was found to be virtually statistically independent of the wave energy.

Studies were made on local wave and wind conditions, and their relationship with conditions in the North Sea. It was found that not only the wind but also the water level, currents and swell entering from the sea exerted influence on the wave movement.

In addition, waves were greatly influenced by the shallows in this area. The wave spectra near the barrier show in general two peaks. It appeared from the data that a loose correlation exists between the storm surge level and the significant wave height. Lack of data prevented a reliable extrapolation of this two-dimensional probability function by purely statistical methods. Therefore a mathematical model has been developed. It is based on the hypothesis that the typical double peaked form of the wavespectrum is caused by the fact that the wave energy originates from two sources. Waves entering the estuary from deep water via the shoals near the mouth of the estuary are influenced by processes of breaking, bottom dissipation and refraction by depth and current. The wave energy reaching the barrier depends strongly on the storm surge level. In addition, waves generated by local windfields, show a loose relation to the general storm intensity. In fig. 3 the outline of the idea is given. A numerical model which incorporates all these effects is tested in a hindcast of several storms. For these storm conditions the model is in good agreement with the measurements (fig. 3).

The input for this mathematical model are the wave conditions on the border of the Oosterschelde, the storm surge level and the local wind-speed. It is clear that for extrapolation to extreme circumstances these quantities have to be known. As reliable statistics of the windfield are difficult to get, starting point is the probability of exceedance curve of the storm surge level. Using a model that relates the wind set up to the windspeed and the maximum storm surge level to the wind set up and the astronomical tide, the two-dimensional probability function of maximum storm surge level and windspeed is obtained. A theory of wavegrowth and wave propagation on water of limited depth gives, combined with the two-dimensional probability density function of windspeed and storm surge level, the two-dimensional probability function of maximum storm surge levels and significant wave heights on the border of the Oosterschelde.

The introduction of the breaker criterion for the shoals shows that nearly all wavefields generated on the North Sea during an extreme storm will break on the shoals. Therefore the wave height at sea will not influence the energy penetrating in the Oosterschelde. The maximum storm surge level is the only parameter that matters for the penetration.

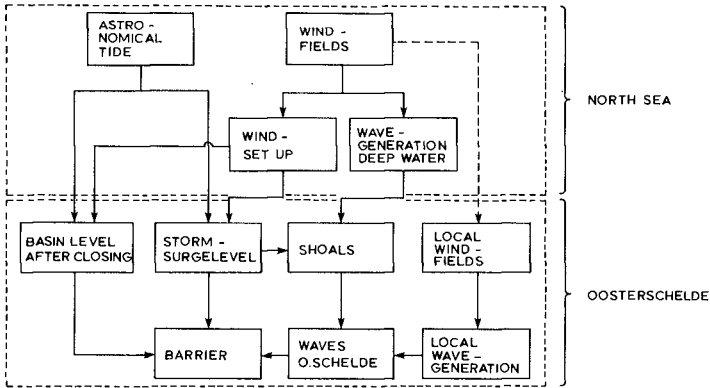

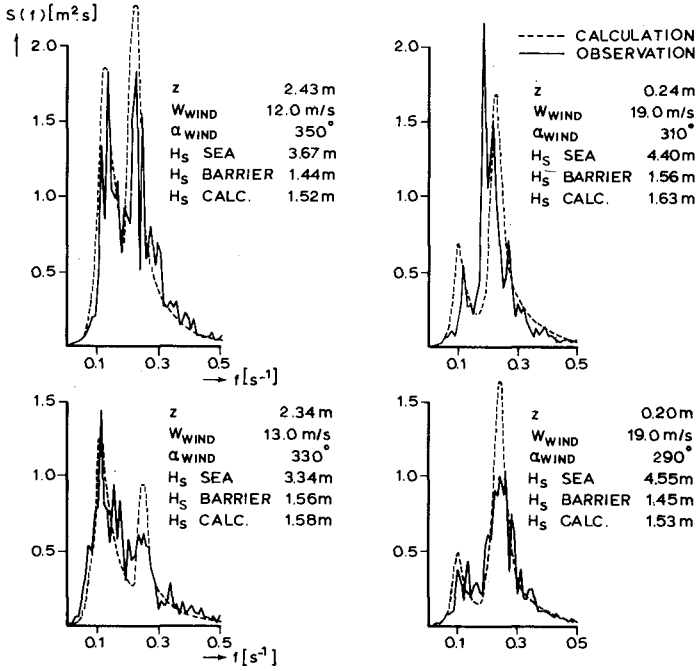

Figure 3: Wave model and results of hindcasts.

The second source of wave energy near the barrier is related to the local windspeed. A relation between local windspeed and the windfields at sea has been established.

The barrier will be maximally loaded during the maximum storm surge level, because the differences between sea level and basin level and the amount of low frequency wave energy penetrating from the North Sea are both maximal.

By joining together the above mentioned models the two-dimensional probability function of maximum storm surge levels and local windspeeds is obtained, where for every combination the wave spectrum near the barrier is known. By adding this to the conditional probability density function of basin levels, the three dimensional probability density function of maximum storm surge levels, wave energy and basin levels is derived. This function is used as input in the calculations of the probability distribution of the hydrodynamic load on the storm surge barrier.

The construction of the barrier across the Oosterschelde mouth will affect the tidal regime in the estuary. Reducing the present 80,000 sq.m. cross-sectional area across the mouth of the Oosterschelde to an effective aperture of 14,000 sq.m. will decrease the discharges through the aperture. As a consequence the tidal range in the basin will be reduced. The tidal regime will not only be affected by the construction of the barrier, however, but also by the construction of compartment dams. Two compartment dams, the Philipsdam and the Oesterdam, (fig. 1), will be incorporated to aid water management and to provide a tide-free shipping route between Antwerp and the Rhine passing through the rear of the Oosterschelde. Due to the compartment dams the storage area of the Oosterschelde basin will be reduced to about 80% of its original value. The tidal movement in the estuary was studied by means of field measurements, one- and two-dimensional mathematical models, a one-dimensional electric analogue model, stationary hydraulic models and a non-stationary overall hydraulic model (fig. 4).

Figure 4: Hydraulic model of the Oosterschelde

The boundary conditions of the models were obtained from extensive measurements in the prototype (fig. 5).

Figure 5: Flow measurements near the Philipsdam.

A comparison between the various types of models shows that each type has its specific advantages and specific drawbacks. Numerical one-dimensional network models can be applied when the estuary is mainly composed of gullies separated by shallow areas. Water levels and discharges are the relevant quantities. Two-dimensional numerical models (two-dimensional in a horizontal plane) are used in coastal areas and seas and in wide estuaries where the current direction is not related directly to the bottom geometry. Hydraulic models are applied for estuaries with complex bottom geometries where information about current velocity distributions is very important. It should be stated, however, that recent development in numerical solution techniques make it more and more advantageous to apply

numerical models instead of hydraulic models. However, there is one important exception: near sluices and closure gaps the flow pattern is so very complicated that only a three-dimensional description is adequate.

For the closure-operations of the Brouwershavense Gat (1971) three methods for predicting the velocities were used simultaneously. The concrete caissons could be sunk only during low water slack tide. With higher velocities the forces acting on the caissons would be too large for positioning. A combination of the predictions of the hydraulic model and the electric analogue model Deltar is given in fig. 6 (prediction Deltar).

Figure 6: Predicted (see text) and observed (Orisant) velocities during Brouwershavense Gat closure 27 april 1971.

The observations of nature were used of about one tidal period preceding the closure operation. In the figure also a curve is given of a prediction based on the analysis of the measurements of a large number of tidal curves preceding the operation (prediction Zierikzee in fig. 6). This method in general proved to be somewhat more accurate. An example is shown in the figure. From this example the importance of field measurements can be derived.

Knowledge of tidal movements in an estuary is also important for the study of the salinity since the salinity distribution is mainly influenced by tidal motion and fresh water input. In the case of the Oosterschelde the main fresh water input is controlled by sluices and kept approximately constant. The discharge of the river Rhine into the North Sea may also influence the salinity in the Oosterschelde under certain circumstances. With northerly winds especially, the water from the Rhine forms a large proportion of the coastal water around the mouth of the Oosterschelde. The construction of the storm surge barrier is intended to maintain the ecological function of the Oosterschelde. An example is given in fig. 7, depicting the number of species living in the water as a function of the chlorinity.

Figure 7: Remane-curve: number of species as a function of chlorinity.

This ecological function depends, amongst others, on the salinity which must be kept as high as possible. This suggests that the fresh water input has to be reduced in order to compensate the decrease of salinity intrusion due to the reduction of the tidal motion.

For the study of the influence of the tidal reduction on the salt intrusion several means have been used:

- the hydraulic model of the Oosterschelde with horizontal scale 1/400 and vertical scale 1/100 (fig. 4),
- the two-dimensional depth integrated mathematical model (4) and
- a one-dimensional tidal averaged mathematical model.

The hydraulic and two-dimensional mathematical model can only deal with vertical homogeneous conditions. In the main part of the Oosterschelde this condition is satisfactory. Because of the small fresh water input the longitudinal salinity gradient is too small to create important density currents and stratifications. This is also the case in the present situation with a much larger fresh water supply. The one-dimensional model may also be used for situations where moderate density currents are present, but it needs more information about the mixing processes than the two other models. This information is contained in the longitudinal dispersion coefficient D . It is not possible to obtain a general theoretical expression for the dispersion coefficient as a function of tidal parameters and characteristic geometrical and morphological quantities. For particular transport processes in simple geometrical configurations one may deduce from theory the dependance of D on tidal parameters, yielding $D = \gamma u_0^2 T$. Here u_0 is the amplitude of the tidal velocity and T the tidal period. The parameter γ may still depend on the tidal parameters in various ways according to the considered transport mechanism. Simulations of the present salinity distribution in the Oosterschelde with the hydraulic scale model by means of a permanent rhodamine injection showed that the tidal flushing was larger in the model than in nature, which might be related to the relative large depth of the model. The influence of the tidal reduction on the salinity distribution in the model was in agreement with $D = \gamma u_0^2 T$ with no significant dependance of γ on tidal parameters. Predictions for the salinity distribution were made with the one-dimensional model using a dispersion coefficient reduced proportional to u_0^2 with respect to its value in the present situation. The study of the salt intrusion in the Oosterschelde is focused on the following questions:

- Which constructions are necessary in order to regulate the salinity regime in the estuary?
- How must the locks and the storm surge barrier be operated in order to prevent low salinities?

Possible constructional devices are:

equipment in the locks to keep the salt and the fresh water separated as much as possible during the passage of ships, as will be discussed later on,

connections with other estuaries through which water can be flushed so that circulation in the connected estuaries is increased.

Finally one might consider the possibility of opening and closing certain gates in the storm surge barrier alternately during flood and ebb, stimulating circulatory currents between the different main channels in the estuary.

The use of such interventions depends on the occurrence of external conditions such as intense rainfall or large Rhine discharges in the coastal area. Therefore studies have been undertaken concerning the intensity and the frequency of these circumstances and their influence on the salinity distribution on the Oosterschelde.

In the Philipsdam and Oesterdam, which are to be built in the eastern part of the Oosterschelde, shipping locks will be constructed. These locks

form the connection between the fresh water lake called Zoommeer and the salt Oosterschelde.

The locks are to be equipped with systems to prevent, as much as possible, the intrusion of salt into the Zoommeer and fresh water into the Oosterschelde caused by passing ships. These systems are called fresh/salt-separation systems.

In the Philipsdam five locks will be built, three large locks, dimensions $24 \times 280 \text{ m}^2$, and two small locks, dimensions $9 \times 80 \text{ m}^2$. The fresh/salt-separation system is, like the lock in the Oesterdam, based on the difference in specific weight between fresh and salt water. During the exchanging of salt and fresh water, the interface between it moves vertically. A similar system has already been designed for a lock in the channel of Mardyck near Dunkirk in France and for the Kreekrak-lock in The Netherlands (5).

When designing the locks in the Philipsdam, it became clear that the quality of the fresh/salt-separation system depends strongly upon the stability of the interface layer between the fresh and salt water. This layer needs to be as thin as possible, as the stability diminished with the thickness of this layer.

In the framework of the study for the locks in the Philipsdam, with a hydraulic model, the factors which influence the mixing during the exchanging process have been investigated. The way fresh water flows into the lock chamber through openings in the wall turns out to be an important factor in the mixing process. As the Kreekraklocks have been designed with valves, that are halfway in the culverts through the walls, the locks in the Philipsdam will be equipped with valves that are on the lock chamber side of the wall.

Two-dimensional model studies show that the thinnest interface layers occur when the valves move in such a way during the beginning of the downward movement of the interface layer, when fresh water flows into the lock chamber, that at this moment a situation exists in which a practically resting salt tongue is above the valve, over which fresh water flows towards the middle of the lock chamber. Therefore the movement of the lock chamber depends in principle upon the drop of head of the fresh water through the culverts, and upon the difference in density across the locks.

Model studies (scale 1:20) show that with valves and culverts of the Kreekrak locks, interface layers of approx. 2 m thickness occur while under comparable circumstances with valves and culverts of the Philipsdam locks, this thickness is reduced to approx. 1 m. Compared with the Kreekrak locks an improvement of the quality of the fresh/salt-separation system is expected with the Philipsdam locks system, based on the possibilities of optimizing the movement of the wall culvert valves of the Philipsdam locks.

The lock that is to be built in the Oesterdam and equipped with a fresh/salt-separation system, has a lock chamber area of $10 \times 90 \text{ m}^2$, incidentally to be enlarged to $14 \times 100 \text{ m}^2$ later. This system differs from that of the locks in the Philipsdam, although this system also means that during the passage of ships the water in the lock chamber around the ships changes with closed gates from salt to fresh water or vice versa. The difference, however, is that this exchange in the Oesterdam lock takes place by moving a large basin, filled with salt water, in a vertical direction.

A ship, sailing from the Oosterschelde towards the Zoommeer, sails into this basin, which is surrounded by fresh water. The edges of the basin are about 10-20 cm above level of the fresh water. After entry the gate is closed and the basin moves downward underneath the ship, while fresh water flows around the basin towards the ship (fig. 8). A similar movement in the opposite direction is performed with a ship sailing towards the Oosterschelde. Such a system is called a submersible salt basin lock.

The submersible salt basin system was chosen for the Oesterdam, as the ecosystem of the Oosterschelde, nearest to the Oesterdam, is more sensitive to fresh water than the part of the Oosterschelde near the Philipsdam.

The sediment movement during and after construction of the barrier is important. The sediment consists mainly of fine sand, mean grain size approximately 0.2 mm. Part of the foundation-bed of the piers and part of the layers of the sill have to be constructed in trenches dredged across the riverbed in all gaps. Siltation in these trenches during the construction may lead to the formation of sandlayers, which may be washed out at extreme storm surge conditions due to the very high pressure gradients over the foundation, when the gates of the barrier are closed. If the sand is washed out unequal settlements may occur which will affect the stability of the barrier.

The degree of siltation per construction stage depends on the duration of the stage, on the supply of sediment, on the hydraulic conditions (wave action and flow) and on the shape of the trench. These factors vary along the alignment of the barrier. The amplitude of the tide is about 3 m, maximum velocities are about 1.5 m/sec.

In order to make a prognosis a calculation method should be available to determine the rate of siltations as function of the above mentioned parameters. A mathematical model¹⁾ to determine the siltation in trenches in tidal rivers with mainly suspended load was already available. Application of this two dimensional model is only useful for trenches with relatively gentle slopes of non cohesive bed material in quasi steady flow conditions.

As in the design relatively steep slopes were introduced for the trenches, the mathematical DHL-model had to be adjusted accordingly. An additional adjustment had to be made to assess the effects of the grainsize distribution of the sediment in suspension. Finally, the calculation method had to be adjusted to non-stationary situations in which the time lag of settling respective resuspension has to be taken into account. Oblique flow towards the trenches and currents in bends will cause secondary flows and inherent sediment transport in longitudinal direction.

It soon became clear, that it was impossible to develop a model that could well reproduce the three-dimensional hydraulic circumstances within the fixed period of time. Moreover, it is expected that three-dimensional effects will occur only locally in the immediate vicinity of the banks. It was therefore decided to develop two dimensional models (streamlines perpendicular on the axis of the trenches).

The DHL-model was extended and Svasek Engineering Consultants developed the SGB-model²⁾.

1) developed by the Delft Hydraulics Laboratory (DHL).

2) SGB stands for the initials of the members of the team which set up the model: J.N. Svasek, M.B. de Groot and A.J. Bliet.

Figure 8: Oosterdam ship lock with vertical shiplift 1-3: Ship traveling from the fresh lake to the salt Oosterschelde, 4-5 ship traveling from Oosterschelde to the lake.

Field tests were made to determine the sediment transport across the alignment of the storm surge barrier and the sedimentation of sand during the construction phase. To establish the reliability of the models the results of the computations were tested against field measurements in trial trenches. Current velocities and sediment concentration were measured simultaneously. The grainsize distribution of the sediment thus collected was analyzed. At the same time the boundary conditions for the flow and the sediment transport could be derived from these field measurements. The storm surge barrier will be built in the three flow channels present in the mouth of the Oosterschelde (see figure 9).

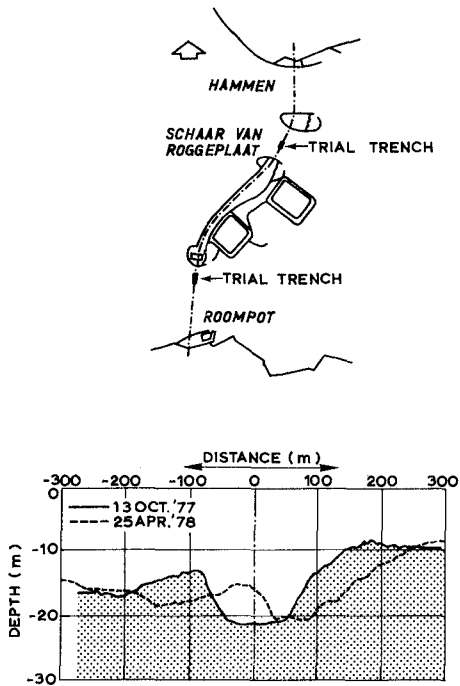

Figure 9: Situation of trial trenches in the mouth of the Oosterschelde. Cross section of trial trench Roompot.

The northern channels, the Hammen and especially the Schaar van Roggenplaat, present a reasonable two-dimensional flow field. The flow field in the Roompot presents a strong three-dimensional character. The two northern channels can be well compared as far as the sediment transport and the presence of a bed protection is concerned. Therefore the result of measurements taken in one of these channels holds also for the other. Measurements taken in a trial trench in one of these channels would be well suited to test the developed mathematical models.

A trial trench was dredged in the Schaar van Roggenplaat as conditions to take measurements there were generally more favourable than in the Hammen. To determine the influence of the three dimensional effects a trial trench was also dredged in the Roompot.

In the trial trench in the Roompot a significant rate of siltation was only found on the steep western slope (1:4); the siltation increased from south to north. Due to the difference in siltation the alignment of the slope rotated and shifted in eastern direction with an average of 0.02 m/day in the southern part and an average of 0.35 m/day in the northern part. As shown in figure 9 the eastern slope was eroded.

The figure shows that the eastern slopes are stable (irrespective of the shifting) and that the eastern slopes are fading away. At the same time on the eastern slope large sand waves have been formed.

Over the whole area of the trial trench in the Schaar van Roggenplaat continuous siltation took place. According to the sounding results a siltation of 0.01 m to 0.02 m/day takes place over the whole of the trial trench Schaar, whereas the area outside the trench remains stable. On the bottom of the trench, ripples were formed up to a height of 0.5 m. In general the slopes of the trenches decrease with time.

In order to gain more insight into the local variations of sediment-increase, divers placed nine measuring tubes in two sections, which protruded right after the installation 1 meter from the bottom.

Periodically the tubes were measured from top to the sand level. It appeared that local significant variations can occur, even more than 0.6 m in a three-day period. This variation is probably caused by migrating bed-ripples.

The rate of deformation of a sandy trench bed was investigated by means of echo soundings. Immediately after having dredged the trial trench in the Roomport, trying to keep the bottom as level as possible, the irregularities proved to be smaller than 20 cm in vertical direction. During the tidal period following the levelling of the trench, ripples were formed up to a height of approximately 1 meter. There was little or no difference between the characteristics of the ripples found one week after dredging the trenches and several months later. The ripples in and adjacent to the trial trench Roompot proved to be approximately twice as high and as long compared to those in the trial trench Schaar, whereas the slopes were more or less equal.

From the results of the field tests and the models, it was concluded that the siltation rate in the trenches will be very high even if short periods are considered. An adaptation of the construction schema was needed so that as many layers of the foundation-bed as possible are constructed in one run. The sandlayers sedimentated in the interval between two runs have to be removed. The period between the removal of the sediment and the next run must be kept very short, less than a few hours. To this end special equipment was developed.

Around 1985 when the Oosterschelde barrier will be completed, the hydrodynamic regime will change and as a result, the sedimentation and erosion pattern will change too.

Under the present conditions the bottom of the Oosterschelde consists mainly of sand. Only the border of the estuary is built up of silt and very fine sand. This area with tidal flats, outer-dike saltings and mudflats, is of very high ecological value. For this reason and because of the use of the shallow areas of the estuary for fishing, a change in silt and clay movement can have important consequences. Silt consists of organic and inorganic matter. Silt can be transported; it is affected by erosion and sedimentation; it can be consumed. The silt concentration is also influenced by mineralisation and primary production. It is obvious that a full understanding of this complex matter is extremely difficult especially with respect to the consequences for the fauna.

As a first approximation a simple erosion-sedimentation-model was used. This model will not supply a new concentration distribution but will merely indicate areas with possible future silt sedimentation. Erosion of a silt layer takes place when the velocity of the current causes a bottom shearstress (τ), larger than a critical value (τ_c). Expressed in terms of shear velocity (v_{*c}) the following relation between erosion and shear velocity is given by Partheniades (6):

$$\frac{dm}{dt} = M \left[\frac{v_*}{v_{*c}}^2 - 1 \right]$$

m is mass of eroded matter per unit area and
 M is constant.

Sedimentation of silt will occur when τ is smaller than the critical shear stress for sedimentation (τ_1).

As the value of τ_1 is smaller than τ_c , there can be a period during the tidal cycle in which sedimentation and erosion are in balance. Krone (7) gives the following relation, expressed in terms of shear velocity:

$$\frac{dm}{dt} = cw \left[1 - \frac{v_*}{v_{*1}} \right]$$

c is concentration of the suspension and
 w is fall velocity.

The constants in the relations are derived from literature and no comparison with field data is yet available. The following values for the constants were used:

$$v_{*c} = 0.03 \text{ m/sec}, v_{*1} = 0.009 \text{ m/sec}, w = 3 \cdot 10^{-4} \text{ m/sec and}$$

$$M = 0.210^{-3} \text{ kg/m}^2/\text{s}.$$

The values of v_* are derived from a one dimensional tidal model.

Figure 10 shows the schematisation of the one dimensional tidal model and the potential silt sedimentation under present conditions. It is remarkable that sedimentation appears only in branches which come to a dead end. This phenomenon corresponds with collected field data. This is also the case for the sedimentation in the channel which was closed in 1972 near the future storm surge barrier. Computations with this simple model show that after completion of the storm surge barrier and the secondary dams the areas with silt sedimentation will expand.

Figure 10: Results of simple siltation model (present situation).

Acknowledgement

The work reported in the paper was performed by the hydraulics division of the Delta Department in close cooperation with the Delft Hydraulics Laboratory .

The author expresses his gratitude to those who assisted him in preparing the paper and are listed below.

CHAPTER 142

PORT OF BRISBANE SILTATION STUDY

N V M ODD

Hydraulics Research Station, Wallingford, UK

and

T BAXTER

Port of Brisbane Authority, Queensland, Australia

SUMMARY

The paper describes the constituent parts of a combined field and mathematical model investigation into the processes causing siltation in the Port of Brisbane. It describes the methods of collecting and using field data and laboratory results in conjunction with a variety of mathematical models which were employed to simulate and predict the interaction of tidal and fluvial flows, saline intrusion and sediment transport in the Brisbane tidal river. A newly developed X-Z-T model was used to simulate the unsteady patterns of mud transport and siltation resulting from the interaction of tidal flows with short flashy fluvial floods, which are the main cause of shoaling in the Port. The paper discusses the structuring of the investigation which involved a carefully phased schedule of desk, field, laboratory and mathematical model investigations with the aim of solving the problem with minimum effort and cost. The paper does not discuss predictions.

INTRODUCTION

The recently formed Port of Brisbane Authority (PBA) is developing new port facilities on Fisherman Islands near the mouth of the Brisbane tidal river. The proposed work in the estuary includes lengthening, deepening and widening the existing swing basin area, and deepening the approach channel. PBA also wish to cease or reduce maintenance dredging upstream in the existing port area some 19km from Moreton Bay, Fig 1. In January 1977, PBA commissioned the Hydraulics Research Station (HRS) at Wallingford in the UK to undertake a field and mathematical model study to determine the processes causing siltation in the Port and to predict the effects of the proposed engineering works on sediment transport and siltation in the tidal river. This paper only deals with the collection and use of the field data in developing a variety of mathematical models for simulating and quantifying the processes causing siltation in the Port. The paper describes the structuring of the investigation which involved a carefully phased schedule of desk, field, laboratory and mathematical model investigations with the aim of solving the problem with minimum effort and cost. It does not discuss predictions.

Mr Baxter is the Assistant General Manager for the Port Authority with responsibilities for planning and development of new port facilities. Mr Odd was responsible for the technical direction of the project at HRS, which had about twelve constituent parts involving fifteen different specialists at HRS. The project also involved a number of staff of the Port Authority who carried out a series of observational programmes in the period 1977/79.

Fig.1 Brisbane River - Port area

Mathematical model techniques were chosen in preference to a physical model because the depositional and erosional properties of muddy sediments cannot be scaled correctly in physical models. The Brisbane study is the first case in which HRS has applied its latest multi-layer (X-Y-T) multi-process, tidal mathematical model, which was developed during the course of the study.

OBJECTIVES OF THE INVESTIGATION

The main objectives of the investigation were to identify, quantify and simulate the processes causing siltation in the navigation channels, swing basins and berths in the seaward reaches of the Brisbane river estuary. And secondly, to predict the effect of capital dredging works associated with port developments at Fisherman Islands and changes in the pattern of maintenance dredging in the existing port area, on siltation in the tidal river.

CONSTITUENT PARTS OF THE STUDY

The study could be considered to be divided into five constituent parts. The type of work and an approximate estimate of the relative effort put into each part of the study in terms of cost were as follows:

	RELATIVE EFFORT(%)	
	HRS	PBA
1. Collection of field data in the tidal river	25	80
2. Analysis of data	25	20
3. Laboratory experiments	5	-
4. Construction and validation of mathematical models	25	-
5. Use of models to predict the effect of engineering works	20	-
	<u>100</u>	<u>100</u>

The above table shows what a large proportion of the effort went into collecting and analysing field data and the relatively small amount of effort that went into the final use of the models to predict the effect of engineering works.

The field studies for the investigation were planned to provide data to determine and quantify processes of tidal propagation, saline intrusion and sediment transport in the estuary, and to validate three types of mathematical model.

HRS supplied the PBA Survey Team with a rapid-drop profiler which was mounted on a fast launch and used to monitor suspended solids and salinity profiles throughout the length of the estuary at regular intervals.

THE BRISBANE RIVER ESTUARY

The river has a typically flashy hydrograph with long periods of practically no flow interspersed with short flood events, which usually occur

in the months between December and April and last on average about twelve days. The tidal regime in Moreton Bay is a mixed one with significant diurnal and semi-diurnal constituents. The M_2 semi-diurnal tidal constituent is the largest one with an amplitude of 0.724 metres.

The tidal compartment of the Brisbane river is narrow compared to its length, which is about 100km from the entrance in Moreton Bay to Mount Crosby weir. The original port was about 30km upstream from Moreton Bay. In 1860, there was a shallow bar across the entrance to the river, and its lower reaches consisted of braided channels. During the past 100 years the channel in the lower estuary has been gradually trained and deepened to accommodate the increasing size of vessels using the Port. The deepest berths have moved progressively seaward during this period.

The dredged channel silts up with muddy sediments at the rate of about 1.5 million cubic metres per annum. The bulk of the siltation being located in the existing port area especially in Hamilton reach (Fig 1). There had been no previous investigation of the physical processes causing siltation in the Port.

INTERACTION OF TIDAL AND FLUVIAL FLOWS IN THE ESTUARY

There are two very well defined conditions that prevail in the estuary. Firstly, in the dry season there are negligible fluvial flows for several months and the limit of saline intrusion moves steadily inland. The estuary is in a vertically well-mixed condition but there are significant longitudinal density currents. In these conditions there are deep, sluggish periodic tidal flows in the port area with peak velocities in the order of 0.5 metre a second, superposed on a longitudinal gravitational circulation.

Secondly, there are short flashy fluvial floods, which last about twelve days with the peak discharge being reached on the second or third days. The peak velocity in the upper estuary may exceed three metres per second and most of the fresh water leaves the estuary via the surface layers flowing over a saline wedge, which forms in the port area. Conditions are very unsteady and strongly dependent on the magnitude and duration of the fluvial flows.

DISTRIBUTION OF BED SEDIMENTS

A study was made of the geology and recent sedimentology of the estuary with the aim of defining the distribution of river bed surface sediment types. A variety of historical data was examined including a mixture of seismic, drilling logs, grab sampling analyses and side scan sonar plots. This historical data was supplemented by a series of new field investigations undertaken by HRS and PBA in the top one or two metres of the river bed. This included collection of bed surface grab samples, vibratory core samples, and bulk density profiles using a radioactive transmission probe.

The main findings of this investigation were that the sediments below the dredged project depth were generally in-erodible rock, gravel or clay. The main silting material in the existing port area is a slightly sandy mud with the following average properties.

Total Bulk Density - 1.3 tonnes/m³
Total Dry Density - 0.5 tonnes/m³
Sand Fraction (60 - 150 microns) about 25% by weight
Bulk Density of Mud Matrix - 1.25 tonnes/m³
Dry Density of Mud - 0.4 tonnes/m³

SOURCES OF SEDIMENTS CAUSING SILTATION

A recurrent problem in all estuarine siltation investigations is the identification of the source of the sediments causing shoaling, namely whether they come from the river catchment or from the coastal region at the mouth of the estuary. This problem was investigated by analysing historical gauging records of discharge and suspended solids at Mount Crosby Weir at the head of the tidal compartment; undertaking velocity and suspended solids sampling in the entrance to the tidal river, and undertaking a radioactive tracer study of the movement of dumped spoil in Moreton Bay.

The main findings of these studies were that fluvial floods carry large mud loads which increase in proportion to the square of the peak discharge, and that the suspended sediment flux at the mouth of the estuary is usually in balance, except in the case of large fluvial floods which flush saline water and suspended sediments out of the estuary. Finally, dredged spoil dumped in Moreton Bay near the approaches to the port hardly moved after an initial period of spreading. However, as usual there was still some doubt about the role of local wave action stirring up mud on the bed of intertidal mud flats which surround the mouth of the estuary.

SUSPENDED MUD LOAD OF THE RIVER

HRS made an analysis of the discharge and suspended sediment records of the Brisbane and Bremer rivers with the aim of determining the frequency and distribution of fluvial flows and the quantities of suspended sediments brought into the estuary. The analysis showed that the river has a typically flashy hydrograph with long periods of practically no flow interspersed with short flood events, which usually occur in the months between December and April. An approximate correlation was established between the mean daily discharge and the suspended sediment load of the rivers. The recent history of the rate of influx of mud (clay particles) from the catchments into the tidal compartment was hindcast by application of the calibrated sediment rating equations to the Mount Crosby Weir flow records for the period January 1972 to August 1977. The analysis showed that the annual influx of mud into the head of the estuary varied from about 30 000 tonnes in 1975 to over 5 000 000 tonnes in 1974. It is estimated that on average about 600 000 tonnes of mud enters the estuary every year from the rivers, which is equivalent to about 1.4 million m³ of siltation. This rate of influx matches the reported long-term average rate of maintenance dredging in the port.

Extreme flood events such as occurred in 1974 tend to flush nearly all their load of suspended sediment into Moreton Bay. Medium floods are incapable of flushing the saline wedge from the estuary and hence a large proportion of the total suspended load, which may be as much as 300 000 tonnes in one flood, is trapped within the estuary by the longitudinal

gravitational circulation and is redistributed and deposited in the deep reaches where the bed stresses are low. The rate of maintenance dredging in the port can be fully accounted for by the influx of suspended fluvial sediments washed down annually by the Brisbane and Bremer rivers, excluding extreme floods such as the 1974 event.

An analysis of the port dredging records showed that in the years prior to the construction of the Fisherman Islands Swing Basin in 1965, over sixty percent of the siltation occurred in Hamilton Reach. There was relatively little maintenance dredging required in any of the reaches seaward of Hamilton Reach. After the construction of the Fisherman Islands Swing Basin there was evidence to suggest that the distribution of maintenance dredging altered so that on average about twenty percent of the siltation occurred in this new swing basin with proportionately less occurring in the Hamilton Reach. HRS are of the opinion that this redistribution can be explained in terms of the gravitational circulation in the port area and the trapping efficiency of the Fisherman Islands Swing Basin.

Although the rivers bring down considerable quantities of sand and gravel in the case of extreme floods, this sediment does not cause a significant shoaling problem in the port area. There is reason to believe that the trapping efficiency of the estuary in its present configuration is high except for extreme floods.

MUD PROPERTIES

A mineralogical analysis of mud from the bed of the tidal river showed that it had an appreciable proportion of montmorillonite, which has a high cation exchange capacity, indicating that it has probably been recently eroded from the land surface. Laboratory flume and viscometer tests were made at HRS to determine the critical stress for the initiation of erosion as a function of the density of the exposed mud layer and the rate of erosion as a function of excess shear stress for erosion varied between 0.1 and 3.0 N/m² for a range of surface densities varying between 0.1 and 0.4 T/m³. The tidal currents near the bed in the port area exert a peak shear stress on the bed of less than about 1 N/m², which is not sufficient to cause erosion of the main body of the mud bed.

Krone¹ has postulated that when flocculated marine muds settle to the bed they form into a series of very thin layers which have shear strengths in the same order as that required to erode it. A consideration of the over-burden pressure exerted by an increasing thickness of these fluffy surface deposits show that they can only be in the order of a few millimetres thick. As a result the only mud available for resuspension in the port are these thin "slack water deposits". During a phase of deposition as each slack water deposit is covered it is consolidated to form the main body of the bed.

An HRS Owen Tube was used to determine the in-situ settling velocity of mud flocks in the estuary as a function of the concentration of mud in suspension. This was found to be negligible in the fresh water region of the estuary and in the range 0.1 - 1.0 millimetres per second in the saline reaches.

SIMULTANEOUS OBSERVATIONS IN THE PORT AREA

HRS and PBA mounted two identical 2-day long intensive simultaneous observations at seven sections between km 4 and km 26 in the port area in the dry season in August 1977 and again during the passage of small fluvial flood in April 1978. An analysis of simultaneous observations of velocity, salinity and suspended solids throughout the depths at the seven sections during spring tides showed that in the absence of wave action very little mud entered the estuary from Moreton Bay. During low fluvial flows the estuary is only weakly stratified. However, the longitudinal density gradients generate small but significant gravitational flows in the landward direction near the bed in the port area. The gravitational circulation tends to hold suspended mud in the middle and upper reaches of the estuary during the dry season. The concentrations of mud in suspension during spring tides in the deep navigation channels were low in the dry season having a maximum value of about 200 ppm. A calculation of the flux of suspended mud passing each section during the flood and ebb phases of the tide at three levels showed that there was a tendency for a net upstream movement of suspended sediment near the bed and a seaward movement near the surface in the port area. However, the net rate of sediment transport was only about 100 tonnes per tide in the upstream direction.

A similar exercise was undertaken during the latter stages of a moderate fluvial flood in April 1978, which is estimated to have carried about 10 000 tonnes of suspended mud into the tidal compartment, increase suspended solids concentration about four-fold at the landward limit of saline intrusion, which was near km 40 and also in the lower layers of the flow in the port area, compared with the dry-season conditions. This exercise showed that very little of the suspended sediment brought down by the river left the estuary.

It appears that most of the fluvial flood water passes fairly rapidly out of the estuary via the surface layers without greatly affecting the longitudinal salinity distribution in the lower layers in the port area. However, there are considerably longer periods of slack-water in the saline wedge near the bed on the ebb tide in Fisherman Islands Swing Basin and in the Hamilton Reach compared to conditions in the dry-season.

Each fluvial flood carries an extra load of mud into the estuary and uniquely and temporarily alters the pattern of tidal propagation, saline intrusion and sediment transport for a period of several weeks. The suspended sediment moves progressively seaward in each tidal cycle until it becomes flocculated by the seawater, periodically eroded, transported and deposited by the tides, and translated by the gravitational circulation until it settles in the deep dredged reaches of the lower estuary where the currents are no longer strong enough to resuspend it.

The rate and pattern of siltation in any one wet season depends on the frequency, magnitude, duration and sediment load carried by each fluvial flood and the manner in which it interacts with the tidal flows. It seems very likely that the sediment brought into the estuary during fluvial floods is reworked and eventually deposited in the deep dredged areas several months after the flood event.

MATHEMATICAL MODELS

Three types of mathematical model were used in the investigation. Firstly, a one-dimensional bulk-flow model was used to quantify the general characteristics of tidal propagation in the estuary, the longitudinal distribution of roughness on the bed of the estuary, the relative flow carrying capacity of the old and new bar cuttings at the mouth of the estuary, peak fluvial flood levels in the estuary and discharge boundary conditions for the second model.

The second one was a steady-state, two-dimensional-in-plan, vertically averaged mathematical model used for the simulation and prediction of peak tidal currents, bed stress and mud deposition patterns in the wide swing basin area at Fisherman Islands between Km 7 and Km 11.

The third one was a two-dimensional-in-depth, laterally-averaged mathematical model of the whole tidal river, which was used to simulate the interaction of fluvial and tidal flows on the scour, transport and deposition of mud in the estuary during flash fluvial floods.

PBA supplied HRS with 1:2500 scale sounding charts of the estuary dating from the years 1974 and 1976. A total of 268 cross-sections were obtained from these charts to provide the basic data for defining the geometry of the estuary in all three models. For the purpose of the bulk flow and two-dimensional in depth model the estuary was divided into 101 storage elements whose length varied between about 500 and 2500 metres, overlapping a similar set of flow or conveyance elements. The results from the survey of sediments in the surface layers of the bed of the estuary were used to prescribe the weight of sand and mud in a series of horizons or layers in each model element.

A viable mathematical model requires sets of equations to describe the processes represented in the model which should be based on well grounded physical concepts and theory and experiments. Certain aspects of the processes of mixing, energy dissipation and sediment transport, as yet, can only be defined by semi-empirical relationships based on field observations and laboratory experiments. The physical equations and functional relationships determine the structure of the model but the results depend heavily on the values of the constants and engineering coefficients applied to a particular calculation. A viable model from the point of view of engineering applications requires an efficient and reliable and accurate method of solution of the equations, giving due regard to the quality of the data and the accuracy required from any predictive calculation. In the case of the Port of Brisbane investigation HRS employed implicit six point finite difference schemes with second order accuracy and a time-step varying between 5 and 10 minutes depending on the particular application of the model. Such a short time-step is required to define the rapidly varying flows and conditions for scour and deposition that occur at the bed of the estuary at certain stages of the tidal cycles.

A model of sediment transport in an estuary requires boundary conditions in terms of water levels and salinities and suspended solids on the incoming tide at the seaward boundary, and the fluvial discharge and suspended concentrations at the landward boundaries. The main problem

in the case of the Brisbane river was defining the salinity and suspended solids at the seaward boundary on the incoming tide during large fluvial floods. The models required a mass of bathymetric and sediment data to define the geometry and distribution and grading of sediments in and along the bed of the estuary. A second mass of field data in terms of water levels, velocity, salinities and suspended solids was required to prove and validate the model for a range of tidal and fluvial conditions.

THE ONE-DIMENSIONAL MODEL OF TIDAL FLOW IN THE ESTUARY

The bulk-flow, area-averaged model of tidal flow in the estuary extended from Km 0 at the Entrance Beacons to the head of the estuary representing both the Old Bar Cutting distributary at the mouth, and the Bremer river a tributary near the head of the tidal compartment. The longitudinal distribution of roughness was adjusted until the model simulated a repeating spring tidal cycle.

The model was then used to simulate a neap spring cycle of tides during the dry season. The results from the model with a smooth bed and with the optimum distribution of roughness were compared with month-long tidal level records made by the Department of Physics at the University of Queensland at nine stations along the estuary in 1974. Both the observations and the results from the model were subjected to a species analysis to define the phase and amplitude of the main constituents of the vertical tide as shown in Fig 2. The length of the tidal compartment is such that the semi-diurnal tide is close to the first resonant mode, with a tendency for the tidal amplitude to increase continuously in the landward direction, as occurred in the case with the smooth bed. However, the middle and upper reaches of the tidal river are hydraulically rough causing a high rate of energy dissipation which damps the resonating semi-diurnal tidal constituents. It should be noted that the muddy bed in the lower reaches of the estuary including the port area acts as an effectively smooth bed, which minimises the shear stress of the bed for a given tidal discharge. A species analysis of the model results showed that the tidal flow in the Brisbane river estuary is mainly semi-diurnal in character as regards the strength of the tidal velocities, which are the main agency for scouring and transporting sediment. The diurnal tidal velocities account for only about 15% of the peak velocities during spring tides. The effect of a high rate of energy dissipation in the middle and upper reaches of the estuary is to keep mud in suspension and to maintain a clear cross-section. The amplitude of the semi-diurnal tidal velocity averaged about 0.5 m/sec over the first 60 km length of the tidal river, except in the vicinity of the swing basins in the port area, where it was considerably lower.

The model showed that the Old Bar Cutting carries only about 10% of the tidal flows entering and leaving the estuary. The tidal discharge at the main run of the flood and ebb phases of a mean spring tide in the Fisherman Islands reach was about 2 600 cumecs. This was used as a boundary condition for the two-dimensional model.

It has been postulated that there is a unique relationship between the peak tidal discharge and local cross-sectional area of an estuary, which is in long-term equilibrium. That is to say that the cross-section is

Fig. 2 Effect of bed roughness on tidal amplitudes

neither silting nor eroding over a period of many years. This condition probably applies to the middle reaches of the Brisbane tidal river. The results of the model did in fact show that there was an approximately linear correlation between peak tidal discharge on spring tide and the local cross-sectional area below mean tide level. The fluvial discharges from the infrequent floods appear to have little effect on maintaining the cross-sectional area below mean tide level. In fact during fluvial floods the water level is much higher. The linear correlation implies that a peak tidal velocity of about 0.5 m/sec averaged over the cross-section is sufficient to maintain equilibrium. The consideration of the actual cross-sectional area in the port area suggests that they greatly exceed the equilibrium area in reaches which contain swing basins.

The bulk-flow model was also used to simulate conditions during the peak of the 1974 fluvial flood event. At a peak discharge of 9,600 cumecs, the water level at the head of the estuary rose over 20m above mean sea level. To achieve a good comparison with observed water levels it was necessary to increase the friction factor of the channel by about 24% compared to the dry season proving tests to allow for the bend losses, which become significant with area-mean velocities exceeding 3.5 metres/second.

X-Y MODEL OF PEAK TIDAL FLOW AND MUD DEPOSITION PATTERNS IN SWING BASINS

A steady-state, two-dimensional-in-plan, vertically-averaged mathematical model was used for the simulation and prediction of peak tidal velocities and mud deposition patterns in the Fisherman Islands swing basin and the Inner Bar Cutting reach. The main purpose of this study was to quantify the velocity and bed shear stress distribution pattern in the turning basin and hence help define future patterns of siltation. The boundary conditions of the two-dimensional model were determined from the results of the aforementioned one-dimensional model of the whole estuary. The model was used to hindcast conditions at times of peak flood and ebb discharges during a spring tide, that is to say 2,600 cumecs. The bed of the estuary was assumed to be smooth and the coefficient of lateral exchange momentum was increased until there was a condition with no significant flow reversal in the re-entrance at either side of the swing basin, as shown by float tracks made in May 1977. The bed stress patterns were used to define areas which would be subject to mud deposition at the peak run of the tide and hence at all other stages of the neap/spring cycle (Fig 3). An analysis of the bed surface sediment types and information supplied by PBA based on experience of the dredge master confirmed that the general pattern of mud siltation simulated by the model for conditions in 1977 in the swing basin agreed with reality. The model was then used to predict conditions for different stages of development of Fisherman Islands Reach. Comparisons were made by comparing the results with the base condition in 1977.

X-Z-T MULTI-PROCESS MODEL OF THE WHOLE ESTUARY

The third mathematical model employed in the study was a two-dimensional-in-depth, laterally-averaged mathematical model of tidal propagation, saline intrusion and mud and sand transport in the whole of the tidal river upstream from the West Inner Bar Cutting Beacons. This is the first case in which HRS has used the model which was developed during

Fig.3 Simulated peak bed shear stress and siltation patterns - 1977

the course of the study as part of HRS's basic research programmes. The method was therefore untried and its application to the Brisbane Siltation Study rather a speculative venture. However, such techniques are the only method of simulating and predicting mud transport and siltation in deep, partially stratified estuaries such as the Brisbane tidal river.

The main purpose of the model was to simulate and predict the interaction of tidal and fluvial flood flows and the resulting pattern of mud transport and siltation for different depths of dredged channels in the port area.

The geometry of the estuary and its roughness were derived from the one-dimensional mathematical model studies, the longitudinal and vertical distribution of bed sediments were determined from an examination of the mixture of seismic, drilling logs, grab sample analyses, sidescan sonar plots, vibratory core samples and density profiles measured with a radioactive transmission probe. The settling properties of Brisbane mud were determined from measurements with an Owen tube in the estuary. The erosional properties of the mud were defined from flume and viscometer tests. The vertical mixing functions employed in the model which took into account the damping effects of saline stratification were based on recent research work² undertaken at HRS.

The tide curve at the seaward boundary was prescribed using harmonic constants determined from long-term records at the West Inner Bar Cutting Beacon. The fluvial discharges into the head of the estuary were based on observations made at the Mount Crosby Weir. The flux of suspended mud into the head of the estuary was based partly on observations and partly on a calibrated sediment load function for the river.

The model was as far as possible based on established laws of physics. However, certain aspects of mixing and sediment transport can only as yet be described by semi-empirical functions based on the analysis of field data. The aim was to prescribe the values of all the various coefficients before the model was used and thereby avoid the complications of a protracted proving process in which the coefficients are adjusted by a trial and error process as has been done in the past. The main unknown was the coefficient of longitudinal dispersion in each of the flow filaments caused by lateral variations in the estuary. However a common scaling factor for the whole estuary was adjusted until the simulated pattern of saline intrusion was in satisfactory agreement with observations.

SIMULATION OF CONDITIONS DURING THE DRY SEASON

Initially, the model was set-up to simulate a repeating 25 hour spring tidal cycle during the dry season. The results from the model were compared with observations made during the simultaneous exercise made in August 1977. This test showed that it satisfactorily simulated the pattern of tidal propagation but there was some difficulty in simulating the absolute values of the salinity in the port area. This was caused in part by the problem of defining the initial conditions from observations solely in the port area and which in the case of the dry season were suspect. However, the model simulated correctly the important features of the pattern of tidal currents in terms of their phase and amplitude throughout the depth (Fig 4). It should be noted that the results from

Fig 4 Tidal velocity profiles in the Port area — dry season

the model refer to laterally averaged values, whereas the observations were generally made at mid-stream in the deepest point of the section. As a result the observed velocities are generally higher than the computed laterally averaged velocities. The two-dimensional model studies demonstrated that there are large lateral variations in the velocity especially in the widened reaches of the estuary. The model simulated the important features of the pattern of suspended mud transport. The actual concentrations in suspension and rate of transport are relatively small and unimportant in terms of siltation in the port. The model simulated how muddy sediment is retained in the estuary by the gravitational circulation, and the longitudinal distribution of siltation in the dry season period. This pattern showed that there are two potential zones of siltation in the dry season, one near the toe of the saline wedge upstream of the port and the second one in the deep port area itself.

SIMULATION OF CONDITIONS DURING AND IMMEDIATELY AFTER A FLUVIAL FLOOD

The x-z-t model was then used to simulate the passage of a moderate fluvial flood that was observed in April 1978 after a long period of low fluvial flows. Such fluvial floods are considered to be the main cause of siltation in the port. The interaction of the tide and such flashy fluvial floods result in a very unsteady pattern of sediment transport which is unique to each flood event and which can be only simulated in an x-z-t type model. The results from the model showed that it simulated all the gross features of the unsteady pattern of tidal propagation, saline stratification and the processes of scour, transport and deposition of mud over a period of about two weeks (Figs 5, 6, 7). The results showed that a large proportion of the load of mud brought into the estuary by the fluvial flood would settle in the upper reaches of the dredged port area. It takes a considerably longer time for the mud to reach the lower estuary than for the fluvial water to be evacuated from the estuary. This occurs because a considerable fraction of the new sediment is periodically resuspended and carried up the estuary in the lower layers on the flood tide, whereas the fluvial water passes fairly rapidly out of the estuary via the surface layers without greatly affecting the longitudinal salinity distribution in the lower layers of the flow. The model showed that the mud trapping efficiency of the port area is enhanced during periods of fluvial floods because there are considerably longer periods of slack-water in the saline wedge near the bed on the ebb tide in the Fisherman Islands Swing Basin and in Hamilton Reach compared with conditions in the dry season.

TRAPPING EFFICIENCY OF THE ESTUARY

The investigation has shown that the trapping efficiency of the estuary and the location and longitudinal distribution of siltation is a function of the volume of each individual fluvial flood and the artificial geometry of the lower estuary imposed by capital and maintenance dredging works. For practical purposes one can assume that most floods in the Brisbane river have a duration of about twelve days and that the volume of flood water is approximately proportional to the peak discharge. The mud load of a flood on the other hand increases with approximately the square of the peak discharge. Observations and mathematical model calculations show that almost the entire sediment load of small and medium

Fig. 5 Longitudinal profiles on flood tide
 - wet season, 4 April 1978

Fig. 7 Pattern of deposition and erosion in Hamilton Reach, 2-12 April 1978

Fig.8 Trapping efficiency of the estuary

floods is trapped within the estuary with little loss to Moreton Bay. The effect of the larger floods is to push the centre of gravity of siltation further seaward and to spread the zone of siltation over a longer reach.

At some critical flood stage, depending on the depth of the estuary, the fluvial discharge is big enough to flush the saline wedge out of the estuary, which allows a large proportion of the mud load brought down by the flood to pass out of the estuary. The flood causing the worst amount of siltation is therefore not the largest one. For example the 1974 flood caused little damage to the port in terms of mud siltation. A consideration of the frequency of given flood events shows that there is some smaller flood which on average causes the most damage to the port. The relationship between the trapping efficiency of the estuary and the size of the fluvial flood is illustrated in Fig 8. The main purpose of the x-z-t multi-process model was to calculate the trapping efficiency of the estuary for a range of flood magnitudes and for several different dredged channel configurations in the lower estuary.

CONCLUSIONS

The paper showed how an analysis of historical data, a programme of intensive field observations using traditional and specialised techniques, laboratory experiments, and a combination of different mathematical model techniques can be used to identify, quantify and simulate the main processes causing siltation in an estuary and be used to predict the effect of engineering works on that pattern.

ACKNOWLEDGEMENTS

The investigation was commissioned by the Port of Brisbane Authority and carried out by the Hydraulics Research Station, Wallingford, UK. Mr N V M Odd was responsible for the technical direction of the project which involved staff from Mr M J Crickmore's Field Studies Section, Dr G V Miles' Coastal, Tidal Hydraulics Section, Mr M F C Thorn's Mud Properties Study Group, the staff of the Port of Brisbane Authority and Mr B M Druery on study leave at HRS from the Coastal Engineering Branch of the Department of Public Works, NSW. Dr J G Rodger was responsible for the development of the x-z-t model and Dr P Cole was responsible for the application of the x-y model. Mr K Mann was responsible for the analysis of the field observations, which were collected under the supervision of Mr C J Teal.

A 3-D MODEL FOR PENOBSCOT BAY, MAINE

by

Bryan R. Pearce¹, Bruce R. Fidler², Adrian C. Humphreys³Introduction

Penobscot Bay is a deep, geometrically complex, partially stratified estuary (Figures 1 & 2) lying on Maine's Atlantic Coast. Like other Maine estuaries, the Penobscot supports economically important fisheries and tourist industries, and is a significant transportation artery. It is frequently proposed as a region suitable for new industrial and port development. Once heavily polluted by upstream paper-mills, the estuary has today been substantially restored by enforcement of discharge regulations under the National Pollution Discharge Elimination System. The goal of this study was to improve our knowledge of

Figure 1: Study Area

³Research Assistant, University of Maine at Orono.

the Penobscot estuary's circulation patterns, as an important factor in maintaining the estuary's water quality and economic resource capacity. A previous effort to model Penobscot Bay (Fidler, 1978) laid the foundation for this study, but concentrated on instantaneous tidal velocities, and was hampered by a shortage of data suitable for model tuning and for comparison of modelled output. The present study concentrated on modelling residual currents, which are somewhat more interesting than instantaneous currents from the point of view of pollution control. In addition, an extensive data set, hitherto largely unanalyzed, became available for tuning and comparison.

The numerical model "GAL" was applied to a 36 km by 51 km rectangular grid covering the entire lower estuary from Fort Point to the southern end of Vinalhaven Island (Figure 3). Developed by Pearce, et al (1978), it is a three dimensional model which has a finite difference formulation in the horizontal but is continuous in the vertical. Model inputs are bathymetry, vertical eddy viscosity, wind velocity, tidal excitation at the seaward boundary, and a river inflow. Model outputs are current velocities at each grid element for specified depths, velocity profiles and net drift information.

Data

The National Ocean Survey collected current data at 37 stations in Penobscot Bay during the spring and summer of 1969; at 103 stations in 1970. In addition, extensive salinity/temperature data was taken coincidentally with the 1970 current survey. Photo-Geodyne meters were used during the 1970 survey; several stations had up to five meters on a mooring. Monitoring periods ranged from a few days to three months. Because of the coincident density information and larger data set available, most of the data analysis was conducted on the 1970 data and particularly on those stations which had simultaneously collected data during the period 23 May to 6 June.

Maximum recorded velocities were 1.3 kts (0.67 m/s) at the near-surface meters at the mouth (southern end) of the bay, which if reduced by a factor of 0.25 to allow for wave rectification, means that actual maximums were on the order of 1 knot (0.5 m/s). In general, the current records were dominated by the semi-diurnal tide, although the near-surface records (meters positioned at 4.6 meter depth) were quite noisy, due to wave action on the surface buoy that was typical of the mooring installations.

In order to examine the residual current characteristics of the estuary, progressive vector plots were made of the data at those stations with the same record period (21 May to 8 June). A typical set of plots is shown as Figure 4. The resultant vector in each case (drawn from the origin to last point of record) represented the residual current with tidal components removed. The resultants are plotted in Figure 5 and indicate the general pattern of the residual circulation in the estuary. Bold arrows indicate data taken during the indicated time period; light arrows show data taken during non-coincident time periods, but also in

the spring. Residual speeds are on the order of 1 to 5 kms/day (1 to 6 cms/sec), and generally trend down estuary in the upper layers and up-estuary in the low layers, although station 201 presents an anomaly at several depths.
