RESTON, VIRGINIA 20191-4400
Abstract: This proceedings, Coastal Engineering 1998, contains over 270 papers presented at the 26th International Conference on Coastal Engineering which was held in Copenhagen, Denmark, June 22-26, 1998. The proceedings is divided into five parts: 1) characteristics of coastal waves and currents; 2) long waves and storm surges; 3) coastal structures; 4) coastal processes and sediment transport; and 5) coastal, estuarine, and environmental problems. The individual papers include such topics as the effects of wind, waves, storms, and currents as well as the study of sedimentation, erosion, and beach nourishment. Special emphasis is given to case studies of completed engineering projects. With the inclusion of both theoretical and practical information, these papers provide the civil engineer and professionals in related fields with a broad range of information on coastal engineering and coastal processes affecting design and operations in the coastal zone.

Cover photo and all photos on section breaker pages 71, 1153, 1393, 2263, and 3373 provided by Danish Hydraulic Institute.
Foreword

The Editor would like to acknowledge the work of the Local Organizing Committee in developing a very successful conference. Being a member of the LOC brings the amount of work required to develop and conduct a successful conference into sharp focus. Nevertheless the members of the LOC worked tirelessly to ensure the success of the ICCE98. In addition to the Local Organizing Committee, the work of the eight members of the technical review panel were critical to selecting the highest quality papers to be presented. Each reviewer was responsible for a critical review of 310 abstracts, of the total 640 abstracts submitted, in a very brief period of time.

The ICCE's are very special in bringing together people from around the world concerned with coastal engineering. Through this conference many special relationships and friendships have been developed. With the addition of the internet to our communication it is very easy to stay in touch with friends developed at the conferences. One very special friend of the ICCE and the many people from around the world who attended these conferences was Professor Yoshito Tsuchiya. He became seriously ill immediately before the 26th ICCE, preventing him from presenting his paper, and he passed away on October 14, 1998. Because of his long and dedicated service to the leadership in the coastal engineering community, the Proceedings of the Twenty-sixth Conference is dedicated to Professor Tsuchiya.

The next ICCE will be held in Sydney, Australia, 16-21 July 2000. ICCE 2000 promises to be a unique opportunity to see Australia including the Great Barrier reef, Uluru (Ayers Rock) and Kakadu National Park, three natural wonders of the world. The 28th ICCE will be held in Cardiff, Wales, 7-12 July, 2002. The 29th ICCE will be held in Lisbon, Portugal, in 2004, and it will be followed by the 30th ICCE in San Diego, California in 2006. Updated information can be obtained from the ICCE web page at http://www.coastal.udel.edu/coastal/icce/. Two special people deserving of recognition are Joyce Hyden and Becky Edge. They continue to support the conference and the preparation of the Proceedings and communicate with authors. They both have unselfishly given time and energy to producing the databases from which the conference and Proceedings are maintained and over the years have developed a network among those who contribute papers to the Conference. To the above and to the many others who have helped to produce these Proceedings, I again say "Thanks."

Dedication

Professor Yoshito Tsuchiya

Professor Yoshito Tsuchiya was a leader in Coastal Engineering in Japan and Asia for many years before becoming involved in the International Conference on Coastal Engineering and the IAHR conferences. He has worked with numerous researchers from outside Japan including Ole Madsen, Richard Sylvester, James Tarrent, John Herbich and David Basco. Although many of his contributions during his thirty-year career were related to wave dynamics, his made contributions in the areas of storm surge, tsunami, beach processes and shoreline restoration. Professor Tsuchiya was born in Nagano Prefecture, Japan, in 1930 and studied at Nagoya Institute of
Technology and Kyoto University where he served from 1961 until his retirement in 1994. In 1968 he became affiliated with the Disaster Prevention Research Institute (DPRI) at Kyoto University and became its director in 1991. While at the DPRI he designed and constructed the offshore research tower at Shirahama and the field research pier at Ogata which are both in continuing service.

After his retirement in 1994 from the DPRI, which still carries forth largely in the directions he established, he became a Professor of Meijo University in Nagoya. While at Kyoto University he supervised 29 doctoral students. He was also well noted as an expert at a card game named "Koi-Koi" which his students and colleagues such as Dr. Ole Madsen at MIT came to respect. In spite of his dedication to his work, he found time to enjoy golf at least once a month with his wife Shoko. We will miss his contributions in coastal engineering research and most importantly his friendship and motivation. Prof. Tsuchiya passed away on October 14, 1998 and left a long list of accomplishments and an equally long list of assignments for his colleagues to continue.
Acknowledgements

Local Organizing Committee
Conference Chairman:
Torben Sørensen, Danish Hydraulic Institute (Chair)

Organizing Committee:
Jens Kirkegaard, Danish Hydraulic Institute (Secretary)

Introduction

A Coastal Engineering Conference is a forum for exchange of technical and scientific ideas and progress in our professional field of activities. How can it make sense in this context to talk about the Art of Coastal Engineering?

I believe it does. Sedimentary coastlines exposed to the dynamic and ever varied effects of waves and currents constitute such an intricate interaction between land and sea that understanding and describing this environment in predictive terms require almost an artistic approach that starts with observation of nature, intuition and imagination before one can proceed to scientific analysis and description.

Through the last 50 years our capability to subject this environment to scientific analysis has increased tremendously, helped by the development in technology, especially the hydraulic laboratories, the computers and sensors, and by the impressive advances in the knowledge of sediment transport under the action of currents and waves as well as in the description of the hydrodynamics of the coastal environment. While the importance of an artistic approach to the problems and tasks of coastal engineering is still significant, one may well say that today coastal engineering is much more a science than an art.

This was not the case 100 years ago. At that time the most important elements of coastal engineering were experience, visual observation of nature, and intuitive understanding and inspiration developed from previous works and features of nature. Of course the engineers of that period strove to express their understanding and ideas in mathematical and scientific terms, and sometimes with remarkable success, as we shall see, but experience and the artistic elements were still of dominating importance.

---

1 Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark, Fax: +45 45 179 200, e-mail: ts@dhi.dk
Except for the most southern part of the North Sea coast the tidal range of astronomical tides is virtually negligible, being in the order of 10 to 30 cm. Extreme water levels are therefore dominated by storm surges, which may reach levels of 1.5 to 2 m above MSL, and are strongly correlated with strong winds from certain directions. The directions causing high water, respectively low water, are of course site specific, and most often - but not always - high water levels occur simultaneously with severe wave action.

The absence of large tidal ranges made it quite simple for Danish engineers of more than 100 years ago to realise that littoral drift - coastal erosion and sedimentation - was totally dominated by the wave action. In contrast to many other places in the world they were not confused by the presence of strong tidal currents running parallel to the coast, and the storm surges - except for the cases of straits connecting large water basins - generally generate only relatively weak currents parallel to the coast.

These conditions, in combination, made Denmark a very good "laboratory" for studying coastal sediment transport in full scale as generated by waves. In those days the technology of physical scale modelling for engineering purposes and research had not been developed. The engineers had only one possibility: To go out in nature and observe before, during and after severe wave action. And this they did, sometimes at an impressive scale, with the advantage that they understood that what had happened was caused by the waves and the currents generated by the waves in and shoreward of the breaker zone.

**Denmark - a Full Scale Laboratory for Coastal Hydraulics**

![Figure 1: Denmark – between the North Sea and the Baltic Sea.](image)

To understand why coastal engineering is and has been such an important and exciting challenge to Danish engineers a glance at the map of Denmark, Fig. 1, would suffice.
Nowhere in the country you are more than about 60 km from the nearest seacoast. Moreover, virtually the entire country is made up of sedimentary soils of marine, fluvial or glacial origin, and as such prone to littoral drift along its coasts to a variety of scales.

The country is located around the centre line of the varying locations of the polar front separating the polar air masses from those of the sub-tropic region giving rise to the development and passage of numerous low-pressure weather systems. These are particularly strong during autumn and winter, but can occur at any time of the year, and they generate predominantly westerly winds. This, together with the fact that Denmark is located at the eastern side of the North Sea, causes the Danish North Sea coast to be in the class of the most dynamic coastlines on an international scale in terms of littoral drift - up to 1 million cu. m. per year.

On the Danish coastlines in the regions East of Jutland the wave climates are less severe because of fetch limitations (up to 200 km). Even so the littoral drift on many parts of these coastlines is in the range of 10,000 to 100,000 cu. m. per year.

The Danish Coasts

The North Sea coast of Jutland offers good illustration of the challenges met and taken up by Danish coastal engineers towards the end of the last century and in the beginning of the present century.

The two first examples from the North Sea coast are of a similar nature. They represent schemes to prevent flooding of low-lying farmland in the coastal fiords - or rather lagoons - Ringkobing Fiord and Nissum Fiord, and at the same time stabilise the entrances to these lagoons and provide road connection across the stabilised entrances. In both cases the entrances were stabilised by means of breakwaters, and the entrances were provided with sluices for discharging the water supplied to the lagoons by rivers, as well as sluices allowing the passage of relatively small vessels.

The works are illustrated by Figs 2 and 3, which are photos taken in recent years. The dramatic coastal development in terms of accretion and erosion caused by these works is clearly visible and has led to the construction of additional breakwaters and groynes, and to nearshore breakwaters for erosion protection, as well as in recent years to substantial sand bypassing and beach nourishment.

Therefore, I have chosen to illustrate the Art of Coastal Engineering by giving examples of the achievements of Danish coastal engineers of 100 years ago. This presentation thus could also have been given a more modest title to reflect this content, but I thought that since, in my opinion, the element of art continues to be important for good coastal engineering and should not be forgotten, I chose the more ambitious title for the presentation.
The works at Hvide Sande at Ringkøbing Fiord became the first hydraulic engineering works in Denmark to be studied in a small physical model built at the Technical University of Denmark in the 1930ies.

Another dramatic situation controlled by engineering works for more than a century is the case of the Thyboron inlet, Fig. 4, which has been described and discussed at various Coastal Engineering Conferences over the last 40 years. The extensive documentation of the development of the coastal profiles provided by annual soundings carried out over more than 100 years has formed the basis for several engineering studies, including
Professor Per Bruun's doctor's thesis of 1954, and studies carried out under the auspices of various committees established by the Danish government.

Figure 4: Thyborøn. The inlet is to the left.

All three cases initially constituted experimenting in nature, and all three of them, but especially the case of Thyborøn, have generated observations and documentation providing much food for thought for contemporary and later coastal engineers.

To the East of Jutland the most severely exposed coastline in the country is that of the North coast of Zealand, on which a number of fishing harbours/marinas and beach landing places protected by offshore breakwaters were built around the beginning of this century. One of these, the port of Hundested, will be the subject of a more detailed discussion below.

The Concept of Island Harbours

Building harbours on open coasts with sediment transport has been known for centuries to give rise to problems of sediment accumulation and erosion around the works. Already in Roman times this was realised, and Roman harbours, such as Ostia, Tarentum and Antium, were built with openings in the breakwaters running crosswise to the coastline in an attempt to let the littoral drift bypass the harbour behind the main breakwater, albeit without much success.

In an attempt to radically solve these problems, engineers, especially in the UK and France, in the middle of the 19th century, developed ideas for proper island harbours, i.e. harbours in the form of a "hollow" island connected to the shore by an open bridge providing minimal obstruction to the littoral drift. Several projects of this nature were
developed and presented by imaginative engineers, but few of them ever built, and some of those that were built had breakwaters parallel to the coastline that were so long in relation to the distance from the coast that the harbour basins were completely filled up, such as the port of Ceara in Brazil, built in 1887, Figs 5 and 6.

Figure 5: Port of Fortaleza, Ceara, Brazil, 1887.

Figure 6: Sand accumulation around Port of Fortaleza, 1895.

Quite naturally, the concept of island harbours caught the interest of Danish coastal engineers because of the need in our country to build harbours on coastlines with littoral drift. In the second half of the 19th century several such harbours were constructed, one of them being the port of Arnager built in 1884 on the South coast of the island of Bornholm in the Baltic Sea, Fig. 7. This harbour is a good illustration of the understanding,
developed at the time, of the importance of placing the harbour at a relatively large
distance from the shoreline to avoid the formation of a tombolo that would eliminate the
character of an island harbour. This harbour still exists, and is still an island harbour.

Figure 7: Arnager Harbour, Bornholm.

However, heated discussions went on in the Society of Engineers of Denmark between
the believers and the non-believers in island harbours, and these discussions were
extensively reported in the Society’s monthly journal. To try to get to the bottom of this
the Ministry of Public Works in July 1902 appointed an expert commission of three
engineers with the task of considering whether and under what circumstances island
harbours would be a suitable solution in lieu of harbours protruding from the coastline.

The commission submitted its deliberations in a hand written report to the Ministry in
November 1903, which was published in lithographed form in view of the general interest
in the subject. A printed version was published in 1909.

The 1903 Commission Report

The report starts with a remarkable overview of projects and ideas for island breakwaters
and island harbours from many countries, including the UK, France, Belgium, Canada,
Italy, USA, South Africa and Brazil. In this way the commission demonstrated that it
realised the need to look beyond national experience in search of knowledge and
inspiration, just as we are doing today through the International Conferences on Coastal
Engineering. It came, however, to the conclusion that on the international scene proper
island harbours (not island breakwaters) were all proposed to be placed so far offshore
that they were located outside of the zone of coastal sediment transport, for which reason they became so expensive that none of them were ever built.

The question facing the commission with regard to the suitability of island harbours for Danish conditions was therefore whether such harbours could be built inside the zone of coastal sediment transport and yet not be blocked by accumulating sand, and the commission states as its first observation that it considers it to be self-evident that this can be achieved, provided that the width of the harbour in the direction parallel to the coastline is not too large and the connecting bridge is sufficiently open.

The commission then proceeds to describe the Danish experience with island harbours as illustrated by three case histories described in considerable detail. One of these is that of Arnager, Fig. 7, which clearly satisfies the condition for success formulated by the commission.

In the report the commission presents a general description of sediment transport as caused by currents and waves, respectively, in the course of which they make some - for the time - remarkable observations. For instance, they distinguish clearly between bed load transport and suspended load transport, and in the case of transport by currents alone they observe that for clay or mud a current velocity of ½ ft. per sec. will move the material, while for small pebbles a current velocity of 3 ft. per sec. is required for transport to commence.

In the case of waves they observe that waves do not transport material as long as their motion is of an oscillating character only, while the breaking waves do cause sediment to be transported, especially, as they state in so many words, due to the longshore currents generated by the breaking of the waves.

They then proceeded to develop a formula describing the littoral drift capacity of waves represented by a littoral drift vector, or - as they more appropriately call it - a “wave-effect rose”. Although the reasoning behind this theory is, of course, open to criticism, the result is nevertheless remarkable. They conclude that the littoral drift is proportional to the square of the wind velocity times the square root of the fetch (provided that the fetch is less than 300 nautical miles) times the frequency of occurrence of the wind (velocity and direction) considered, and they represent this wave effect in a vectorial form, Fig. 12. This is not very different from what was developed some 40 years later by engineers in other countries.

The commission's studies of the concept of island harbours located inside the zone of coastal sediment transport is also remarkable. It concentrates on the case history of the port of Hundested, which was - and probably still is today - by far the most well-documented such case history.
The Island Harbour of Hundested

Hundested is located on the coast of North Zealand at the eastern side of the entrance to the Isefiord, see the map of Denmark, Fig. 1, and the map of the Isefiord entrance, Fig. 8. The coast at the site of the port is actually facing West, and the littoral drift on this coast is southward, probably in the order of a few thousand cu. m. per year.

![Figure 8: Isefiord entrance and approaches to Hundested.](image)

The site has the special feature of being located at the relatively narrow strait between the sea North of Zealand named Kattegat and the large basin of the Isefiord. The winds in the sector West to North, which cause the southward littoral drift, are strongly correlated with storm surge high waters in the Kattegat resulting in strong southgoing currents in the strait, while the return flow from the fiord to the sea takes place after the wind has abated or turned towards easterly directions. Thus there is a strong correlation between severe wave action and strong currents in the southgoing direction.

The bathymetry of the entrance to the Isefiord, Fig. 8, clearly reflects these conditions. It may be added that the southgoing currents are generally stronger along the western part of the entrance, while the northgoing currents are stronger towards the eastern side near the location of Hundested.

The first harbour facility was built in 1868 as a 60 m long stone breakwater with a quay on the South side. It quickly got virtually buried in sand, Fig. 9. In 1886 a small octagonal harbour basin was built at the end of this breakwater, but sand accumulation quickly occurred around the harbour and in front of the entrance, Fig. 10. Even in the harbour basin sand accumulated, chiefly by passing through and over the stone breakwaters, to such an extent, that rumour has it, you could grow potatoes in the harbour!
Figure 9: Hundested Breakwater, built in 1862. Subsequent sand accumulation indicated.

Figure 10: Hundested Harbour, 1886. (Bathymetry from before 1862).
After these frustrating experiences and costly futile efforts to develop a usable harbour at Hundested the leading proponent of island harbours in Denmark, engineer Hans Zahrtmann, was commissioned to design the conversion of the port into an island harbour, Fig 11, in the hope and expectation that this would solve the problems of sedimentation around and in the harbour. This conversion into an island harbour was completed in 1892 by replacing the connecting stone breakwater with a wooden bridge, and at the same time the harbour breakwaters were reconstructed so as to prevent sand from passing through the breakwaters.

![Figure 11: Hundested Island Harbour and depth soundings 1893-1896.](image)

During the years 1893 through 1896 the bathymetry in a considerable zone around the harbour was surveyed every spring and every autumn, clearly for no other purpose than to study the effect of the harbour's conversion into an island harbour. Such soundings were also made in the autumn of 1898, the spring and autumn of 1902 and in January 1903. An example of results from these soundings is shown on Fig.11.

Between the harbour and the original coastline a tombolo shaped formation remained, and the commission, in addition to calculating the "wave-effect rose", also attempted to calculate the shape of the tombolo based upon diffraction calculations!

The studies demonstrated that the island harbour concept was indeed in this case effective. The sand accumulation between the harbour basin and the original coastline was quickly broken through, and the accumulation of sand at the harbour entrance was substantially reduced.
Figure 12: Wave-effect rose and tombolo formation at Hundested, Report of 1903.

Figure 13: Hundested Harbour, 1900.
In 1900 a small outer harbour was constructed, Fig. 13, probably chiefly to provide better shelter for the fishing boats in the harbour basin, but possibly also in the hope of further reducing sand accumulation at the harbour entrance, and in 1907 the wooden access bridge was replaced by a reinforced-concrete structure, Fig. 14.

![Access bridge to Hundested Harbour.](image)

Detailed study of the numerous soundings - at a larger and more readable scale - shows interesting features observed by the 1902 commission, including the fact that between the harbour and the coast, sand tended to accumulate during the calmer summer season, and to be eroded during the winter, as well as various other interesting features. In the context of the present presentation the most interesting point, however, is the extent to which engineer Zahrtmann and others used observations and measurements in nature in a much similar way as today where we use a hydraulic scale model test.

The development of the port of Hundested did not by any means stop in 1907. During the First World War a large outer basin was constructed as a general cargo and ferry traffic port, and in the 30ies further expansions were implemented, Fig. 15. On this figure careful scrutiny can identify the remaining portions of the breakwaters of 1886 and 1900. Already the expansion made during the First World War caused the tombolo to connect the harbour to the shoreline and to bury the concrete bridge in sand, such as was indeed predictable on the basis of the analysis of the 1902 commission. However, this tombolo did not have any negative effect because by this expansion the new outer breakwaters reached out so far that the strong outgoing currents after severe storms were capable of keeping the entrance region free of sand deposits so that after this expansion virtually no maintenance dredging has been required.
Further expansions have followed after the Second World War, and it is quite possible that all of these expansions and the associated economic development might never had materialised if imaginative and courageous engineers of the turn of the century had not exercised to the best of their ability, and with success, the Art of Coastal Engineering.
The European Research Programmes in Coastal Engineering
by
Hans-Werner Partenskeky

1. General Introduction

Since 1989, the European Union has established a number of scientific programmes to promote and coordinate a wide range of activities such as transport, fisheries, environment, tourism, etc. which also have an impact on the coastal zone.

The efforts of the European Commission to promote an overall concept of Integrated Coastal Zone Management (ICZM) encompass activities from the research carried out under the Marine Science and Technology programme (MAST) to the Environment and Climate programme (ENV).

2. The MAST-programme

The MAST-programme (Marine Science and Technology) has grown in three stages: first as a pilot programme (1989-92, budget ECU 50 million), then as MAST-II (1991-94, budget ECU 118 million), and finally as MAST-III (1994-98, 244 million ECU). From the start, coastal zone science and engineering has played an important part among the areas covered by the programme, absorbing about 20% of the budget. In the on-going MAST-III, coastal zone research will receive about 50 million ECU.

According to the detailed contents of the first pilot programme, the objectives of coastal zone research were: "to strengthen European research in coastal processes, thereby allowing for better management of resources and for engineering designs; to provide the information and data required for application of modern tools in coastal management, such as mathematical numerical modelling; to advance and harmonise design of coastal..."
engineering works and to help prepare for the consequences of the currently predicted rise in sea level in the next century" /1/.

Up to now, the MAST-programme has focussed on two areas of coastal zone research: morphodynamics and coastal structures.

Coastal morphodynamics refers to the fact that the state of a sandy coast is a manifestation of the dynamic system which is formed by the water motion (waves, currents), the sediment motion and the bed topography. These elements mutually interact in a highly dynamic, non-linear way. As a result, the behaviour of a coast is not a straightforward response to the inputs (storms, tides, etc.), but includes the effects of complex forms of autonomous behaviour at a variety of length and time scales. Examples of such autonomous behaviour are the formation of beach cusps, nearshore bars, sand waves, channel/shoal systems, etc. This makes the predictive modelling of coastal morphodynamics a complicated task /2/.

In coastal engineering, MAST supports work both on hard structures (rubble mound breakwaters, berm breakwaters, monolithic vertical walls, etc.) and on soft options (beach nourishment techniques, maintenance of intertidal flats, salt marshes and other defence mechanisms where Nature performs the actual work). The aim is to improve criteria and guidelines for the design of structures or schemes in a manner, which ensures reliability, economy and environmental compatibility. Here, research again covers a wide range of issues, such as overtopping, scouring, wave impact forces on caissons, the role of biological factors in the consolidation of cohesive sediments, etc. /3/.

Under the MAST-umbrella, leading European hydraulic institutes have set up, for the first time, systematic cooperation projects on issues that are too complex to be tackled individually.

At the beginning, there were, of course, some difficulties in bringing the scientific ideas and basic approaches of University laboratories together with the more mission-oriented research aspects of commercial and governmental institutes. However, very soon an excellent cooperation was established between the partners from universities and government research institutes, with the common aim of promoting European research and knowledge in coastal engineering.

Six European institutes participated in the project on coastal morphodynamics as the main contractors: Delft Hydraulics, HR Wallingford, Danish Hydraulic Institute, Sogreah Electricité de France and the Technical University of Braunschweig. In addition, 26 associated contractors from European universities, state laboratories and consulting companies participated from Italy, Great Britain, Ireland, Spain, Denmark, France, The Netherlands, Belgium, Norway and Portugal.
Five European institutes participated as the main partners in the programme on coastal structures: The Franzius and Leichtweiss Institute, HR Wallingford, Delft Geotechnics, University of Sheffield and Delft University of Technology. The research work was in addition supported by 18 associated partners from Denmark, Great Britain, Spain, The Netherlands, Italy, Germany, France and Norway.

3. Scientific Results of the Morphodynamics-Project

The morphodynamics-project was subdivided into several sub-projects dealing with waves, currents, non-cohesive sediment transport, cohesive sediments and morphodynamics, respectively. The project also had a structure of working groups addressing cross-discipline problems such as wave-current-sediment interaction.

The morphodynamics-project had the following focal points:

1. medium-term coastal profile modelling,
2. medium-term-coastal area modelling,
3. rhythmic features ("bars and banks"), and
4. long-term modelling.

Fundamentally different approaches were used: process-based simulation models for the medium-term applications, mathematical stability analyses for the rhythmic features and a range of more or less empirical large-scale modelling techniques for the long-term modelling.

3.1 Medium-term coastal profile models

The work on medium-term profile modelling concerned the evolution of the coastal profile in the case of longshore uniformity. These PC-based models are based on state-of-the-art knowledge of waves, current and sediment transport and their interactions with the changing bed topography.

Special attention was paid to bar formation, taking into account phenomena such as non-linear wave kinematics, low-frequency waves, the wave breaking process, undertow and induced streaming, bottom boundary layer effects, sloping-bed effects, sediment transport mechanisms and sediment sorting effects. A range of profile models was intercompared and tested against laboratory data, mainly from the Large-Wave-Flume-facility in Hannover. These models were extended, improved and validated against data from other laboratory and field experiments /4/. Figure 1 shows an example of measured and computed beach profile evolution /5/.
The availability of comprehensive data sets for validation of the profile evolution is an prerequisite for morphodynamic modelling. Therefore a significant effort was spent on getting access to new data. For field data, a link was made with the MAST-project NOURTEC, which concerns the coastal response to underwater nourishment /5/. Other field data were obtained from the German coast and from El Saler Beach, near Valencia, Spain. A valuable set of laboratory data for model validation was obtained from a series of experiments in Delft Hydraulics' Delta Flume.

3.2 Medium-term coastal area models

There are many situations in which the assumption of longshore uniformity does not work and the coastal profile modelling approach is an over-simplification of reality. In such cases, a coastal area model is needed. Process-knowledge, modelling know-how and software implementation of this type of model is much less advanced than in the profile case, because of the extra complexity due to the second horizontal dimension. Also, there is a need for field and laboratory data to help develop and validate coastal area morphodynamic models. The effort, which this requires, is beyond the capacity of most research projects. This is why the validation of coastal area models was based, so far, on model intercomparisons for hypothetical cases and on comparisons with small-scale laboratory experiments /7, 8/.
Although the necessity to include 3-D effects is obvious, the morphodynamic modelling is still far from operational. Instead, some 2-D depth-integrated models have reached a level of operational use.

Figure 2 shows, as an example, the results of a coastal area model with the morphological response of the shore-line due to a shore-parallel breakwater for different angles of wave approach /5, 6/.

![Figure 2: Morphological changes behind a shore parallel breakwater for different angles of wave approach. Results of a morphological model of DHI /5, 6/.

3.3 Rhythmic features

The main focus in the domain of rhythmic features was the analysis of free instabilities of the morphodynamic system. This involved non-linear analyses of wave-induced bed-ripple patterns, formed by turbulent boundary layers and effected by grain sorting and steady drift, but also much larger features, such as tidal sand banks, sand waves and shore face ridges. Such an analysis, including the 3-D velocity field, revealed the essential mechanisms of the formation of large-scale rhythmic features on a horizontal seabed (sand banks, sand waves or tide-parallel ridges).

One example concerns sand waves on the seabed which can influence the effective depth of navigation channels. Here the deepening of the channel might lead to higher sand waves and to a smaller effective depth.
3.4 Long-term modelling

The driving factor behind the work on long-term modelling is the need for knowledge and model concepts with the scales of long-term/large-scale phenomena. There are practical as well as theoretical arguments for not relying exclusively on medium-term models to bridge the gap between the scales of the existing process knowledge and the scales of interest.

Large-scale modelling must be considered as being in an early stage of development. Only recently, new data-abundant monitoring techniques have been developed which enable us to study phenomena at time-scales up to a decade with a resolution of hours. These techniques are now being deployed all over the world and they are producing results, which offer perspectives to the use of advanced analysis techniques from other disciplines. For the time being, long-term modelling is still a matter of a number of ad-hoc models for specific applications /9, 10/.

3.5 Present and future projects on morphodynamic modelling

At present, research on morphodynamic modelling is being carried out in projects on large scale modelling (PACE), shore nourishment techniques (SAFE), tidal inlets (INDIA) and nearshore dynamics (SASME). Underlying processes are further investigated in several sub-projects /2/.

In a large field programme field data are gathered to support and validate the morphodynamic models.

The results of the research work carried out so far in the MAST-programme on morphodynamics have been published in over 460 papers, in reports, theses, congress proceedings and papers in journals. In addition, a special volume on the project was issued in 1993 in Coastal Engineering /9/ and the scientific results obtained are summarised in a book in preparation from De Vriend /10/.

Some of the software for the morphodynamics model concepts is commercially available through the big hydraulic laboratories, which participated in the projects (Delft Hydraulics, Danish Hydraulic Institute, HR Wallingford, etc.).

4. Results of the MAST-project on coastal structures

The first large European project on Coastal Structures was co-ordinated by HR Wallingford in 1990 - 1992. This project created strong links between European research groups and formed the basis for the following MAST-projects /11/.
Monolithic coastal structures, coordinated by H. Oumeraci, Techn. Univ. of Braunschweig/Germany.

Rubble mound breakwater failure modes, coordinated by H.F. Burcharth, Aalborg University/Denmark.

Full-scale dynamic load monitoring of rubble mound breakwaters, coordinated by J. De Rouck, Univ. of Ghent/Belgium.

Berm breakwater structures, coordinated by J. Juhl, Danish Hydraulic Institute/Denmark.

Reflection of waves from natural man-made coastal structures, coordinated by M. Losada, Cantabria Univ./Spain.

The following MAST 3 projects are ongoing as a continuation of two of the above mentioned projects /12/: 

Probabilistic design tools for vertical breakwaters, coordinated by H. Oumeraci, Techn. Univ. of Braunschweig/Germany.

The optimisation of crest level design of sloping coastal structures through prototype monitoring and modelling, coordinated by J. De Rouck, Univ. of Ghent/Belgium.

### 4.1 Monolithic coastal structures

For the stability calculation of monolithic structures the wave loading must be known. Although the front face geometry of a caisson is very simple, the wave pressures are very complicated functions of the sea state.

The character of the force histories and the pressure distributions due to breaking waves have therefore been intensively studied in the Hannover Large Wave Flume of the Universities of Hannover and Braunschweig /11/ (Figure 3).
In the tests, four principal breaker types could be distinguished (Figure 4) /13/. The highest wave impact as well as horizontal force at the structure occurs when waves are breaking against the breakwater.

Figure 3: Cross-section of the Large Wave Channel in Hannover /11/.

Figure 4: Classification of breaker types and loading cases /13/.

Here, two cases must be distinguished: Waves with an almost vertical front hit the breakwater (Figure 5), and breaking waves with an entrapped air pocket under the overturning tongue (Figure 6).
Phase 1: Wave approaching the wall
Phase 2: Wave before hitting the wall
Phase 3: Maximum wave impact on the wall

Figure 5: Breaking of wave without an enclosed air pocket /15/.

Phase 1: Beginning of wave breaking at the wall
Phase 2: Compression of enclosed air volume
Phase 3: Maximum wave force against the wall

Figure 6: Breaking of wave with an enclosed air volume /15/.

The first case has up to now been considered the most unfavourable condition with the highest impact force at the structure. Figure 7 shows the development of the dynamic pressure distribution at the structure during the wave impact. The maximum pressure occurs slightly above the mean water level. The impact duration, however, is very short (t \leq 0.02 \text{ s}) and in general not long enough to displace the structure (Figure 8).
Figure 7: Development of the dynamic pressure distribution at the structure during the wave impact /15/.

Figure 8: Duration of impact pressure /15/.

A theoretical distribution of the impact pressure is shown in Figure 9 /14/. However, this pressure distribution is only valid for a completely rigid structure without structural elasticity. In case of a displacement of the breakwater under the wave impact the resulting horizontal wave force will be considerably dampened.
The displacement or reaction of a caisson-like structure under the wave impact is dependent on the kind of foundation, its structure and on the duration of the wave impact. Figure 10 shows some types of vertical and composite breakwaters.

In order to determine the reaction of a caisson under wave impact, some systematic tests were carried out in the Large Wave Flume in Hannover with an instrumentated caisson that has accelerometers for vertical and horizontal motions, pressure cells for impact and uplift pressures as well as pore pressure cells in the foundation (Figure 11) /14). The tests...
showed only small displacements of the caisson due to the wave impact. However, depending on the breaker characteristics, the caisson oscillated with periods of 0.06 to 0.08 s, leading to structure oscillation amplitudes of 0.5 to 1.0 mm /13/.

In another series of tests, the second case of a breaking wave with an entrapped air volume was investigated. Here, the pressure and force diagram generally showed two peaks with a time interval of approximately 0.02 to 0.03 s (Figure 12). The second peak was in this case caused by the compressed air volume. Depending upon the amount of air enclosed, the second peak pressure was in some cases higher than the first.

---

**Figure 11**: Cross-section of the caisson model with installed instrumentation /14/.
Figure 12: Horizontal impact force due to a breaking wave with an enclosed air pocket /11/.

This means that the wave impact with an entrapped air volume can under certain conditions be the most unfavourable case for the structure. When the time lapse between the two peak forces is in the same order of magnitude as the natural period of the structure itself, the consecutive wave impact could initiate a structural oscillation. The same applies for the low-frequency force oscillations following the peak values (Figure 12). The test results showed that the force oscillations have a period in the range of 0.3 to 0.7 s (Figure 13) /13, 14/.
Figure 13: Pulsation Period of an entrapped air pocket versus height of breaking wave /14/.

Figure 14 shows the natural periods of some vertical structures which have been determined by means of a dying-out test /15/. As can be seen, the natural periods of vertical coastal structures lie partly in the same order of magnitude as the force oscillations due to the wave impact.
In addition, wave loads on crown walls were investigated. For the crown wall stability, the simultaneous wave induced pressures on the front face and the uplift pressures had to be analysed. A first systematic study of wave forces on crown walls of different heights including the influence of water level, berm height and width is presented by Pedersen /16/. The results comprise the statistics of the horizontal force, the tilting moment and the wall base pressure, providing the basis for stability calculations of the crown wall.

Based on experience from offshore platform designs and on extensive advanced laboratory soil tests, some guidelines for the design of foundation under caisson structures have been presented. The work continues and will probably result in sets of constitutive equations necessary for numerical stability calculations.

4.2 Rubble mound breakwaters

In a world-wide survey of existing breakwaters carried out in 1992 by an International Working Group of PIANC, some 150 rubble-mound and composite structures were investigated and the observed damage was analysed. The results showed that damage varied from slight to about 100% and occurred to more than 25% of all breakwaters under investigation. The most spectacular cases within the last 15 years, with high damage or complete failure, were those at Sines/Portugal in 1978, Arzew/Algeria and San Ciprian and Bilbao/Spain /17/.
This damage and these failures show clearly that the existing design criteria for these structures are still inadequate and must be replaced by new approaches in which not only the hydraulic stability of the cover layer, which is generally composed of artificial armour units (Figure 15), is considered, but also the structural resistance of the individual armour unit against breaking due to rocking and displacement under wave impact as well as the geo-technical stability of the foundation. Figure 16 shows a typical cross-section of a rubble-mound breakwater with a crown wall.

Figure 15: Artificial armour units for the cover layer of rubble-mound breakwaters.

Figure 16: Typical Cross-section of a rubble-mound breakwater.
The MAST-projects of the European Union were closely coordinated with the activities of the PIANC-working groups /12/. In particular wave overtopping, wave run-up, wave reflection, internal porous flow and pore pressure distributions have been tested in different laboratories. Special attention was payed to the displacement of armour units (Accropodes, Tetrapods, Cubes, hollowed Antifer cubes, etc.) and the breakage of slender concrete armour units (Dolosses, etc.). Corporation between Aalborg University, Techn. University of Delft, Franzius-Institut and WES/USA resulted in formulae for a number of broken units /12/.

The breakage of slender units depends on the wave height, the interlocking effect between the unit blocs and on the strength of the concrete. For this reason prototype measurements of concrete strength in Tetrapods and Dolos units were carried out in Italy /18/. In addition, the effects of thermal stresses, solar stress and fatigue on the strength of the concrete in the armour units were investigated /12/.

The structural resistance of Tetrapod-blocs was investigated in the Franzius-Institute / University of Hannover. Static tests, pendulum tests and drop tests were carried out with Tetrapods of different sizes (Figure 17 and 18). Figure 19 shows a summary of the investigations performed. The results showed that for increasing wave heights the structural resistance of the armour units required bloc weights higher than those determined by the HUDSON-formulae. These investigations must be continued for other kinds of slender armour units (Dolos, etc.).

Figure 17: Set-up for static tests with tetrapods of 250 kg and 1.8 t.
4.3 Berm breakwaters

A Berm breakwaters is a rubble-mound breakwater with a berm above the still water level on the seaward side. During exposure to wave action of a certain intensity and duration, the berm reshapes until a final equilibrium profile on the seaward face of the breakwater is reached (Figure 20). The advantage of this type of breakwater is that the average armour rock size required for the structure is in general smaller than for a traditional rubble-mound breakwater /19/.

In order to study the physics of berm breakwaters, their profile development as well as the stone transport at the trunk and the roundhead stability, eight European institutes from Denmark, The Netherlands, United Kingdom, Norway, Italy and Iceland participated in a joint research project co-sponsored by the European Commission under the second research and development programme MAST II (1994-1997). In addition, physical processes involved in the hydraulic and structural response of berm breakwaters under wave attack were examined, and a predictive numerical model for wave interaction with
berm breakwaters developed. The results obtained were in good agreement with prototype measurements (Figure 20).

Figure 19: Summary of the laboratory tests performed with tetrapods.
A summary of all the results obtained in the MAST-project can be found in the final report of JUHL, J. et al. on “Berm Breakwater Structures” of May 1997 /19/ as well as in a number of individual papers /12, 20, 21, 22, 23/.

4.4 Probabilistic failure mode analysis

The basic principle in reliability analyses is that the probability of damage is assessed for each failure mode. On this basis it is possible to estimate the safety or reliability of the whole structure by system analysis.

In each failure mode analysis all the load and resistance parameters are treated as stochastic variables. Consequently, it is necessary to introduce the uncertainty of these parameters, e.g. on the sea-state parameters (load) and the soil/strength parameters (resistance). The uncertainties with the parameters are given by their probability distributions. For most parameters a normal distribution with a certain standard deviation is used. The same holds for uncertainties concerning formulae. Most often a safety-index method is used for the estimation of the damage probability related to each failure mode /24/.

---

**Figure 20: Comparison between measured and computed reshaped profiles of a berm breakwater /19/.
On the basis of extensive numerical simulations the PIANC working group developed a system of safety factors for most of the rubble mound breakwater failure modes and for the overall stability failure modes related to caisson breakwaters. Verification of the use of the coefficients in a fully dynamic analysis will be checked in a MAST-project and the system will be extended to include important local structure failure modes for caisson breakwaters.

### 4.5 Publications on breakwater research programmes

The results of the research work carried out in the MAST-projects on breakwaters and coastal structures have been published in a great number of papers in congress proceedings, scientific journals, internal reports and in theses. A summary of the findings on wave impact on vertical structures is found in the report of H. Oumeraci et al. on "Coastal structures - overview of MAST2-projects" /11/ and on rubble mound breakwaters in the book of H.F. Burchardt on "Reliability-based design of coastal structures" /24/.

### 5. Future research required in coastal engineering

The results of the different MAST-programmes have certainly essentially contributed to the solution and understanding of coastal problems and to the safer construction of coastal structures.

However, there are at least some main problems which must be dealt with in coastal engineering in the next decades /25/:

1. The effect of the predicted rises of the sea water level on existing and future coast protection works as well as on the human community. (According to the latest predictions the water level rise in the next 100 years will be approximately 0.60 m/100 years, Figure 21).
2. The deposit of contaminated dredging material from harbours and navigation channels.

3. The increasing thermal and waste water pollution of tidal rivers, estuaries and near-shore coastal regions.

The predicted global sea level rises up to the year 2050 vary considerably, they have nevertheless sent alarming signals to all countries bordering the oceans /26/. Here more investigations are needed, based on reliable prototype data, in order to narrow the gap between the results of statistical approaches and interdisciplinary studies by means of mathematical models.

This opens a wide field of new activities for the coastal engineer in the future. All problems to be solved are more or less linked to the adaptation of coast protection measures to the rising mean sea level. Examples in this respect are the development and construction of new harbours and access channels to them, the modification of existing jetties, the exploration and exploitation of marine resources as well as the reduction of pollution in estuaries and near shore regions, - to name a few.

The deposit of contaminated dredging material from navigation channels and harbours represents a world-wide problem for all countries bordering the sea. Here, methods must be developed to process the contaminated material in order to make it usable for reclamation purposes.

On the other hand, hydraulic measures must be investigated to reduce the annual maintenance dredging quantities in existing navigation channels as well as in the access channels to seaports.
The tendency of new industrial plants to be constructed on the coast as well as on tidal rivers and estuaries leads to a steady increase of thermal and wastewater pollution in these areas. The cooling water systems of industrial factories and conventional as well as nuclear power plants, when designed as fresh water systems, cause increasing thermal pollution in these coastal regions due to the discharge of heated cooling water into the ambient bodies of fresh or sea water.

In addition, the continuous wastewater discharge from communities, harbours and industrial factories into coastal waters must be considered a very serious problem in environmental engineering. Therefore, intensive further research on pollution problems must be carried out in estuaries as well as on the interaction of rivers and ocean regions /25, 26/.

In addition, international standards of permissible loads should be elaborated and measures to reduce the environmental impact must be developed.

However, there is still another problem in which coastal engineering and environmental engineering is closely related. Our present population on Earth amounts to approximately 6 billion, but shows a steady increase of some 300,000 people per day /27/. Our present population will therefore double in about 50 years, i.e. in the year 2050 a total of approximately 12 billion people must be expected on Earth (Figure 22).

![Figure 22: Increase in world population and rates of daily increase /25, 26, 27/.](image-url)
This enormous increase in population in the near future has produced alarming signs for the whole of mankind, since the available food and water resources as well as the limited resources for the production of energy are not sufficient and will be used up at a steadily increasing rate.

This certainly involves a great number of future problems in which also the coastal engineer has a world-wide task.

In addition, the increasing demand of our population for leisure and recreation requires the urgent preservation of existing natural beaches as well as the creation of new, artificial resorts. This means that new methods must be developed and tested to sustain and protect our sandy coasts from erosion by means of artificial beach nourishment, stabilisation of the bar-systems as well as by use of tombolo-effects (Figures 23, 24, 25).

**Figure 23**: Beach nourishment on the Island of Sylt / Germany /25/.

**Figure 24**: Principle of beach nourishment on the Island of Sylt /25/.
Ladies and Gentlemen, the time is certainly not sufficient to discuss all aspects of future research required in coastal engineering.

However, the presentation of the present European Research Programmes already shows that international cooperation is required to solve a few urgent problems in our field. It is hoped that the already existing connections of our European research laboratories with scientists of overseas countries such as Japan, USA, Canada, Australian, etc. will be intensified in the years to come because the solution of the before mentioned world-wide problems, I have mentioned, need the international collaboration of all scientists and research institutes in the world.

Abstract

A limited review of methodologies for design and prediction of beach nourishment performance is presented and some recent results of the evolution of the total plan area of a nourishment project on a long straight beach are examined. The emphasis is on rather simple approaches which may be more applicable for preliminary design and screening of candidate designs rather than final design. Most beach nourishment projects are placed at slopes that are steeper than equilibrium. Thus the project is initially out of equilibrium both in the planform and profile. The simple approaches represent the planform evolution and cross-shore processes separately. Planform evolution can be represented by the Pelnard Considère equation, which in addition to providing a basis for representing the performance of a particular design, also provides a good overall basis for understanding the behavior of beach nourishment projects. Several solutions of the Pelnard Considère equation are examined and some of the general results obtainable from this equation are presented and discussed. Particular results include the insensitivity of evolution to storm sequence, the reduction of spreading "losses" due to refraction around a planform anomaly, relative insensitivity of planform evolution to wave direction for nourishment sand that is compatible with the native, and the effects of nourishing on beaches with sand coarser and finer than the native. Profile evolution is best modeled over short time scales when the profile is significantly out of equilibrium. Limited observations indicate that profile equilibration time scales associated with over-steepened nourished profiles are on the order of 5 years. Application of equilibrium beach profile methodology demonstrates the sensitivity of additional dry beach width to sand size. Recent results of the evolution of the total plan area of a beach nourishment project are presented. It is found that nourishment with sands coarser and finer than the native, results in total plan areas that increase and decrease, respectively, with time.

1 Professor, Coastal and Oceanographic Engineering Department, University of Florida, PO Box 116580, Gainesville, Florida 32611-6580
Because the results obtained considering nourishment sands of a single size are unrealistic, a method is applied in which the nourishment sands are characterized by two sizes of different proportions. The results for this approach are more reasonable and consistent with expectations.

**Introduction**

Beach nourishment comprises the placement of large quantities of good quality sand on the beach to advance the shoreline seaward. In most cases, beach nourishment is applied in areas where erosion exists and thus the effect of the nourishment is to restore the beach to a position which it occupied at some previous time. The erosion compensated by the nourishment can be due to natural causes or may be due to a littoral obstruction placed updrift of the area of concern or other human-induced causes. In such cases, in addition to beach nourishment, it is important to attempt to minimize any human causes of erosion. This most likely action would be bypassing of sand around a constructed obstruction or removal of the obstruction.

The earliest beach nourishment projects in the U.S. were placed in the 1930's along fairly short stretches of beaches as "projects of opportunity." These projects of opportunity usually occurred at locations where substantial volumes of good quality sand were available from some other project, such as the excavation of a harbor. For many years starting in the 1950s, the recommended approach to addressing beach erosion was structures usually in the form of groins to trap sand from the littoral system. With greater development of the shoreline, the adverse impacts of structures built in one area became more apparent in another and there was a transition from the use of structures to softer approaches, namely beach nourishment. Often there are only two options for stabilization of areas facing beach erosion. One option is armoring such that the erosion is limited by the armoring. The second is beach nourishment which has the potential to both advance the shoreline seaward and to restore the natural characteristics of the eroded beach.

With the increasing value of the shoreline and its popularity for both residential and commercial development and recreational purposes, and the loss of the beach as an environmental resource if armoring is carried out, beach nourishment becomes a much more attractive option. However, the future of beach nourishment faces serious challenges. One of these challenges is the availability of large quantities of good quality sand within a proximity that will allow the economic placement of these sediments on the eroded beaches. The second challenge which has emerged is in the environmental arena and includes concerns regarding the potential adverse impacts of beach nourishment. Although a significant number of beach nourishment projects have been monitored to quantify both their physical and biological performances, questions remain. Undoubtedly, these will only be resolved through careful monitoring and interpretation of many future beach nourishment projects.
A Limited Review of Beach Nourishment

When a beach nourishment project is placed, the initial profile slopes are usually steeper than those of the equilibrium profile and the nourishment planform represents a perturbation which is out of equilibrium. Thus the beach nourishment induces both cross-shore and longshore sediment transport, see Figure 1. One of the principal challenges facing the coastal engineer in the design of such projects is the reasonable prediction of the time scales associated with both the profile and planform equilibrations. This paper considers the evolution in the longshore and cross-shore directions separately although, of course, in actuality the evolution of these two components proceeds simultaneously and may be interrelated.

Figure 1. Sand transport “losses” and beach profiles associated with a beach nourishment project.
In general, there are two approaches to the design and performance prediction of beach nourishment projects. The first which will be the main subject of this paper is through the use of relatively simple models that readily allow estimation of the physical performance of such projects. The second, which will be discussed only briefly, involves the application of much more complicated numerical models in which the particular wave climate can be introduced as well as any specific initial planform and complicated boundary conditions. Of course, in the application of either level of model, it is important to ensure that the proper boundary conditions and forcing functions are applied. In the following paragraphs, we will address a number of planform models and describe their applications to various situations.

**Simple Models of Planform Evolution**

The simple models of planform evolution are based on the so-called Pelnard Considere Equation which is the result of combining the linearized sediment transport equation with the continuity equation, resulting in

\[
\frac{\partial y}{\partial t} = G \frac{\partial^2 y}{\partial x^2}
\]  

in which \(y\) is the displacement of the shoreline from some reference baseline, \(x\) is the longshore coordinate of that baseline defined as positive to the right of a seaward looking observer, \(t\) is time and \(G\) is the so-called "longshore diffusivity" defined as

\[
G = \frac{K H_b^{5/2}}{8(s-1)(1-p)(h_*+B)}
\]

In Eq. (2), \(K\) is the sediment transport coefficient (usually taken as 0.77, but more likely a function of sediment size), \(H_b\) is the representative breaking wave height, \(g\) is gravity, \(\kappa\) is the ratio of breaking wave height to water depth (=0.78), \(s\) is the ratio of specific weight of the sediment to that of the water in which it is immersed and \(p\) is the in-place porosity. The quantities \(h_*\) and \(B\) are the depth to which the sediment is mobilized and the berm height, respectively. Eq. (1) is the classical heat conduction equation for which many solutions exist. Several useful solutions are reviewed in the following paragraphs.

**Initially Rectangular Beach Planform**

The solution representing placement of an initially rectangular beach nourishment project on an infinitely long beach is useful both for preliminary design and pedagogical purposes. The solution for this case is

\[
y(x,t) = \frac{Y}{2} \left\{ \text{erf} \left[ \frac{\ell}{4\sqrt{Gt}} \left( \frac{2x}{\ell} + 1 \right) \right] - \text{erf} \left[ \frac{\ell}{4\sqrt{Gt}} \left( \frac{2x}{\ell} - 1 \right) \right] \right\}
\]  

(3)
in which \( Y \) is the initial beach width and \( \ell \) is the project length. It can be shown that the portion of material remaining in the area placed, \( M(t) \), is related to the parameter, \( \sqrt{Gt/\ell} \), as follows

\[
M(t) = \frac{\sqrt{4Gt/\ell}}{\sqrt{\pi}} \left( e^{-\left(\frac{\sqrt{Gt/\ell}}{\sqrt{\pi}}\right)^2} - 1 \right) + \text{erf}\left(\frac{\ell}{\sqrt{4Gt}}\right)
\]

(4)

This equation is plotted in Figure 2 where it is seen that the volume remaining within the region placed decreases rapidly at first and then decreases much more slowly. Eq. (3) or (4) can be used to investigate the longevity of a project in terms of the variables causing changes. Examining Eqs. (3) and (4), it is seen that the proportion of material remaining at any time, \( t \), is dependent on the variable \( \sqrt{Gt/\ell} \). We can select any proportion remaining and determine the life of that project in terms of the relevant variables. As an example, if we select a proportion equal to 50% of the material placed, then the associated time is the so-called "half-life" of the project. We see that the value of \( \sqrt{Gt/\ell} \) associated with an \( M \) value of 0.5 is 0.46. Solving for the half-life, \( t_{50\%} \), we find that

\[
t_{50\%} = \left(\frac{0.46}{\sqrt{G}}\right)^2 \frac{\ell^2}{G}
\]

(5)

Using reasonable values for all variables but leaving breaking wave height, \( H_b \), and project length, \( \ell \), arbitrary, Eq. (5) can be simplified to the following

\[
t_{50\%} = K' \frac{\ell^2}{H_b^{5/2}}
\]

(6)
where $K'' = 0.179 \text{ years}^{-5/2}/\text{km}^2$ for $l$ in kilometers, $t_{50\%}$ in years and $H_b$ in meters. For purposes here, the values of $K$, $h_*$, $B$, $S$, $p$, and $g$ were taken as 0.77, 7 m, 2 m, 2.56, 0.35 and 9.81 m/s$^2$, respectively. As an example of the application of Eq. (6), if the project length, $l$, is 1 kilometer and the associated wave height, $H_b$, is 1 meter, the half-life is 0.18 years, i.e., slightly in excess of 2 months. However, if the project length is 10 kilometers and the wave height is 1 meter, the project life is 17.9 years.

Other Initial Planforms

Due to the linearity of Eq. (1), solutions exist for many initial planforms. Walton (1994) has developed the solution for a trapezoidal planform. Larson, et al. (1997) have developed solutions for many additional initial planforms.

Nourishment on a Barrier Island

An example of interest is that of an initially rectangular nourishment on a barrier island in which the nourishment can extend to the limits of the barrier island at an inlet or the nourishment can be set back from the inlet. In this case, approximating the shoreline displacement as zero at the inlet is the most logical boundary condition. The results for an initial nourishment extending along an entire barrier island are presented in Figure 3 in which the results are compared with a shoreline of infinite length. The advantages

![Figure 3](image-url)
of nourishment on a long beach are clearly evident since the effect of an inlet is to cause the sand to be drained off much more rapidly. Figure 4 shows the proportion remaining for different lengths of the nourishment relative to the length of the barrier island.

![Figure 4](image)

Figure 4. Proportion remaining, $M(t)$, for nourishment ends sent back from ends of a barrier island.

Additional Characteristics of the Pelnard Considère Approach

There are several additional characteristics associated with or results obtained from application of the Pelnard Considère approach that are worthy of note.

**Wave Refraction Effect.** It can be shown that because the placement of a beach nourishment project on a long straight shoreline results in a planform anomaly that causes wave refraction, the effect of the waves "wrapping around" the planform anomaly is to reduce the value of the longshore diffusivity, $G$, by the ratio $C_b/C_*$, where $C_b$ is the wave celerity at breaking and $C_*$ is the celerity at the depth to which the nourishment extends. In some locations, this effect can increase the longevity of the project by 40%.

**Sequencing of Storms.** Our previous discussions have considered the wave height appearing in the longshore diffusivity term to be constant. However, it is seen that it is the product of the longshore diffusivity and time that is relevant to the project evolution (cf., Eqs. (3) and (4)). It is readily shown that on a long straight beach the sequencing of storms is irrelevant to the evolution of a nourishment project. Rather it
is \( \int_0^t G(t) \, dt \) that governs the evolution of a project. Stated differently, it is the general cumulative energy loading due to the waves affecting the project that causes the project evolution. Appealing to the same fundamental property of the Pelnard Considère Equation, it can be shown that it is possible to quantify an "effective wave height" \( H_{\text{eff}} \) to represent any sequence of waves (Dean and Yoo, 1992).

**Innsensitivity to Wave Direction.** For the case of beach nourishment with compatible sand on a long, straight beach, the planform evolution is very insensitive to reasonable ranges of wave direction. This can be seen by noting that Eqs. (1) and (3) do not include any effect of wave direction. Dean and Yoo (1992) have carried out detailed numerical modeling and compared these results with the simple method applied here. It was shown that the simple approaches provided a good approximation to the more detailed and complex approaches which include the effect of wave direction.

**Nourishment with Sands that are Finer or Coarser than the Native.** Dean and Yoo (1994) have shown that nourishments with sands that are finer or coarser than the native result in centroid migrations of the nourishment planform in the downdrift and updrift directions, respectively.

**Nourishment on a Seawalled Coast.** Beach nourishment along a coast that does not have any sand available for transport will migrate in the downdrift direction and the planform length and centroid migrational speed will increase with time (Dean and Yoo 1994).

**Multiple Nourishments**

In the case of multiple nourishments and in the absence of background erosion, renourishment intervals required to maintain a particular minimum volume within the nourishment area will increase with successive renourishments. The interpretation is that after the first nourishment has spread out to some degree and renourishment occurs, the subsequent evolution is the superposition of the continued spreading out of the first nourishment and the spreading out of the second nourishment. Because the first nourishment is now an effectively longer project, it will lose material much more slowly, see Figures 2 and 5. Thus the aggregate rate of loss is less than it was for the first nourishment and the duration before the next required renourishment is increased. Thus, the periods between subsequent renourishments increase with the renourishment number. However, it can be shown that in the presence of background erosion, the periods between successive renourishments can increase for low renourishment numbers, then decrease for successive nourishments. The explanation, though rational, is complicated.

**Effect of Background Erosion**

Beach nourishment projects usually take place in locations where a substantial background erosion has been operative. In evaluating the evolution of a nourishment
Figure 5. Renourishment characteristics. No background erosion. Breaking wave height = 0.5 m, project length = 6 km, $h_\text{B} + B = 9$ m, $V_{\text{max}} = 3,000,000$ m$^3$, $V_{\text{min}} = 2,000,000$ m$^3$. (From Dean, 1985).

Project it is important to account for the background erosion, usually by superimposing the losses due to planform spreading and those due to background erosion. The background erosion is usually due to gradients in the longshore sediment transport. The reasons for these gradients are poorly known and in general it is difficult to calculate the background erosion unless it is due to a major perturbation such as construction of a littoral barrier. Figure 6 shows the effect of background erosion for an initially rectangular nourishment project on a long straight beach. The vertical axis is the product of the background erosion rate, $e$, and time, $t$, divided by the initial uniform additional beach...
Figure 6. Isolines of $M(t)$ vs spreading and background erosion parameters, $e =$ erosion rate, $\Delta y_0 =$ initial equilibrium shoreline displacement, $G =$ longshore diffusivity and $t =$ time. Long straight beach.

width, $\Delta y_0$. The proportion of sand remaining in the nourishment area, $M(t)$ is a function of time (represented on the horizontal axis) and different amounts of background erosion relative to the initial planform width (represented on the vertical axis). For a background erosion rate of 0, the values of $M(t)$ along the horizontal axis correspond to Figure 2. It is noted that for non-dimensional erosion values greater than 0.2, the portion of material remaining in the project area, $M(t)$, becomes negative after a non-dimensional time (horizontal axis) of approximately 1.5.

Detailed Numerical Models of Planform Evolution

As noted previously, the main advantages of numerical planform models over the simple models described earlier is their ability to represent time varying forcing functions, arbitrary initial planforms, and background erosion distribution and to represent complex boundary and internal conditions as might be associated with a field of groins. Another very significant advantage is the capability to incorporate all available knowledge of mechanisms and detail into the numerical model.

There are two predominant levels of detail of numerical models of planform evolution. For these models, it is not necessary to linearize the transport equation as was done for the simple models. The most direct is the one-line model in which it is assumed that the beach profile responds by moving seaward or landward without change of form in response to gradients in the longshore sediment transport. The next level of complexity includes the cross-shore transport through a so-called “n line model” in
which a number of contours is represented or a model that represents the area of interest by a series of cells. The advantage of representation by a series of cells is that bars are readily represented whereas this is quite complicated with an n-line model. An example of a one-line model is GENESIS (Hanson, 1989; Hanson and Kraus, 1989) and an example of an n-line model has been presented by Perlin and Dean (1985).

Models of Profile Characteristics

There are two issues that will be discussed in relation to the evolution and form of nourished profiles: equilibration time and equilibrium dry beach width.

Equilibration Time

The first issue is the time required for equilibration and will be treated only briefly here. Profile equilibration time is significant because an observer may interpret the results of this equilibration (narrower beach) as a loss of material and a consequent poor performance of the project. Thus it is incumbent on the engineer to inform and educate the client and the general public of the expected equilibration and associated narrowing of the dry beach width due to this process which can be especially rapid due to major storms. It has been our experience that the equilibration times for beach profiles placed steeper than normal are on the order of 5 years to achieve approximately 50% of the equilibration. This is based in part on our 7 year monitoring program of the beach nourishment project at Perdido Key, Florida in which approximately 4.5 million cubic meters of compatible sand were placed along the beach.

Equilibrium Dry Beach Width

The second issue related to profile considerations is the equilibrium effect of using sands which are of different sizes than the native. For this purpose, methodology developed for equilibrium beach profiles (EBP) is especially useful. The simple form of the EBP is that found initially by Bruun (1954) and later explored by Dean (1977, 1991)

\[ h(y) = Ay^{2/3} \]  

in which \( h \) is the water depth at a distance, \( y \), from the mean sea level shoreline and \( A \) is the so-called “sediment scale parameter” which depends on the median sand size, \( D \). Moore (1982) examined many profiles from nature and laboratory tests and developed the relationship between median sediment size, \( D \), and the sediment scale parameter, \( A \), as shown in Figure 7. For ease of application, the \( A \) values in Figure 7 have been tabulated for 0.01 mm increments of the usual beach sand size range in Table 1.

It is well known that consistent with Eq. (7) and Figure 7 beach profiles associated with coarse sands are steeper than those associated with fine sands. Applying the concepts of equilibrium beach profiles, (Dean 1991) has shown that 3 types of equilibrated nourished profiles are possible as shown in Figure 8. Commencing with the upper
Figure 7. Variation of sediment scale parameter, A, with sediment size and fall velocity (Dean 1987 modified from Moore, 1982).

</table>
Figure 8. Three generic types of nourished profiles. (Dean, 1991)
only occur if the nourishment sand is finer than the native. Figure 9 shows the effect of nourishing with equal volumes of sands that are coarser than, equal to, and finer than the native. Progressing from the upper to lower panel, it is clear that sediment size is a critical parameter in terms of the volumes required to obtain a particular additional dry beach width.

Figure 9. Effect of nourishment scale parameter, $A_F$, on width of resulting dry beach. Four examples of decreasing $A_F$ with same added volume per unit beach length (Dean, 1991).
Foregoing detailed discussion and development, it can be shown that the non-dimensional additional dry beach width, \( \Delta y_0/W_* \), is a function of three non-dimensional variables: non-dimensional volume, \( V/W_*B \), the ratio of sediment scale parameters \( A_F/A_N \) and \( h_*/B \).

\[
\frac{\Delta y_0}{W_*} = f \left( \frac{V}{W_*B}, \frac{A_F}{A_N}, \frac{h_*}{B} \right)
\]  

(8)

In the above, \( A_F \) and \( A_N \) are the sediment scale parameters for the “fill” and “native” sands, respectively and \( W_* \) is the cross-shore distance to \( h_* \) on the native profile, i.e., \( W_* = (h_*/A_N)^{3/2} \). There are three equations of the form of Eq. 8, one for each of the profile types described earlier. The solution for a particular value of \( h_*/B = 4 \) is presented in Figure 10. For a particular case and three grain sizes, the additional dry beach width as a function of nourishment volume is presented in Figure 11. It is again evident that sediment size is very important to the performance of a project.

Models of Profile Evolution

Cross-shore sediment transport processes are so complex that practically all models of profile evolution require numerical solution. Two types of profile evolution exist which can be termed as “open loop” and “closed loop.” All such models employ a transport equation and the conservation of sand equation.

Open Loop Profile Evolution Models

Open loop profile evolution models require detailed or idealized representation of the hydrodynamics and sediment transport processes. As an example, the suspended sediment distribution and mean velocity may be a component of, or the dominant transport mechanism. Some models include bed load transport as a principal component. Most, if not all, of these open loop models if allowed to run indefinitely under the action of steady forcing will become unstable unless some artificial “smoothing” of the results is introduced. Examples of open loop models include: Bailard and Inman (1981), Dally and Dean (1984), Watanabe (1988), Southgate and Nairn (1993) and Nairn and Southgate (1993). Roelvink and Hedegaard (1993) have presented a review of several open-loop models.

Closed Loop Models

Closed loop profile models are characterized by the specification of a particular “target profile,” to which the computed profile will converge if the forcing mechanisms are held constant indefinitely. Thus, computational stability is ensured by this approach. As noted previously, Eq. (7) has been used as the target profile in at least two of these models. Since Eq. (7) is consistent with uniform wave energy dissipation per unit water volume, \( D_* \), within the surf zone, (where the subscript “*” denotes the value for equilib-
Figure 10. Variation of non-dimensional shoreline advancement \( \Delta y_0 / W_* \), with \( A' \) and \( V' \). Results shown for \( h_* / B = 4.0 \). (Dean, 1991)
Figure 11. Additional dry beach width versus volume of sand added per unit length of beach. $h_\ast = 6$ m, $B = 1.5$ m.

In equilibrium conditions, the seaward transport, $q$, is related to the actual (non-equilibrium) wave energy dissipation per unit volume by

$$q = K'(D - D_\ast)^m$$

where $K'$ and $m$ are constants and in two of the models, $m = 1$. Examples of closed loop profiles include EDUNE (Kriebel and Dean, 1985), and SBEACH (Larson and Kraus, 1989). In EDUNE, the cross-shore positions of the contours are specified and it is thus not efficient to represent non-monotonic profiles. SBEACH represents the offshore distance as a series of grids which readily allows representation of offshore bars. The closed loop models are much more effective and reliable for the beach and dune erosion phase than for the recovery phase which occurs on a longer time scale and can be characterized by the sediment moving onshore in "pulses."

Closed loop models are considered much more in the engineering applications arena as compared to the open loop models which are more in the research and development arena.
Some Recent Results: Planform Area Evolution

The contributions to be described here relate to the evolution of the additional total plan area associated with a beach nourishment project. In addressing this problem it will be assumed for convenience that the profile equilibration occurs instantaneously such that the additional dry beach at any particular location can be determined from one of the three equations of the type of Eq. 8.

Starting with sand that is compatible, which is the most simple case, the relationship between the additional dry beach width and the volume density per unit beach length, $V$, at any location is given by $\Delta y(x) = V(x)/(h_* + B)$. Integrating this additional dry beach width we obtain the following result which, since the total volume, $V_{TOT}$, does not vary with time, neither does the plan area, $PA$. That is, the total plan area $PA$ is constant

$$PA(t) = \int_{-\infty}^{\infty} \Delta y(x) \, dx = \int_{-\infty}^{\infty} \frac{V(x)}{(h_* + B)} \, dx = \frac{V_{TOT}}{(h_* + B)} \tag{9}$$

Consider next nourishment sand sizes which differ from the native sand. For a sand which is coarser than the native, reference to Figures 8 and 9, will demonstrate that as the volume density decreases as the planform spreads out, the intersection point will occur closer and closer to the shoreline and the ratio of additional dry beach width to volume density of sand will increase. In the limit, as the volume density of sand approaches zero, the vertical dimension of the active profile approaches the berm height, $B$, and the relationship between $\Delta y$ and $V$ will be

$$\Delta y(x, t \to \infty) = \frac{V(x)}{B} \tag{10}$$

Thus it can be shown that with time the total planform area will increase for sands that are coarser than the native and in the limit will achieve the asymptotic total plan area

$$PA(t \to \infty) = \frac{V_{TOT}}{B} \tag{11}$$

The same procedure as demonstrated for sands which are coarser than the native also applies for sands that are finer than the native. In this case, as the volume density becomes smaller and smaller due to spreading out of the beach nourishment project, the dry beach width becomes smaller and smaller (see Figure 11) and in the limit the plan area associated with the finer sands approaches zero. An example of total plan area evolution results for single sized sands which are coarser, finer and the same size as the native is presented in Figure 12 for non-dimensional time.

The previous treatment of nourishment with sands composed of only one diameter results in asymptotes at large time that are not realistic, particularly for sands that are finer than the native. We now consider the nourishment sand to be composed of
sands of two sizes which can vary in proportion from 100% of the finer sands to 100% of the coarser sands. Consistent with findings in nature it will be assumed that the coarser sands always remain in the landward portion of the nourished profile, see Figure 13. In Figure 13, since the nourishment material is generally coarser than the native, the sands of the same size as the native are located in the seaward portion of the profile. Also, one of the sand sizes will be chosen to be the same size as the native; the remaining fraction can be coarser or finer than the native. This involves a procedure for size characterization of the nourishment sediment which will not be discussed here. In this case, the evolution of the beach nourishment planform can be determined using a somewhat more complicated numerical model. Figure 14 shows the results for a case in which the native sand is 0.20 mm and nourishment sands are generally coarser than the native. The proportion of coarser (0.23 mm) sands ranges from 0.0 to 0.9 of the total volume placed. Figure 15 illustrates the planform evolution for cases in which the nourishment sands are generally coarser than the native with equal proportions of nourishment sand equal to and coarser than the native. In this example the size of the coarser friction varies. Again, the sensitivity of both initial and asymptotic plan areas on sand size are substantial. Figures 16 and 17 are the counterparts of Figures 14 and 15, respectively, for the case in which the nourishment sand is generally finer than the native.
Figure 13. Example of $V_1 = V_2$ with $D_N = 0.20$ mm, $D_{F1} = 0.50$ mm, $D_{F2} = 0.20$ mm, $h_* = 6$ m, $B = 1.5$ m.

Figure 14. Example calculation for nourishment sand coarser than the native. Effect of proportions of coarser sand. Two nourishment sizes considered.
Figure 15. Example calculation for nourishment sand coarser than the native. Effect of sand size. Two nourishment sizes considered.

Figure 16. Example calculation for nourishment sand coarser than the native. Effect of proportions of finer sand. Two nourishment sizes considered.
As a summary statement, the effects of nourishment sand size on the initial and asymptotic total additional plan area for a project constructed on an infinitely long beach are substantial. For projects constructed in other settings, the effects of sand size on plan area evolution are also expected to be significant.

Summary

This paper has presented a limited review of the available methodology for simple calculations of prediction of beach nourishment performance. Additionally, recent results describing the importance of sediment size on beach planform evolution are provided.

The predicted performance of beach nourishment projects can be aided by considering the planform and profile evolution separately. Although these two processes occur simultaneously, it is reasonable to separate them for preliminary design and performance prediction purposes. The Pelnard Considere Equation, the heat conduction equation, can be applied with confidence to a number of significant problems if the boundary conditions and initial planforms are satisfied reasonably well. Solutions are available for nourishment with initially rectangular or trapezoidal planforms on a long, straight beach or nourishment on a beach with one or both lateral boundaries located at inlets. Many solutions for other initial planforms and boundary conditions exist. Simple relationships for the longevity as affected by the project length and wave height can be developed and
applied readily. Other useful results relate to refraction due to the perturbation associated with the beach nourishment planform, the insensitivity of the planform evolution to wave sequencing, the planform effects of nourishing with sands which are finer or coarser than the native, nourishment along a coastline for which no other sand is available for transport, multiple nourishments, and the effects of background erosion.

Two issues are examined with respect to profile equilibration. Response time has been found through monitoring of full scale projects to be on the order of five years. The second issue, and probably the more important, relates to the effect of nourishment sand size on the equilibrated dry beach width. It is shown that three profile types occur depending on the relative sizes of the nourishment and native beach sands. Due to the steeper profiles associated with coarser grain sizes, the additional dry beach width can be substantially greater than for the case of finer nourishment sediments. The sensitivity of equilibrated dry beach width to sediment size is significant.

The results of recent investigations of the evolution of the total additional beach planform area are presented in which it is shown that the effects of nourishment sand size are again significant. For single size nourishment sands that are coarser than the native a simple model is developed which allows determination of the asymptotic (at large times) beach planform area. For sands that are finer than the native the asymptotic planform area due to the nourishment project is zero. Due to the unrealistic results for single size nourishment sands, especially for sands finer than the native, a more representative model is investigated in which the nourishment sands are composed of two sizes which can vary in their proportions. The coarser sand fraction is assumed to occupy the landward portion of the profile, one size is the same as the native and the remaining component can be coarser or finer than the native. Results based on this model appear to be much more realistic and to allow the computation of reasonable total additional plan area evolution.

The modelling of a spilling breaker: strong turbulence at a free surface.

M. Brocchini † and D.H. Peregrine ‡

Abstract

A brief review is given of the initial development of a model for the turbulence generated by a spilling breaker riding on an unsteady wave. The turbulent volume of water in a spiller is modelled as a thin layer. The basis for such a model comes from the analysis of the interaction between an air-water interface with patche of turbulence. Hence, the behaviour of a free surface which is affected by strong turbulence is being studied. We summarise some of the salient points of our work. These include a derivation of averaged boundary conditions which include mass and momentum flows in the surface layer and the transfer to the bulk liquid. A brief account is also given of the type of equations needed to represent the motion of the front edge of the breaker. Illustration of the method is only given in terms of the equations derived by integration from the equation of mass conservation. Finally, there is description of the various free surface regimes that occur and need to be considered in order to determine suitable closures for the averaged terms.

Motivation and Methodology

This study is motivated by a wish to model the spilling breakers that arise from the crests of steep water waves (e.g. see figure 1). Spilling breakers are classified in a wider class of types of breaking where the wave form changes relatively slowly. Together with the bore (or turbulent bore) they form the class of the quasi-steady breakers. If the turbulence is confined to a region near the crest of the wave the wave is a spilling breaker but if the whole face of the wave is turbulent it is a bore.

In their analysis of spilling breakers, bores and hydraulic jumps Peregrine & Svendsen (1978) suggested that the volume of turbulent flow in a spilling breaker resembles a turbulent mixing layer. The roller model in which the turbulent

‡Professor of Applied Mathematics, School of Mathematics, University of Bristol, (D.H.Peregrine@bristol.ac.uk)
region is modeled as a separate flow region passively riding the wave crest is seen to be only a partial solution as it is evident that the fluid content of the roller itself is continually mixing with the rest of the turbulent fluid in the wave.

Peregrine (1992) also suggests that a spilling breaker may be considered as a quasi-steady system in a frame of reference moving with the wave where deformations of the spiller shape occur at longer time scales than those typical of the motion of water through the turbulent region. The structure of such a quasi-steady breaker is thus an initial mixing layer region, followed by a region beneath the crest of the wave where gravity influences and restrains the turbulent motions near the surface.

Figure 1: Example of a spilling breaker. Photograph taken at the Fluid Dynamics unit of the University of Edinburgh. (Courtesy of T.C.D. Barnes.)

Developing some of the ideas suggested in Peregrine & Svendsen (1978) and Peregrine (1992) we are trying to build a model which is:

1. as reliable and accurate as possible in terms of numerical solver \(\Rightarrow\) use a boundary integral solver for the irrotational flow of the bulk of the breaking wave (for a detailed description please refer to Dold & Peregrine, (1984) and Cooker et al (1990);
2. as complete as possible in terms of physical phenomena → take into account: two-phase flow, turbulence, flow unsteadiness and curvature, response of turbulence to curvature ...;

3. as simple as possible → lump the effects of two-phase and turbulent flow into Boundary Conditions for the solver used to model the bulk of the propagating wave.

[for more details on this model we refer the reader to Brocchini (1996).]

As a result we are working at a ‘three-layer-model’ a sketch of which is reported in figure 2. Note that in this model three different time scales are of relevance. They are respectively the time scale for the water particles to cross the layer, the time scale for the evolution of the layer shape and the time scale for the evolution of the shape of the underlying wave. Even if the spilling breaker is said to be quasi-steady because its evolution occurs at a larger time scale than that for a particle to cross the layer, it can be considered unsteady when referring to the motion of the wave because the evolution of the wave shape occurs at a larger time scale than the evolution of the thin layer.

Figure 2: Global geometry adopted in the model for the system wave - turbulent thin layer - surface layer.

One of the main difficulties in modelling a spilling breaker is that at present
there is no good description of free surface boundary conditions for a turbulent flow. The most interesting, and difficult, flows are those breakers which are strongly nonlinear and splashing, but even the much smoother flows occurring in small “micro-scale” breakers, that are restrained by surface tension, require special attention. Hasselmann (1971) is the only paper we know that describes similar surface flows in the context of both wave and turbulent averaging.

In that paper a perturbation is made about the undisturbed free surface, assuming Taylor series make good approximations. This may be a good approximation for irrotational motions but is clearly more limited for turbulence. An interaction stress tensor and a surface mass transfer must be introduced to take proper account of interactions between short and long period motions. However this particular analysis is no longer appropriate when turbulent eddies cause the interface to develop sharply curved features or to disintegrate into splashes. In this case the problem to be faced is of a twofold nature as both turbulence and two-phase flow must be taken into account (e.g. see top layer of figure 2). The interface between the air and water can be extremely complex.

Here we only analyse the problems of modelling the top layer (‘surface layer’). At first we illustrate the physical/mathematical framework which concerns both the averaging within the two-phase layer and the subsequent definition of suitable model equations and boundary conditions. Then, a brief account is given on the equations which are needed to represent the motion of the front edge of the breaker (‘toe of the breaker’). Finally, in recognition of the need for closures which depend on specific flow regimes, we describe the main features of such regimes leaving open (for moment) the question of quantifying closures.

The boundary conditions for the ‘surface layer’.

The top region of the spilling breaker is studied as a layer consisting of an air-water mixture (‘surface layer’ of figure 3). The analysis of the flow of two fluids, one dispersed throughout the other, is most often carried out by solving equations which arise from averaging over each phase. In recent research this is achieved by introducing a ‘phase function’ or ‘intermittency function’, which is essentially a step function, and then averaging (e.g. Drew, 1983). The properties of the phase function are such that a number of conservation equations are obtained for each dispersed phase.

Within the layer flow properties (e.g. velocities) are not continuous functions of time and space hence we introduce a ‘phase function’ or ‘intermittency function’ such that:

\[
I(s, n, t) = \begin{cases} 
1 & \text{if } (s, n) \text{ is in the water at time } t \\
0 & \text{if } (s, n) \text{ is in the air at time } t.
\end{cases}
\] (1)

The we introduce an averaging process \( \langle \cdot \rangle \) such that if \( G(s, n, t) \) is a generic flow variable then \( \langle G(s, n, t) \rangle = G(s, n, t) \) is the corresponding average. The most appropriate averaging process is the ‘ensemble average’ however many of the flows studied in the laboratory are statistically stationary with respect to time. If this is so, the ergodic hypothesis asserts that the time average is equivalent to the ensemble average and \( \langle \cdot \rangle \) can simply be regarded as a time average.
Surface layer

Mean free surface $\bar{\eta}(s, t)$

$n = h, \gamma = 0$

$n = b, \gamma = 1$

Figure 3: Global geometry adopted in the model for the surface layer.

After averaging the intermittency function becomes an average volume fraction $\gamma(s, n, t)$ also called 'intermittency factor' such that

$$\gamma(s, n, t) = \langle I(s, n, t) \rangle = \begin{cases} 1 & \text{below trough level } n = b \\ 0 & \text{above crest level } n = h. \end{cases}$$

(2)

Within the surface layer there can be regions in which only the air, or only the water, or both, are connected. Whether connected or not there is a range of $\gamma$ from 0 to 1. Somewhere within the layer a mean interface can be defined. Several possible definitions are available, e.g. the surface $\gamma = 0.5$, or the surface corresponding to an equi-distribution, within the surface layer, of the two phases on each side of the chosen surface (see figure 3). In principle this interface can be regarded as a local reference for defining the origin of a local curvilinear coordinate set $(s, n)$, where $s$ follows the mean surface and $n$ is normal to it. However, following experience developed in defining mean shorelines for waves on a beach (Brochini & Peregrine, 1996) we choose to avoid any specific definition of the mean surface since it seems more meaningful to deal with the surface layer as a whole. For interaction with the water below, the lower boundary of the layer is most relevant, this we denote as $b$.

Since the intermittency factor $\gamma$ is a continuous function of time and space it is most useful to characterize different flow conditions. For example three cases are here reported of a wavy surface (figure 4a), a 'scarified' surface (figure 4b) and a splashing surface. This has been modelled by considering a Normal distribution
for \( \eta \) such that a simple result is obtained for \( \gamma \):

\[
\gamma(s, n, t) = \frac{1}{2} \left[ 1 - \text{erf} \left( \frac{n - \overline{n}(s, t)}{\sqrt{2} \sigma(s, t)} \right) \right].
\]  

(3)

[In this model \( \sigma \) is a measure of the lateral extent of the surface layer].

For each of the three types of surfaces we have a different \( \gamma \) factor which is reported in figure 5.

Figure 5: The intermittency factor (or residence time) \( \gamma \) for: (a) wavy air-water interface (dashed line), (b) periodically scarified interface (dot-dashed line) and (c) turbulent splashing interface (solid line).

It is evident that for wavy regimes water is present at the top of the surface layer \((n = 1)\) for a longer time than for a splashing regime in which water drops are present for a shorter time near the top of the layer. This behaviour is reversed at the bottom of the layer where large values of \( \gamma \) \((\gamma \approx 1)\) are reached faster while
approaching the base of the layer \((n = -1)\) in a splashing regime. The relative residence time is nearly 1 for most of a periodic scarified air-water interface.

In order to obtain the boundary conditions use the following steps:

1. obtain conservation equations using integral equations within a control volume \(V\) (for more details see Brocchini & Peregrine, (1998b)). With this method there is no need to rely on the usual assumption that each phase can be considered as a continuum;

2. for simplicity in initial studies assume air flow has negligible effect and no phase change occurs;

3. integrate conservation equations across the 'surface layer' i.e. from the base level \(n = b(s, t)\) to crest level \(n = h(s, t)\);

4. define the amount of water contained in the layer as:

\[
d(s,t) = \int_b^h \gamma \, dn. \tag{4}
\]

To get the required boundary conditions we apply the above procedure to each conservation equation (i.e. conservation of mass, linear momentum ...).
For example application to the conservation of mass gives the following kinematic boundary condition:

\[
\frac{\partial b}{\partial t} + U|_b \frac{\partial b}{\partial s} - V|_b = W = - \left( \frac{\partial d}{\partial t} + \frac{\partial}{\partial s} \int_b^h \gamma U_w \, dn \right). \tag{5}
\]

where $U_w$ is the mean flow velocity in the water (i.e. phase average in the liquid phase) and $W$ represents an extra normal-to-surface velocity which would be zero if there were no surface layer. [Note that $U_w(n = b) = U$ and $V_w(n = b) = V$].

Formally, this is very similar to that of Hasselmann (1971) valid for a continuous interface [see surface flow term], but it is applied at base of the layer rather than at a mean surface $\bar{\eta}$.

Note that the equation can be regarded as:

*either* the kinematic B.C. for the flow below $n = b$ for which $W$ must be given, 
*or* as an equation for the conservation of mass inside the layer.

To use the equation as a boundary condition it is necessary to find a suitable closure for the surface flow term

\[
\frac{\partial}{\partial s} \int_b^h \gamma U_w \, dn.
\]

Closures are required for even more complicated contributions which appear in the dynamic boundary conditions (e.g. terms corresponding to momentum flow in and into the surface layer giving effective stresses). 

**The toe (2D) or the foot (3D) of the breaker.**

For a physically sound representation of the spilling breaker a crucial point is the modelling of the region where turbulence is generated at the free surface. In a 2D description of the flow this is called the 'toe of the breaker'.

Figure 7: Sketch of the flow and of the velocity profile at the toe of a breaker propagating with celerity $c$.

According to Peregrine & Svendsen (1978) at the inception point (line) there's meeting of two layers of water travelling in opposite direction. More recently, this
scenario has been also reported by Lin & Rockwell, (1995) in their experimental investigation of the early stages of generation of a quasi-steady spilling breaker. In that case, however, since turbulent blobs spill down the wave face (figure 7) generation of turbulence is greater than in a normal mixing layer (where the velocities are in the same direction).

A quantitative description of the inception region has been obtained following the method used by Brocchini & Peregrine (1996) for averaging the flow at the swash zone. Notice that:

- averaging over the turbulence is inadequate in the region right in front of a spiller which the turbulent water only reaches rarely;
- there is little dynamical significance in such a thin intermittent layer of turbulent water;

As a consequence of the above, the whole region which the turbulence only meets intermittently is taken as a ‘Boundary Region’ (see figure 8) such that there is a non-zero mean depth at the front edge of the layer.

\[
\text{‘Boundary region’} \quad (\text{volume } \hat{V})
\]

\[
\text{Figure 8: Sketch of the flow properties used in the modelling of the toe of the breaker.}
\]

In more detail first introduce the following definitions:

\[
d(s_l) = d_* \quad ; \quad d(s_h) = 0 \quad ; \quad h(s_h) = b(s_h) \quad ; \quad \hat{V} = \int_{s_l}^{s_h} d \, ds.
\] (6)

Within our model the toe of the breaker is the mathematical boundary characterized by the coordinate \( s_l \) and by a non-zero mean depth \( d_* \).

Following on our illustration based on the equation for the conservation of mass (see Brocchini & Peregrine, 1998b for more details) we integrate the kinematic boundary condition in the streamwise direction from \( s_l \) to \( s_h \) to get:

\[
\frac{\partial \hat{V}}{\partial t} + d_* \frac{\partial s_l}{\partial t} = \left[ \int_b^h \gamma U_w \, dn \right]_{s=s_l} - \int_{s_l}^{s_h} \left[ \frac{\partial b}{\partial t} + U_b \frac{\partial b}{\partial s} - V_b \right] ds.
\] (7)
This equation is formally very similar to one of the shoreline boundary conditions of Brocchini & Peregrine (1996) and it can be regarded as an equation for the motion of the front edge of the layer \( s_i \) when rewritten as:

\[
\frac{\partial s_i}{\partial t} = d_i \left\{ \left[ \int_{s_i}^{s_f} \gamma U_w \, ds \right] - \frac{\partial \hat{V}}{\partial t} - \int_{s_i}^{s_f} \left[ \frac{\partial b}{\partial t} + U_b \frac{\partial b}{\partial s} - V_b \right] \, ds \right\}
\]  

(8)

Closure is now needed not only for the surface flow term but also for the volume of water in the ‘Boundary Region’ \( \hat{V} \) and for the mean depth \( d_*. \)

**Analysis and description of the flow regimes.**

In is clear that an in depth analysis of the flow regimes is needed to determine the closures both for the boundary conditions and for the equations relative to the motion of the toe of the breaker. However, analysis of the interaction of turbulence with an air-water interface is interesting per se as a large number of natural flows are characterized by strong turbulence at a free surface and they fall in two main classes:

- **turbulence generated at the free surface** (breaking waves, sprays...),
- **turbulence generated far from the surface** (steep rivers, artificial spillways...).

In our description of the flow regimes we assume it is possible to characterize different flow regimes in terms of two flow properties only (Brocchini, 1996; Brocchini & Peregrine, 1997 and Brocchini & Peregrine, 1998a). These are:

1. the turbulence intensity
   \[
   q = \sqrt{2k}
   \]  
   (9)
   where \( k \) =turbulent kinetic energy;

2. the length scale \( L \) of the most energetic flow feature (wavelength, eddy size, water blob size, ...)

Considering the two stabilising factors of the water surface (gravity and surface tension) four main regions can be found in the \((L,q)\) plane (see figure 9).

For gravity we compare the specific potential energy \( gL \) with the specific kinetic energy of turbulence \( k = \frac{1}{2}q^2 \) and find the Froude number

\[
Fr = \frac{q}{\sqrt{gL}},
\]  

(10)

while for surface tension we compare the specific surface energy \( S = T/\rho \) with \( \frac{1}{2}q^2L \) to get the Weber number:

\[
We = \frac{q^2L}{2S}.
\]  

(11)

\( Fr_c \) and \( We_c \) have been obtained working on literature data dealing with wave generation, bubble and drop formation... Here we only summarize some of the results which can be found with more detail in Brocchini & Peregrine (1998a).
Figure 9: Diagram of the \((L, q)\) plane. The shaded area represents the region of marginal breaking and has been obtained two values for both the critical Weber number \((0.3 < We_c < 5)\) and the critical Froude number \((0.5 < Fr_c < 1.5)\).

**Region 0:** \(Fr \ll Fr_c \text{ and } We \ll We_c\)

In this region the stabilizing effects are dominant leading to a nearly flat surface. Hence, the free surface behaviour in this quadrant may be described as either flat or wavy (see figure 10).

Figure 10: Illustration of a flat or wavy surface.

**Region 1:** \(Fr > Fr_c \text{ and } We < We_c\)

For large Froude number and small Weber number we are concerned with relatively small scale turbulence: of the order 1 cm and less for water, region
1 of figure 9. Here surface tension is well able to maintain the cohesion of the liquid but gravity fails to keep the surface flat. The result is smooth rounded surfaces. If the turbulence is below the critical region then there is not much wave generation and we describe the surface as **knobbly** or **microbreaking**.

**Region 2:** $Fr \gg Fr_c$ and $We \gg We_c$

When turbulence is so strong that neither surface tension nor gravity can maintain surface cohesion the flow breaks up into drops and bubbles, region 2 of the $(L, q)$ plane. This is an essentially two-phase flow region. At a free surface there is the growth and decay of the strong turbulence to consider as well as the structure of the transition between gas and liquid. When strong turbulence, generated elsewhere, meets a free surface it 'erupts' as the fluctuating eddies form blobs of liquid that are no longer restrained by the inertia of surrounding non-turbulent liquid. This eruption may be exemplified by the 'rooster tail' seen at the rear of high speed vessels as the turbulent flow from their driving mechanism meets the free surface. Sometimes the flow is sufficiently well organised that some of the 'tail' is due to a discrete splash.
We can contrast this case with the weak turbulence case of an almost flat surface. For weak turbulence the vertical velocity fluctuations \( v \) approach zero at the free surface, on the other hand for strong turbulence \( v \) can be expected to be larger than \( u \) and \( w \) since the horizontal fluctuations are more constrained by the inertia of the surrounding liquid. This complete contrast in the variation of \( v \) gives the clearest indication that different surface regimes need different approaches in developing turbulent models. At the very least different closures are needed for averaged terms.

**Region 3: \( Fr < Fr_c \) and \( We > We_c \)**

Region 3 of our \( (L, q) \) diagram has gravity dominating the turbulence, \( Fr \gg 1 \), with weak surface tension, \( We \ll 1 \). It is by far the commonest state since it applies to almost all terrestrial water bodies with flow: stream, rivers, seas and oceans. The free surface is essentially flat or nearly so. Linearised boundary conditions are generally satisfactory. However, there are a range of interesting flow properties in this regime as the turbulent energy is increased towards the splashing case. These are local effects and their significance in various applications is not well determined.

![Scars](image)

Figure 13: Illustration of a *scarified* surface.

These phenomena arise since the turbulence has more than adequate energy to disturb the free surface, but only at length scales which are smaller than the main turbulent eddies. At the edge of the eddies, where strong shear develops, or where the eddy boundary is moving or there is a strong surface convergence shorter length scales, \( L/10 \) or \( L/100 \) or even less becomes important. The surface develops linear features, or scars, which may be a sharp downward trough as shown in figures 4 and 13, or else involve localised breaking.

Time-Dependent Depth-Integrated Turbulence Modeling of Breaking Waves

Kazuo Nadaoka¹ and Osafumi Ono²

Abstract

A breaking wave model is presented to simulate non-equilibrium evolution of turbulence with a time-dependent depth-integrated equation of turbulence intensity, which is to be coupled with nonlinear wave. As the crucial part of the modeling, a method to estimate the production rate of turbulent kinetic energy is developed. This method is based on the experimental observation of the pseudo-periodic generation of large-scale eddies near the wave crest of turbulent bore. As a demonstration to show the performance of the present model, numerical examples are given for regular and irregular waves on a slope and regular waves on a double step, indicating that this model can give favorable features of evolution of regular and irregular breaking waves and the production and diffusion of turbulent kinetic energy.

Introduction

Although the recent progress in the developments of nonlinear-dispersive wave equations enables us to precisely describe even nonlinear evolution of irregular waves up to breaking, the broken wave simulation is still limited mainly because of the lack of proper turbulence model with wide applicability and sound physical background.

In the previous studies, many efforts have been made to incorporate the effect of wave breaking by introducing damping terms in a time-dependent wave model. Among these, e.g., Karambas and Koutitas (1992) presented a breaking wave model based on Boussinesq equations with a diffusion-type term, in which the damping factor is determined by time-averaged equation of the turbulence energy. However their model has a difficulty in further extension to unsteady wave field.

Schäffer et al. (1992) and Madsen et al. (1997) developed a breaking wave

¹ Prof., Department of Mechanical and Environmental Informatics, Graduate School of Information Science and Engineering, Tokyo Institute of Technology, 2-12-1 O-okayama, Meguro-ku, Tokyo 152-8552, Japan. (Email: nadaoka@mei.titech.ac.jp, Fax: +81-3-5734-2650)

model based on a surface roller concept and a time domain formulation of Boussinesq-type equations. As the wave breaking criterion they assumed the presence of a critical value in the local water surface slope according to Deigaard (1989). However Nadaoka et al. (1997a) indicated through a laboratory experiment of irregular breaking waves that the front surface slope at the breaking exhibits appreciable scatter. Besides there is no experimental evidence to support the validity of the surface roller concept as the physical process, although it has been one of useful concepts for the breaking wave modeling. For example Nadaoka et al. (1989) found experimentally that the actual process of turbulence production is governed by a pseudo-periodic generation of large-scale eddies near the wave crest.

In the present paper, a new breaking wave model is presented to simulate non-equilibrium evolution of the turbulence with a time-dependent depth-integrated equation of turbulence intensity, which is to be coupled with nonlinear wave equations. As the crucial part of the modeling, a method is developed to estimate the production rate of turbulent kinetic energy, which governs the non-equilibrium development of turbulence and hence the breaking wave evolution. This method is based on the experimental observation of the pseudo-periodic generation of large-scale eddies near the wave crest as mentioned above. As the wave breaking criterion the free-fall condition by Nadaoka et al. (1997a), which is based on the vertical pressure gradient near the wave crest, is adopted for the simulation. Numerical examples as a demonstration to show the performance of the present model are given for regular and irregular waves on a slope and regular waves on a double step.

Depth-Integrated Turbulence Modeling

Since the turbulence production of breaking waves is closely related with the instantaneous wave profile, the turbulence model developed in the present study is in a form to be simultaneously solved with the wave equations. In general, the existing equations to describe evolution of water waves such as Boussinesq equations are those of the depth-integrated type. Therefore, as a consistent way of formulation, the present turbulence model is to be of a depth-integrated type.

For the subject of suspended sediment transport in the surf zone, as one of important applications of the turbulence model, one needs to know the variation of turbulence intensity within a wave cycle for the evaluation of the sediment pick-up from the sea bottom. For such a purpose a time-dependent formulation is required for the turbulence modeling.

Besides in the turbulence development on a beach with an arbitrary profile like a stepped beach, the non-equilibrium aspect becomes crucial. Therefore both the turbulence production and dissipation must be properly estimated in the turbulence model.

For these requirements, the depth-integrated equation of the turbulent kinetic energy transport may be used, which is
\[
\frac{\partial k}{\partial t} + \bar{u} \frac{\partial k}{\partial x} = P_k - \varepsilon + D_k,
\]

where \(k\) denotes the depth-averaged turbulent kinetic energy, \(\bar{u}\) the depth-averaged velocity, \(\varepsilon\) the energy dissipation rate, \(D_k\) the diffusion term and \(P_k\) the production rate of the turbulent kinetic energy. The energy dissipation rate, \(\varepsilon\), may be evaluated with \(k\) and the turbulence length scale \(l\) according to the usual \(k\)-equation model,

\[
\varepsilon = c^* \frac{k^{3/2}}{l},
\]

The length scale \(l\) may be estimated according to Svendsen (1987),

\[
l = 0.2h,
\]

where \(h\) is the local water depth. The energy diffusion term is simply evaluated with the turbulent eddy viscosity, \(\nu_p\), as

\[
D_k = \frac{\partial}{\partial x} \left( \frac{\nu_p}{\sigma_k} \frac{\partial k}{\partial x} \right).
\]

For the model parameters, \(c^*\) and \(\sigma_k\), in eqs.(2) and (4), the standard values, \(c^*=0.17,\ \sigma_k=1.0\) are adopted. The eddy viscosity, \(\nu_p\), is estimated as

\[
\nu_p = k^{1/2} l.
\]

Although eqs.(1) to (5) constitute a depth-integrated one-equation model\(^*\), one may employ a two-equation model such as \(k-\varepsilon\) model as the turbulence equations to be vertically integrated.

One of the crucial points for the present turbulence modeling is the estimation of the turbulence production near the bore crest, which governs the non-equilibrium development of the turbulence. The local production rate of the turbulent kinetic energy is usually estimated with the product of the local shear stress, \(\tau\), and the shear rate, \(\partial u/\partial z\). Hence the depth-averaged form of the turbulent energy production rate, \(P_k\), may be obtained by the vertical integration of \(\tau \partial u/\partial z\). However this idea, as described below in detail, may not be applicable directly to the modeling of the surf zone turbulence, in which the large-scale eddy generation near the wave crest is the dominant turbulence source.

\(^*\) Recently Nwogu (1996) proposed a time-dependent breaking wave model based on Boussinesq-type equations, in which a one-equation type model is adopted to estimate turbulence development. The evaluation of the turbulence production is made by the assumption that it is proportional to the vertical gradient of the horizontal velocity at the wave crest and that the breaking process is of spilling-type.
Turbulence-Energy Production Modeling

In the initial development of turbulence at the breaking point, the entire process is governed by the generation of a large-scale eddy due to the water mass impingement at the front surface. This process, as illustrated in Fig. 1, is a conversion from an irrotational motion in a simply connected region to the rotational flow in the doubly connected region with a circulation, \( \Gamma \), at the moment when the water jet reaches the front surface. This circulating flow motion, in other words, the horizontal large-scale vortex involves ample vorticity and air bubbles in the water, providing subsequently smaller scale turbulence. In this process the initial turbulence generation may not be evaluated simply by \( \tau \partial u / \partial z \). Our question is then what about in the inner region of the surf zone?

In the conventional modeling of the breaking waves, a concept of steady vortex attached at the bore front such as “surface roller” (Svendsen, 1984) as illustrated in Fig. 2 has been employed. However the actual process of the eddy formation at the bore front exhibits pseudo-periodic generation of large-scale eddies, which are advected behind the bore crest with appreciable diffusion (Fig. 3; Nadaoka et al., 1989). The essential feature of the development of each eddy is the same with that for the initial vortex development in terms of the generation of the circulation and associated supply of the vorticity and air bubbles.

Based on this observation, in the present model, the turbulent energy production rate, \( P_k \), is estimated with the kinetic energy of a large-scale eddy, \( e_L \), and its generation frequency per unit time, \( n \); both of which may be evaluated with the circulation of the large-scale eddy, \( \Gamma_0 \) as described below.

The kinetic energy of a large-scale eddy, \( e_L \), is estimated here with the Rankine eddy model,

![Fig. 1: Illustration of initial development of a large-scale eddy with the circulation \( \Gamma \), which involves ample vorticity and air bubbles into the water.](image)
Fig. 2  Illustration of the surface roller model.

Fig. 3  Pseudo-periodic generation of large-scale eddies at the bore front (Nadaoka et al., 1989).
where \( r_0 \) denotes the eddy radius. On the other hand, the number of eddies generated per unit time, \( n \), may be evaluated simply as

\[
 n \approx \frac{\Gamma_0}{2(\pi r_0)^2}. \tag{7}
\]

Therefore, with the assumption that all the kinetic energy of the large-scale eddies is supplied to the turbulence, the production of kinetic turbulent energy within a wavelength per unit time, \( E_L \), is

\[
 E_L = ne_L = \frac{\rho |\Gamma_0|^3}{16(\pi r_0)^2}. \tag{8}
\]

The circulation, \( \Gamma_0 \), itself is estimated by equating the vorticity production rate associated with the eddy generation, \( n\Gamma_0 \), with the mean production rate of the vorticity at the singular point of the bore front, A, as indicated in Fig. 4. The latter may be evaluated as

\[
 \Omega = \frac{(u_w - c)^2}{2} \tag{9}
\]

where \( c \) denotes the bore celerity and \( u_w \) represents the velocity of orbital motion at A. Equating this with \( \Omega = n\Gamma_0 \), we obtain

\[
 \Gamma_0 = \pi r_0 (u_w - c). \tag{10}
\]

Therefore the turbulence production rate, \( P_k \), is estimated as,

---

**Fig. 4** Definition sketch of \( u_w \) in a turbulent bore.
where \( L_1 \) represents the horizontal length of the vorticity supply region in a wave and is assumed here to be the horizontal length between the zero-up crossing point and the wave crest. Besides the eddy radius, \( r_0 \), and the horizontal velocity, \( u_{w_0} \), are simply assumed here to be the half of the crest height and zero, respectively. For further improvement of the evaluation of \( P_k \), one should develop more reasonable way to specify the location of \( A \) and the corresponding values of \( L_1, r_0 \) and \( u_{w_0} \).

### Depth-Integrated Wave Equation

Although the turbulence model described above may be coupled with any depth-integrated time-dependent wave equations including Boussinesq-type equations. In the present study, the new wave model developed by Nadaoka et al. (1994, 1997b) has been used. This wave model can describe nonlinear dispersive waves under general conditions, such as nonlinear random waves with a broad-banded spectrum at an arbitrary depth. Among the various versions of the model, the following multi-component equations are adopted here.

\[
\frac{\partial \eta}{\partial t} + \sum_{m=1}^{N} \nabla \cdot \left[ \left( \frac{\omega_m}{g k_m} + \eta \right) U_m \right] = 0,
\]

\[
\sum_{m=1}^{n} A_{nm} \frac{\partial U_m}{\partial t} + B_m \nabla \left[ g \eta + \frac{B_m}{2} \left( u_0 + w_0 \right) \right] =
\]

\[
\frac{\partial}{\partial t} \sum_{m=1}^{N} \left[ C_{nm} \nabla \cdot (\nabla \cdot U_m) + D_{nm} \left( \nabla \cdot U_m \right) \right] + \sum_{m=1}^{M} L_{nm} \nabla \cdot \nabla^2 U_m
\]

(\( n = 1, 2, \ldots, N \))

where,

\[
\omega_m^2 = g k_m \tanh k_m h, \quad A_{nm} = \frac{\omega_m^2 - \omega_n^2}{k_m^2 - k_n^2}, \quad A_{nn} = \frac{g \omega_n^2 + h \left( g^2 k_n^2 - \omega_n^4 \right)}{2 g k_n^2},
\]

\[
B_n = \frac{\omega_n^2}{k_n^2}, \quad C_{nm} = B_n - A_{nm}, \quad D_{nm} = \nabla C_{nm},
\]

\[
D_{nm} = \frac{2}{k_m^2 - k_n^2} \left[ \frac{2 \nabla k_m}{k_m} \left\{ A_{nm} - \left( k_m^2 - k_n^2 \right) C_{nm} \right\} + \frac{\nabla h \sqrt{g^2 k_n^2 - \omega_n^4}}{g h k_n k_m} \frac{g^2 k_n^2 - \omega_n^4}{g^2 k_m^2 - \omega_n^4} \right].
\]

(14)

\( u_0 \) and \( w_0 \) in eq.(12) are the velocities at \( z=0 \) and may be evaluated as

\[
u_0 = \sum_{m=1}^{N} U_m, \quad w_0 = - \sum_{m=1}^{N} \nabla \cdot \left( \frac{B_m}{g} U_m \right).
\]

(15)

The last term in eq.(13) represents the damping effect due to wave breaking.
Wave Breaking Criterion

By developing a method to experimentally evaluate pressure field of irregular waves with a time sequence of the wave profile data, Nadaoka et al. (1997a) found out that at the wave breaking the vertical pressure gradient near the wave crest becomes nearly zero even for irregular waves. This fact may be used as a general wave-breaking criterion which is applicable to regular or irregular and progressive or standing waves. Nadaoka, et al. (1997a) called this criterion “free-fall condition” and showed that the breaker depths computed by eqns. (12) and (13) with this breaking condition give good agreements with those by the Goda (1970)’s empirical breaking criterion. Therefore, in the present study, this free-fall condition has been used to detect the breaking point and to impose the production rate of turbulent kinetic energy, $P_k$, according to the occurrence of the wave breaking; i.e.,

$$
\begin{align*}
\text{if } \frac{1}{\rho g} \left. \frac{\partial p}{\partial z} \right|_{\text{crest}} \leq 0, & \text{ then } P_k \neq 0, \\
\text{if } \frac{1}{\rho g} \left. \frac{\partial p}{\partial z} \right|_{\text{crest}} > 0, & \text{ then } P_k = 0.
\end{align*}
$$

(16)

Numerical Examples and Discussion

To demonstrate the fundamental performance of the present model, numerical simulations for various conditions of regular and irregular waves were made both for uniform slope and stepped bottom.

As the most fundamental case, Fig.5 shows the evolution of the spatial distribution of the water surface elevation $\eta$ and the turbulent kinetic energy $k$ in case of regular waves with $T=8s, H_0/L_0=0.02$ on a uniform slope of 1:50. At the shore-side end of the slope a shallow horizontal section was connected for better computational performance in the treatment of outgoing waves. The generation of turbulence near the wave crest and its subsequent decay behind the wave crest are reasonably simulated. Figure 6 represents the results for the irregular waves with the Bretschneider spectrum having the significant wave height of $8s$. The irregular feature of the occurrence of the wave breaking can be observed with the subsequent development and decay of the turbulence energy. Figure7 shows the results for regular waves with $T=8s, H_0/L_0=0.02$ on a double step. This is a typical case in which the non-equilibrium feature of the wave evolution becomes appreciable due to the imbalance between the turbulence production and dissipation rates. After the first breaking of waves the turbulence intensity attenuates with the corresponding reform of waves on the step, which is followed by another breaking on the second slope.

Conclusion

With the time-dependent depth-integrated formulation of turbulence, which is to be coupled with nonlinear wave equations, and the development of a method to estimate the turbulence production due to wave breaking, a new model for the breaking wave simulation is presented in this study. As a governing factor to describe
non-equilibrium turbulence evolution of breaking waves on a beach with arbitrary profile, the turbulence production is modeled based on pseudo-periodic generation of large-scale eddies at the bore front. Through numerical simulations, the present model has been demonstrated to give favorable features of evolution of regular and irregular breaking waves and the production and diffusion of turbulent kinetic energy.

Wave Crest Interaction in Water of Intermediate Depth

C.C. Bird † and D.H. Peregrine ‡

Abstract

Numerical computations using a fully nonlinear potential flow solver are carried out on water of intermediate depth. Properties of single and multiple wave groups are examined on horizontal and sloping beaches. Comparisons are made with linear and weakly nonlinear theories. An important result is that the increase in wave amplitude due to wave shoaling is likely to be much less than the linear theory result for short steep wave groups because of the tendency for the group to spread.

Introduction

This paper is part of a series of studies of waves on a beach, which aims to learn more of finite amplitude effects on irregular waves. It follows Bird & Peregrine (1997) where attention is directed towards the long waves associated with and generated by a single wave group. Here the waves within one or more wave groups are studied in water of intermediate depth, that is for $1.36 > kh > 0.7$, where $h$ is the water depth and $k$ is the wavenumber.

The characteristic behaviour of wave groups on deep water differs greatly from that on shallow water. On deep water the waves are dispersive, and thus their energy travels at a speed different from that of the individual waves. Typically the group and its energy travel at half the speed of the individual waves in that group (the group velocity concept). In wave groups where the wave number is constant, the individual waves do not meet, and their interaction is in the form of energy 'slipping' back through the group relative to the wave crests.

‡Professor of Applied Mathematics, School of Mathematics, University of Bristol (D.H.Peregrine@bristol.ac.uk)
In shallow water, energy flows with the wave crests. In the Boussinesq region, which often occurs before the waves break, the waves are typically solitary type waves, and as is described by two-soliton solutions of the Korteweg-de-Vries equation, they may merge temporarily if a wave of high amplitude catches up a smaller one ahead of it. However, unless the waves break at the point at which they merge, they separate again, suffering only a change of phase. The case of two waves of almost equal amplitude is slightly different; the solution of the KdV equation indicates if such waves are close, then they do not merge, but exchange amplitudes and shift phases as if they had. Figure 1 shows an example of the first case, computed using a fully nonlinear potential flow solver (described in a later section). Successive surface elevation profiles are plotted, shifted with time. The initial conditions consist of a single group of 5 modulated solitary waves, a large central one and much smaller outer waves. A small amount of set down is added, but not enough to balance the mass of the waves. They are propagated on a beach of slope 1:60. It is clear to see that the largest wave merges with the one ahead of it. The waves have almost passed through each other when the largest one breaks.

![Figure 1: Surface elevation profiles of a single wave group progressing up a 1:60 beach.](image)

After breaking, waves can be modelled by bores (discontinuities of the shallow water equations). Bores frequently catch up one another and merge. This has been observed in the field study carried out by Packwood and Peregrine in 1980; some details are given in Peregrine (1998). Unlike solitary waves however, a merged bore retains its unity. Peregrine (1974) uses invariants of the nonlinear shallow water equations to show that in this situation, a small backward travelling wave of depression is formed.
at the merger.

However, the present topic of interest is the region between deep water and the Boussinesq regime, i.e. intermediate depth water. Barnes & Peregrine (1995) used a fully nonlinear potential flow model to study the progress of individual wave groups travelling up a plane beach in the context of low frequency waves. Instead of the converging type behaviour seen in figure 1, they noted that the group and its energy appeared to spread significantly, and also that the waves shoaled far less than is predicted by (regular wave) linear theory. We address these last points by carrying out computations using the same nonlinear potential flow solver. Both single and multiple wave groups are considered, on horizontal and sloping beaches. It is useful to examine the behaviour of groups over a horizontal bed in order to clarify the processes at work since then the effect of the slope is separated out. But first we briefly review the relevant theory for wave groups.

Brief review of applicable linear and weakly nonlinear theory

To model modulated waves it is useful to consider the wave elevation to be described by

\[ \eta(x, t) = A(X, T)e^{i(kx - \omega t)} + \text{complex conjugate} \]  

(1)

(eg. see Mei, 1983). Here \( X \) and \( T \) represent the 'slow' space and time coordinates, and \( \omega \) and \( k \) are related by the dispersion equation

\[ \omega^2 = gk \tanh(kh) \]  

(2)

The water depth \( h \) is a function of the slow space variable, i.e. \( h(X) \), and \( g \) is the gravitational acceleration.

From the assumption of slow variations of the wave amplitude \( A \), linear theory gives a first approximation:

\[ \frac{\partial A}{\partial T} + c_g \frac{\partial A}{\partial X} = 0; \quad c_g = \frac{\partial \omega}{\partial k} \]  

(3)

This result corresponds to geometrical ray theory if extended to two dimensions. It gives the usual linear shoaling theory for varying depth, and indicates that a wave group simply translates with the group velocity \( c_g \). As already noted, unless \( kh \) is small, the wave speed \( c = \omega/k \neq c_g \).

Including the next linear terms in the slow modulation approximation gives

\[ \frac{\partial A}{\partial T} + c_g \frac{\partial A}{\partial X} = i \omega'' \frac{\partial^2 A}{\partial X^2}; \quad \omega'' = \frac{\partial^2 \omega}{\partial k^2} \]  

(4)

which is a Schrödinger equation, or a linear parabolic wave equation. The extra term on the right hand side gives an extra dispersion to the wave groups.
Including weakly nonlinear terms in the above approximation gives

\[ i \frac{\partial A}{\partial t} + c_2 \frac{\partial A}{\partial X} + \frac{1}{2} \omega'' \frac{\partial^2 A}{\partial X^2} = \lambda |A|^2 A \]  

(5)
a nonlinear Schrödinger (NLS) equation. Here \( \lambda \) is a function of \( kh \). In deep water, \( \omega'' < 0 \) and the equation has soliton solutions corresponding to special groups that propagate unchanged. This equation then gives the Benjamin-Feir modulational instability, which can also be described as 'self-focussing' of the waves. However for intermediate water depths, \( kh < 1.36 \), \( \omega'' \) has the opposite sign, and the equation has a more stable 'defocussing' character. This aspect of wave modulations can be seen in the following computations with an accurate flow solver.

The numerical model

The computations were carried out using an accurate fully nonlinear irrotational flow solver. This is able to solve from deep water up to the first occurrence of wave breaking. The spatial domain is of finite length, bounded by uniform conditions.

The fluid is considered to be two-dimensional, inviscid, incompressible and irrotational, and surface tension is neglected. Defining points \((x, y)\) on the free surface by \((X(s, t), Y(s, t)) = R(s, t)\), where \( s \) is a particle-following (Lagrangian) coordinate, we have:

\[ \nabla^2 \phi = 0 \]  
in fluid body  

(6)

\[ \frac{D R}{D t} = \nabla \phi \]  
on free surface  

(7)

\[ \frac{D \phi}{D t} = \frac{1}{2} |\nabla \phi|^2 - g Y \]  
on free surface  

(8)

with the appropriate bed boundary conditions. The velocity potential is represented by \( \phi(x, y, t) \).

If the spatial domain is a plane sloping beach, then the model first transforms this into a horizontal plane using a conformal mapping. The above system of equations is solved using a Cauchy theorem boundary integral, and hence the velocity at the free surface is computed. The surface is then stepped in time using a Taylor series truncated at the sixth order. Further details may be found in Tanaka et al. (1987) and Cooker (1990).

A single wave group propagated on a horizontal bed

Once one departs from considering a regular periodic wave train there is a huge range of incident waves that may be considered. For simplicity and uniformity we have
chosen initial conditions in the form of a wave group with the surface properties of
the deep water soliton of the same steepness, ie. to linear approximation

$$\eta(x,0) = \frac{1}{2} \left( a \sech \left( \sqrt{2} a k^2 x \right) e^{ikx} + c.c. \right)$$  \hspace{1cm} (9)

$$\phi(x,0) = -\frac{g}{2\omega} \left( i a \sech \left( \sqrt{2} a k^2 x \right) e^{ikx} + c.c. \right) .$$  \hspace{1cm} (10)

The subsurface velocities adjust appropriately in the computation when the frequency
$\omega$ comes from the linear dispersion relation given above (equation 2), chosen to be
appropriate to the depth.

In the initial conditions the higher order corrections to equations (9) and (10) were not
fully included. Usually only the second harmonic terms were added, thus generation
of associated long waves occurs. See Bird & Peregrine (1997) for discussion of this
feature.

![Figure 2: Selected surface profiles for single wave group progressing over a horizontal
bed, in a frame of reference moving with the group velocity.](image)

Results from a typical computation over a horizontal bed are given in figure 2. Se-
lected surface profiles illustrate the progress of the free surface with time. Time in
non-dimensionalised units ($t^* = t/\sqrt{h/g}$) is shown on the relevant axes. We summa-
rize results from several such computations.

In every case the expected defocussing, or spreading out of the group is evident.
Such behaviour might be expected to scale with the Ursell number, $Ur = a/k^2 h^3$, 
but it depends most strongly on wave steepness $ak$, and less so on $Ur$ or $kh$. As
Peregrine (1983) notes, all NLS equations can be transformed to the same canonical
form, with either a $+$ or $-$ sign for the nonlinear terms. The canonical equation can
then have any solution transformed in the wave amplitude, space and time to give a
whole family of solutions, depending on amplitude as a parameter. Here, because of
the dependence of $\omega$ and $\lambda$ on $kh$ such transformations do not give any particularly
simple result. However, they do show that if the waves are not too steep or long, e.g.
$U\tau < 0.3$ then this defocussing behaviour is to be expected from our knowledge of
solutions of NLS equations.

Linear theory is appropriate for small waves at the margins of a wave group, and
hence, as we can expect, for a lengthening group the waves at the front of each group
are longer than those at the rear. The additional trailing group of very short waves
comes from the waves' requirement for bound high harmonics that were not included
in the initial conditions. Corresponding short free waves are emitted. Similarly, the
long set-down wave was not included and a free long wave can be seen emerging from
the front of the group, see Bird & Peregrine (1997) for more details.

![Figure 3: Maximum wave amplitude of a single wave group progressing over a hori-
zontal bed; solid = fully nonlinear method, dash dot = basic linear theory, dash dot
dot dot = linear theory including higher order dispersion, dash = weakly nonlinear
theory (NLS).](image)

The maximum surface height as computed by the fully nonlinear potential flow solver,
is compared with the theories described in the previous section (linear, linear
with higher order dispersion, weakly nonlinear) in figure 3. A method by Taha &
Ablowitz (1984) is used to compute solutions of the nonlinear Schrödinger equation;
this is easily adjusted to compute the solutions to the linear equations. Since no
higher order correction terms were added to the initial conditions when computing
the solutions to the approximate theories, there is a difference in the initial heights
of the surfaces.

A more accurate description of the value plotted for the fully nonlinear method is
that it is of the highest grid point, and since no interpolation is carried out, this
differs slightly from the maximum height of the surface. This results in the small
oscillations evident on this plot. The larger oscillations are due to the difference in the phase and group velocities of the waves. Individual waves still pass through the group in the manner described above for deep water (although they no longer travel at twice the speed of the group), and thus the largest wave persists only for a limited time, marked by the length of these oscillations. These oscillations are not seen in the solutions to the theories since these give only details of the wave envelope rather than the individual waves.

We can see that the NLS equation gives a good approximation after the initial transients whereas the linear theories are poor. From consideration of other examples we find that the basic linear theory is adequate only for very gentle waves which, because of our special choice of initial conditions, also corresponds to very long groups. The linear theory with higher-order dispersion is noticeably better, and in a number of cases is almost as good as the NLS.

**Three wave groups propagated on a horizontal bed**

Here the initial conditions consist of three envelope soliton groups alongside each other, centred a distance of 6 or more wavelengths apart. These distances were chosen to ensure that the groups were sufficiently far enough apart to have initial identities, but not so far apart as to prevent significant interaction between them. The example presented has the same initial wave steepness and depth as that in the section on single groups above. Again terms of the second harmonics are added. This example is illustrated in figures 4 and 5.

![Figure 4: Selected surface profiles for three wave groups progressing over a horizontal bed in a reference frame moving with the group velocity.](image)

Selected profiles illustrating the progression of the surface elevation in time are given in figure 4. Again the groups spread to varying degrees depending on their initial
steepnesses, but the interactions between the waves slightly limit this effect. The individual waves interact with each other. Initially waves in each group are in phase, but the phase changes involved in the spreading out of the groups lead to significant irregularities as the groups overlap.

Figure 5: Maximum wave amplitude of three wave groups progressing over a horizontal bed; solid = fully nonlinear method, dash dot = basic linear theory, dash dot dot = linear theory including higher order dispersion, dash = weakly nonlinear theory (NLS).

The maximum surface height of the wave group as computed by the fully nonlinear potential flow solver is compared with the basic linear, linear with higher order dispersion and weakly nonlinear theories in figure 5. In the fully nonlinear plots we observe additional oscillations on different (and varying) lengthscales from the short and long ones discussed above for single wave groups. These are due to both the forward travelling free long waves passing through the groups and elevating individual waves for short periods of time, wave interference, and differing modulations giving the highest wave. This latter behaviour is the source of the large kink in each of the nonlinear curves in figure 5.

The basic linear theory is slightly more successful in predicting the maximum wave amplitude, as it is generally slightly higher than for an isolated group. However, the envelopes of the steeper groups do not progress without change of form, thus basic linear theory is still not appropriate for changes on these length scales. Again the weakly nonlinear theory and the linear higher order dispersion theory perform better. One of the reasons for this is the inability of the theories to model the free long waves and harmonics which emerge from the group. We have already noted that the long waves computed in the fully nonlinear computation pass through the group and elevate individual waves, thus effectively increasing the maximum surface elevation. The long waves are higher for the steeper groups, and so it is for these groups that we see the greater difference in maximum amplitude. However, modulation equations
corresponding to the NLS level of approximation can model the long waves. Such free long waves and very short waves are also generated in real situations of depth variation.

So in summary, the multiple groups spread out slightly less than isolated groups of the same steepness on the same depth. The maximum surface elevation is higher, due to the interactions between the waves. Basic linear theory is again the least appropriate for the steeper groups. Both linear theory which includes higher order dispersion and the weakly nonlinear theory are more successful, but the free long waves formed by the group are important.

A single wave group propagated on a plane sloping beach

In this section we repeat and extend some of the computations of Barnes & Peregrine (1985). The bed topography is a sloping beach leading onto a shelf of constant depth. The initial condition is a single deep water envelope soliton, with no added higher order terms. Beach slopes of 1:10 and 1:40 are used. The beach corners are located at \( x = 10 \) for the 1:10 beach and \( x = 20 \) for the 1:40 beach. The depth of the water at the centre of the group's initial position may be computed by adding the shelf depth \( h \) (indicated in figures 6 and 9) to either 1.0 for the 1:10 beaches or 0.5 for the 1:40 beaches. This means that the groups start in a water depth of at least half a wavelength.
Figure 6 shows a comparison between the linear shoaling coefficient (dashed line) and the shoaling of the computed wave groups (solid line), calculated as the maximum surface elevation at each depth. The irregularity of the computational results is due both to the irregularities explained earlier, and to the finite intervals at which the computation is sampled. We note that the maximum surface elevation increases quite suddenly and significantly as the waves propagate on the constant depth shelf. It is easy to verify the conclusions of Barnes & Peregrine (1995), that shorter, steeper groups spread out and thus shoal much less than longer, less steep groups, and that this effect is more marked on gentle beaches. After considering the horizontal bed case, this conclusion is not surprising. The group does not encounter other waves around it as it spreads and thus cannot interact with any other waves. On a gentler beach the group spreads more since it has more time in which to spread.

1:10 beach, $ak=0.05$

Selected surface profiles from two of the examples are shown in figure 7. The space coordinate has been shifted with linear group velocity, and thus we mark the beach corner position (ie. that point where the slope changes to constant depth shelf) by crosses. It is easy to see the transformation of the sinusoidal waves to near solitary type waves in the shallowest water.

Many of the features of the groups observed on the horizontal bed topography may be seen here too in our full range of examples. The steeper groups spread more than the shallower ones; again the wave groups formed of waves of steepness $ak = 0.05$ barely spread at all. Higher-order harmonic corrections are emitted from the back of the group, as before, but there is no easily visible evidence of free long waves until the group passes onto the shelf. Longer waves are towards the front and shorter waves towards the back of the group while it is on the sloping section, and the envelope becomes asymmetric. However as the waves pass onto the shelf, their wavelength reduces (in addition to their amplitude suddenly increasing). This is quite dramatic in the cases of the wave groups of steepness $ak = 0.05$, due to particularly shallow depth chosen for those shelves. On a plane beach without a shelf, breaking would occur just after the point where the corner is placed.
It is easy to observe that the group does not always travel with the linear group velocity. The trend is for the group to travel a little slower than $c_g$ shortly before it reaches the shelf, and faster as it passes onto and travels along the shelf. This may be observed more clearly in figure 8, which compares the speed of the computed groups (squares) with the linear group velocity (solid line). The dotted line represents the start of the shelf; above it the depth is constant (the markings on the vertical axis are inappropriate there).

The speed of the computed groups is estimated as follows: at each time, a Hilbert transform of the surface elevation is taken to give the group envelope. Since the waves are nonlinear, this envelope is very ‘noisy’, and so we use a Fourier filter to remove the higher harmonics. We denote the position at which this smoothed envelope has a maximum to be the centre of the group. Numerically differentiating the positions of the group centres with respect to time gives the group velocity.

It is not very surprising that the comparison is poor at the shallower depths; with the waves being more nonlinear there (behaving more as individual solitary-type waves) we can expect the linear group velocity concept to fail.

In summary, the maximum amplitude of a single wave group propagated up a sloping beach is almost always less than that predicted by the linear shoaling coefficient. This effect is most marked for steep groups on gentle beaches, but is not surprising, since the regular wave theory is least appropriate for short isolated wave groups. Many of the features of the groups observed on the horizontal beach are also seen on the
sloping beach. The group travels with the linear group velocity in deeper water, but not in shallower water where we may expect the group velocity concept to fail.

**Three wave groups propagated on a plane sloping beach**

Here the initial conditions were formed of 3 adjacent envelope soliton groups, again with no higher harmonic corrections added, spaced by either 10 wavelengths \((ak = 0.05)\) or 6 wavelengths (other steepnesses). We choose the same combinations of beach slopes and wave steepnesses as for the single groups, except that for the case of beach slope 1:10, initial wave steepness \(ak = 0.05\), the beach corner is now located at \(x = 15.0\).

![Figure 9: Normalised maximum amplitude of three wave groups progressing on a plane beach (solid line), shoaling coefficient (dashed line).](image)

A comparison between the shoaling coefficient and the maximum height of the computed surface is shown in figure 9. The results are very similar to those for the isolated groups (see figure 6); the computed maximum amplitudes are generally slightly higher for 3 groups than for one, but the differences are quite small.

Examining the surface profiles shown in figure 10, it is not difficult to see why the changes are small: there is not enough time for any significant interactions between the waves to occur, unlike the horizontal bed case. Also there are no significant long waves to raise the individual waves of the group, as there was on the horizontal bed. The tendency of the very short steep groups to spread is very strong, with the maximum amplitude below the shoaling coefficient, as before.
Conclusions

We have examined the behaviours of wave groups in water of intermediate depth. Features of both the deep water and Boussinesq type behaviours were evident; however the primary area of concern was the differences between the linear shoaling coefficient and the shoaling of the computed groups. It was noted that basic linear theory is the least appropriate for short, steep isolated groups and that on a horizontal bed, both linear theory including higher order dispersion and the weakly nonlinear theory give better results. The differences with the linear shoaling theory were explained by the tendency of the groups to spread and the lack of interaction with other waves; the differences are smaller when the initial conditions consisted of three wave groups instead of just one. An important result is that the increase in wave amplitude due to wave shoaling is likely to be much less than the linear theory result for short steep wave groups because of the tendency for the group to spread.

Energy Dissipation Model for Irregular Breaking Waves

Winyu Rattanapitikon\textsuperscript{1} and Tomoya Shibayama\textsuperscript{2}

Abstract

A simple model is presented to compute the average rate of energy dissipation in irregular breaking waves. The average rate of energy dissipation rate is assumed to be proportional to the difference between the local mean energy flux and stable energy flux. The local fraction of breaking waves is determined from the derivation of Battjes and Janssen (1978). Root mean square wave height deformation is computed from the energy flux conservation. The model is validated using root mean square wave height data from small and large scale laboratory and field experiments. Total 144 wave height profiles are used in the calibration and verification of the model. Reasonable good agreement is obtained between the measured and computed root mean square wave heights. The root mean square relative error of the model is 10.2\%.

1. Introduction

In studying many coastal engineering problems it is essential to have accurate information on wave conditions. When waves propagate to the shore, they increase in height and decrease in length wave and eventually waves break. Once the waves start to break, energy flux from offshore is dissipated to turbulence and heat and causes the decreasing of wave height towards the shore in the surf zone. Irregular wave breaking is more complex than regular wave breaking. In contrast to regular waves there is no well-defined breaking point for irregular waves. The highest waves tend to break at greatest distances from the shore. Thus, the energy dissipation of irregular waves occurs over a considerably greater area than that of regular waves.

For computing beach transformation, the wave model should be kept as simple as possible because of the frequent updating of wave field for accounting the variability of mean water surface and the change of bottom profiles. In the present study, wave height transformation is computed from the energy flux conservation:

\[
\frac{\partial(Ec_g \cos \theta)}{\partial x} = -\bar{D}_B
\]

where \( E \) is the wave energy density, \( c_g \) is the group velocity, \( \theta \) is the mean wave angle, \( x \) is the distance in cross-shore direction, and \( \bar{D}_B \) is the average energy dissipation rate of the breaking waves. Snell's law is employed to describe wave refraction.

The wave height transformation can be computed from the energy flux balance equation (Eq. 1) by substituting the formula of the average energy dissipation rate, \( \bar{D}_B \), and numerical integrating from offshore to shoreline. The main difficulty of energy flux conservation approach is how to determine the average energy dissipation rate, \( \bar{D}_B \). Owing to the complexity of wave breaking mechanism, an empirical approach based on measured data is the only feasible way of describing the energy dissipation rate.

In order to make the empirical formula reliable, it is necessary to calibrate or verify that formula with wide range of experimental results. Since many energy dissipation models were developed based on data with the limited experimental conditions, there is still a need for more data to confirm the underlying assumptions and to make the model more reliable. The main target of this study is to develop the energy dissipation model based on wide range of experimental conditions. Small and large scale laboratory and field experiments have been collected for calibration and verification of the present models. A summary of the collected experimental results is given in Table 1.

**Table 1.** Summary of collected experimental data used to validate the present models.

The energy dissipation model of irregular breaking wave will be developed based on a similar concept as regular breaking wave model of the authors. The summaries of related regular wave models are as follows.

a) Dally et al. (1985) assumed $D_b$ is proportional to the difference between the local energy flux and the stable energy flux of breaking wave:

$$D_b = \frac{K_d C_g \rho g}{8h} \left[ H^2 - \left( \Gamma h \right)^2 \right] \tag{2}$$

where all variables are computed based on linear wave theory, $K_d$ is the wave decay factor (0.015), $H$ is the local wave height, $h$ is the local water depth, $\Gamma$ is the stable wave factor (0.4).

b) Rattanapitikon and Shibayama (1996) modified the model of Dally et al. (1985) and proposed to compute the stable wave factor, $\Gamma$:

$$\Gamma = \exp \left[ -0.36 - 1.25 \frac{h}{\sqrt{LH}} \right] \tag{3}$$

where $L$ is the wavelength.

Nine sources of published laboratory results, totally 332 wave profiles, were used to verify the formula.

2. Model Development

Dally (1992) used the regular wave model of Dally et al. (1985) to simulate transformation of irregular wave by using wave-by-wave approach. This means that Dally assumed that $D_b$ is proportional to the difference between local energy flux of a breaking wave and stable energy flux. Also wave-by-wave approach requires much computation time. Therefore it may not suitable to use in a beach deformation model.

However, the model becomes simple if we consider the macro-features by set an assumption that the average rate of energy dissipation in irregular breaking waves is proportional to the difference between local mean energy flux and stable energy flux. After incorporating the fraction of breaking, the average rate of energy dissipation in irregular wave breaking, $\bar{D}_b$, can be expressed as

$$\bar{D}_b = \frac{K_1 Q_s C_g}{h} \left[ E_m - E_s \right] \tag{4}$$

where

$$E_m = \frac{1}{8} \rho g H_{rms}^2 \tag{5}$$
\[ E_s = \frac{1}{8} \rho g H_s^2 = \frac{1}{8} \rho g (\Gamma_r h)^2 \]  

(6)

in which all variables are computed based on the linear wave theory, \( K_1 \) is the proportional constant, \( Q_b \) is the fraction of breaking waves, \( c_g \) is the group velocity related to the peak spectral wave period \( T_p \), \( E_m \) is the local mean energy density, \( E_s \) is the stable energy flux, \( H_{rms} \) is the root mean square wave height, \( H_s \) is the stable wave height and \( \Gamma_r \) is the stable wave factor of irregular wave.

Rewriting Eq. (4) in term of wave height:

\[ \overline{D_B} = \frac{K_1 Q_b c_g \rho g}{8h} \left[ H_{rms}^2 - (\Gamma_r h)^2 \right] \]  

(7)

The stable wave factor, \( \Gamma_r \), is determined by applying Eq. (3) as

\[ \Gamma_r = \exp \left[ K_2 (-0.36 - 1.25 \frac{h}{\sqrt{L_p H_{rms}}} \right) \]  

(8)

where \( K_2 \) is the coefficient, \( L_p \) is the wavelength related to the peak spectral wave period.

The local fraction of breaking waves, \( Q_b \), is the ratio of the number of breaking waves to the total number of waves. To determine the fraction of breaking waves, Battjes and Janssen (1978) assumed that the probability density function of wave heights is the Rayleigh-type. The fraction of breaking waves is derive based on the assumption of truncated Rayleigh distribution at the breaking wave height:

\[ \frac{1 - Q_b}{-\ln Q_b} = \left( \frac{H_{rms}}{H_b} \right)^2 \]  

(9)

where \( H_b \) is the breaking wave height.

Various empirical formulas have been proposed to compute the breaking wave height, e.g., Goda (1970), Weggel (1972), Singamsetti and Wind (1980), and Hansen 1990. However there is no conclusion that which one is the best. Since the breaking criterion of Goda (1970) was developed from wide range of experimental results, it is selected for inclusion into the present model. The breaking criteria of Goda (1970) is

\[ H_b = K_3 L_o \left\{ 1 - \exp \left[ -1.5 \frac{\pi h}{L_o} \left( 1 + 15 m^{4/3} \right) \right] \right\} \]  

(10)
where $K_3$ is the coefficient, $L_0$ is the deep-water wavelength, and $m$ is the bottom slope. The published value of $K_3$ is 0.17 for regular breaking waves. For the present study, $K_3$ is the adjustable coefficient to allow for effect of the transformation to irregular waves.

Since Eq. (9) is an implicit equation, the iteration process is necessary to compute the fraction of breaking waves, $Q_b$. It will be more convenient if we can compute $Q_b$ from the explicit form of Eq. (9). From the multi-regression analysis, the explicit form of $Q_b$ can be expressed as the following (with $R^2 = 0.999$):

$$ Q_b = \begin{cases} 0 & \text{for } \frac{H_{rms}}{H_b} \leq 0.43 \\ -0.738 \left( \frac{H_{rms}}{H_b} \right) - 0.280 \left( \frac{H_{rms}}{H_b} \right)^2 + 1.785 \left( \frac{H_{rms}}{H_b} \right)^3 + 0.235 & \text{for } \frac{H_{rms}}{H_b} > 0.43 \end{cases} $$ (11)

The energy dissipation model (Eqs. 7, 8 and 10) contains 3 coefficients, $K_1 - K_3$, that can be found from model calibration.

3. Model Calibration

The model is calibrated for determining the optimal values of the coefficients $K_1 - K_3$ in Eqs. (7), (8) and (10). The calibration is carried out with the large-scale experimental data from the SUPERTANK Laboratory Data Collection Project (Kraus and Smith, 1994). The SUPERTANK project was conducted to investigate cross-shore hydrodynamic and sediment transport processes, during the period August 5 to September 13, 1992, at Oregon State University, Corvallis, Oregon, USA. A 76-m-long sandy beach was constructed in a large wave tank of 104 m long, 3.7 m wide, and 4.6 m deep. Wave conditions involved regular and irregular waves. The 20 major tests were performed and each major test consisted of several cases (see Table 2). Most of the major tests were performed under the irregular wave actions, except the test No. STBO, STEO, STFO, STGO, STHO, and STIO. The collected experiments for irregular waves include 128 cases of $rms$ wave height profiles, covering incident $rms$ wave heights from 13.9 cm to 60.1 cm, peak wave periods from 2.8 sec to 9.8 sec. Sixteen resistance wave gages were deployed at 3.66 m intervals from the mid surf zone to the wave paddle. Ten capacitance wave gage were placed at 0.61-to 1.83-m intervals in the vicinity of the shoreline and on the beach face to measure runup properties. The measured data from 18 wave gages (16 from resistance wave gage and 2 from capacitance wave gages) are used in this study.

In order to evaluate the accuracy of the prediction, the verification results are presented in term of root mean square ($rms$) relative error, $ER$, which is defined as
where \( i \) is the wave height number, \( H_{ci} \) is the computed wave height of number \( i \), \( H_{mi} \) is the measured wave height of number \( i \), and \( tn \) is the total number of measured wave height. Smaller values of \( ER \) correspond to a better prediction.

The \( rms \) wave height transformation is computed by the numerical integration of energy flux balance equation (Eq. 1) with the energy dissipation rate \( \overline{D}_n \) of Eq. (7):

\[
\frac{\partial \left( H_{rms}^2 c_e \cos \theta \right)}{\partial x} = - \frac{K_3 Q_b c_e}{h} \left[ H_{rms}^2 - \left( h \exp\left( -0.36K_2 - 1.25K_2 \frac{h}{\sqrt{L_p H_{rms}}} \right) \right) \right]^{2}
\]  

where \( Q_b \) is computed from Eq. (11), and \( H_h \) is computed from Eq. (10).

The measured water depth and wave height and wave period at the most seaward wave gage are used as input to the model. Eq. (13) is solved by backward finite difference scheme. Trial simulations indicated that \( K_1 = 0.10, K_2 = 1.60 \), and \( K_3 = 0.10 \) give good agreement between measured and computed \( rms \) wave heights. Finally, the energy dissipation rate of irregular wave breaking can be written as

\[
\overline{D}_n = \frac{0.1Q_b c_e \rho g}{8h} \left[ H_{rms}^2 - \left( h \exp\left( -0.58 - 2.00 \frac{h}{\sqrt{L_p H_{rms}}} \right) \right) \right]^{2}
\]  

where \( Q_b \) is computed from Eq. (11) and

\[
H_h = 0.1L_o \left\{ 1 - \exp\left( -1.5 \frac{\pi h}{L_o} \left( 1 + 15m^{4/3} \right) \right) \right\}
\]  

Comparison between measured and computed \( rms \) wave heights for all 128 cases are shown in Fig. 1. Table 2 shows the \( rms \) relative error, \( ER \), of the present model for each major tests. The average \( rms \) relative error, \( ER \), for all 128 cases is 10.0\% which indicates very well prediction. Typical examples of computed \( rms \) wave height transformation for each major test are shown in Figs. 2 and 3. From Table 2 and Figs. 2-3, it can be seen that the model results generally show very well prediction, except the test no. STKO (broad-crested offshore mound). Furthermore, for some cases, the model tends to under-predict the wave heights very close to the shore.

4. Model Verification

Since the present model is calibrated with only the data from the large-scale experiments, there is still a need of data from small-scale and field experiments for confirming ability of the present model. Two sources of experimental results are collected to verify the model, i.e., small-scale experimental data of Smith and Kraus (1990), and field data of Thornton and Guza (1986).

The wave height transformation is computed from the energy flux balance equation (Eq. 1) using $\overline{D}_b$ from Eq. (14) and numerical integration, using backward finite difference scheme, from offshore to shoreline. All coefficients in the model are kept to be constant for all cases in the verification.

4.1 Comparison with small-scale laboratory data

The small-scale laboratory data of Smith and Kraus (1990) is used in this subsection. The experiment was conducted to investigate the macro-features of wave breaking over bars and artificial reefs using small wave tank of 45.70-m-long, 0.46-m-wide, and 0.91-m-deep. Submerged triangular-shaped obstacles representing bars and reefs were installed on a 1/30 concrete slope to cause wave breaking. Both regular and irregular waves were employed in this experiment. Total 12 cases were performed for irregular wave tests. Three irregular wave conditions were generated for three bar configurations each, as well as for the control case of plane beach. The wave conditions were developed from input JONSWAP spectrum for spectral peak periods of 1.0, 1.5, and 1.75 sec, with significant wave heights of 11.3, 14.3, and 13.7 cm, respectively. Eight resistance wave gages were installed in the wave tank, 3 gages were placed in the offshore zone, 1 gage was place at the incipient break point, and 4 gages were placed in the surf zone.

Comparison between measured and computed $rms$ wave heights for all cases are shown in Fig. 4. The average $rms$ relative error, $ER$, for all cases is 11.2 % which indicates a good prediction of the model. Fig. 5 shows the typical examples of computed $rms$ wave height transformation for incident $rms$ wave height of 10 cm, peak period of 1.75 s and four bottom conditions. The model results generally show good agreement with the measured data. However, the model could not predict the rapid increase and decrease in wave heights near the narrow-crested bar.

4.2 Comparison with field data

The field data from Thornton and Guza (1986) are used in this subsection. The experiment was conducted on a beach with nearly straight and parallel depth contours at Leadbetter Beach, Santa Barbara, California, USA, to measure longshore currents, waves, and beach profiles, during the period January 30 to February 23, 1980.

Comparison between computed and measured $rms$ wave height for all four cases are shown in Fig. 6. The average $rms$ relative error, $ER$, is 14.5%. Fig. 7 shows the typical examples of computed and measured $rms$ wave height transformation for the cases of Thornton and Guza (1986). The model results also generally show good agreement with the measured data.
Figure 4 Comparison between computed and measured $rms$ wave height for 12 cases of small-scale experiments (measured data from Smith and Kraus, 1990).

Figure 5 Examples of computed and measured $rms$ wave height for incident $rms$ wave height of 10 cm, and peak period of 1.75 s (measured data from Smith and Kraus 1990).
Figure 6 Comparison between computed and measured $rms$ wave height for 4 cases of field experiments (measured data from Thornton and Guza, 1986).

Figure 7 Examples of computed and measured $rms$ wave height transformation for cases 3Feb - 6Feb (measured data from Thornton and Guza, 1986).
5. Conclusions

The energy dissipation model for irregular breaking waves is developed and applied to compute $\text{rms}$ wave heights by using energy flux conservation law. The model is developed based on the modified regular breaking waves model of Dally et al. (1985) and on the local fraction of breaking waves of Battjes and Janssen (1978). The computed $\text{rms}$ wave heights agreed well with the measured data for general cases, except the case of broad-crested offshore mound which is shown only fairly well prediction. The model is capable of simulating the increase in $\text{rms}$ wave height due to shoaling and subsequent decrease due to wave breaking over wide range of wave conditions and various shape of beach profiles. The validity of model is confirmed by small scale laboratory data from Smith and Kraus (1990), large scale laboratory data from SUPERTANK project and field data from Thornton and Guza (1986). Table 3 shows the average $\text{rms}$ relative error, $ER$, of the present model for each data sources. The average $\text{rms}$ relative error, $ER$, of the model is 10.2 %.

STOCHASTIC MODELLING OF NONLINEAR WAVES IN SHALLOW WATER

Henrik Kofoed-Hansen¹ and Jørgen H. Rasmussen²

Abstract

In this paper we shall study and model the nonlinear transformation of frequency wave spectra using two different types of stochastic models. The nonlinear processes considered include triad wave interaction and dissipation due to depth-induced wave breaking. The two stochastic models are the two-equation model proposed by Kofoed-Hansen and Rasmussen (1998) and the one-equation Lumped Triad Approximation (LTA) originally proposed by Eldeberky and Battjes (1995). Model results are compared with laboratory experiments and results obtained by the underlying deterministic time-domain Boussinesq model. The two stochastic models are found in good agreement with measurements of wave height (\(H_{mo}\)) and wave period (\(T_{01}\)). In case of wave transformation on a horizontal bottom, the LTA model fails as the rapid oscillations are neglected. The two-equation model predicts the energy transfer to sub-harmonics and non-resonant interaction excellently. In the inner surf zone and where the nonlinearity is strong, only the underlying deterministic model predicts the spectra and higher order wave statistics accurately.

Introduction

In recent years, considerable effort has been put on modelling of shallow water phenomena such as quadratic nonlinear wave interaction and depth-induced wave breaking using stochastic models. One of the major objectives is to extend third generation wind-wave models, like the well-known WAM model developed for oceanic waters and shelf seas, to coastal waters where triad interaction and wave breaking are the dominating phenomena, see e.g. Cavaleri and Holthuijsen (1998). The starting point is typically

deterministic evolution equations for the complex amplitudes of a weakly nonlinear wave field using either Boussinesq type equations (e.g., Freilich and Guza, 1984; Madsen and Sørensen, 1993) or the Laplace equation with leading order nonlinearity in the surface boundary conditions (e.g., Agnon and Sheremet, 1997; Madsen and Eldeberky, 1998).

In this study we have adopted the Boussinesq type equations with enhanced linear dispersion characteristics derived by Madsen and Sørensen (1993). Eldeberky and Battjes (1996) extended their equations by including energy dissipation due to depth-induced wave breaking. Based on these deterministic formulations, coupled stochastic evolution equations for the power spectrum and bispectrum have been derived recently by Eldeberky (1996) and Kofoed-Hansen and Rasmussen (1998) assuming that the trispectrum may be formulated as products of the power spectrum. The stochastic evolution equations suggested by Herbers and Burton (1997) are derived on basis of an extension of Freilich and Guza's (1984) deterministic model with lowest order dispersion and nonlinearity. Kofoed-Hansen and Rasmussen (1998) solved numerically the coupled evolution equations in order to calculate the wave spectrum and higher order nonlinear measures such as skewness and asymmetry (integral measures of the wave shape). For application in coastal energy-based wave models, Eldeberky and Battjes (1995) introduced a series of simplifications in order to avoid solving the evolution equation for the bispectrum. This resulted in a simple source function accounting for the effect of triad wave interaction, which can be used in conventional phase-averaged transport equations for the wave energy spectrum.

Stochastic Nonlinear Models

Time-domain Boussinesq type equations
The stochastic models considered in this paper are based on Boussinesq type equations derived by Madsen et al. (1991) and Madsen and Sørensen (1992). These equations incorporate enhanced linear dispersion characteristics and shoaling properties, which are important for an accurate representation of the nonlinear energy transfer. This paper considers unidirectional waves propagating normally to the bottom contours (one horizontal dimension). The depth-integrated equations of continuity and momentum can then be formulated as

\[
\frac{\partial \eta}{\partial t} + \frac{\partial P}{\partial x} = 0
\]  

(1)

\[
\frac{\partial P}{\partial t} + \frac{\partial}{\partial x} \left( \frac{p^2}{d} \right) + g d \frac{\partial \eta}{\partial x} - B g h \frac{\partial^2 \eta}{\partial x^2} \left( B + \frac{1}{3} \right) h^2 \frac{\partial^2 P}{\partial x^2 \partial t} - \frac{\partial h}{\partial x} \left( 2 Bh \frac{\partial^2 \eta}{\partial x^2} + \frac{1}{3} h \frac{\partial^2 P}{\partial x \partial t} \right) + R_{xx} = 0
\]  

(2)
where \( \eta \) is the surface elevation, \( P \) the depth-integrated horizontal velocity, \( h \) the still water depth, \( g \) the acceleration due to gravity, \( d \) the instantaneous total water depth, and \( B \) the dispersion coefficient. Variable \( x \) is the horizontal space coordinate and \( t \) denotes time. The inclusion of wave breaking is based on the surface roller concept, see Madsen et al (1997). The effect of the roller on the wave motion is taken into account by the excess momentum term (term \( R_{xx} \) in Eq. 2) originating from a non-uniform velocity profile due to the presence of the roller. The equations have lowest order nonlinearity as the classical Boussinesq equations. For a dispersion coefficient of \( B=1/15 \), accurate dispersion characteristics are obtained for \( kh \) less than about 3.2.

**Deterministic evolution equations**

Now the surface elevation is represented as a Fourier series

\[
\eta(x,t) = \sum_{p=-\infty}^{\infty} A_p(x) e^{i(\omega_p t + \varphi_p(x))}
\]

where \( A_p \) is a complex amplitude, \( \omega_p \) is the angular frequency, \( \varphi_p(x) \) is a phase function and \( i \) denotes the imaginary unit. Following Madsen and Sørensen (1993), the spatial evolution of the complex amplitude, \( A_p \), is to leading order given by the differential equation

\[
\frac{dA_p}{dx} = (L_p \frac{dh}{dx} + \gamma_p) A_p + i \sum_{m=-\infty}^{\infty} J_{m,m-p} A_m A_p e^{-i\delta\varphi(x)}
\]

which describes the spatial evolution of a weakly nonlinear wave field on a mildly sloping bottom. In the derivation it has been assumed that the amplitudes are slowly varying in space. The first term on the right-hand side of Eq. (4) represents the linear shoaling and the dissipation due to wave breaking \( \gamma_p \), whereas the second term describes the nonlinear triad wave interaction (bound waves as well modulated free waves). Here \( \delta\varphi(x) = \int \left( k_p + k_m - k_n \right) dx \) is the phase-mismatch and may be considered as a measure of the departure from exact resonance. Variable \( k_p \) denotes the wave number. The detailed expression for \( L_p \) and \( J_{m,m-p} \) is given in Kofoed-Hansen and Rasmussen (1998). Eq. (4) is identical to Eq. (7.1) in Madsen and Sørensen (1993) when \( \gamma_p = 0 \), and is the starting point for the derivation of the stochastic models suggested by Eldeberky and Battjes (1995), Eldeberky (1996) and Kofoed-Hansen and Rasmussen (1998).

**Two-equation stochastic model**

Stochastic evolution equations for the various order of spectra are derived by manipulating the deterministic evolution equations for the complex amplitude followed by ensemble-averaging. At lowest order, this procedure leads to an evolution equation for the power or wave energy spectrum including terms involving the next order spectrum, i.e. the bispectrum. An evolution equation for the bispectrum is derived at the following order, where terms including the trispectrum appear. In order to close the system of equations we
write the trispectrum as products of the power spectrum, the well-known Gaussian closure approximation. Hence, the evolution equation for the power spectrum and bispectrum constitutes the two-equation stochastic model describing the spatial evolution of a weakly nonlinear unidirectional wave field propagating on a mildly sloping bottom, see Kofoed-Hansen and Rasmussen (1998) for a thorough derivation. The coupled evolution equations are written as

\[
\frac{dF_p}{dx} = 2 \left( L_p \frac{dh}{dx} - \gamma_p \right) F_p + 2 \sum_{m,n=-\infty}^{\infty} J_{m,p,m} \mathcal{H}(B_{m,p,m})
\]

(5)

\[
\frac{dB_{m,p,m}}{dx} = \left[ (L_n + L_{p,m} + L_p) \frac{dh}{dx} - (\gamma_n + \gamma_{-m} + \gamma) \right] B_{m,p,m}
\]

\[
+ 2i J_{m,p,m} \left( \frac{k_m}{k_p} F_p F_{p,m} + \frac{k_{p,m}}{k_p} F_p F_m - \frac{k_p}{k_m} F_m F_{p,m} \right)
\]

(6)

where \(F_p\) and \(B_{m,p,m}\) denote the discrete power and bispectrum, respectively. The bispectrum describes the degree of coupling and phase relationship in triads of nonlinearly interacting wave components. It describes statistically the shape of shoaling waves, i.e., skewness \(\mathcal{R}(B_{m,p,m})\) and asymmetry \(\mathcal{H}(B_{m,p,m})\), see Elgar and Guza (1985). \(\mathcal{R}\) and \(\mathcal{H}\) denote the real and imaginary part, respectively. The discrete spectrum is converted into a continuous spectrum by dividing the power spectrum by the frequency resolution and the bispectrum by the frequency resolution squared, respectively.

**One-equation model**

Based on the evolution Equations (5) and (6), Eldeberky and Battjes (1995) derived a parameterised model for application in conventional phase-averaged models, the Lumped Triad Approximation, LTA. They introduced a series of simplifying assumptions in order to avoid the computation of the evolution equation for the bispectrum. First, they integrated this equation, then they neglected the rapid oscillations involving the wave number mismatch. Finally, they restricted the formulation to self-self interaction and parameterised the biphase in terms of the local Ursell number as originally suggested by Doering and Bowen (1995). The evolution equation for a continuous wave spectrum can be written as

\[
\frac{dF_p}{dx} = 2 \left( L_p \frac{dh}{dx} - \gamma_p \right) F_p + S_p - S_{2p}
\]

(7)

where the quadratic term, \(S_p\), is expressed by

\[
S_p = \alpha c_p J_{p/2,p/2}^2 \sin(\beta_{p/2,p/2}) \left[ F_{p/2}^2 - 2F_p F_{p/2} \right]
\]

(8)
The relation between the biphase, $\beta_{p, p}$, and the Ursell number is given by

$$\beta_{p, p} = -\frac{\pi}{2} + \frac{\pi}{2} \tanh \left( \frac{0.2}{U_r} \right), \quad U_r = \frac{g}{8\sqrt{2}\pi^2} \frac{H_{m0}^2 T_{01}^2}{h^2}$$

(9-10)

where $H_{m0} = 4 \sqrt{m_0}$ and $T_{01} = m_0/m_1$. The moments are calculated as $m_n = \int f^n Fdf$ and the tuning parameter $\alpha$ appearing in Eq. (8) is of order 1. The variable, $c_p$, denotes the phase speed.

**Dissipation due to wave breaking**

The dissipation rate, $\gamma_p$, incorporated in the stochastic models is either taken as frequency independent as suggested by Eldeberky and Battjes (1996) or as a frequency squared dependent dissipation term as suggested by Chen et al (1997). In general the dissipation rate, $\gamma_p$, should be treated as a complex quantity. Here we restrict ourselves to consider the dissipation as purely real.

The coupled set of stochastic evolution equations for the power spectrum and bispectrum are solved numerically using standard numerical integration techniques and with linear upwind boundary conditions, i.e., $B_{m, n} = 0$.

**Numerical Results and Comparison with Experimental Data**

Results of numerical simulations using the two stochastic models are compared with experimental data and results obtained by the underlying phase-resolving time-domain deterministic model.

**Submerged bar**

The measurements of Beji and Battjes (1993) are used to evaluate the two stochastic models for propagation of non-breaking waves over a trapezoidal submerged bar. Figure 1 illustrates their experimental setup. We consider the case with a very narrow-banded target spectrum. At WG1 this spectrum has a peak frequency of $f_p = 0.4$ Hz and a significant wave height of $H_{m0} = 0.023$ m, see Figure 2. A spatial resolution of 0.1 m is used and the frequency resolution is 0.03906 Hz. The tuning parameter $\alpha$ used in LTA is set to 1.

![Figure 1. Layout of experiment of Beji and Battjes (1993). All lengths are given in meter.](image-url)
Figure 2 presents a comparison of simulated and measured frequency spectra at locations WG1 and WG5. It has previously been shown (e.g., Kofoed-Hansen and Rasmussen, 1998 and Eldeberky, 1996) that the power spectrum is very accurately modelled on the uphill slope of the bar using the two stochastic models. On the top of the bar (see Figure 2) the two-equation model shows too much energy transfer to particularly the second harmonic components. The reason for the discrepancies is due to violation of the basic assumption of quasi-Gaussianity. At the crest section of the bar, the medium is almost non-dispersive for the primary waves ($k_p h \approx 0.26$). The LTA model underestimates the energy transfer towards higher harmonics ($f > 2f_p$) as well as to lower frequencies ($f < \sqrt{2}f_p$) as a consequence of the introduced simplifications.

The spatial evolution of quantities such as the significant wave height, $H_{m0}$, and the characteristic mean wave period, $T_{01}$, determined by the two stochastic models is compared measured data and the results obtained with the time-domain Boussinesq model in Figure 3.

![Figure 2. Comparison of frequency spectra from numerical simulations and measurements. (—) two-equation stochastic model, (—) LTA model and (ooo) experimental data by Beji and Battjes (1993).](image1)

![Figure 3. Spatial evolution of characteristic integral measures. (— and •) Deterministic model, (—) two-equation stochastic model, (—) LTA model and (ooo) experimental data by Beji and Battjes (1993). The bathymetry is sketched on the right panel.](image2)
From Figure 3 it appears that all three types of model result in similar growth of the wave height up-slope. Here the generated bound waves are phase-locked to the primary free waves and thus having almost the same group velocity. On the horizontal bar crest, two-way exchange of energy between free and bound waves takes place, which results in spatial inhomogeneity. This phenomena is only included in the deterministic as well as in the two-equation stochastic model. As LTA model neglects the rapid oscillations involving the wave number mismatch, the significant wave height will here remain constant. The reduction of the mean wave period over the bar is well predicted by all three types of model. Kofoed-Hansen and Rasmussen (1998) have shown that higher order statistical quantities (ie skewness and asymmetry) can be predicted reasonably well using the two-equation model for this non-breaking bar test. The results will not be shown here.

**Barred beach**

In this case, we consider the spatial evolution of an incident Pierson-Moskowitz type spectrum over a barred sandy beach (test no LIP 11D, Case C, Arcilla et al, 1994) as illustrated in Figure 4. This figure also indicates the location of the wave gauges. The power spectrum of the measured surface elevation at WG1 yields a significant wave height of $H_{m0} = 0.58$ m and a peak frequency of $f_p = 0.125$ Hz. This spectrum is applied as boundary condition for the stochastic models at the boundary 20 m seawards of WG1. The most energetic waves are characterised by having very weak dispersion as $k_p h = 0.53$. The spatial resolution is again set to 0.1 m and the frequency resolution is 0.0097 Hz. The tuning parameter used in LTA is set to $\alpha = 0.5$, which results in best agreement with the measured data.

![Figure 4. Layout of the large-scale laboratory flume experiment of Arcilla et al (1994).](image)

In Figure 5 the predicted frequency spectrum is compared to the measured spectrum at the four locations WG1, WG3, WG6 and WG11. In this case, the frequency-independent wave breaking dissipation model (suggested by Eldeberky and Battjes, 1996) is used. At WG3 is seen that the two stochastic models predict accurately the measured spectrum until a frequency of approximately $3f_p$. Here mainly one way of energy transfer
occurs (as was the case for the bar test). At WG6 and WG11 there is an increasing tendency of too strong transfer rates in both models, which is probably due to violation of the basic assumption of a quasi-Gaussian sea state. Although some discrepancies appear between the model results and measurements, the overall performance is reasonable. Particularly the energy transfer towards low-frequency wave components is excellently predicted by the two-equation model.

The spatial evolution of the significant wave height, the mean wave period, skewness and asymmetry determined by the stochastic models are compared to the measured data and the results obtained with the time-domain Boussinesq model in Figure 6. It is seen that the three models predict almost the same significant wave height and mean wave period in reasonably good agreement with measurements. The LTA model shows a slightly better agreement with the measured mean wave period than the deterministic and two-equation model at a distance of 100-130 m. The mean wave period decreases as the higher order spectral moments increase during the nonlinear shoaling. In a linear model the wave period will be almost constant. Figure 6 also shows that the skewness and asymmetry are in good agreement with the measurements for distances less than, say, 100 m. For larger distances both measures deviate significantly from the measurements most likely as a consequence of too strong nonlinearity.

![Figure 5. Comparison of frequency spectra from numerical simulations and measurements. (—) two-equation stochastic model, (—) LTA model and (○○○○) experimental data by Arcilla et al (1994).](image-url)
The assumption of using a wave breaking dissipation rate in proportion to the spectral density (ie independent of the frequency) is not found to be the major reason for the discrepancy between measured and simulated (by the two-equation stochastic model) skewness and asymmetry as suggested by Chen et al (1997). The results of simulations using a frequency-independent and frequency-dependent ($f^2$) formulation are depicted in Figure 7. As seen from the figure the skewness and asymmetry were not improved by weighting the dissipation towards higher frequencies in this case. It is also seen that by setting $F=1$ (frequency-independent formulation) in the model by Kaihatu and Kirby (1996), the third-order statistical quantities are almost identical to the results obtained using the model Eldeberky and Battjes (1996). As the basic assumption of Gaussianity is highly violated in the inner surf zone and the statistical closure is highly questionable, only a phase-resolving model (including an advanced wave breaking formulation) is applicable there.

Figure 6. Spatial evolution of characteristic integral measures. (—) Deterministic model, (—) two-equation stochastic model, (—) LTA model and (oo) experimental data by Arcilla et al (1994). The bathymetry is sketched at the lower right panel.
Figure 7. Spatial evolution of skewness and asymmetry simulated by the two-equation model using different wave breaking dissipation models. (—) Kaihatu and Kirby (1996), $F=0$, (—) Kaihatu and Kirby (1996) model, $F=1$, (—) Eldberky and Battjes (1996) model and (ooo) experimental data by Arcilla et al (1994). When $F=1$ the dissipation is frequency-independent and for $F=0$ the dissipation has a frequency squared dependency.

Horizontal bottom

The numerical results for the bar test show that the LTA model predicts no spatial variation of the total wave energy on the horizontal crest contrary to the measured data and the results of the two-equation stochastic model. In the following, we shall examine the long-term evolution of a narrow-banded spectrum at a constant depth a bit more using the two stochastic models. The simulations have been performed using similar parameters as used in Elgar et al (1990), see their Figure 6 p. 11552. The initial spectrum $(x=0)$ consists of a single large primary peak at $f_p = 0.0625$ Hz as illustrated in Figure 8. The water depth is 2.0 m. As the significant wave height is $H_{m0} = 0.169$ m, the Ursell number $Ur = (\sqrt{2}H_{m0}/h)(kph)^2 = 1.33$, $kph = 0.18$. The frequency resolution is 0.0625 Hz, and the tuning parameter $\alpha$ used in the LTA model is set to 1.

The spatial evolution of the primary spectrum is presented in Figure 8 at $x = 0, x = 7L_p, x = 30L_p,$ and $x = 70L_p$, where $L_p$ denotes the wave length corresponding to the initial peak frequency. The results obtained by the two-equation model shows that harmonics of the primary wave components grow during the initial stages of evolution. As the wave field evolves further, spectral valleys are filled in at the expense of spectral peaks. After about 70 wave lengths, the frequency spectrum is essentially featureless, and almost all traces of the initial spectrum and its harmonics are gone. In this case the beat length for the super-harmonic interaction between the primary peak and its second harmonic is 31-32$L_p$, but as the nonlinear transfer is very strong no clear evidence of recurrence is found in this particular case. Test cases with recurrence is presented and discussed in Rasmussen (1998). The simulated results presented in Figure 8 are in quite good agreement with the results presented by Elgar et al (1990) based on integration of Freilich and Guza's (1984) evolution equations.
Figure 8. Evolution of a narrow-banded frequency spectrum on a horizontal bottom simulated by the two-equation model (left) and the LTA model (right). The power spectrum is presented at different distances a) $x=0$, b) $x=7L_p$, c) $x=30L_p$, and d) $x=70L_p$, where $L_p=70.5$ m is the wave length corresponding to the initial ($x=0$) peak frequency of $f_p=0.0625$ Hz. The water depth is $h=2.0$ m.
The spectral evolution simulated with the LTA model (see Figure 8), shows initially energy transfer to the second and fourth harmonics. After a few wavelengths (<10), the wave spectrum remains almost unaltered. From Eq. (8), it is seen that an 'equilibrium' spectrum is obtained, where $F_p = \frac{1}{2}F_{2p}$, i.e., the spectral density at the second harmonic is half of the spectral density at the primary peak and so on. Thus, the LTA model is not applicable for simulation of recurrence and white-noise type spectra on constant or nearly constant water depth. This is a result of neglecting the phase-mismatch between free and bound wave components.

Discussion

Having examined the performance of the two stochastic models, we may define the area of model application. As discussed in Kofoed-Hansen and Rasmussen (1998) the two-equation model can be used to predict the evolution of the frequency spectrum and bispectrum and associated characteristic integral measures in shallow water when the Ursell number (based on the peak frequency of the primary waves) is less than 1-2. Beyond that limit, the basic assumption of a quasi-Gaussian sea state is highly violated and the underlying phase-resolving model (including a proper description of the wave breaking process) is more accurate. In cases with a high degree of frequency dispersion, say, $kph > 2$, a more accurate description of the dispersion is required as shown in Madsen and Eldeberky (1998).

The LTA model, which is presently used in the public domain third-generation wind-wave model SWAN, see eg Cavaleri and Holthuijsen (1998), shows excellent agreement with the measurement of the significant wave height, $H_{\text{rms}}$, and mean wave period, $T_\text{ol}$, for the two cases considered in this paper. The tuning parameter $\alpha$ is set to 1.0 for the bar test and 0.5 for the barred beach test. In case of a constant water depth the model predicts an unphysical long-term spectral evolution of the frequency spectrum, which is different from the expected featureless white-noise type spectrum. As a consequence of the introduced simplifications, the LTA model is mainly appropriate for relatively short evolution distances on sloping bathymetries, where the generation of bound super-harmonics is substantial.

Further, as the LTA model only includes self-self interactions the approach can in general only be applied for uni-modal (and unidirectional) frequency spectra. In cases of sea states involving swells and wind-waves, the LTA model is not expected to model accurately the nonlinear energy exchange between the two frequency regimes.

Although both types of stochastic models are of phase-averaged type, the required spatial resolution is different. Using the two-equation model, the wave number mismatch has to be resolved. Therefore the resolution is typically of the same order as for the underlying deterministic model. The spatial resolution used for solving the conventional phase-averaged energy transport equation including the LTA model (as source function for triad wave interaction) is usually at least 100 times larger.
Summary and Conclusions

This paper compared results of numerical calculations obtained from phase-averaged one- and two-equation stochastic models as well as the underlying deterministic (phase-resolving) model with laboratory experiments in case of a submerged bar (Beji and Battjes, 1993) and on a barred beach (Arcilla et al, 1994). Also the long-term evolution of a narrow-banded frequency spectrum on a horizontal bottom has been examined. The sensitivity of wave breaking formulations on third-order wave statistics derived from the two-equation model has been studied as well.

The simplified one-equation stochastic model (LTA) represents an average effect of triad wave interaction, transferring energy from lower to higher frequencies through self-self interaction. The model is in excellent agreement with measurements of $H_{m0}$ and $T_{01}$ in the two cases considered. The two-equation model also takes into account the energy transfer to sub-harmonics as well as the non-resonant wave interaction and provides third-order statistics too. In general, the agreement between the simulated results and measurements is found to be acceptable, even beyond the domain where Gaussianity may be justified. However, in the inner part of the surf zone, the stochastic model underestimate significantly the skewness and asymmetry. Results of simulations using frequency-dependent formulations did not improved the accuracy. As the basic assumption of Gaussianity is highly violated in the inner surf zone and the statistical closure is highly questionable, only a phase-resolving model is applicable there.

The results of the simulations performed on a horizontal bottom indicate that the LTA model is not applicable for prediction of long-term evolution on a nearly horizontal bottom in shallow water. As the two-equation model retains the phase-mismatch between free and bound waves, the frequency spectrum considered here tends to evolve towards a white-noise type spectrum after several wave lengths.

Acknowledgements

We would like to thank Yasser Eldeberky for providing the subroutine for the LTA model. Thanks are also due to Per A. Madsen and Hemming A. Schäffer for drawing our attention to the limitations of the LTA model for spectral evolution on a horizontal bottom. The present work was financed by the Danish National Research Foundation. Their support is greatly appreciated.

COMPARING 1st-, 2nd- AND 3rd-GENERATION COASTAL WAVE MODELLING

L.H. Holthuijsen, N. Booij and U.G. Haagsma

ABSTRACT

The SWAN wave model for shallow water is used in three generation modes to show the differences in results between these modes and with observations in two real, rather field situations. These are situations of waves approaching two different sites in the Netherlands and Germany: one closed part of an estuary and one region between and beyond barrier islands with channels and tidal flats. The differences between the modes are significant (more than 25% locally) in terms of significant wave height and mean wave period. These differences are ascribed, at least partially to the indirect effects of triad wave-wave interactions which shorten the wave period. The observations are located at positions where the differences between the modes are hardly significant.

INTRODUCTION

Over the last decade, the traditional wave ray models to compute waves in coastal regions are being replaced by models that compute the waves on a regular grid. In analogy with ocean wave models, three generations of such grid models can be distinguished. The differences between these generations are essentially in the approximation of the physical processes, in particular in the representation of the nonlinear wave-wave interactions. Here we compare computational results of all three generations against each other and against observations in two real, rather complex field cases.

THE WAVE MODEL

In the present study the three modes of the spectral wave model SWAN of Booij et al. (1996) are used. The 1st- and 2nd-generation mode are essentially those of the DOLPHIN model of Holthuijsen and de Boer (1988; see also Holthuijsen et al., 1993) in which wave generation and dissipation are formulated with fairly simple expressions. In the 3rd-generation mode all processes are represented explicitly as in the WAM Cycle 3 model (WAMDI group, 1988), supplemented with depth-induced wave breaking and triad wave-wave interactions which shorten the wave period. The observations are located at positions where the differences between the modes are hardly significant.

1) Delft University of Technology, Department of Civil Engineering and Geosciences, Stevinweg 1, 2628 CN Delft, the Netherlands
wave-wave interactions. The formulations of these three modes that are used in the present study are briefly described next without the effects of currents.

**Basic equation**

In the absence of ambient currents, the basic equation of SWAN is the discrete spectral energy balance which can be written as (e.g. Hasselmann et al., 1973):

$$\frac{\partial}{\partial t} E + \frac{\partial}{\partial x} c_x E + \frac{\partial}{\partial y} c_y E + \frac{\partial}{\partial \sigma} c_\sigma E = S$$

where $E$ is the energy density as function of intrinsic frequency, spectral direction, spatial coordinates and time $E=E(\sigma, \theta;x,y,t)$. The first term in the left-hand side of this equation represents the local rate of change of energy density, the second and third term represent wave propagation in geographical space. The fourth term represents propagation is the spectral domain (refraction and frequency shifting due to (time) variations in depth). The expressions for the propagation speeds in these terms are taken from linear wave theory. The term $S (=S(\sigma, \theta;x,y,t))$ at the right hand side of the action balance equation is the source term representing the effects of generation, dissipation and nonlinear wave-wave interactions (to be addressed below).

**Generation**

Transfer of wind energy to the waves is described in SWAN with a resonance mechanism (linear growth in time) and a feed-back mechanism (exponential growth). In the 1st- and 2nd-generation mode of this model, the expression for the linear growth is due to Cavaleri and Malanotte-Rizzoli (1981). In the 3rd-generation mode it is ignored. In all three generation modes the expression for the exponential growth is due to Snyder et al. (1981) with different coefficients in the three modes: for the 1st- and 2nd-generation mode they have been obtained from fitting results to standard, fetch-limited deep water growth curves and for the 3rd-generation mode they are taken from WAM Cycle 3.

**Dissipation**

The formulations for bottom friction and depth-induced wave breaking are the same for all three modes of SWAN. Bottom friction is represented with the JONSWAP expression of Hasselmann et al. (1973) with the bottom friction coefficient of Bouws and Komen (1983). Depth-induced wave breaking has been modelled with a spectral version of the random-bore model of Battjes and Janssen (1978) that retains the shape of the spectrum during breaking. The remaining dissipation due to whitecapping is simulated in 1st- and 2nd-generation mode by terminating the wave growth per spectral component when an upper limit in energy density is achieved. This upper limit is a shallow-water version of the Pierson-Moskowitz (PM) spectrum formulated in terms of wave number and with a $\cos^2(\theta - \theta_{wind})$ directional distribution. Its peak frequency is taken from the SPM (1973; with deep water obviously as a special case). The energy scale coefficient $\alpha$ of this limit spectrum is an increasing function of decreasing depth that is tuned to standard shallow-water growth curves (it has the conventional value of $\alpha = 0.0081$ in deep water). If the energy density is larger than this limit spectrum (e.g. due to a change in wind speed or direction), whitecapping is simulated with a relaxation model with a frequency-dependent time scale that is small for high frequencies and very long for low frequencies. In 3rd-
generation mode, the whitecapping formulation is based on the pulse-based model of Hasselmann (1974), as adapted by the WAMDI group (1988) for the WAM model.

**Nonlinear wave-wave interactions**

The effects of quadruplet wave-wave interactions on wave growth in 1st- and 2nd-generation mode is simulated by enhancing the above described wind input term with a factor five. In 2nd-generation mode, the overshoot effect of these interactions is additionally simulated: the energy scale parameter $\alpha$ of the assumed limit spectrum is taken to be a decreasing function (obtained by tuning to standard deep-water growth curves) of the dimensionless energy of the wind sea part of the spectrum. The actual spectrum thus obtained with 1st- and 2nd-generation mode in standard, deep-water, fetch-limited situations is very similar to the JONSWAP spectrum, slowly changing into the PM spectrum with $\alpha = 0.0081$ for the fully developed situation. In 3rd-generation mode the quadruplet interactions are computed explicitly with the Discrete Interaction Approximation (DIA) of Hasselmann et al. (1985).

Triad wave-wave interactions are computed explicitly only in 3rd-generation mode with the Lumped Triad Approximation (LTA) of Eldeberky (1996).

**APPLICATIONS**

The three modes of modelling are applied to two real field cases in the Netherlands with complex bathymetry, 95% reduction in the observed wave energy due to depth-induced wave breaking with subsequent local generation by wind. These cases will first be shown here with the results of the 3rd-generation mode of SWAN. In the next section the results of the other modes will be addressed in terms of differences with these 3rd-generation results.

**Haringvliet**

The Haringvliet is a branch of the Rhine estuary in the south-west of the Netherlands that is separated from the main estuary by sluices. The bathymetry of the area and the locations of the (eight) observation stations are shown in Fig. 1. A local storm generated on October 14, 1982 waves from north-westerly directions and the SWAN computations are carried out for 23:00 UTC on this day. The incident wave conditions and the wind are given in Table 1 (significant wave height $H_s$ and the mean wave period $T$ defined as $H_s = \sqrt{\int_0^\infty \omega^4 P(\omega) d\omega}$ and $T = 2 \pi \left( \frac{m_2}{m_0} \right)$ where $m_m = \int_0^\infty \omega^2 P(\omega) d\omega$). Figures 2 and 3 show the 3rd-generation results for the significant wave height and the mean wave period. The waves approach the estuary from deep water and break over a shoal with a reduction of significant wave height from about 3.6 m in deep water to 2.5 m just in front of the shoal to about 0.6 m just behind the shoal. The local wind regenerates the waves behind the shoal to about 1.1 m significant wave height at station 8.

**Norderneyer Seegat**

The Norderneyer Seegat (Fig. 4) is a tidal gap between the barrier islands of Juist and Norderney in the northern part of Germany. The region behind this gap is an intertidal area with shoals and channels over a distance of 7.5 km to the main land. A high-tide case (November 17, 1995, 04:00 UTC) has been selected (no currents, Table 1). Figures 5 and 6 show the computed pattern of the significant wave and mean wave period. As the
Fig. 1 The bathymetry of the Haringvliet with the eight observation stations.

Fig. 2 The computed pattern (3rd-generation) of the significant wave height and mean wave direction (unit vectors; Haringvliet)

Fig. 3 The computed pattern (3rd-generation) of the mean wave period (Haringvliet).
waves propagate from deep water to the barrier islands the wave height gradually decreases from about 3 m to about 2.5 m at station 2. As the waves propagate through the gap they refract out of the channels to the shallower parts where wave energy is dissipated rapidly and local wind regenerates high-frequency waves.

**MODEL INTERCOMPARISON**

The results of the 1st- and 2nd-generation modes are qualitatively very similar to those of the 3rd-generation mode shown above. Therefore only the differences will be shown. These are presented as relative differences, defined as \( \Delta H_s = \frac{H_{s,3} - H_{s,1}}{H_{s,3}} \) and \( \Delta T = \frac{T_{3} - T_{1}}{T_{3}} \) where the subscript 3 refers to the 3rd-generation results and the subscript 1 to either the 1st-generation or 2nd-generation results. The differences for the Haringvliet for the regeneration mode are given in Fig. 7 where it is obvious that the differences are relatively large over and behind the shoal, north of the shoal and in the sheltered area deep in the bay (south of station 8). Beyond the shoal the significant wave height is typically 15% lower in the 1st-generation results than in the 3rd-generation results and the mean wave period is some 20% longer (50% over the shoal). In the 2nd-generation results the differences are qualitatively very similar but they are quantitatively considerably smaller, as shown in Fig. 8. The differences in significant wave height in the areas lateral of the shoal (seen in the direction of wave propagation) seem to be due to differences in refraction (not shown here). These in turn seem to be induced by the differences in mean wave period up-wave from these locations (to be addressed later). The differences in the sheltered area south of station 8 may well be due to differences in short-fetch wave growth.

For the Norderneyer Seegat, the differences for 1st-generation mode are given in Fig. 9. Again, it is obvious that the differences are relatively large, particularly in the channels and in the short-fetch areas behind the islands. The differences for 2nd-generation mode are again qualitatively equal to those in 1st-generation mode but quantitatively smaller as shown in Fig. 10. As in the Haringvliet case, the differences seem to be related to differences in refraction (due to differences in period) and short-fetch wave growth.

Fig. 8 The relative differences in significant wave height and mean wave period for the Haringvliet (2nd-generation compared to 3rd-generation).

DISCUSSION

The above differences are attributed (partly) to differences in refraction which in turn would be due to differences in wave periods due to the absence of triad wave-wave interactions in the 1st-generation and 2nd-generation mode. This is inferred from the stronger refraction in 1st-generation and 2nd-generation results than in the 3rd-generation results (not shown). The computations were therefore repeated for the Norderneyer Seegat.
where the refraction effect seems to be particularly clear, with the 3rd-generation mode without triad wave-wave interactions. These results seem to confirm that indeed refraction is affected by these interactions (through the difference in wave periods). To show that other effects can be ignored, these computations have been repeated without refraction (by de-activating the refraction term in the basic equation). The results are shown in Fig. 11 and they confirm the speculation about the indirect effect of the triad wave-wave interactions on refraction.

The observations (see Figs. 3 and 6 for locations) should tell which of the three modes of SWAN provide the best wave estimates. Unfortunately, most of the observations have been taken in regions where the differences between the three modes are rather small (less than 10%). This is also obvious from the small differences between the errors in the three modes (see Table 2).

CONCLUSIONS

In the rather complex coastal field conditions of this study, the triad wave-wave interactions in the SWAN model (3rd-generation mode) generate a shorter wave period in very shallow water than in either the 1st- or 2nd-generation mode of SWAN. This affects the refraction pattern of the waves which in turn affects the pattern of significant wave height. Moreover, the short-fetch wave growth is very different between the three modes.
Although a fair amount of observations is available, the locations of these observations are not well suited to discriminate between the three modes.

ACKNOWLEDGEMENTS

We are very grateful to John de Ronde, Joska Andorka Gal and their co-workers at the Ministry of Transport, Public Works and Water Management (the Netherlands) for providing us with the data of the Haringvliet. We are equally indebted to Hanz Niemeyer and Ralf Kaiser of the Niedersächsisches Landesamt für Ökologie - Forschungsstelle Küste - (Germany) for providing us with the data of the Norderneyer Seegat.

ABSTRACT
Two sets of observations of wave transformation near two quasi one-dimensional coasts, from deep water (22 m) to shallow water (0.5 m) have been simulated with the third-generation spectral wave model SWAN. The first set of observations contains wind waves that are generated by a local storm off the North Sea coast of the Netherlands. The second set contains a mix of swell and local wind waves at the Pacific coast of Japan. Repeated computations without triad wave-wave interactions show that the inclusion of this process in the model is essential. A $f^2$-dependency of the depth-induced dissipation (rather than the conventional frequency independence in SWAN), causes too much energy dissipation in the high frequencies, shifting the mean frequency to too low values.

INTRODUCTION
As waves approach a gently sloping coast, both the significant wave height and the mean wave period are reduced. The former is mostly due to depth-induced breaking. The latter can be ascribed to a transfer of energy from lower frequencies to higher frequencies (triad wave-wave interactions; e.g. Beji and Battjes, 1994) which is often evident from the generation of a secondary high-frequency peak in the observed spectra. To properly describe and understand such evolution, field observations and models that take into account the relevant physical processes are required. In the present study, observations of such waves approaching two, quasi-1D coasts (one in the Netherlands and one in Japan) are modelled with a third-generation spectral wave model. The computational results are compared with observations.

THE OBSERVATIONS
The waves that are considered in this study have been observed off the beach near the town of Petten in the Netherlands (waves from the southern North Sea; courtesy Ministry
Fig. 1 The bathymetry and observation locations off the Petten coast.

Fig. 2 The bathymetry and observation locations off the Kashimanada coast.

of Transport, Public Works and Water Management, the Netherlands) and off the beach at the Kashimanada coast in Japan (waves from the Pacific Ocean; courtesy Hazaki Oceanographical Research Facility, Port and Harbour Research Institute, Japan; Nakamura and Katoh, 1992). In both cases the coast is rather straight with two sand bars (Figs. 1 and 2).

The observations are made from deep water to the shore, along a line normal to the beach over a distance of about 8.3 km in the Petten case (from 22.0 m to 4.2 m water depth). The data set from Kashima overlaps this range on the shallow water with the observations starting at about 300 m from shore, from 5.4 m to 0.5 m water depth. Several
techniques were used to measure the waves along these transects: buoys (directional and omni-directional), wave gauges and a pressure transducer (Petten) and ultra-sonic wave gauges (Kashima). From the Petten data set, a storm situation is selected with a uni-modal, deep-water spectrum (characteristic for a local storm in a sheltered sea). It has been described by Eldeberky et al. (1997). From the Kashima data set a situation is available with a bi-modal, deep-water spectrum (characteristic for the mix of wind sea and swell along an open oceanic coast). It has been described by Beji and Nadaoka (1998). In the Petten case, the wind speed was 18.6 m/s, the deep-water significant wave height was 4.61 m and the mean wave period was 8.4 s (peak period 10.0 s). In this case the (uni-modal) spectrum shows qualitatively the above described characteristic behaviour as the waves propagate along the transect. In the measurements the significant wave height reduces to 3.07 m at the shallowest station. Remarkably the observed significant wave height-to-depth ratio remains well above the value of 0.4 which is often used in engineering practice. The mean wave period reduces to about 6.4 s while the peak period remains constant. In the Kashima case, the wind is ignored, the deep-water significant wave height was 1.68 m and the mean wave period was 5.7 s (peak period 14.9 s). Here the observed wave height reduces to 0.32 m at the shallowest station (0.5 m water depth so that the observed ratio of significant wave height-to-depth ratio equals 0.64). The evolution of the observed spectra and of the significant wave height $H_s$ and the mean wave period $T$ defined as $H_s = 4 \sqrt{m_0}$ and $T = 2 \pi (m_1 / m_0)^{-1}$ where $m_n = \int_0^\pi \sigma^n E(\sigma, \theta) d\sigma d\theta$, are given in Figs. 3 through 6.
THE WAVE MODEL

The wave model is a discrete spectral model which is based on the action balance equation of random, short-crested waves (the SWAN wave model; e.g. Booij et al., 1996). It is a discrete spectral model based on the action balance equation which for Cartesian coordinates is

\[
\frac{\partial}{\partial t} N + \frac{\partial}{\partial x} c_x N + \frac{\partial}{\partial y} c_y N + \frac{\partial}{\partial \sigma} c_{\sigma} N + \frac{\partial}{\partial \theta} c_{\theta} N = \frac{S}{\sigma}
\]

in which \(N(\sigma, \theta, x, y, t)\) is the action density as a function of intrinsic frequency \(\sigma\), direction \(\theta\), horizontal coordinates \(x\) and \(y\) and time \(t\). The first term in the left-hand side of this equation represents the local rate of change of action density in time, the second and third term represent propagation of action in geographical space (with propagation velocities in \(x\) - and \(y\) - space, \(c_x\) and \(c_y\), respectively). The fourth term represents shifting of the intrinsic frequency due to variations in depths and currents (with propagation velocity in \(\sigma\) - space, \(c_\sigma\)). The fifth term represents depth- and current-induced refraction (with propagation velocity in \(\theta\) - space, \(c_\theta\)). The expressions for these propagation speeds are taken from linear wave theory. The source terms are taken from the WAM model (WAM Cycle 3; WAMDI, 1988: exponential growth by wind, quadruplet wave-wave interactions, whitecapping and bottom friction). They are supplemented with a spectral version of the dissipation model for depth-induced breaking of Battjes and Janssen (1978)and a discrete interaction approximation for the triad wave-wave interactions (Eldeberky 1996). It was verified that the processes of depth-induced wave breaking and
Laboratory observations (e.g., Battjes and Beji, 1992; Vincent et al. 1994; Arcilla et al., 1994 and Eldeberky and Battjes, 1996) have shown that the shape of initially uni-modal spectra propagating across simple (barred) beach profiles, is fairly insensitive to depth-induced breaking. This has led Eldeberky and Battjes (1995) to formulate a spectral version of the bore model of Battjes and Janssen (1978) which conserves the spectral shape. Expanding their expression to include directions, the expression that is used in SWAN is:

\[
S_{\omega \omega br}(\omega, \theta) = -\frac{D_{\text{tot}}}{E_{\text{tot}}} E(\omega, \theta)
\]

in which \(E_{\text{tot}}\) is the total wave energy and \(D_{\text{tot}}\) is the rate of dissipation of the total energy due to wave breaking according to Battjes and Janssen (1978). The value of \(D_{\text{tot}}\) depends critically on the breaking parameter \(\gamma = H_{\text{max}}/d\) (in which \(H_{\text{max}}\) is the maximum possible individual wave height in the local water depth \(d\)). The value in the SWAN computations is \(\gamma = 0.73\) (the mean value of the data set of Battjes and Stive, 1985).

A first attempt to describe triad wave-wave interactions in terms of a spectral energy source term was made by Abreu et al. (1992). However, their expression is restricted to non-dispersive shallow water waves and is therefore not suitable in many practical applications of wind waves. The breakthrough in the development came with the work of Eldeberky and Battjes (1995) who transformed the amplitude part of the Boussinesq model of Madsen and Sorensen (1993) into an energy density formulation and who parameterized the biphase of the waves on the basis of laboratory observations (Battjes and Beji, 1992; Arcilla et al., 1994). A discrete triad approximation (DTA) for co-linear waves was
subsequently obtained by considering only the dominant self-self interactions. Their model has been verified with flume observations of long-crested, random waves breaking over a submerged bar (Beji and Battjes, 1993) and over a barred beach (Arcilla et al., 1994). The model appeared to be fairly successful in describing the essential features of the energy transfer from the primary peak of the spectrum to the super harmonics. The slightly different version of Eldeberky (1996) is used in SWAN (the lumped triad approximation).

**COMPUTATIONS AND RESULTS**

The Petten case has been computed as a two-dimensional case (although the coast is fairly straight) with the two-dimensional spectrum at deep-water taken from the observations (a directional buoy at station 1, Figs.1 and 5). The Kashima case has been computed as a one-dimensional case (see Beji and Nadaoka, 1998) with the two-dimensional, deep-water spectrum constructed from the observed one-dimensional spectrum with the assumption that the mean wave direction is normal to the shore and that the directional spreading is relatively narrow for the swell part of the spectrum ($\sigma_\theta = 5^\circ$ for $f < 0.1$ Hz) and typical for wind sea for the higher frequencies ($\sigma_\theta = 30^\circ$ for $f > 0.1$ Hz). For both cases the model results in terms of the significant wave height and the mean wave period are shown in Figs. 3 and 4, respectively. The agreement with the observations is fairly good with a slightly better model performance in the Petten case than in the Kashima case: the rms-error in the significant wave height and mean wave period are about 7 % and 5 % of the deep water values respectively in the Petten case, versus 7 % and 16 % in the Kashima case. The difference in performance is also illustrated with the computed spectra in Fig. 5 and 6 where it is obvious that the amount of energy at the peak frequency for the shallowest stations is slightly better predicted in the Petten case.
DISCUSSION

As noted above, the computations were carried out with triad wave-wave interactions active. To illustrate the effect of these triad wave-wave interactions, the computations have been repeated without these interactions. The results in terms of significant wave height and mean wave period are shown in Figs. 3 and 4 and in terms of the spectra in Figs. 7 and 8. It is evident that the significant wave height is only marginally affected but that the mean wave period is greatly affected, especially in the shallowest region. The inclusion of these interactions also gives a much better agreement with the observations of the spectra (notably near the low-frequency peak).

In the above computations, the spectral distribution of the depth-induced wave breaking is proportional to the energy density and independent of frequency. This is based on observations of initially unimodal spectra. However, Mase and Kirby (1992, supported by Elgar et al., 1997) found a $f^2$-dependency in many observations, although Chen et al. (1997) inferred from observations and simulations with a Boussinesq model that the high-frequency (i.e. above the lowest peak frequency) levels in the spectra are insensitive to such frequency dependency. This is due to the approximate compensation of the increased dissipation at high frequencies by increased nonlinear energy transfer (but they did find the frequency dependency to be relevant in time domain). To investigate this for the Kashima case, the computations have been repeated for this case with such $f^2$-dependency ($F = 0$ in the notation of Chen et al., 1997). The results are shown in Figs. 9 and 10. The significant wave height is only marginally affected but the mean wave period is significantly affected in the shallowest region. The spectra at stations 4 and 5 show that this
Observations of SWAN computations (no triads) are shown in Fig. 8. The computed spectra for the Kashima case without triad wave-wave interactions (with $\sigma_0 = 5^\circ$ for $f < 0.1$ Hz and $\sigma_0 = 30^\circ$ for $f > 0.1$ Hz), compared with measured data (compare with Fig. 6).

The overestimation of the amount of energy at the lower frequencies is due to the overestimation of the amount of energy at the lower frequencies.

Separate computations with individual processes of generation, dissipation and wave-wave interactions deactivated show the relatively minor importance of wind generation, bottom friction, whitecapping and quadruplet wave-wave interactions and the dominant effect of depth-induced wave breaking and triad wave-wave interactions.

CONCLUSIONS

The observed evolutions of a uni-modal spectrum and of a bi-modal spectrum, approaching a gently sloping, barred coast of a shelf sea (North Sea) and an oceanic coast (Pacific Ocean) respectively have been numerically simulated with the third-generation SWAN wave model. The agreement between the observed and computed evolution, both in terms of integral wave parameters and spectra is rather good. Repeated computations without triad wave-wave interactions show that the inclusion of this process in the model is essential. A $f^2$-dependency of the depth-induced dissipation (rather than the conventional frequency independence in SWAN), causes too much energy dissipation in the high frequencies, shifting the mean frequency to too low values.

A new formulation of deterministic and stochastic evolution equations for three-wave interactions involving fully dispersive waves

Per A. Madsen¹ and Yasser Eldeberky¹

Abstract

This paper presents a new and more accurate set of deterministic evolution equations for three-wave interactions involving fully dispersive, weakly nonlinear, irregular, unidirectional waves. The equations are derived directly from the Laplace equation with leading order nonlinearity in the surface boundary conditions. It is demonstrated that previous fully dispersive formulations from the literature have used an inconsistent linear relation between the velocity potential and the surface elevation. As a consequence these formulations are accurate only in shallow water, while nonlinear transfer of energy is significantly underestimated for larger wave numbers. In the present work we correct this inconsistency. In addition to the improved deterministic formulation, we present improved stochastic evolution equations in terms of the energy spectrum and the bispectrum for unidirectional waves.

1. Introduction

Three-wave interactions (or triad interactions) generally play an important role in the nonlinear transformation of irregular waves in shallow or intermediate depth waters. Very often these phenomena can be described quite accurately by Boussinesq-type formulations either in terms of time-domain equations (see e.g. Madsen & Sørensen, 1993) or in terms of evolution equations for the spatial variation of the complex amplitudes at discrete frequencies (see e.g. Freilich & Guza, 1984; Madsen & Sørensen, 1993). In both cases the phase information is retained and we talk about deterministic formulations.

Recently, Herbers & Burton (1997) and Kofoed-Hansen & Rasmussen (1998) presented stochastic formulations derived from deterministic Boussinesq-type evolution equations. In their formulations the second- and third-order statistics of random, shoaling waves are described by a coupled set of evolution equations for the energy spectrum and the bispectrum.

¹ International Research Centre for Computational Hydrodynamics (ICCH), Agern Allé 5, DK-2970 Hørsholm, Denmark.
While Boussinesq-type formulations are generally more or less restricted by weak dispersion, the approach by Agnon et al. (1993) and Kaihatu & Kirby (1995) retains full dispersion. They presented deterministic evolution equations derived directly from the Laplace equation with leading order nonlinearity in the surface boundary conditions. On this basis Agnon & Sheremet (1997) derived stochastic evolution equations for the energy spectrum and the bispectrum.

One of the key arguments by Agnon et al. (1993) and Kaihatu & Kirby (1995) for deriving equations with full dispersion was the need for a nonlinear evolution equation describing the interaction processes all the way from deep to shallow water. Indeed, triad interaction models based on fully dispersive equations can be expected to be superior to those based on Boussinesq-type formulations for large wave numbers not only in terms of improved dispersion but also in terms of a higher accuracy in nonlinear transfer functions. This should generally result in more accurate estimates of higher-order statistics such as skewness and asymmetry.

On the other hand, this expectation of a superior accuracy relative to existing Boussinesq formulations, has not yet been demonstrated in the literature. In fact, Kaihatu & Kirby (1995, 1996) concluded that “the lowest order Boussinesq model, despite its shallow water formalism, yields skewness and asymmetry values closer to those of the experimental data than those of the fully dispersive model”. This conclusion was indeed disappointing.

In the present work we shall demonstrate that while the previous formulations by Agnon et al. (1993), Kaihatu & Kirby (1995, 1996), and Agnon & Sheremet (1997) presented consistent nonlinear equations for the velocity potential, they invoked an inconsistent linear relation to obtain the corresponding equations for the surface elevation. We shall show that high accuracy for larger wave numbers is achieved only if a nonlinear transformation is invoked, and we shall derive a new set of fully dispersive evolution equations for the surface elevation. Section 2 contains a brief review of the derivation of deterministic evolution equations in terms of the velocity potential. In Section 3 these equations are converted into equations for the surface elevation using: 1) a linear transformation; 2) a second order transformation. In section 4, a coupled set of stochastic evolution equations for the energy spectrum and the bispectrum is presented. Model validation is given in Section 5, while summary and conclusions can be found in Section 6.

2. Deterministic evolution equations in terms of the velocity potential

In this section we give a brief outline of the derivation of deterministic evolution equations in terms of the velocity potential at the still water level. The equations include leading order nonlinearity and full dispersion. The derivation follows the work by Agnon et al. (1993) and Kaihatu & Kirby (1995).

We adopt a Cartesian co-ordinate system \((x, z)\) with \(z\) measured upwards from the still water level. The fluid domain is bounded by the sea bed at \(z = -h(x)\) and the free surface \(z = \eta(x,t)\). The fluid is assumed incompressible and inviscid, and the flow is assumed to be irrotational. Dimensional quantities are retained with the understanding that leading order nonlinearity is \(O(\varepsilon^3)\), where the nonlinearity parameter \(\varepsilon\) is defined by \(kA\) (\(k\) being the wave number and \(A\) the wave amplitude). After expanding the nonlinear free surface boundary conditions in Taylor series about \(z=0\) and retaining terms to \(O(\varepsilon^3)\), the truncated boundary value problem in terms of the velocity potential \(\Phi\) reads,
\[ \nabla^2 \Phi + \Phi_{zz} = 0; \quad -h \leq z \leq 0, \]  
(1)

\[ \Phi_z + \nabla h \cdot \nabla \Phi = 0; \quad z = -h, \]  
(2)

\[ \eta_t - \Phi_z + \nabla \cdot (\eta \nabla \Phi) = O(\varepsilon^1); \quad z = 0, \]  
(3)

\[ \Phi_z + g \eta + \eta \Phi_{zz} + \frac{1}{2} (\nabla \Phi)^2 + \frac{1}{2} (\Phi_z)^2 = O(\varepsilon^3); \quad z = 0, \]  
(4)

where \( \nabla \) is the horizontal gradient operator. We note that the linearized dynamic free surface boundary condition, i.e.,

\[ \beta + g \Phi_z = O(\varepsilon^2); \quad z = 0, \]  
(5)

can consistently be applied to eliminate \( \eta \) in the nonlinear terms in (3) and (4) by which we get

\[ \eta_t - \Phi_z - \frac{1}{g} \nabla \cdot (\Phi_z \nabla \Phi) = O(\varepsilon^1); \quad z = 0, \]  
(6)

\[ \Phi_z + g \eta - \frac{1}{g} \Phi_t \Phi_{zz} + \frac{1}{2} (\nabla \Phi)^2 + \frac{1}{2} (\Phi_z)^2 = O(\varepsilon^3); \quad z = 0. \]  
(7)

Substituting (7) into (6) yields

\[ \Phi_{tt} + g \Phi_z - \left[ \frac{1}{g} \Phi_t \Phi_{zz} - \frac{1}{2} (\nabla \Phi)^2 - \frac{1}{2} (\Phi_z)^2 \right] + \nabla \cdot (\Phi_t \nabla \Phi) = O(\varepsilon^3); \quad z = 0 \]  
(8)

The system of equations (1), (2) and (8) is the starting point for the derivation of evolution equations for weakly nonlinear and fully dispersive water waves.

First, we express the surface elevation and the velocity potential as a linear superposition of unidirectional waves,

\[ \eta(x,t) = \sum_{p=1}^{\infty} A_p \phi_p(x) \exp \left[ i \left( \omega_p t - k_p x \right) \right] + \text{c.c.} \]  
(9a)

\[ \Phi(x,z,t) = \sum_{p=1}^{\infty} f_p(z) \Phi_p(x) \exp \left[ i \left( \omega_p t - k_p z \right) \right] + \text{c.c.} \]  
(9b)

where \( \omega_p = \omega \Delta \omega_p \) is the frequency, \( \Delta \omega \) is the band-width in the Fourier representation, \( k_p \) is the wave-number satisfying the linear dispersion relation, \( A_p \) and \( \Phi_p \) are the complex spatially varying Fourier amplitudes, \( f_p \) represents the vertical structure of the velocity potential and c.c. indicates the complex conjugate.

The specification of the vertical structure \( f_p \) is one of the key elements in the derivation of evolution equations for fully dispersive waves. Agnon et al. (1993) initially considered the influence of bound waves as well as free waves on the vertical structure of the potential, but eventually they ignored the effect of the bound wave structure on their equations. Here we simply adopt the procedure of Kaihatu & Kirby (1995) and assume a vertical structure dictated by linear theory, i.e.
\[
f_p(z) = \frac{\cosh k_p (h + z)}{\cosh k_p h}
\]

where \( k_p \) is obtained from

\[
\omega_p^2 = g k_p \tanh k_p h
\]

The spatial variations of water depth, wave numbers and complex amplitudes are assumed to be weak, and consequently the formulation will include only first derivatives of these quantities, while no derivatives will be included in connection with nonlinear terms. The resulting evolution equations derived by Agnon et al. (1993) and by Kaihatu & Kirby (1995) can be expressed by

\[
\frac{d\tilde{\Phi}_p}{dx} = -\frac{\tilde{\Phi}_p}{2c_{g,p}} \frac{dc_{g,p}}{dx} + \left( \sum_{m=1}^{p-1} \beta^m \tilde{\Phi}_m \tilde{\Phi}_{p-m} e^{i\lambda_p} + 2 \sum_{m=1}^{N-p} \beta^m \tilde{\Phi}_m \tilde{\Phi}_{p+m} e^{i\lambda_p} \right)
\]

where

\[
\beta^m = \frac{1}{8g^2 c_{g,p}} \left( \frac{2g}{\omega_p} \left( \omega_{p+m} k_m^2 \pm \omega_m k_{p+m}^2 \right) \pm 2g^2 k_m^2 k_{p+m}^2 + \omega_m^2 \omega_{p+m}^2 \mp \omega_p^2 \omega_m \omega_{p+m} \right)
\]

\[
\Delta \psi^2 = \int \delta^2 dx, \quad \delta^2 \equiv \left( k_p \mp k_m - k_{p+m} \right)
\]

and where \( c_g \) is the group velocity. The first term in the right-hand-side of (12a) represents linear shoaling, while the second/third terms represent the nonlinear super/sub-harmonic interactions.

3. Deterministic evolution equations in terms of the surface elevation

In comparison with the evolution equations derived from Boussinesq-type equations (e.g., Freilich and Guza, 1984; Madsen and Sørensen, 1993), the set given by (12a-c) has the potential of being applicable to a wider range of wave numbers as it incorporates full dispersion. However, in order to utilise this potential, it is important to make a consistent transformation from the velocity potential to the surface elevation. In the following we convert (12a-c) into evolution equations for the amplitudes of the surface elevation using two different approaches: a) A linear transformation (Section 3.1); b) A second order transformation (Section 3.2).

3.1 Using the linear relation between the velocity potential and the surface elevation

In this section we follow Kaihatu & Kirby (1995) and apply the linear approximation (5) in combination with the Fourier representation (9), which yields

\[
\tilde{\Phi}_p = \frac{i g}{\omega_p} A_p
\]

By substituting (13) into (12a) we obtain
\[
\frac{dA_p}{dx} = -\frac{A_p}{2c_{g,p}} \frac{dc_{g,p}}{dx} + i \left( \sum_{m=1}^{N-p} \bar{\alpha}_m A_{p-m} e^{i\omega_m t_0} + 2 \sum_{m=1}^{N-p} \bar{\alpha}_m^* A_m A_{p+m} e^{i\omega_m t_0} \right)
\]  
(14a)

with
\[
\bar{\alpha}^z = \pm \frac{g \omega_p}{\omega_m \omega_{p+m}} \beta^z.
\]
(14b)

where \( \beta^z \) is given by (12b). These are the deterministic evolution equations derived by Agnon et al. (1993), and Kaihatu & Kirby (1995). Also Agnon & Sheremet (1997) used these equations as the basis for their stochastic formulation.

It turns out that the use of the linear approximation (5) results in inaccuracies in the nonlinear transfer functions. This can easily be demonstrated by the following example:

Let us consider a velocity potential (at \( z=0 \)) determined from Stokes second-order theory for regular waves, i.e.,
\[
\Phi(x,t) = \Phi_1 \sin(kx-\omega t) + \Phi_2 \sin(2kx-2\omega t)
\]
(15)

If we apply the linear approximation (5) on (15) we obtain as a consequence the second-order surface elevation
\[
\eta(x,t) = A \cos(kx-\omega t) + G_{L} \frac{A^2}{h} \cos(2kx-2\omega t)
\]
(16)

where
\[
G_L = -\frac{3}{4} kh \frac{\cosh 2kh}{\cosh kh \sinh^3 kh}
\]
(17)

This obviously deviates from Stokes reference solution, which reads
\[
G_{\text{Stokes}} = \frac{1}{4} kh \frac{\cosh kh}{\sinh^2 kh} (2 + \cosh 2kh)
\]
(18)

A Taylor expansion of (17) and (18) yields
\[
G_L \quad \to \quad \frac{3}{4} k^2 h^2 \left( 1 + \frac{k^2 h^2}{3} - \frac{11}{15} k^4 h^4 + O(k^6 h^6) \right)
\]
(19)

\[
G_{\text{Stokes}} \quad \to \quad \frac{3}{4} k^2 h^2 \left( 1 + \frac{2}{3} k^2 h^2 + \frac{7}{45} k^4 h^4 + O(k^6 h^6) \right)
\]

which shows that the two expressions converge in shallow water. For comparison we may also consider the transfer function corresponding to the Boussinesq formulation of Madsen & Sørensen (1993), i.e.
\[
G_{\text{Boussinesq}} = \frac{3}{4} k^2 h^2 \left( 1 + \frac{8}{45} k^2 h^2 \right)
\]
(20)
Fig. 1 shows the variation with \( kh \) of \( G \) and \( G_{\text{non}} \) relative to the target solution \( G_{\text{target}} \). In both cases the nonlinearity is significantly underestimated for larger \( kh \) values. This lack of accuracy in nonlinear transfer shows up in the numerical calculations in Section 5.

### 3.2 Using the nonlinear relation between the potential and the surface elevation

In the following we shall use (7) to establish the second-order relation between the surface elevation and the velocity potential. To a first approximation (9b) and (10) yield

\[
\nabla \Phi = -ik \Phi, \quad \Phi_x = i \omega \Phi, \quad \Phi_z = \frac{\omega^2}{g}\Phi, \quad z = 0
\]

(21)

Hence by the use of (21), the Fourier transformation of (7) now yields

\[
A_p = \frac{-i \omega_p}{g} \Phi_p + 2 \left( \sum_{m=1}^{p-1} \gamma^+ \tilde{\Phi}_m \tilde{\Phi}_{p-m} e^{i \delta y^+} + 2 \sum_{m=1}^{N-p} \gamma^- \tilde{\Phi}_m^* \tilde{\Phi}_{p+m} e^{i \delta y^-} \right)
\]

(22a)

where

\[
\gamma^\pm = \frac{1}{8g^3} \left[ \pm \frac{\omega^2}{\omega_p} \frac{k_p^2 k_{p \pm m}}{\omega_{p \pm m}} \right]
\]

(22b)

One possibility is to solve (22) along with the evolution equation (12) in order to calculate the local variation of the surface elevation (see e.g. Chen et al., 1997). A better option is, however, to invert (22a) by the use of successive approximations and to eliminate the velocity potential from the evolution equations. Thus, we apply the linear approximation (13) in the nonlinear terms of (22a) and obtain

\[
\tilde{\Phi}_p = \frac{i g}{\omega_p} A_p + 2 i \left( \sum_{m=1}^{p-1} \gamma^+ A_m A_{p-m} e^{i \delta y^+} + 2 \sum_{m=1}^{N-p} \gamma^- A_m^* A_{p+m} e^{i \delta y^-} \right)
\]

(23a)

where

\[
\gamma^\pm = \pm \frac{g^3}{\omega_p \omega_{p \pm m}} \gamma^\pm
\]

(23b)

The next step is to differentiate (23a) with respect to \( x \) while retaining terms to \( O(\varepsilon^2) \). Consistent with the derivation of (12a-c), we ignore, in connection with the nonlinear terms, spatial derivatives of the slowly varying amplitudes and of the group velocity. With this assumption the differentiation of (23a) yields

\[
\frac{d\tilde{\Phi}_p}{dx} = \frac{i g}{\omega_p} \frac{dA_p}{dx} - 2 \left( \sum_{m=1}^{p-1} \delta^+ \gamma^+ A_m A_{p-m} e^{i \delta y^+} + 2 \sum_{m=1}^{N-p} \delta^- \gamma^- A_m^* A_{p+m} e^{i \delta y^-} \right)
\]

(24)

where \( \delta^\pm \) is defined by (12c). Finally after substituting (23a-b) and (24) into (12a), we get
\[
\frac{dA_p}{dx} = -\frac{A_p}{2c_{g,p}} \frac{dc_{g,p}}{dx} + i \left( \sum_{m=1}^{\infty} \alpha^* A_m A_{p-m} e^{i\omega_m^*} + \frac{N_p}{2} \sum_{m=1}^{\infty} \alpha^- A_m^* A_{p+m} e^{i\omega_m} \right) \tag{25a}
\]

with

\[
\alpha^\pm = \pm \frac{g \omega_p}{\omega_m \omega_{p \mp m}} \left( \beta^\pm - \frac{\gamma^\pm}{c_{g,p}} \Gamma^\pm \right), \quad \Gamma^\pm = \frac{2\delta^\pm c_{g,p}}{\omega_p} \tag{25b}
\]

which, by inserting \(\beta^\pm\) and \(\gamma^\pm\) from (12b) and (22b), can be expressed as

\[
\alpha^\pm = \pm \frac{\omega_p}{8g c_{g,p} \omega_m \omega_{p \mp m}} \left[ g^2 \omega_p^2 \left( \omega_{p \pm m} k_m^2 \pm \omega_m k_{p \mp m}^2 \right) \right. \\
+ \left. \left( 2 - \Gamma^\pm \right) g^2 \omega_m k_m k_{p \mp m} + \left( 1 - \Gamma^\pm \right) \left( \omega_m^2 \omega_{p \mp m} \mp \omega_p^2 \omega_m \omega_{p \pm m} \right) \right] \tag{25c}
\]

The new deterministic evolution equation (25) is the main result of this work. The dispersion characteristics of the model are dictated by fully-dispersive linear theory. The present evolution equation insures, through the new complex interaction coefficient \(\alpha^\pm\), a higher accuracy in the nonlinear transfer function. We emphasize that the nonlinear transformation between the velocity potential and the surface elevation is retained in the parameter \(\Gamma\). The formulation (14a-b), as used by Agnon et al (1993), Kaihatu & Kirby (1995), and Agnon & Sheremet (1997), corresponds to setting \(\Gamma = 0\) in (25).

The importance of including the \(\Gamma\)-terms in (25) is illustrated in Fig. 2, which shows the ratio of \(\alpha^\pm_{\Gamma=0}\) to \(\alpha^\pm\) as a function of \(\omega_m\) and \(\omega_{p \mp m}\). The upper triangle in Fig. 2 illustrates the super-harmonic interactions while the lower triangle illustrates the sub-harmonic interactions. The second-harmonic interaction is represented by the diagonal line and this result agrees with Fig. 1. It can be concluded that neglecting \(\Gamma\) has a major effect on super-harmonics which are consequently significantly underestimated, while the sub-harmonics are less sensitive.

4. Stochastic evolution equations for the energy spectrum and the bispectrum

Stochastic evolution equations for the energy spectrum and for the complex bispectrum can be derived on the basis of the deterministic evolution equations given by (25). We follow the procedure as outlined e.g. by Agnon and Sheremet (1997), Herbers & Burton (1997), and Kofoed-Hansen & Rasmussen (1998): Firstly, we multiply equation (25a) by the conjugate of \(A_p\); secondly, the conjugate of equation (25a) is multiplied by \(A_p\); thirdly, the former is added to the latter and finally the result is ensemble averaged. This leads to

\[
\frac{dE_p}{dx} = -\frac{E_p}{c_{g,p}} \frac{dc_{g,p}}{dx} - 2 \left[ \sum_{m=1}^{\infty} \alpha^+ \Im \left( B_{m,p-m}^* \right) + 2 \sum_{m=1}^{\infty} \alpha^- \Im \left( B_{m,p+m}^* \right) \right] \tag{26}
\]

where

\[
E_p \equiv \langle A_p^* A_p \rangle, \quad B_{m,p-m}^* \equiv \langle A_p^* A_m A_{p-m} e^{i\Delta \omega} \rangle, \quad B_{m,p+m}^* \equiv \langle A_p^* A_{p+m} A_{m} e^{i\Delta \omega} \rangle \tag{27}
\]
and where $\Im$ denotes the imaginary part and $\langle \ldots \rangle$ is the ensemble average operator. The right-hand-side contains the average of the third-order moment, the so-called bispectrum, $B$. In order to obtain a stochastic description of the effect of the nonlinear interactions one needs to go to higher-order moments, and evaluate the bispectrum. An evolution equation for the bispectrum is derived and the terms including the trispectrum, i.e., fourth-order statistical average, appear. In order to close this system of equations, the trispectrum is expressed as products of second-order averages (the so-called Gaussian closure), and we retain only products of terms with opposite-signed phases. The resulting evolution equations of the bispectrum can be written as follows

$$\frac{dB^*}{dx} = (i\delta^* + F) B^* - 2i \left[ \alpha_{p,0} E_p E_p E_p + \alpha_{p,m} E_p E_p E_p + \alpha_{p,m,m} E_p E_p E_p \right]$$  (28)

$$\frac{dB^*}{dx} = (i\delta^{-} + F^{-}) B^* - 2i \left[ \alpha_{p,0} E_p E_p E_p + \alpha_{p,m} E_p E_p E_p + \alpha_{p,m,m} E_p E_p E_p \right]$$  (29)

where we emphasise that the $\alpha^\pm$ defined by (25c) is actually a short hand notation for $\alpha_{p,0}$, while $F^\pm$ denotes the shoaling term defined by

$$F^\pm = \frac{1}{2} \left( \frac{1}{c_{g,p}} \frac{dc_{g,p}}{dx} + \frac{1}{c_{g,m}} \frac{dc_{g,m}}{dx} + \frac{1}{c_{g,p+m}} \frac{dc_{g,p+m}}{dx} \right)$$  (30)

We note that (26), (28) and (29) comprise a coupled set of stochastic evolution equations for the energy spectrum and the bispectrum. The formulation is identical to Agnon and Sheremet (1997) except for the inclusion of the $\Gamma$-terms in $\alpha^\pm$.

The stochastic model explicitly takes into account, via the bispectrum, the development of the phase correlation between wave triads due to nonlinearity. In this model, the bispectrum is required to calculate the effects of triad wave interactions on the wave spectrum evolution. It can also be used to calculate the overall third-order statistical parameters such as the skewness and asymmetry.

5. Model verification

In order to validate the models from Sections 3 and 4, we concentrate on the experimental data from Cox et al. (1991). This test case considers the shoaling (and breaking) of irregular waves on a plane beach. The water depth at the offshore boundary is 47 cm and the beach slope is 1:20. The surface elevations are measured at eleven locations (denoted WG1 to WG11) in still water depths of 47, 35, 30, 25, 20, 17.5, 15, 12.5, 10, 7.5, and 5 cm. The target spectrum is a Pierson-Moskowitz type with a peak frequency of 1.0 Hz and with a significant wave height of 6.5 cm. At the incoming boundary the peak frequency corresponds to fairly large wave numbers ($kh=1.9$), and in combination with the broad-banded spectral shape this allows significant energy on frequencies that are well into the deep water range. Hence this test is quite demanding for models incorporating only weak dispersion and it is well suited for checking the applicability of fully dispersive models.
First we apply the stochastic formulation (26)-(30) with $\Gamma = 0$, which is basically the model of Agnon & Sheremet (1997). We note that similar results (not shown here) can be obtained by using the deterministic evolution equations of Agnon et al. (1993) and Kaihatu & Kirby (1995). Fig. 3a shows the computed and measured values of the skewness, while the asymmetry is shown in Fig 4a. Two different simulations are shown corresponding to offshore boundary conditions based on the measured bispectrum and a zero bispectrum, respectively. With the zero bispectrum, the skewness starts off with a zero and stays at that level on most of the shoal. The computed skewness is clearly significantly underestimated in most of the model area. This is in agreement with the analysis shown in Figs. 1 and 2. On the other hand, using the measured bispectrum as input does not really improve the simulation. Although the skewness is now correct right at the boundary, the mismatch between this value and the nonlinearity sustained by the model equations introduces a local recurrence phenomenon with a sudden decrease in the skewness and an increase in the asymmetry. Further inshore the skewness values computed by the two different boundary conditions are not very different. The large discrepancies between the computed and measured values of the asymmetry (Fig 4a) further inshore are due the mechanism of wave breaking, which is absent in the models considered here. It is emphasised that it requires a rather sophisticated breaking formulation in order to capture the variation of the asymmetry in the surf zone. A few examples of frequency domain formulations of wave breaking are discussed by Chen et al. (1997). This topic is, however, outside the scope of the present work.

For reference we have included the result of using the stochastic Boussinesq model of Kofoed-Hansen & Rasmussen (1998). As seen in Figs. 3b and 4b the computed skewness and asymmetry are quite similar to the ones obtained in Figs. 3a and 4a, and again the significant underestimate of the skewness is in agreement with the analysis in Fig. 1.

Figs. 3c and 4c show the result of including the new $\Gamma$-terms in the stochastic formulation. From Fig. 3c we notice that the computed skewness is significantly improved. The best result is now obtained by using the measured bispectrum as input, but even with a zero initial bispectrum the skewness and asymmetry values quickly fall in line with the measurements after a short distance dominated by recurrence.

Finally, Fig. 5 shows the energy spectra of the surface elevation computed by the stochastic model (26)-(30) including and excluding the new $\Gamma$-terms. In both cases the measured bispectrum is applied at the offshore boundary. The spectra are shown at three locations: WG2 (h=0.35m), WG5 (h=0.20m), and WG8 (h=0.125m). With $\Gamma=0$ we notice that the lack of nonlinearity in the model results in an artificial release of higher harmonics and an overestimation of the high-frequency tail of the spectrum. On the other hand, the model results obtained with the new $\Gamma$-terms are generally in good agreement with the measured spectra.
Figure 1. Transfer function for second harmonics. $G_L/G_{Stokes}$; $G_{Bouss}/G_{Stokes}$.

Figure 2. Isoline map of the ratio of $\alpha_{\gamma=0}^\pm$ to $\alpha^+$ (from eq. 25c) as a function of the interacting frequencies $\omega_m$ and $\omega_{m'} = \omega_{p+m}$. Super-harmonic results shown above the diagonal; sub-harmonic results shown below it.
Figure 3. Spatial variations of the skewness during shoaling. Computations made with the measured bispectrum at the boundary. — Stochastic model of Agnon & Sheremet (1997); ---- Stochastic model based on the present formulation i.e. eqs (26)-(30) incl. the new T-terms; Dotted line indicates measurements of Cox et al. (1991).
6. Summary and conclusions

This paper presents a new and more accurate set of deterministic evolution equations for triad interactions involving fully dispersive, weakly nonlinear, irregular waves. Previous formulations from the literature have included consistent nonlinear evolution equations for the velocity potential, while an inconsistent linear relation has been invoked to obtain the corresponding surface elevation. This approximation is only valid in shallow water and as a result, the previous formulations significantly underestimate nonlinear energy transfer for larger wave numbers. As a consequence bound higher harmonics and nonlinear statistical measures such as the skewness are typically underestimated in these formulations.

In the present work we have corrected this inconsistency. Furthermore, in addition to the improved fully dispersive deterministic equations, we present a set of coupled stochastic evolution equations in terms of the energy spectrum and the bispectrum.

The influence of the new terms is demonstrated on a test case involving irregular waves in intermediate water depths. This case requires a combination of dispersion and nonlinearity and it is shown that existing formulations from the literature fail to predict the evolution of the energy spectrum and of the third-order statistics. A considerable improvement is found by including the new terms presented in this work. Further details and results can be found in Eldeberky & Madsen (1998).

The Horizontal Eddies in the Offshore Zone

Li Li¹, Robert A. Dalrymple²

Abstract:
The mean flow outside the surf zone can be unstable and form a train of submerged vortices, which migrate slowly in the offshore direction, as discovered by Matsunaga, Takehara & Awaya (1988, 1994). Li and Dalrymple (1998) conducted large scale experiments and a numerical study. They showed that two layers of vortices could exist over the water depth. Eddies near the water surface rotated in the opposite direction of eddies at mid-depth. For example, for the surface wave propagating to the right, the rotation direction of eddies near mid-depth was counterclockwise, while the rotation direction of eddies near surface was clockwise. The vortices decay offshore where there was no shear layers over water depth. Experimental and numerical studies show the velocity of long time scale vortical motion is uniform over water depth and is much slower than the undertow. A theoretical analysis shows that the stresses due to turbulence and wave serve as the source of the vorticity and this vortex train is formed by the shear instabilities of the mean flow in the cross-shore direction.

1 Introduction

The nearshore circulation system induced by wave breaking plays an important role in sediment transport. This circulation system (longshore, rip and cross-shore currents) has been studied for years to develop predictive models. The theory of longshore currents changed abruptly with the introduction of radiation stresses, which codified the momentum input to the surf zone by the waves, and lateral mixing, which is

necessary to create a smooth transition of longshore current from onshore to offshore of the breaker line.

In addition to the longshore currents, there are cross-shore currents flowing perpendicularly to the shoreline. The cross-shore currents consist of the mass transport to the shoreline carried by waves and return flow known as undertow. The undertow inside the surf zone has drawn much attention in the literature (e.g. Nadaoka et al. (1982), Svendsen et al. (1992), Okayasu et al. (1992) and Cox et al. (1995)).

Matsunaga et al. (1988, 1994) conducted an experiment on the flow outside the surf zone in a small wave tank (12 m long, 0.4 m deep, 0.15 m wide and equipped with a sloping planar bed). They discovered that the mean flow in the cross-shore direction outside the surf zone could be unstable and formed a single-layer vortex train. The vortices rotate at the direction opposite the direction of the wave-induced water particle trajectories. They also found that these offshore migrating vortices would decay when it reached the region with deeper water depth. The formation of eddies is independent of the breaker type. Li and Dalrymple (1998) studied this offshore vortex train and concluded that the vortices formed due to the instability of undertow seaward of the breaker line. They also found that the vortices decayed when the velocity profile of the undertow becomes linear over the water depth.

Bagnold (1947) studied mass transport outside the surf zone by experiments. He discovered that there were a fast shoreward current along the bed and a slow seaward current under the water surface when two-dimensional surface wave propagating over a horizontal smooth bed. This phenomenon is due to the existence of Stokes layer and viscosity (Longuet-Higgins (1953)). Dore (1970) studied the mass transport outside the surf zone theoretically by taking into account the air-water interface. He concluded that on a clean interface the surface viscosity greatly affected the drift velocity of short waves and the air boundary layer greatly affected the long waves. The mean Eulerian velocity near the surface which is in the onshore direction had a greater onshore velocity than the Stokes drift. On the study of clean and contaminated fluid, Craik (1982) obtained similar results. Through a experimental study, Nadaoka et al. (1982) obtained linear velocity profile outside of the breaker line: a weak seaward velocity at the bed and a strong seaward velocity under the trough level. Cox et al. (1995) obtained similar velocity profile on the experiment of regular waves spilling on a 1 : 35 impermeable slope. Okayasu et al. (1992) conducted detailed laboratory measurements of the undertow due to regular and random waves on a 1 : 20 smooth uniform slope. Rather than a straight-line distribution over the depth outside the surf zone, their measured undertow velocity profiles are curved; it has a shoreward directed velocity at the bed and a seaward oriented velocity under the trough level. In the present study, we obtained the velocity profiles experimentally at the place where the vortices can be observed and at the place that the vortices decayed. This paper also investigate the offshore vortices experimentally and numerically.
2 Experimental Set-up

The wave experiments were conducted in a Precision Wave Tank (PWT) at the Center of Applied Coastal Research at the University of Delaware. This section describes the experimental setup and data acquisition procedure.

The experimental wave tank was 35 m long, 0.6 m deep and 0.6 m wide. It was 3 times longer, 4 times wider and 1.5 times deeper than the wave tank used by Matsunaga et al. (1988, 1994). Figure 1 shows a schematic of the experimental setup. The region at the wavemaker had constant depth, and the region at the other end had a sloping planar bed with 1 : 35 slope. A piston wavemaker was used to generate the two-dimensional periodic surface waves. As shown in Figure 1, three 3-D Acoustic Doppler Velocimetrics (ADV) were used to obtain the Eulerian velocity outside of the surf zone. Two capacitance wave gages were used to measure the local wave height $H$ and wave period $T$. The local phase velocity $C$ was calculated from the time lag of signals from two wave gages that were located 20 cm apart. The local wavelength $L$ was then determined from the product of the celerity and wave period.

The vortex train offshore of the breaker point was observed by flow visualization. Granules of water-soluble aniline blue dye was used as a tracer. Flow patterns were photographed through the glass sidewall of the tank using a 35 mm camera.

![Figure 1: Schematic of experiment set-up.](image)

Based on Matsunaga et al. (1994) (Figure 2), eight tests were designed to explore the effects of varying local water depth $h$ and wave frequencies on the offshore vortex train (Table 1). Tests 1 through 4 were designed in the formation region: the combinations of the dimensionless wave height $(H/L)$ and dimensionless water depth $(h/L)$ would always generate vortices. Test 5 and Test 6 were in the region where the occurrence of vortex varies. Test 7 and Test 8 were designed in the region that no vortices were observed.

Figure 2: Formation regions of offshore vortices from Matsunaga, Takehara & Awaya (1994): open symbols, formation of offshore vortex; solid symbols, non-formation. Lines (a) and (b) indicate the limit of wave steepness and $H_0/L_0 = 4.2 \times 10^{-2}$, respectively. Line (c) is the offshore border of vortex formation.
3 Experimental Results and Discussion

3.1 Flow Pattern

Figures 3 through 5, are a sequence of photos taken at a fixed location for a typical flow pattern: a 2.0s wave train propagates in the wave tank with still water depth $h = 0.297m$ in the constant depth region. The direction of wave propagation was from left to right in all the photos presented below. They show the vortices migrating in the offshore direction (left) as reflected by the movement of the dye. The pictures were taken 2 m offshore from the injection point five seconds apart. They clearly show that there are two layers of vortices: one layer with small vortices exists near the water surface (approximately 0.05 m below water surface), and the other near the mid-depth (approximately 0.1 m below water surface). Vortices near the water surface rotate in the opposite direction of vortices at mid-depth. For example, for the surface wave propagating to the right, the rotation direction of vortices near mid-depth was observed to be counterclockwise as shown by Matsunaga et al. (1994), while the rotation direction of vortices upper in the water column was observed to be clockwise. The upper layer vortices migrate in the same offshore direction as the lower layer vortices, propagate at the same slow speed as the lower layer vortices, and have the same separation distance as those in the lower layer.

![Figure 3: Dye pattern of vortices, 150 wave periods after dye injection. The water wave propagates from left to right.](image)

The velocity of the vortex migrating offshore $V_{vm}$ was obtained by determining the time taken for a vortex to move a given distance. For example, the surface wave phase speed for Test 2 is $C = 1.33m/s$, average instabilities speed is $V_{vm} = 0.0072m/s$. The average rotating time of vortices $T_{rot}$ is 21.5 s, about 10 times of the surface wave period. These vortices in the offshore direction migrate with the speed slower than the undertow. They rotate with longer time than the water particle orbital motions.
Figure 4: Dye pattern of vortices, 155 wave periods after dye injection.

Figure 5: Dye pattern of vortices, 160.9 wave periods after dye injection.
3.2 Mean Velocity Profile

The measured velocity $u, w$ can be split into 4 components: a steady wave-induced current component $U$, longer time scale components $u_{vor}$, $w_{vor}$ due to the vortices, the orbital wave motions components $u_w$, $w_w$ and turbulent components $u_t$, $w_t$. The velocity due to the vortices is defined as angular frequencies less than 1.25 $Hz$ for test 1 through 8. The $ut$ represents the turbulent contribution to the momentum transfer, whereas the $u_w$ and the $w_w$ and the $u_{vor}$ represent the wave contribution and the vortices contribution, respectively. The average $u_{vor}w_{vor}/u_ww_w$ is less than 10%, implying that the vortices contribution to the momentum transfer is insignificant compared to the wave contribution.

The mean velocity profiles measured by the ADV for the eight experiments are shown in figure 6. When we filtered the high frequency components, the mean velocity was obtained from low frequency component which includes the mean current and the longer time scale component. From figure 6, the velocity profiles are curved over the depth. Changes in the curvature of these profiles correspond to the presence of shear layers, there are two shear layers existing over the depth. Tests 7 and 8 show linear distribution over the depth.

![Figure 6: Undertow profile for each test versus depth.](image-url)
3.3 Long Time Scale Component Velocity Profile

Figure 7 shows the distribution of horizontal velocity of the low frequency component due to vortices for Test 1 and 2. The root-mean-square value $u_{vorr}$ were obtained by using the low pass filter. The cutoff frequency is 0.2 Hz, while the sampling frequency is 50 Hz. The velocity profile for longer time component is uniformly distributed. The speed of vortices with long time scale is much slower than the undertow. It indicates that upper layer vortices migrate in the same offshore direction as the lower layer vortices and propagate at the same slow speed as the lower layer vortices, which was shown by the dye pattern.

![Figure 7: Undertow profile for each test versus depth.](image)

3.4 Nonlinearity

In figure 2, line (c) is the boundary of nonlinearity. Ursell number $U_T$ represents the ratio of wave nonlinearity to frequency dispersion. The importance of nonlinearity of the surface wave to the presence of the vortices is discussed here. The value of $U_T$ for all eight tests are shown in Table 2. For the tests that vortices were observed (tests 1 through 6), Ursell numbers are higher, and lower Ursell numbers exist for the tests that no vortices were noticed (tests 7 through 8). Thus the nonlinearity of the surface wave is important for the presence of vortices.

4 Theoretical Analysis

4.1 Stability Equation

The experimental study shows that the vortices are embedded in orbital wave motion, have longer time scales and shorter length scales than the incident waves. Therefore, the velocity $u$, $w$ consist of a steady wave-induced current component $U$, longer time scale components $w_{vor}$, $w_{vor}$ due to the vortices, the orbital wave motions components $u_w$, $w_w$, and turbulent components $u_t$, $w_t$.

For the study of fluid motion outside of the surf zone when surface wave runs up at the beach, viscosity should be considered. The governing equations for the homogeneous and incompressible flow is the Navier-Stokes equations and continuity equation. As shown in Li and Dalrymple (1998), the nondimensional equation for the longer time scale motion can be obtained by averaging first over the high frequency turbulence scale, and then over the orbital wave period.

$$\frac{\partial \vec{u_R}}{\partial t} + (\vec{u_R} \cdot \nabla) \vec{u_R} = -\nabla p + \frac{1}{Re} \nabla^2 \vec{u_R} - \vec{R}_t - \vec{R}_w$$

(1)

where $\vec{u_R} = \{U + u_{vor}, w_{vor}\}$. $Re$ is Reynolds number $U_{ref}L_{ref}/\nu >> 1$. $\nu$ denotes the kinematic viscosity. $L_{ref}$ is the water depth. $U_{ref}$ is the maximum velocity of the undertow. The turbulent stresses $R_{ts} = \frac{\partial u_v}{\partial x} + \frac{\partial u_w}{\partial y}$, $R_{sw} = \frac{\partial w_u}{\partial x} + \frac{\partial w_v}{\partial y}$, $R_w$ denotes the time-averaged Reynolds stress resulting from the wave field (Radiation stress):

$$R_{ws} = \frac{\partial w_u}{\partial x} + \frac{\partial u_w}{\partial y}, \quad R_{wz} = \frac{\partial u_w}{\partial y} + \frac{\partial w_w}{\partial x}.$$

As shown in Li and Dalrymple (1998), through a perturbation analysis of equation 1, at the zeroth order the governing equations for the mean flow are obtained, and at the first order the equations of the interaction between disturbances and mean flow are generated. The equation of the interaction between disturbances and mean flow is the Orr-Sommerfeld equation which governs the stability of fluid motion:

$$\frac{1}{iaRe} (D^2 - \alpha^2)^2 \phi = (U - c)(D^2 - \alpha^2) \phi - U'' \phi$$

(2)

where $D\phi = \psi$, $\psi(x, z, t) = \phi(z)e^{ia(x-ct)}$, $\psi$ is a stream function, $\alpha$ is the wave number and $c$ is the wave phase speed.

The wave number $\alpha$ is real. Solutions of the Orr-Sommerfeld equation are progressive disturbance waves with phase speed equal to the real part of $c$. If $c$ has a negative imaginary component, the solution has an exponentially growing amplitude.
which indicates that mean velocity profile, $U(z)$, is unstable to perturbations of the velocity field with that wavenumber. In cases where more than one such $c$ are present, it is assumed that the one with the largest imaginary component will dominate the instability of that wavenumber. This correspond to the point of maximum $\alpha c_{im}$, where $c_{im}$ is the imaginary part of $c$. If $c$ has zero imaginary component, the solution is neutrally stable to disturbance of the velocity field with that wavenumber.

The boundary conditions are that the normal and shear stresses are zero at the free surface, and the rigid boundary condition applies at the bottom.

Equation 2 is difficult to solve analytically for a general velocity distribution $U(z)$. Therefore, a numerical approach was attempted, which was discussed in Li and Dalrymple (1998).

**4.2 Vorticity Equation**

The vorticity equation derived from the momentum equations 1 is:

$$\frac{\partial \omega}{\partial t} + (\mathbf{u}_R \cdot \nabla) \omega = \frac{1}{Re} \nabla^2 \omega + \omega \nabla \cdot \mathbf{u}_R - \nabla \times \mathbf{R}_\text{t} - \nabla \times \mathbf{R}_w$$

(3)

The first term on the right hand side represents the diffusion of vorticity due to the action of viscosity. $\omega \nabla \cdot \mathbf{u}_R$ provides the mechanism of vortex stretching. The stress terms due to turbulence and radiation stress serve as the source of vorticity. The vortices that we observed are due to instabilities of the undertow.

**5 Numerical Results and Discussions**

Since we do not have a theoretical profile of mean velocity with shear layers, the measured undertow profiles will be used in our numerical calculations that follow. The smooth velocity profile was obtained by fitting a 5-th order polynomial to the measured wave-averaged data, Li and Dalrymple (1998). Tests 7 and 8 are neutrally stable to any disturbance to the corresponding mean flow.

Numerical approach was used to predict the vortices generation under the flow conditions similar to the cases in the experimental study. The numerical predictions are then compared with the results measured in the experimental study.

**5.1 Numerical Predicted Vortices**

As stated in Li and Dalrymple (1998), the numerical instability model successfully obtained single layer vortex, by using the assumed velocity profile based on the deformation of dye lines shown in Matsunaga et al. (1988, 1994). Figure 8 shows the numerically predicted flow for one surface wave wavelength using the undertow velocity profile and water depths of Tests 1 and 2. The stream lines are gained by summing the mean flow and the fastest growing unstable wave. Figure 9 show velocity field and the spatial patterns of the streamlines for a quarter surface wave for Test 2. More
figures of predicted instabilities are shown in Li and Dalrymple (1998). These figures show similar results as the observations in the experiments: there are two layers of unstable waves exist over depth. The rotation direction of vortices near surface was the same as the wave-induced water particle trajectories, while the rotation direction of vortices near mid-depth was in opposite direction. The unstable wavelength is much shorter than the surface wave length.

Figure 8: Streamline of the instabilities over one surface wavelength. The surface wave propagates to the left, top: test 1, bottom: test 2.

5.2 Velocity of Vortical Motion

Li and Dalrymple (1998) also showed the good agreement of horizontal length scales and vertical positions between the numerical instabilities and the corresponding experimental results. The experimental and numerical results of the speed of the instabilities are shown in Table 3. Good agreement between the experiment and numerical model is observed. As stated in the experimental study, the instabilities move offshore

slower than the undertow do. Clearly, the linear perturbation model can predict the speed, the position, length scale of the vortices and the existence of the vortex.

6 Conclusions

In this paper, both experimental and numerical studies on the offshore vortex train were conducted. The following conclusions can be drawn.

It has been shown that an undertow seaward of the surf zone can cause oscillations that are different from regular surface waves. These oscillations are below water surface with shorter length scale and longer time scale. Two vortex layers exist over the water depth, because of the existence of two shear layers. The resulting vortices near the water surface rotate in the opposite direction as one at mid-depth. Vortices near the water surface migrate in the same offshore direction as the vortices at mid-depth, propagate at the same speed which is slower than undertow as vortices at mid-depth.

Using the flow conditions similar to those in the experiments, the speed for the instabilities calculated from the numerical model is compared with the corresponding experimental results. Good agreement between the experiment and numerical model is observed. It may be concluded that the linear stability model can predict the occurrence of the vortices from the velocity profile.

The stresses due to turbulence and wave serve as the source of the vorticity. The nonlinearity of the surface wave may play an important role in the presence of vortices.

Nonlinear Distribution of Neashore Free Surface and Velocity

Nobuhito MORI * and Nobuhisa KOBAYASHI †

ABSTRACT

The Edgeworth expansion with the measured skewness and kurtosis is shown to be capable to describe the measured nonlinear distributions of the surface elevation and horizontal velocity in the shoaling and surf zones. The moments involved in the energetics-based model are expressed in terms of the skewness and kurtosis and shown to be in agreement with available data. Stokes wave theory is applied to obtain a relationship between skewness and kurtosis. The relationship is adjusted empirically because of the limitation of Stokes wave theory in the shoaling and surf zones. The relative simple relationship for the higher moments obtained here may be applied for cross-shore sediment transport analysis.

INTRODUCTION

Nonlinear waves in nearshore regions are important in estimating sediment transport and designing coastal structures. The estimation of an extreme wave crest is an important factor in predicting the deck elevation of an offshore structure. The wave profile in the surf zone is significantly skewed because of wave breaking and bottom topography effects. Time dependent numerical models based on extended Boussinesq equations have been shown to be capable of predicting the nonlinear profile of the surface elevation outside the surf zone (e.g., Nwogu 1993). Time dependent numerical models, however, require large computation time to calculate the wave profiles.

On the other hand, time-averaged models for random waves are more efficient computationally at the expense of the loss of the detailed temporal information (e.g., Battjes and Janssen 1978; Thornton and Guza 1983; Mase and...
Kobayashi 1991). However, time-averaged models may not be accurate enough, because random wave are expressed as the superposition of regular waves or by a representative wave. Guza and Thornton (1985) has pointed out that both randomness and nonlinearity are necessary to predict the moments of the cross-shore fluid velocity on a beach. Hence, the purpose of this study is to develop a probabilistic model of the surface elevation and cross-shore velocity in the nearshore including both random and nonlinear effects.

Many studies have were performed to describe the nonlinear distribution of the free surface elevation. Ochi and Ahn (1994) and Kobayashi et al. (1998) used Siegert solution and the exponential gamma distribution, respectively, to describe the distribution of the surface elevation and velocity. These distributions agree fairly with the measured skewed distributions. However, it is difficult to obtain the relationships among the various moments of the distribution analytically. In contrast, attempts were made to describe the nonlinear distribution of the free surface elevation using perturbations of the Gaussian distribution(Longuet-Higgins 1963; Haung and Long 1980; Bitner 1980). These methods based the Gram-Charlier or Edgeworth approximation can be expanded as a function of skewness and kurtosis. Then, it is much easier express the various moments in terms of the skewness and kurtosis, although these approximations give negative density values for certain skewed distributions.

In the following, the probability density distributions and moments of the measured free surface elevation and horizontal velocity in a large wave flume are compared with the Edgeworth expansion and the measured skewness and kurtosis. Stokes wave theory is applied to derive a relationship between the skewness and kurtosis.

EXPERIMENTS

The experimental data used here was reported in Japanese by Shimizu et al. (1996). The experiment was conducted in a large wave flume that was 205m long, 3.4m wide, 6m high. The water depth in the flume was 4m. A sand beach of a 1:30 slope was installed at the end of the wave tank. Water surface displacements at 17 locations in Fig.1 were measured using capacitance type wave gages located in the still water depth range of 0.1-4.0m. Fluid velocities were measured with six electro-magnetic current meters. The current meters in Fig.1 were located in the still water depths 2.25, 1.92, 1.58, 1.25, 0.92 and 0.48m, respectively. The measurements with a sampling frequency of 20Hz were performed for the duration of 819s.

Random waves based on the JONSWAP spectrum and random phases were generated using linear wave theory with a computer-controlled piston-type wave paddle. Two cases were reported by Shimizu et al. (1996) as summarized in Table 1 where $H_{1/3}$ and $T_{1/3}$ are the significant wave height and period above the horizontal bottom. In Table 1, the wave amplitude $a_0=H_{1/3}/2$, the water

Figure 2 Measured cross-shore variations of $rms$ values of horizontal fluid velocity $u$ and surface elevation $\eta$.

depth $h_0=4.0$ m on the horizontal bottom, and $k$ is the linear wave number based on $T_{1/3}$ and $h_0$. The value of $k_a$ and $k_h$ in Table 1 indicate wave steepness and nondimensional water depth at the wave paddle. Case 2 was more nonlinear than case 1.

The surface displacement $\eta$ and the horizontal fluid velocity $u$ near the bottom are analyzed in the following. Fig. 2 shows the spatial distributions of the root-mean-square($rms$) values of the horizontal fluid velocity $u$ and the surface elevation $\eta$. Solid lines with open symbols indicate the $rms$ values of $u$ and dashed lines with filled symbols indicate the $rms$ values of $\eta$. Circles $\bigcirc$ are
for case 1 and triangles $\triangle$ are for case 2. Fig.2 illustrates the difference in the width of the surf zone for case 1 and 2. The $rms$ values of $u$ increased landward, whereas the $rms$ values of $\eta$ decreased monotonically landward.

The moments $\mu_3$, $\mu_4$, $\mu_5^*$ and $\mu_6^*$ for $f=\eta$ or $u$ are defined as follows:

$$\mu_n = \frac{1}{N} \sum_{i=1}^{N} \left( \frac{f_i - \bar{f}}{f_{rms}} \right)^n$$

$$\mu_r^* = \frac{1}{N} \sum_{i=1}^{N} \left| \frac{f_i - \bar{f}}{f_{rms}} \right|^n$$

$$\mu_r^* = \frac{1}{N} \sum_{i=1}^{N} \left( \frac{f_i - \bar{f}}{f_{rms}} \right) \left| \frac{f_i - \bar{f}}{f_{rms}} \right|^{n-1}$$

where $\bar{f}$ is the mean value of $f$, $f_{rms}$ is the $rms$ value of $f$, and $N$ is the number of data point. Eq.(1) with $n=3$ and 4 gives $\mu_3=$ skewness and $\mu_4=$ kurtosis. The moments are calculated after removing the high-frequency components with frequency larger than 4 times of the peak frequency to reduce the statistical sensitivity. The third order absolute moment $\mu_3^*$ and the fourth order signed moment $\mu_4^*$ for the velocity are related to the energetics-based sediment transport model (Bailard 1981). The measured third and fourth moments are shown in Fig.3. The measured moments of $\eta$ show systematic trends. The values of the moments of $\eta$ are close to the Gaussian values, $\mu_3=0$, $\mu_4=3$, $\mu_5^*=1.6$ and $\mu_6^*=0$, offshore. These values then increase landward before their decrease toward the shoreline. On the contrary, the measured moments of $u$ are below the values of the Gaussian offshore. $\mu_4$ and $\mu_5^*$ are reduced first and then increase landward, whereas $\mu_3$ and $\mu_6^*$ increase monotonically.

In summary, the spatial variations of the moments of the horizontal fluid velocity $u$ and the surface elevation $\eta$ deviate from the Gaussian values near and inside the surf zone. The measured moments of $u$ are close to the Gaussian values but the moments of $\eta$ exceed the Gaussian values significantly inside the surf zone. These results are consistent with the small scale tests on a 1:16 slope by Kobayashi et al. (1998).

### STATISTICAL MODELING OF SURFACE AND VELOCITY MOMENTS

The data shown in Fig.3 indicates strong nonlinearity of $\eta$ in the shoaling and surf zones. The horizontal velocities near the bottom have weaker nonlinearity. Hence, the Edgeworth expansion (Kendall and A.Stuart 1963) is applied to describe the probability density function (PDF) of the surface elevation and horizontal velocity. The Edgeworth expansion is adequate to describe random and weak nonlinear stochastic processes. The Edgeworth expansion is derived in the same manner as the Gram-Charlier expansion but the terms of the series are expressed in terms of cumulants.
The PDF $p(x)dx$ of the normalized statistical variables $x$ with zero mean and its standard deviation of unity can be described as (Kendall and A. Stuart 1963)

$$p(x)dx = \sum_{r=0}^{\infty} c_r H_r(x)G(x) dx$$

with

$$G(x) = \frac{1}{\sqrt{2\pi}} \exp \left( -\frac{x^2}{2} \right)$$

where $G(x)$ is the Gaussian distribution, $H_r(x)$ is the Chebyshev-Hermite poly-
nominal and $c_r$ is the $r$th order coefficient of the Gram-Charlier expansion. Introducing the characteristic function, the Edgeworth expansion of type A is given by (e.g., Longuet-Higgins 1963)

$$p(x)dx = G(x)\left\{1 + \frac{\kappa_3}{6} H_3(x) + \left[\frac{\kappa_4}{24} H_4(x) + \frac{\kappa_3^2}{72} H_6(x)\right] + \left[\frac{\kappa_5}{120} H_5(x) + \frac{\kappa_3 \kappa_4}{144} H_7(x)\right] + \cdots\right\}dx$$

where $\kappa_r$ is the $r$th order cumulant. The cumulants with $r=3-6$ are related to
the $r$th order moments $\mu_r$ as follows:

$$
\begin{align*}
\kappa_3 &= \mu_3 \\
\kappa_4 &= \mu_4 - 3 \\
\kappa_5 &= \mu_5 - 10\mu_3 \\
\kappa_6 &= \mu_6 - 15\mu_4 - 10\mu_3^2 + 30
\end{align*}
$$

(7)

where the mean value $\mu_1$ of $x$ is equal to zero ($\kappa_1 = 0$) and the standard deviation of $x$ is unity ($\kappa_2 = 1$). Therefore, $\mu_3$ is skewness and $\mu_4$ is kurtosis.

It must be noted that an asymptotic expansion does not have monotonic convergence for high order corrections. There are many studies about the truncation of (6) (Longuet-Higgins 1963; Haung and Long 1980; Ochi and Wang 1984; Mori and Yasuda 1996). They have shown that the first three terms of (6) are sufficient for describing the nonlinear property of the PDF of the surface elevation. Hence, the first three terms in (6) are used to represent the PDF of $x$ denoting the normalized the surface elevation and horizontal velocity

$$
p(x)dx = G(x)\left\{1 + \frac{\kappa_3}{6}H_3(x) + \left[\frac{\kappa_4}{24}H_4(x) + \frac{\kappa_5}{72}H_5(x)\right]\right\}dx
$$

(8)

which requires $\kappa_5 = \mu_3$ = skewness and $\kappa_4 = (\mu_4 - 3)$ with $\mu_4$ = kurtosis. The truncation of high order terms in (6) gives the following relationships based on $\kappa_5 = 0$ and $\kappa_6 = 0$ for the high order moments:

$$
\begin{align*}
\mu_5 &= 10\mu_3 \\
\mu_6 &= 10\mu_3^2 + 15\mu_4 - 30
\end{align*}
$$

(9)\hspace{1cm}(10)

The other higher moments related to the energetics-based sediment transport model (Bailard 1981) can be calculated using (8)

$$
\begin{align*}
\mu_3^* &= \int_{-\infty}^{\infty} |x|^3 p(x)dx = \frac{1}{6\sqrt{2\pi}}(3\mu_4 - \mu_3^2 + 15) \\
\mu_5^* &= \int_{-\infty}^{\infty} |x|^5 p(x)dx = \frac{2}{3\sqrt{2\pi}}(15\mu_4 + 5\mu_3^2 - 21) \\
\mu_4^* &= \int_{-\infty}^{\infty} x|x|^3 p(x)dx = \frac{8}{\sqrt{2\pi}}\mu_3
\end{align*}
$$

(11)\hspace{1cm}(12)\hspace{1cm}(13)

Fig. 4 show the comparisons of the measured PDF of $u$ and $\eta$ with (8) for case 2 where the measured values of $\mu_3$ and $\mu_4$ are used in (8). The PDF of $u$ is skewed negatively offshore but positively in the surf zone. The measured spatial variation of $\mu_3$ shown in Fig. 3a indicates the corresponding sign shift. This may be important for the cross-shore sediment transport. On the other hand, the PDF of $\eta$ is always skewed positively as expected from nonlinear wave theory. The nonlinear PDF given by (8) agrees better with the data than the linear Gaussian distribution partly because of the additional input of $\mu_3$ and $\mu_4$. 
Figure 4 Measured PDF of $u$ and $\eta$ for case 2 in comparison with the theory.
To check the validity of (9)-(13), the comparisons between the measured moments $\mu_n$ and the calculated moments $\mu'_n$ indicated by the prime are shown in Fig. 5. Eq. (9) gives a simple relationship between $\mu_3$ and $\mu'_3$. The correlation coefficient of in Fig. 5a is 0.98, indicating good agreement between the measured $\mu_3$ and the calculated $\mu'_3$. The sixth moments $\mu_6$ given by (10) for $u$ and $\eta$ show similar results (not shown). Fig 5b-d also show good agreement between the measured moments ($\mu'_5$, $\mu'_3$, and $\mu'_4$) and the calculated moments ($\mu''_5$, $\mu''_3$, and $\mu''_4$) using (11)-(13). The PDF of $u$ and $\eta$ in the shoaling and surf zones can be described by the Edgeworth expansion given by (8). As a consequence, the associated moments can be estimated by (9)-(13).

Eq. (8) requires both skewness $\mu_3$ and kurtosis $\mu_4$ as input. An attempt is made to express $\mu_4$ in terms of $\mu_3$. 

**Figure 5** Comparison between measured $\mu_5$, $\mu'_5$, $\mu'_3$, and $\mu'_3'$, and calculated $\mu''_5$, $\mu''_3$, $\mu''_3'$, and $\mu''_4'$ for measured $\mu_3$ and $\mu_4$. 

(a) measured $\mu_5$ vs. calculated $\mu'_5$

(b) measured $\mu'_3$ vs. calculated $\mu''_3$

(c) measured $\mu'_3$ vs. calculated $\mu''_3$

(d) measured $\mu'_4$ vs. calculated $\mu''_4$
RELATIONSHIP BETWEEN SKEWNESS AND KURTOSIS

Tayfun (1980), Srokosz and Longuet-Higgins (1986) and Winterstein et al. (1991) derived the PDF of the surface elevation based on the assumption that random waves can be expressed as a summation of Stokes 2nd or 3rd waves. This assumption considers only the self wave interaction components, although there are random wave-wave interaction components. This approach is easy to apply and calculate the moments in comparison with the fully nonlinear random interaction method (e.g., Sharma and Dean 1979). Admittedly, Stokes wave theory may not be valid in shallow water and the derived relationship will be interpreted in view of this limitation. The 3rd order Stokes wave in finite water depth \( h \) is given by:

\[
\eta = \frac{1}{2} (ak)^2 D_1 + ak \cos \theta + \frac{1}{2} (ak)^2 D_2 \cos 2\theta + \frac{3}{8} (ak)^3 D_3 \cos 3\theta
\]  

where \( a \) is the amplitude, \( k \) is the wave number, \( \theta \) is the phase with \( \theta = (kx - \omega t + \epsilon) \) in which \( \omega \) is the angular frequency, and the phase \( \epsilon \) is assumed to random. Eq. (14) neglects the phase shift of the second and third harmonics which may be important for the wave profile pitched landward in the surf zone. \( D_i \) is the function of the nondimensional water depth \( kh \):

\[
D_1 = \coth kh \\
D_2 = \coth kh \left( 1 + \frac{3}{2 \sinh^2 kh} \right) \\
D_3 = 1 + \frac{1}{\sinh^2 kh} \left( 3 + \frac{3}{\sinh^2 kh} + \frac{9}{8 \sinh^4 kh} \right)
\]

It is assumed that the PDF of the first order component \( a \cos \theta \) is the Gaussian and that the amplitude \( a \) and the phase \( \epsilon \) are independent of each other with \( \epsilon \) being distributed uniformly between 0 to \( 2\pi \). These assumptions yields the joint PDF of \( a \) and \( \theta \) as

\[
f(a, \theta) = \frac{a}{2\pi \sigma^2} \exp \left( -\frac{a^2}{2\sigma^2} \right),
\]

where \( \sigma \) is the rms value of the first order component \( a \cos \theta \). The moments \( \lambda \) with \( n=0,1,\cdots \) can be calculated using (14) and (16):

\[
\lambda_n = \int_{\theta=0}^{2\pi} \int_{a=0}^{\infty} [\eta(a, \theta)]^n f(a, \theta) \, da \, d\theta
\]

which yields

\[
\lambda_0 = \sigma D_1 \alpha \\
\lambda_2 = \sigma^2 \left[ 1 + (D_1^2 + D_2^2) \alpha^2 + O(\alpha^4) \right] \\
\lambda_3 = \sigma^3 \left[ 3(D_1 + D_2) \alpha + \frac{1}{2} (4D_1^3 + 12D_1D_2^2 + 27D_2D_3) \alpha^3 + O(\alpha^4) \right] \\
\lambda_4 = \sigma^4 \left[ 3 + 3(6D_1^2 + 6D_2^2 + 8D_1D_2 + 3D_3) \alpha^2 + O(\alpha^4) \right]
\]
where $\alpha$ is the wave steepness $ak$ of the linear component. Dividing $\lambda_3$ by $\lambda_2^{3/2}$, the leading skewness contribution is given by

$$\mu_3 = 3\alpha(D_1 + D_2)$$

(22)

The low frequency component involving $D_1$ in (14) was retained by Vinje (1989) but was neglected by Tayfun (1980) and Winterstein et al. (1991). Dividing $\lambda_4$ by $\lambda_2^2$, neglecting $D_1$ and $D_3$ and substituting (22), the leading kurtosis contribution obtained

$$\mu_4 = 3 + \left(\frac{4}{3} \mu_3\right)^2$$

(23)

The effect of the water depth $D_2$ on $\mu_4$ is included in (23) through $\mu_3$ given by (22) with $D_1=1$.

To examine the validity of (23), Fig.6a shows the comparison between the measured and calculated $\mu_4$ as a function of the measured $\mu_3$. Eq.(23)(solid line) follows the trend of the data point but overpredicts the kurtosis $\mu_4$. The measured $\mu_4$ corresponding to $\mu_3 \approx 0$ is smaller than 3. It means that for zero skewness the kurtosis is smaller kurtosis than linear random wave theory. The field data of Ochi and Wang (1984) also showed similar tendency. Therefore, (23) is adjusted empirically as follows:

$$\mu_4 = \beta + \left(\frac{4}{3} \mu_3\right)^2$$

(24)

where $\beta$ is the empirical constant. Eq.(24) reduces to (23) for $\beta=3$. Eq.(24) with $\beta=2.3$ is shown as a dashed line in Fig.6. The value of $\beta=2.3$ is determined by a
least-square method using the laboratory data in Fig.6a. Additional two lines are plotted in Fig.6a. One is derived by Kobayashi et al. (1998) using the exponential gamma distribution and another is the empirical relationship obtained by Ochi and Wang (1984) using extensive field data on the free surface elevation. The exponential gamma distribution tends to overpredict $\mu_4$ and is almost the same as (23). The empirical equation (24) and that by Ochi and Wang (1984) give better agreement with the data. Fig.6b shows the comparisons among (23), (24), the laboratory data, the empirical relation and the field data by Ochi and Wang (1984). Eq.(24) with the measured $\mu_3$ underpredicts the field data but (23) overestimates the field data.

Substituting (24) into (11) and (12) gives $\mu_3^*$ and $\mu_5^*$ as a function of $\mu_3$ only:

$$\mu_3^* = \frac{1}{18\sqrt{2\pi}} \left[ 13\mu_3^2 + 9(\beta + 5) \right], \tag{25}$$

$$\mu_5^* = \frac{2}{9\sqrt{2\pi}} \left[ 95\mu_3^2 + 9(5\beta - 7) \right]. \tag{26}$$

The measured $\mu_3^*$ and $\mu_5^*$ are compared with (25) and (26) in Fig.7. The predicted $\mu_3^*$ and $\mu_5^*$ as a function of the measured $\mu_3$ are reasonable and the agreement is similar to Fig.5b and 5c.

**COMPARISON WITH FIELD DATA**

Finally, (9), (11) and (12) using the measured $\mu_3$ and $\mu_4$ are compared with the field data on cross-shore(c) and longshore(l) velocities measured by Guza and Thornton (1985) at Torreys Pines Beach, San Diego, California, during
November 1978. The observed moments in Table 2 are spatially-averaged values. Table 2 also includes the predicted moments using (23), (25) and (26) with $\beta=3$ for the measured $\mu_3$ only. Guza and Thornton (1985) analyzed their velocity data to estimate the sediment transport rates using the energetics model by Bailard (1981).

For the cross-shore velocities, the calculated moments $\mu_5$, $\mu_5^*$ and $\mu_5^{**}$ using the measured $\mu_3$ and $\mu_4$ are in good agreement with the data on Nov.20th but the agreement is worse for Nov.17th. This is due to the unexpected combination of $\mu_3$ and $\mu_4$ for the Nov.17th data (high skewness and low kurtosis). For the alongshore velocities, the measured skewness was almost zero and the Gaussian distribution with $\mu_3=0$ appears to be acceptable except for $\mu_5^*$.

Table 2 Comparison between velocity moments field data by Guza and Thornton (1985) and theory with $\beta=3$.

CONCLUSION

Nonlinear wave statistics of irregular waves are examined in the shoaling and surf zones on a beach. First, the probability density function of the surface elevation and velocity can be represented by the Edgeworth expansion. Second, the analytical relationships among the order odd and even moments involved in the energetics-based sediment transport model are derived and verified using laboratory and field data. Third, semi-empirical relationship between the skewness and kurtosis is proposed to facilitate future applications.

Evolution Equations for Edge Waves and Shear Waves on Longshore Uniform Beaches

James T. Kirby, M.ASCE¹, Uday Putrevu, A.M.ASCE² and H. Tuba Özkan-Haller³

Abstract

A general formalism for computing the nonlinear interactions between triads of coastally-trapped gravity and vorticity waves is developed. An analysis of the linearized problem reveals that gravity (or edge) waves and vorticity (or shear) waves exist as members of the same non-Sturm-Liouville eigenvalue problem, with unstable shear waves representing the complex eigenvalue portion of the resulting spectrum. Interaction equations derived here cover resonant interactions between three edge waves, three shear waves, or a shear wave and two edge waves. Numerical examples are shown for the case of three edge waves on a planar beach in the absence of a longshore current. It is found that edge waves can exchange significant amounts of energy over time scales on the order of ten wave periods, for realistic choices of edge wave parameters.

Introduction

The low frequency wave climate on an open coastal beach contains a complex mix of trapped gravity wave motions (edge waves) as well as vorticity (or shear) waves associated with the instability of the longshore current. To date, there has been a tendency in the literature to treat both classes of motion as isolated systems in which the principle effect of nonlinearity is through amplitude dispersion. Formulations of this type typically treat the wave field in terms of a wave envelope modulated by cubic nonlinearity, leading to the cubic Schrödinger equation for conservative edge wave systems (Yeh, 1985) or Ginzburg-Landau equation for marginally unstable shear waves (Feddersen, 1998). However, in field conditions, all of these motions occur in a relatively dense spectral environment, and the existence of combinations of waves satisfying three-wave resonance conditions makes it likely that the dominant nonlinear mechanism affecting edge or shear waves would be through resonant interactions at second order.

Direct numerical simulations (Allen et al., 1997; Özkan-Haller and Kirby, 1998)

suggest that the growth to finite amplitude of the shear wave climate involves strong nonlinear interaction between the various length scales in the motion. It is likely that there are also opportunities for edge waves to undergo strong interactions, although this pathway has not been heavily investigated to date. All of these interactions contribute to the final evolution of the low frequency climate on a beach, which may or may not have some sort of equilibrium configuration.

The goals of present study are to:

1. Derive evolution equations describing the nonlinearly-coupled evolution of the discrete modes of the low frequency wave climate.
2. Use these equations to investigate the full range of edge wave - edge wave, shear wave - shear wave, and edge wave - shear wave interactions.
3. Couple the resulting system to incident wave conditions.
4. Investigate the equilibrium statistics of the resulting low-frequency wave climate, and compare to field measurements.

The core of our approach to this problem is the development of a spectral model describing nonlinear interactions between the free waves of the system by means of resonant interactions at second order. To date, the literature has identified the possibility of these resonances for the case of three edge waves (Kenyon, 1970; Bowen, 1976) or three shear waves (Shrira et al, 1997). We wish to add to this list the possibility of a triad involving a single shear wave and two edge waves, either of which can be propagating with or against the shear wave. Figure 1 illustrates such a case with all three waves propagating in the same direction as the longshore current. A general framework for computing these interactions is outlined below, and then specialized to the case of edge waves on a planar beach with no current in order to obtain analytical results.

Formulation of the Problem

For simplicity, our attention here is restricted to the case of unforced, undamped nonlinear long wave motions on a longshore uniform beach. The inclusion of forcing would lead to a coupling of the low-frequency motion to the incoming short wave climate (Lippmann et al, 1997). The introduction of longshore variability would extend the present analysis to include both the slow variation of model parameters in the longshore direction as well as the direct scattering of wave modes by wavelength-scale bottom features (Chen and Guza, 1998). These topics will be addressed in extensions of the present work.

The dependent variables in the present analysis are the surface displacement \(\eta(x, y, t)\), cross-shore velocity \(u(x, y, t)\) and longshore current \(v(x, y, t) + V(x)\), where a distinction is made between the mean current profile \(V(x)\) and the wave-induced fluctuations \(v(x, y, t)\). The governing equations are given by

\[
\frac{d\eta}{dt} + (hu)_x + hv_y = - (\eta u)_x - (\eta v)_y \equiv \eta N
\]  

(1)
Figure 1: Diagram illustrating hypothetical resonant triad interaction involving a shear wave and two edge waves. Identifying the shear wave as the first wave in the triad, the origin of the edge wave dispersion curve is translated up the shear wave dispersion curve to the locus of shear wave frequency and wavenumber. Resonances involving two edge waves are then indicated by the intersections of the original and the translated edge wave dispersion curves. The two dashed lines here indicate two edge waves with the same mode number and propagating downstream with the longshore current.

\[
\frac{d(hu)}{dt} + gh\eta_x = -huu_x - huv_y \equiv \nu N
\]  
(2)

\[
\frac{d(hv)}{dt} + V'(hu) + gh\eta_y = -huv_x - hvv_y \equiv \nu N
\]  
(3)

where a prime denotes differentiation with respect to \( x \), and where

\[
\frac{d}{dt} = \frac{\partial}{\partial t} + V(x) \frac{\partial}{\partial y}
\]  
(4)

is a time derivative following the local mean current. Eliminating \( u \) and \( v \) from linear terms gives

\[
\frac{d}{dt} \left\{ \frac{d^2\eta}{dt^2} - g(\eta_x)x - g\eta_{yy} \right\} + 2ghV'\eta_{xy} = (\epsilon)N.L.T.
\]  
(5)

where

\[
N.L.T. = \frac{d}{dt} \left\{ \frac{d}{dt} \left( \eta N \right)_x - (\nu N)_x - (\nu N)_y \right\} + 2V'(\nu N)_y
\]  
(6)
and where $\epsilon$ denotes a small parameter characterizing the weakness of the wave motions.

**The Linearized Problem**

We first seek solutions to the linearized problem, obtained by taking the limit $\epsilon = 0$ in (5). Solutions will be of the form

\[
\eta = F(x)e^{i(\lambda y - \omega t)}
\]

\[
u = G(x)e^{i(\lambda y - \omega t)}; \quad G(x) = \frac{-ig}{\sigma} F'(x)
\]

\[
v = H(x)e^{i(\lambda y - \omega t)}; \quad H(x) = \frac{g}{\sigma} \left\{ \lambda F - \left( \frac{V'}{\sigma} \right) F' \right\}
\]

where

\[
\sigma = \omega - \lambda V(x)
\]

is the local intrinsic frequency of the wave with respect to the local longshore current velocity. Substituting (7)-(9) in (5) gives an eigenvalue problem which may be written in self-adjoint form (Howd et al, 1992) as

\[
\left( 1 - \frac{g\lambda^2 h}{\sigma^2} F \right)' + \left( \frac{ghF'}{\sigma^2} \right)' = 0 \quad 0 \leq x \leq \infty
\]

\[
F \text{ bounded at } x = 0, \quad F \downarrow 0 \text{ as } x \to \infty
\]

which is not convenient for solution of the eigenvalue problem but which serves as a basis for establishing solvability conditions in the nonlinear problem. The resulting eigenvalue problem is a non-Sturm-Liouville eigenvalue problem for $\{F(x), \omega(x)\}$ given $\lambda$ and $h(x)$. There are possible singularities at $\sigma^r = \omega' - \lambda V_c = 0$, where $V_c$ denotes the critical longshore current velocity. Possible types of solutions include:

1. Gravity motions without a critical level in the current profile $\rightarrow$ Distorted "regular" edge waves (Howd et al, 1992)

2. Gravity motions in the presence of a double set of critical levels, including:
   
   (a) Waves trapped against the shore by the faster offshore velocity (Falqués and Iranzo, 1992).
   
   (b) Waves trapped between the critical levels, propagating upstream relative to the current (Bryan and Bowen, 1998)
   
   (c) Waves trapped between the offshore critical level and deep water (hypothetical).

3. Vorticity motions representing the unstable growth of meanders in the longshore current (where $\omega'$ is complex; Bowen and Holman, 1989) or the stable propagation of similar meanders (Falqués and Iranzo, 1992; Bowen and Holman, 1989).
For a given $\lambda$, the orthogonality condition for two modes with distinct mode numbers $n, m$ and frequencies $\omega^n, \omega^m$ is easily established,

$$\int_0^\infty g h (\sigma^n + \sigma^m) \left\{ F_n' F_m' + \lambda^2 F_n F_m \right\} dx = 0$$

but we do not have a theorem for the completeness of the $F_n$ basis. Since the system is of non-Sturm-Liouville form, we expect to obtain a complex spectrum of eigenvalues, of which the components containing positive imaginary parts will correspond to unstable and growing vorticity modes, or shear waves. We wish to emphasize here that the edge waves and shear waves are members of the same basis of eigenfunctions.

### The Nonlinear Problem

Returning to the full problem, we follow the usual approach for obtaining evolution equations for variation of modal amplitudes on slow time and longshore space scales. We introduce multiple scales in order to identify slow changes of modal amplitudes in time and in longshore distance.

\[
t \to t + \epsilon t = t + T \\
y \to y + \epsilon y = y + Y
\]

We then introduce an expansion for $\eta$,

$$\eta = \eta^{(1)} + \epsilon \eta^{(2)}$$

The solution for $\eta^{(1)}$ corresponds to a superposition of all eigenmodes of the linearized system,

$$\eta^{(1)} = \sum_n \sum_r \frac{1}{2} A_n^r (Y, T) F_n (x) E_n^r + \text{complex conjugate}$$

where

$$E_n^r = e^{i(\lambda_n y - \omega_n t)}$$

is the oscillatory dependence on fast time and longshore distance, and the $F_n^r$ are the eigenmodes of the linear eigenvalue problem. At $O(\epsilon)$, we get a forced problem for each $n, r$ combination. We require the forcing for each component to be orthogonal to the solution of the adjoint of the original eigenvalue problem. Nonlinear terms in the system may be simplified by imposing resonance conditions, given by

$$\pm \lambda_n \pm \lambda_m - \lambda_n = 0$$

$$Re \{ \pm \omega^r_p \pm \omega^m_q - \omega^r_n \} = 0$$

The final evolution equation for each discrete mode in the system has the form

\[
A_{n'r'} + C_{yn} A_{n'y} = i \sum_l \sum_m \sum_p \sum_q \left\{ + T_{lmn}^{pp'} A_l^{p} A_m^{q} \delta (l + m - n) \delta (\omega_p^r + \omega_q^m - \omega_n^r) \right. \\
+ T_{lmn}^{pp'} A_l^{p} A_m^{q} \delta (l - m - n) \delta (\omega_p^r - \omega_m^q - \omega_n^r) \right. \\
+ \left. T_{lmn}^{pp'} A_l^{p} A_m^{q} \delta (m - l - n) \delta (\omega_m^q - \omega_l^p - \omega_n^r) \right\}
\]
where \( +T \) and \( -T \) are complicated interaction coefficients for sum and difference interactions respectively. The group velocity \( C_{gn} \) for each mode is given by

\[
C_{gn} = \frac{\int_0^\infty \left[ \frac{2\lambda_n V}{\sigma_n^2} h(F_n) F_n^2 + \frac{2V^2}{\sigma_n^2} (F_n^2)^2 - \frac{2\lambda_n V V' h F_n F_n'}{(\sigma_n^2)^2} - \frac{2V' V F_n F_n'}{(\sigma_n^2)^3} \right] dx}{\int_0^\infty \left[ \frac{2V}{\sigma_n^2} (F_n^2)^2 - \frac{2\lambda_n V V' h F_n F_n'}{(\sigma_n^2)^2} \right] dx}
\]

In the no-current limit, the corresponding group velocity for edge waves on an arbitrary profile reduces to

\[
C_{gn} = g \left( \frac{\lambda_n}{\omega_n} \right) \frac{\int_0^\infty h(F_n^2)^2 dx}{\int_0^\infty (F_n^2)^2 dx}
\]

given originally by Pearce & Knobloch (1994).

In order to proceed beyond this point to a numerical determination of a solution, a number of steps need to be carried out. First, a reliable method of determining solutions for the linear eigenvalue problem must be established. Then, given eigenvalue pairs \( \{ \lambda_n, \omega_n \} \), we require an algorithm to reliably search for solutions to resonance conditions. Finally, an accurate means for evaluating integrals in expressions for \( C_g \) and the nonlinear coupling coefficients must be developed.

**Edge Wave Interactions**

In this section, we consider the special case of interaction between triads of edge waves on a planar beach in the absence of currents. In this case, the mode structure and wave dispersion relation is known, and model interaction coefficients may be evaluated analytically.

The possibility of triad interactions between progressive edge waves has been mentioned many times but not often addressed in a direct way. Kenyon (1970) provides a version of the Hasselmann interaction equations for random edge wave interactions, but provided no calculations. Kochergin and Pelinovsky (1989) consider the case of a colinear triad (all waves propagating the same direction) and show results for a single interacting triad. We will establish below that their results are wrong.

For the case of no currents, the interaction coefficients reduce to:

\[
\pm T_{lmn}^{ppr} = \omega_p^2 \left( \pm \omega_m^2 \right) \left[ 8\omega_n^3 \int_0^\infty (F_n^2)^2 dx \right]^{-1} \cdot \\
\int_0^\infty \left\{ 2(\omega_p^2 \pm \omega_m^2) F_p F_m F_n + \omega_p^2 F_p F_n^2 \mp \omega_m^2 F_p F_m F_n \right. \\
\left. + \left[ 2(\omega_p^2 \pm \omega_m^2) \lambda_p^2 (\mp \lambda_m^2) - \omega_p^2 (\lambda_m^2)^2 \mp \omega_m^2 (\lambda_p^2)^2 \right] F_p F_m F_n \right\} dx
\]

For a planar beach, the \( F_n^r \) are given in terms of Laguerre polynomials by

\[
F_n^r(x) = e^{-|\lambda_n|^x} L_r(2|\lambda_n|/x)
\]

Solutions for isolated triads are obtained in terms of Jacobi elliptic functions. In the cases we have investigated, we have found that cases involving counterpropagating

Waves show strong interactions with energy exchange time scales on the order of 10 wave periods. In contrast, cases involving colinear waves have interaction coefficients of zero, indicating an absence of interaction, contrary to the results of Kochergin and Pelinovsky (1989). Because this result is at odds with the existing literature, we verify it using a direct numerical simulation. The spectral-collocation method of Ozkan-Haller and Kirby (1997) is used to obtain direct numerical solutions of the nonlinear shallow water equations with shoreline runup.

Results and Numerical Verification

As a first example, we consider the lowest-order triad involving two counter-
propagating zero-mode edge waves, with the relation between frequencies, wavenum-
bers and mode numbers as indicated in Table 1. The geometry of the triad in wavenumber-frequency space is indicated in Figure 2. The resulting interaction equa-
tions are given by

$$iu_1 > \frac{i \omega_1^3}{8gs^2} A_2^* A_3$$  \hspace{1cm} (25)

$$A_{1T} = \frac{i \omega_1^3}{64gs^2} A_1^* A_3$$ \hspace{1cm} (26)

$$A_{3T} = \frac{9i \omega_1^3}{64gs^2} A_1 A_2$$ \hspace{1cm} (27)

$$|A_1|^2 + |A_2|^2 + |A_3|^2 = \text{constant}$$ \hspace{1cm} (28)

In this case, the parameters are chosen such that $\omega_1$ corresponds to a wave with a period of 20s on a beach with a slope of 1 : 10. In the results illustrated in Figure 3, we have initialized the triad by giving waves 1 and 2 amplitudes of 10cm, with wave three having no amplitude to start. The resulting solution for the triad interaction is shown in Figure 3 by the smooth curves. The results indicate a complete exchange of energy between one of the Mode 0 waves and the Mode 1 wave propagating the same direction. The exchange occurs in somewhat less than 20 periods of the Mode 0 wave. The counterpropagating Mode 0 wave is crucial to the interaction but exchanges only a small amount of energy with the other modes. This non-reactivity of the counterpropagating wave has been noted for a wide range of initial conditions.

The analytic results shown in Figure 3 have been verified using direct numerical
simulation with the pseudospectral model of Özkan-Haller and Kirby (1997). Results from that model were obtained by Fourier transforming the longshore dependence of the runup tip. Results are shown in Figure 3 as the curves with smaller-scale jitter in time. (This jitter occurs at wave-period or sub-wave-period scales, and is probably associated with the fact that the linear edge waves input as initial conditions differ from fully nonlinear solutions to the problem.) Agreement between analytical triad results and numerical solutions are close, with the numerical solutions indicating a slightly slower energy exchange time and a tendency for energy to leak out of the three components making up the triad.

The fate of the missing energy can be seen in the plot of the frequency-wavenumber spectrum computed from the numerical solution, shown in Figure 4. The spectrum is dominated by the three waves making up the resonant triad, but there are clear contributions at forced, non-resonant peaks representing sum and difference interactions lying off the edge wave dispersion curves. There has also been an excitation of the Mode 0 edge wave at twice the wavenumber of Wave 1, and at a frequency that is not commensurate with any sum or difference combination in the original triad. The mechanism for exciting this free wave is not clear and may be associated with start-up transients in the initial value problem.

Figure 5 shows one longshore period of the numerically computed wave field at two instances in time. The top panel shows the situation at 20 wave periods into the simulation, where the wave field is dominated by the higher-frequency Mode 1

wave riding on the longer, counterpropagating Mode 0 wave. The lower panel shows the situation at 40 periods (close to the end of the recurrence cycle), where the two counterpropagating Mode 0 waves dominate the wavefield.

As a second example, we consider the case elaborated by Kochergin and Pelinovsky (1989) with all waves travelling the same direction, illustrated in Figure 6. The parameters for the lowest-order case are indicated in Table 2. The present theory indicates that nonlinear interaction coefficients reduce to zero, giving solutions $A_1, A_2, A_3 = \text{constant}$. Figure 7 shows time histories for the first twelve Fourier modes of the longshore runup in a direct numerical simulation, with modes $k = 1$ and $k = 3$ corresponding to the initialized low-frequency modes in the triad. The numerical results indicate no interaction between the initialized modes and an absence of growth of the third member of the possible triad. This result is also clear in the resulting frequency-wavenumber spectrum shown in Figure 7, which shows an almost complete lack of energy appearing at the third component, which would appear at scaled wavenumber $k = 4$ and frequency $f = 2$.

Conclusions

In this paper, we have described a framework for deriving coupled-mode equations for a sea of edge waves and shear waves. Interaction coefficients have been obtained for the special case of edge waves on a plane beach in the absence of currents. For this system, interactions have been shown to exist and to be fairly rapid for triads involving counterpropagating waves. Triads involving unidirectional propagation have been found to not lead to interaction, in contradiction to the existing literature. We do not yet have a conclusive proof that this result holds for all colinear edge wave triads on a planar beach, but it has been found to hold for all combinations tested so far. Results for both cases have been verified by direct numerical simulation. The close agreement between numerical and analytic results also indicates that a weakly nonlinear formulation is appropriate for examining edge wave interactions. This result is to be expected due to the strongly dispersive nature of the edge wave motions.

The work on edge wave interactions is presently being extended to look at more complicated systems involving multiple coupled triads, leading up to an evaluation of equilibrium distribution of energy in a random sea of edge waves. In order to further this goal, we need to:

1. Automate the process of identifying resonances.
2. Extend calculations to a large number of components, in order to investigate the assumptions to be made in going over to a stochastic version of the equations.
3. Implement the stochastic version and couple it to the incident wave climate.

In addition, the limitation of the present analytical theory to the case of waves on planar beach topographies is restrictive, and needs to be extended to the case of non-planar topographies such as the exponential profile of Ball (1967). It is also possible that the non-interaction of edge wave triads involving waves propagating the same direction, found here for waves on a planar beach, is an anomalous result that will not hold for arbitrary topographies.

For the case with a net longshore current added to the system, we need to elaborate the process for numerically determining the eigenmodes for an arbitrary topography and longshore current distribution, and then repeat the steps outlined above.

\textbf{ABSTRACT:} The effects of lateral mixing on the stability of longshore currents are examined. For the model problem originally considered by Bowen and Holman (1989), it is shown that the inclusion of lateral mixing changes the stability characteristics of the longshore current. In particular, it eliminates the low wavenumber cutoff predicted by the inviscid theory.

\textbf{INTRODUCTION}

In this paper we investigate how lateral mixing affects the stability of longshore currents. Bowen and Holman (1989; BH89 hereafter) showed that longshore currents in the surf zone are frequently unstable and that these instabilities manifest themselves as wavelike oscillations of the longshore current of the kind found by Oltman-Shay \textit{et al.} (1989).

BH89 derived the equations governing the linear stability of the longshore current in the absence of bottom friction and lateral mixing. They showed that the stability of the longshore current is governed by a modified Rayleigh equation. BH89 solved the stability equation for a model problem in which a longshore current of the form sketched in figure 1 flows over a horizontal bottom. They demonstrated that the longshore current is unstable for wavenumbers in a certain range and that many properties of the waves generated due to the instability of the longshore current are consistent with the observations of shear waves reported by Oltman-Shay \textit{et al.} (1989).

Since the pioneering work of Bowen and Holman, several contributions have been made that have clarified many aspects of the shear wave generation problem [see Özkan-Haller and Kirby (1998) for a brief review]. Here we consider how the inclusion of lateral mixing affects the stability of longshore currents.

Figure 1: Velocity profile used by BH89. This same velocity profile is also used in our model problem. In all of the calculations below, we use $x_0 = 100$ m and $V_0 = 1$ m/s.

Falqués and Iranzo (1994) and Falqués et al. (1994) have already included lateral mixing in the calculations of the stability of longshore currents. Our work differs from that of Falqués et al. in that here we consider how the inclusion of lateral mixing changes the stability of a simple longshore current profile of the type considered by BH89. The simplicity of the current profile allows us to perform analytical calculations of how the addition of the lateral mixing changes the stability characteristics of the longshore current. This, in turn, makes the interpretation of the results easier.

The outline of the rest of the paper is as follows. We first derive the equation that governs the stability of the longshore current in the presence of lateral mixing. We then solve the resulting equation for the model problem considered by BH89. Example results are then presented that demonstrate that the inclusion of lateral mixing can destabilize the longshore current. A discussion of the mechanism by which lateral mixing can destabilize the longshore current follows the example results. The paper concludes with a summary.

**MATHEMATICAL FORMULATION**

We start with the depth-integrated equations of continuity and momentum

\[
\frac{\partial \zeta}{\partial t} + \frac{\partial (h + \zeta) u_i}{\partial x_i} = 0
\]

\[
\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -g \frac{\partial \zeta}{\partial x_i} + \frac{1}{\rho h} \frac{\partial S_{ij}}{\partial x_j} + \nu h \left( \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) - \frac{\tau_{b,i}}{\rho h}
\]

where $\zeta$ is the surface elevation, $h$ is the water depth, $u_i$ is the depth-integrated horizontal velocity, $S_{ij}$ is the radiation stress, $\nu$ is a lateral mixing coefficient, and
\( \tau_{b,i} \) is the bottom shear stress. The lateral mixing represented by the \( \nu \) terms in (2) could be either due to turbulent lateral mixing (generated by breaking waves) or due to dispersive mixing generated by the interaction of the cross-shore and longshore currents (Svendsen and Putrevu 1994; Smith 1997). Since these lateral mixing terms have the same form as viscous terms, the terms \textit{viscosity} and \textit{lateral mixing} will be used interchangeably in the rest of this paper.

We now assume that the total flow consists of a steady longshore current \( V(x) \) and a shear wave with surface elevation \( \eta(x, y, t) \) and depth-averaged horizontal velocities \( u(x, y, t) \) and \( v(x, y, t) \) in the cross-shore \((x)\) and longshore \((y)\) directions. We further assume that \( u \) and \( v \) are much smaller than \( V \). Under these assumptions the momentum equations governing the shear wave reduce to (neglecting the forcing and the bottom shear stress)

\[
\frac{\partial u}{\partial t} + V \frac{\partial u}{\partial y} = -g \frac{\partial \eta}{\partial x} + \frac{2}{h} \frac{\partial}{\partial x} \left( \nu h \frac{\partial u}{\partial x} \right) + \frac{1}{h} \frac{\partial}{\partial y} \left[ \nu h \left( \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) \right] \tag{3}
\]

\[
\frac{\partial v}{\partial t} + u \frac{\partial V}{\partial x} + V \frac{\partial v}{\partial y} = -g \frac{\partial \eta}{\partial y} + \frac{2}{h} \frac{\partial}{\partial x} \left( \nu h \frac{\partial u}{\partial y} \right) + \frac{1}{h} \frac{\partial}{\partial x} \left[ \nu h \left( \frac{\partial v}{\partial y} + \frac{\partial v}{\partial x} \right) \right] \tag{4}
\]

The continuity equation under the rigid lid assumption [see BH89 or Dodd and Thornton (1990) for a justification of the rigid lid assumption] reduces to

\[
\frac{\partial}{\partial x} (hu) + \frac{\partial}{\partial y} (hv) = 0 \tag{5}
\]

The nondivergence of the continuity equation allows us to introduce a stream function \( \Psi \) such that

\[
\Psi_x = hv \quad \Psi_y = -hu \tag{6}
\]

Since we are seeking wavelike solutions, we assume that

\[
\Psi(x, y, t) = \phi(x) \exp i(ky - \omega t) \tag{7}
\]

where \( k \) is the wavenumber and \( \omega \) is the frequency. The stream function can be used to combine (3) and (4) [by cross-differentiation followed by subtraction] into a single equation in \( \phi \):

\[
(V - c) \left( \frac{\phi_x}{h} \right)_x - k^2 \phi - \phi \left( \frac{V_x}{h} \right)_x = \frac{\nu}{ik} \left( \frac{\partial^2}{\partial x^2} - k^2 \right) \left[ \frac{\phi_x}{h} \right]_x - k^2 \phi \left( \frac{\phi_x}{h} \right) + \frac{1}{ik} \left\{ \nu_x \left( \frac{\phi_x}{h} \right)_x - k^2 \phi_{xx} \right\} - \frac{k^2 (\nu h)_x (\phi_x)}{h} \left( \frac{\phi_x}{h} \right)_x \tag{8}
\]

where \( c = \omega/k \) is the wave speed. The boundary conditions corresponding to (8) are

\[
\phi, \frac{d\phi}{dx} = 0 \quad x = 0, x \to \infty \tag{9}
\]

(8) subject to (9) forms an eigenvalue problem. As is usual in stability calculations, we assume that the wavenumber \( k \) is known and treat the frequency \( \omega \) as the eigenvalue.
If \( \omega \) has a positive imaginary component for a given \( k \) it implies that the longshore current is unstable to disturbances of that wavenumber.

The terms on the RHS of (8) are terms that arise due to the inclusion of the lateral mixing. For \( \nu = 0 \), (8) reduces to the equation derived by BH89. [The appropriate boundary conditions for the reduced equation are \( \phi = 0 \) at \( x = 0, x \to \infty \).] For small values of \( \nu \) the RHS of (8) is small and unimportant except at the shoreline and the singular points of the inviscid equation. At the shoreline, the necessity of satisfying an additional boundary condition leads to the generation of a boundary layer. At the locations where \( V = c \), the inviscid equation is, in general, singular whereas the full equation is not. Therefore, at these locations, internal boundary layers will develop when lateral mixing is included.

**MODEL PROBLEM**

We consider the stability of the longshore current sketched in Figure 1. The bottom is assumed to be horizontal. The inviscid stability of this current profile was calculated by BH89. Here we modify their solution to account for lateral mixing. For a horizontal bottom (8) reduces to the Orr-Sommerfeld equation

\[
(V - c) \left( \frac{d^2}{dx^2} - k^2 \right) \phi - V_{xx} \phi = \frac{\nu}{ik} \left( \frac{d^2}{dx^2} - k^2 \right)^2 \phi
\]  

We assume that the strength of the lateral mixing is such that a typical term on the RHS of (10) is much smaller than a typical term on the LHS. Formally, this requires that

\[
\frac{k \nu}{V_0} \ll 1
\]  

where \( k \) is a typical wavenumber, \( \nu \) is a typical value of the lateral mixing coefficient, and \( V_0 \) is the maximum longshore current. Note that since \( k \sim 0.01 \text{ m}^{-1} \), \( \nu \sim 0.1 \text{ m}^2/\text{s} \), \( V_0 \sim 1 \text{ m/s} \), (11) is easily satisfied.

For the longshore current sketched in figure 1, (10) reduces to

\[
(V - c) \left( \frac{d^2}{dx^2} - k^2 \right) \phi = \frac{\nu}{ik} \left( \frac{d^2}{dx^2} - k^2 \right)^2 \phi
\]  

in each of the three regions. In this case, the singular points of the inviscid equation are the points \( x = \delta x_0 \) and \( x = x_0 \) and internal boundary layers develop at these points to smooth out the discontinuities predicted by the inviscid theory.

At \( x = 0 \) and \( x = x_0 \), the boundary layer correction to the inviscid solution is governed approximately by

\[
-c \frac{d^2 \phi_{BL}}{dx^2} \approx \frac{\nu}{ik} \frac{d^4 \phi_{BL}}{dx^4}
\]

which implies that at these locations

\[
\phi_{BL} \propto \exp \left[ \pm (1 - i) \beta_1 x \right]
\]

where \( \beta_1 = \sqrt{\omega/2 \nu} \gg k \). At \( x = \delta x_0 \) the boundary layer correction is approximately governed by

\[
(V_0 - c) \frac{d^2 \phi_{BL}}{dx^2} \approx \frac{\nu}{ik} \frac{d^4 \phi_{BL}}{dx^4}
\]
which leads to

$$\phi_{BL} \propto \exp[\pm (1 + i)\beta_2 x]$$

where $$\beta_2 = \sqrt{(kV_0 - \omega)/2\nu} \gg k$$.

The solution to (12) can therefore be written as

$$\phi = \begin{cases} 
\sinh(kx) + B_1 \cosh(kx) + F_1 \exp[-(1 - i)\beta_1 x] \\
+ G_1 \exp[(1 + i)\beta_2 (x - \delta x_0)] & x < \delta x_0 \\
A_2 \sinh[k(x - \delta x_0)] + B_2 \cosh[k(x - \delta x_0)] \\
+ F_2 \exp[-(1 + i)\beta_2 (x - \delta x_0)] + G_2 \exp[(1 - i)\beta_1 (x - x_0)] & \delta x_0 < x < x_0 \\
A_3 \exp[-k(x - x_0)] + F_3 \exp[-(1 - i)\beta_1 (x - x_0)] & x > x_0 
\end{cases}$$

(17)

The unknown coefficients (the A's, B's, F's, and G's) and the eigenvalue ($\omega$) have to be determined by imposing the boundary conditions at $x = 0$ and the matching conditions at $x = \delta x_0$ and $x = x_0$. [The boundary conditions at infinity have already been imposed in (17).] The appropriate matching conditions are:

1. $hu$ continuous $\Rightarrow \phi$ continuous
2. $hu$ continuous $\Rightarrow \phi_x$ continuous
3. $\eta$ continuous $\Rightarrow ik\phi dV/dx + \nu d^2\phi/dx^2$ continuous
4. $-g d\eta/\partial x + \nu d^2u/\partial x^2$ continuous $\Rightarrow (V - c)d^2\phi/dx^2 + (\nu/ik)[2k^2d^2\phi/dx^2 - d^4\phi/dx^4]$ continuous

The last of these conditions follows from the cross-shore momentum equation (3).

Applying the boundary and matching conditions leads to (after a fair amount of algebra)

$$\omega^2 + F(\delta, kx_0)\omega + G(\delta, kx_0) + \left(\frac{k}{\beta_1}\right)T(\omega, kx_0, \delta, \beta_1/\beta_2) = O\left(\frac{k}{\beta}\right)^2$$

(18)

where

$$F = -kV_0 \left[1 - \frac{S_0}{(S_0 + C_0) kV_0} - \frac{(S_{1-\delta} + C_{1-\delta})S_0 V_{x2}}{(S_0 + C_0) kV_0}\right]$$

(19)

$$G = (kV_0)^2 \left[\frac{V_{x2} V_{x2}^* S_0 S_{1-\delta}}{(kV_0)^2 (S_0 + C_0)} - \frac{S_0 S_{1-\delta}}{(S_0 + C_0) kV_0}\right]$$

(20)

$$T = \left\{2(1 + i) \left\{\sigma \left[C_0 + \frac{\omega}{V_{x2}}(S_0 + C_0)\right] + \Delta V_2 C_0 \left[S_{1-\delta} + \frac{\omega}{V_{x2}}(S_{1-\delta} + C_{1-\delta})\right]\right\}\right. \\
+ \left.\sigma (1 + i) \left[\frac{C_0 + \omega}{V_{x2}} + S_0 \frac{\Delta V_x}{\sigma}(S_{1-\delta} + C_{1-\delta})\right]\right\} \\
- \frac{\beta_1}{\beta_2} \frac{(\Delta V_x)^2}{\sigma}(1 - i)S_0 \left[S_{1-\delta} + \frac{\omega}{V_{x2}}(S_{1-\delta} + C_{1-\delta})\right] = \frac{V_{x2}}{4(S_0 + C_0)}$$

(21)

In the above, $S_0 = \sinh(kx_0), S_{\delta} = \sinh(k\delta x_0), S_{1-\delta} = \sinh[kx_0(1-\delta)]$ and the $C$'s are short forms for the corresponding cosh functions. Additionally, $V_{x1}$ and $V_{x2}$ represent $dV/dx$ in regions 1 and 2 respectively, $\Delta V_x = V_{x1} - V_{x2}$, and $\sigma = \omega - kV_0$. 
In the limit of $\nu \to 0$ ($\beta_1, \beta_2 \to \infty$), $F$ and $G$ reduce to the expressions given by BH89's (16), and we then recover Bowen and Holman's solution. The term denoted by $T$ represents the effects of including the lateral mixing.

For $\nu = 0$, (18) has two solutions for $\omega$ for a given value of $k$ - these are the solutions found by BH89. For small $\nu$, the $T$-term modifies these solutions. These modifications can be calculated in a straightforward manner. In addition to modifying the BH89 solution, the $T$-term also introduces new roots to (18). The significance of these new roots is, at present, unknown. In the following, we discuss only the roots that can be interpreted as modifications of the BH89 solution.

RESULTS

Figure 2 shows the variation of the growth rate $\omega_{im}$ as a function of the wave number. For comparison, we also show Bowen and Holman's inviscid solution. It is clear from this figure that including lateral mixing in the calculations significantly alters the stability characteristics. In particular, the range of wavenumbers over which the instability occurs is significantly enhanced, the location of the most unstable wave is changed, and the low wavenumber cutoff predicted by the inviscid theory is removed.

![Figure 2: Plot of growth rate, $\omega_{im}$, vs wavenumber for the model problem. The parameters used in this calculation are $\delta = 0.5$, $\nu = 5 \times 10^{-3}$ m$^2$/s, $x_0 = 100$ m, and $V_0 = 1$ m/s.](image)

In a recent paper, Shrira et al. (1997) solved the weakly nonlinear version of the model problem considered by BH89. They showed that the triad interactions between individual shear wave modes could remove the low wavenumber cutoff predicted by the linear inviscid theory. Our results show that including the lateral mixing leads to
the same result. Thus, a plausible scenario is that the low wavenumber oscillations are initially generated by the present mechanism and grow to finite amplitude by the mechanism discussed by Shrira et al.

Figure 3 shows the variation of the real part of the frequency as a function of the wavenumber for the branches of the solution that have a positive growth rate. We see from this figure that the addition of lateral mixing does not alter the dispersion relationship significantly in the region where the inviscid theory predicts an instability.

Figure 3: Plot of the real part of the frequency, $\omega_{re}$, vs wavenumber for the model problem. The parameters used in this calculation are $\delta = 0.5$, $\nu = 5 \times 10^{-3}$ m$^2$/s, $x_0 = 100$ m, and $V_0 = 1$ m/s. Note that only the branches that have a positive growth rates are shown.

Figure 2 showed the growth rate as a function of wavenumber for a particular choice of the lateral mixing coefficient $\nu$. It is also of interest to examine the sensitivity of the growth rate at a fixed wavenumber to the choice of the mixing coefficient. This is done in figure 4 which shows the variation of the growth rate as a function of $\nu$. Realistic values of $\nu$ for the nearshore are expected to be in the range $10^{-3}$ to $0.1$ m$^2$/s. The lower end of the range would apply if the lateral mixing were due to the turbulence generated by breaking waves (Svendsen 1987; George et al. 1994). The higher end would apply if, as is more likely, the lateral mixing were due to dispersive mixing generated by the interaction of the cross-shore and longshore currents (Svendsen and Putrevu 1994). We see from figure 4 that the growth rate increases with $\nu$ for $\nu$ in the range that is normally expected.

BH89 found that the backshear parameter $\delta$ controls the strength of the instability in
the inviscid problem – the stronger the backshear, the stronger is the instability. It is therefore of interest to see whether this behavior carries over to the case where lateral mixing is included. Figure 5 shows the variation of the growth rate with $\delta$. For this calculation we have chosen the parameters such that the inviscid calculations predict stability. This figure clearly shows that the backshear $\delta$ also controls the stability of the viscous problem.

**MECHANISM**

The calculations presented so far have shown that including the lateral mixing can destabilize an otherwise stable longshore current. Since this result is somewhat counter-intuitive, it is useful to examine it in more detail. Therefore, we discuss below the mechanism by which lateral mixing (or viscosity) can destabilize a longshore current. The discussion here largely follows Lin’s (1967) discussion (see pp. 60-63 of Lin’s book).

For $h = \text{constant}$, the equations governing the stability of the longshore current reduce to

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0$$  \hspace{1cm} (22)

$$\frac{\partial u}{\partial t} + V \frac{\partial u}{\partial y} = -g \frac{\partial \eta}{\partial x} + \nu \left( \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right)$$  \hspace{1cm} (23)
Figure 5: Variation of the growth rate as a function of the backshear parameter. The values used in the calculations are $\nu = 5 \times 10^{-3}$, $m^2/s$ and $kx_0 = 1$, $x_0 = 100$ m, and $V_0 = 1$ m/s. The inviscid solution is stable for this choice of parameter values.

\[
\frac{\partial v}{\partial t} + u \frac{dV}{dx} + V \frac{\partial v}{\partial y} = -g \frac{\partial \eta}{\partial y} + \nu \left( \frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} \right)
\]  

(24)

From these equations, it is straightforward to derive the following energy equation

\[
\frac{dE}{dt} = - \int_0^\infty h \overline{uv}(dV/dx)dx \\
- \nu \int_0^\infty h \left[ (\partial u/\partial x)^2 + (\partial u/\partial y)^2 + (\partial v/\partial x)^2 + (\partial v/\partial y)^2 \right] dx
\]  

(25)

where an overbar denotes averaging over a shear wave period and $E$ is the total kinetic energy defined by

\[
E = \frac{h}{2} \int_0^\infty (u^2 + v^2)dx
\]  

(26)

(Because of the rigid-lid assumption, the potential energy does not enter the energy equation.)

The first term in (25) represents the energy transfer from the longshore current to the shear wave and the second term represents the dissipation of the shear wave energy by the viscosity-like terms. Now the introduction of viscosity changes the phase between the cross-shore and longshore velocities so that the first term on the RHS of (25) is
changed relative to the inviscid solution. Thus, viscous terms modify the inviscid solution in two important ways: 1) they change the phase between the velocity components of the shear wave which leads to an extraction of energy from the longshore current and 2) they lead to direct dissipation of the shear wave energy. Therefore, viscous terms can destabilize an otherwise stable longshore current profile if the energy extracted from the longshore current exceeds the direct dissipation.

To explore the changes caused by the inclusion of viscosity-like terms further, we show in figures 6, 7, and 8 the cross-shore variations of $\phi$ (which is proportional to $u$), $\phi_x$ (proportional to $v$), and $-uv(dV/dx)$ respectively. (The parameter values are chosen such that the inviscid calculation predicts stability whereas the viscous calculation predicts instability.) It is clear from figures 6 and 7 that the introduction of lateral mixing terms changes the phase of $u$ and $v$. Figure 8 shows that this change in phase results in an extraction of energy from the longshore current. Figure 8 further demonstrates that most of the energy extraction takes place on the seaward face of the longshore current, thereby explaining the importance of the backshear on the stability found in figure 5.

SUMMARY

In this paper we considered how the addition of lateral mixing affects the stability of longshore currents. We showed that the inclusion of lateral mixing can destabilize an otherwise stable longshore current. The instability induced by the lateral mixing is such that it removes the low-wavenumber, low-frequency cutoff predicted by the inviscid theory. As in the inviscid case, the parameter that controls the stability of the longshore current is the shear on the seaward face of the longshore current.

The inclusion of lateral mixing destabilizes the longshore current as follows: it provides a Reynolds' stress that enables the shear wave to extract energy from the longshore current. We showed that this extraction of energy takes place mainly on the seaward face of the longshore current.

Finally, note that Falqués and Iranzo (1994) and Falqués et al. (1994) have already investigated the effects of lateral mixing on the stability of longshore currents using a numerical model. While Falqués et al. did find that the inclusion of lateral mixing increased the instability in certain cases, they did not find the instability at low
Figure 8: Cross-shore variation of $-\overline{uv}dV/dx$. Top panel inviscid (BH89) solution. [The inviscid solution is stable for the choice of parameter values used in this calculation (see below). This is the reason why $\overline{uv}$ is zero for the BH89 solution.] Bottom panel calculation including lateral mixing terms. Note that the scale of the $y$ axis is arbitrary. The parameter values used in the calculations are $kx_0 = 1$, $x_0 = 100$ m, $\delta = 0.5$, $V_0 = 1$ m/s, and $\nu = 5 \times 10^{-3}$ m$^2$/s.

wavenumbers found here. At present we do not know whether this discrepancy is due to the artificial nature of our model problem or due to the boundary conditions used by Falqués et al. Therefore, it is necessary to extend the present analysis to more realistic longshore current variations.

Shear waves over longshore nonuniform barred beaches

F.E. Sancho¹ and I.A. Svendsen²

Abstract

In the present paper we address the far-infragravity motion (0.001–0.01 Hz) associated with shear (or vorticity) waves over a fixed-bed, longshore nonuniform beach. The model equations are simplified forms of the fully nonlinear, depth-integrated, wave-averaged Reynolds equations, which are solved by the SHORECIRC numerical model. The currents are forced by stationary, monochromatic, incident short waves. The formation of flow instabilities depends on physical model parameters (e.g., bottom friction), the incident wave field, and the beach topography. The latter two effects are analysed here in the prediction of shear waves and unsteady rip-currents.

1 - Introduction

Shear waves were first observed in the field by Oltman-Shay et al. (1989), and were recognized by Bowen and Holman (1989) as instabilities of the longshore currents. The latter authors analysed the dynamics of these motions over a simple geometry for the linear and frictionless system of equations governing the perturbed velocities. Other analytical and numerical studies included the effect of bottom shear stresses and lateral turbulent mixing, and extended the analysis to planar and barred longshore uniform beaches (Putrevu and Svendsen, 1992b; Dodd et al., 1992; Allen et al., 1996; Özkan-Haller and Kirby, 1996). These studies gave insight into the shear wave dynamics, and comparisons with field data (collected during the SUPERDUCK experiment) showed a good agreement of the predicted versus the observed range of frequencies and wavelengths at which these motions were strong.

The studies mentioned above, however, only considered a longshore uniform beach. The problem studied here deals with the effect that the longshore variation of the topography has on the development of shear waves. Sinusoidally longshore varying topographies have been considered in the analysis of shear waves by Deigaard et al. (1994) and Slinn et al. (1996). The results of the former suggest that growing amplitudes of the longshore bottom disturbances act to suppress the shear instabilities of the background flow. In another example, Sancho et al. (1997) showed model predictions of shear instabilities over a surveyed bathymetry at Duck, North Carolina. The beach was characterized by the presence of an almost uniform longshore bar.

In the present paper we isolate and study the effect of well-defined longshore bottom variations on the characteristics of the shear instabilities. The goal is to analyze the nonlinear evolution of shear (vorticity) instabilities over canonical longshore varying, fixed bed, beach configurations. Hence, we look at the influence of rip-channels in the mean and time-varying (unstable) flow field.

2 - Model equations and numerical method

In this study we make use of the depth-integrated, short-wave averaged Reynolds equations. We assume turbulent flow, but neglect the turbulent normal stresses, and we also assume zero surface shear stress. For depth-varying currents the governing equations for conservation of mass and momentum can be written in Cartesian coordinates \((x,y,z) = (x_a,z)\) in tensor notation) as (e.g., Van Dongeren et al., 1994):

\[
\frac{\partial \xi}{\partial t} + \frac{\partial \bar{Q}_{\alpha}}{\partial x_{\alpha}} = 0 ,
\]

\[
\frac{\partial \bar{Q}_{\beta}}{\partial t} + \frac{\partial}{\partial x_{\alpha}} \int_{-h_{\alpha}}^{\xi} V_{\alpha} V_{\beta} \, dz + \frac{\partial}{\partial x_{\alpha}} \int_{\xi}^{h_{\alpha}} \left( u_{\omega \alpha} V_{\beta} + u_{\omega \beta} V_{\alpha} \right) \, dz =
\]

\[
- g \left( h_{\alpha} + \xi \right) \frac{\partial \xi}{\partial x_{\beta}} - \frac{1}{\rho} \frac{\partial}{\partial x_{\alpha}} \left[ S_{\alpha \beta} - \int_{-h_{\alpha}}^{\xi} \tau_{\alpha \beta} \, dz \right] - \frac{\tau^{B}_{\beta}}{\rho} .
\]

In these equations \(\xi\) is the mean surface elevation, \(h_{\alpha}\) is the still water depth, and \(\rho\) is the fluid density. \(\tau_{\alpha \beta}\) represents the turbulent shear stress tensor, \(V_{\alpha}\) is the horizontal current velocity and \(Q_{\alpha}\) is the depth-integrated volume flux, defined as

\[
Q_{\alpha} = \int_{-h_{\alpha}}^{\xi} V_{\alpha} \, dz + Q_{\omega \alpha} ,
\]

where \(Q_{\omega \alpha}\) is the shortwave-induced mean volume flux. In equation (2), \(u_{\omega \alpha}\) is the short-wave velocity component, \(S_{\alpha \beta}\) is the radiation stress tensor (defined according to Mei, 1999), and the bottom shear stress is represented by \(\tau^{B}_{\beta}\).

The system of equations above constitute the basis of the Quasi-3D numerical model SHORECIRC (Van Dongeren et al., 1994). A somewhat simplified version of that model is used here.
The turbulent shear stress (the turbulent lateral mixing) is modeled according to the eddy viscosity closure, assuming that

$$\tau_{\alpha\beta} = \rho \nu_t \left( \frac{\partial V_\alpha}{\partial x_\beta} + \frac{\partial V_\beta}{\partial x_\alpha} \right), \tag{4}$$

where the eddy viscosity $\nu_t$ is calculated by (Sancho and Svendsen, 1997)

$$\nu_t = C_1 \kappa \sqrt{\frac{f_w}{2}} u_0 h + M h \left( \frac{D}{\rho} \right)^{1/3}. \tag{5}$$

The first term of equation (5) represents the bottom-induced turbulence and it is always present (Coffey and Nielsen, 1984), whereas the second term accounts for the turbulence generated by the breaking waves (Battjes, 1975), and it is only active in the surf region. In the above, $D$ is the energy dissipation rate per unit area, $M$ and $C_1$ are constants, $\kappa$ represents the von Karman constant, $f_w$ is the bottom friction coefficient, and $u_0$ is the amplitude of the short-wave orbital velocity at the bottom. We choose $M = 0.1$, which is one order of magnitude smaller than the value suggested by Battjes (1975), because it gives estimates of $\nu_t$ in agreement with those estimated by Svendsen (1987). Similarly we choose $C_1 = 0.75$, which yields values of $\nu_t$ outside the surf region of the same order as the experimental results of Cox et al. (1995).

The shortwave-averaged bottom shear stress is computed according to the nonlinear wave-current formulation of Putrevu and Svendsen (1992a),

$$\tau_B = \frac{1}{2} \rho f_w u_0 (\beta_1 V_\alpha + \beta_2 u_{0\alpha}), \tag{6}$$

where $\beta_1$ and $\beta_2$ depend on the short-wave phase angle, and the current and short-wave orbital velocity magnitude and direction. The friction factor is chosen as $f_w = 0.006$. The orbital velocity amplitude $u_0$ is calculated according to linear wave theory, and the energy dissipation rate $D$ is given by Dally et al. (1985), with the wave field obtained from REF/DIF1 (Kirby and Dalrymple, 1994) model applications. The results from this model (wave height and direction) are also used to estimate the radiation stress $S_{\alpha\beta}$, and the wave-induced volume flux $Q_{wa}$, using linear wave theory. Inside the surfzone, an extra term has been added to $Q_{wa}$ in order to account for the effect of the mass of water transported shorewards by the roller (Svendsen, 1984).

The system of equations above is solved numerically by a third-order ($O(\Delta t^3)$) predictor-corrector finite difference method. Spatial derivatives are 4th-order accurate (Sancho and Svendsen, 1997). The (horizontal) domain of integration is discretized by a rectangular grid with open boundaries everywhere, except at the shoreline. At the seaward boundary, a generating-absorbing condition is used (Van Dongeren and Svendsen, 1997), and at the shore-normal boundaries a periodicity condition is implemented. At the landward boundary, the shoreline (horizontal) position is held fixed with the boundary condition $V_{\alpha} = 0$ at a small water depth ($\approx 0.005 - 0.05$ times the water depth at breaking, $h_b$). We note that a similar treatment of the shoreline is utilized by Özkan-Haller and Kirby (1997), as those authors found minor differences between the results obtained by including the shoreline runup and those from calculations with a zero-velocity condition at the shore.
3 - Applications

3.1 - Longshore uniform plane beach

Although most natural beaches can exhibit complicated bottom contours, it is interesting to analyze the development and propagation of shear waves on a longshore uniform plane beach. We choose to first investigate the nonlinear shear instabilities on a 1/20 sloping beach with the same characteristics as that studied by Allen et al. (1996) and Özkan-Haller and Kirby (1995, 1997). We also use this example to test the numerical accuracy of our model versus the accuracy of the different numerical schemes of those other models.

Hence for the purpose of the comparison, we assume the currents are depth uniform. We also consider a longshore uniform beach and assume the short-wave forcing in the cross-shore direction to be in balance with the setup gradient, and in the longshore direction it balances the bottom shear stress associated with the steady (time-averaged over the infragravity oscillations) longshore current $V_s$ and the lateral mixing (see above references and Sancho and Svendsen, 1997, for details). This implies that the lateral mixing from turbulence and the mixing effects of the nonlinear integrals in (2) are included for the $V_s$-part of the total velocity. However, we neglect turbulent and dispersive mixing effects generated by the deviations in the velocity from $V_s$. Similarly (6) is linearized so that the bottom shear stresses are linear functions of $U$ and $V$

$$\tau_x^B = \rho \mu U,$$  \hspace{1cm} (7)

$$\tau_y^B = \rho \mu (V - V_s),$$  \hspace{1cm} (8)

with a constant friction coefficient $\mu = 0.006$. This essentially reduces the complete equations to the model equations of Özkan-Haller and Kirby (1997). Those are a slightly modified set of the equations solved by Allen et al. (1996), who further introduced the rigid lid approximation. Initial and boundary conditions are also similar to those of the authors above.

The longshore domain length $l_y$ equals that of the most unstable wavelength calculated from linear instability theory, $l_y = 5x_b'$, where $x_b' = 90$ m is the distance from the shoreline to the position of the maximum of the longshore current. In the cross-shore direction the domain length is $l_x = 4x_b'$. The grid spacings are the same as those used by Allen et al., namely $\Delta x = \Delta y = \frac{x_b'}{18} = 5$ m.

Fig. 1 shows the time series of $\eta, U$ and $V$ at $f_- = 0.75$ and $f_- = 0.5$, predicted both by the present model (upper three panels) and the numerical model of Özkan-Haller and Kirby (1997) (lower three panels). The landward-oriented cross-shore direction with origin at the seaward domain boundary is denoted by $x$. For both model results, we see that the amplitude of the shear waves grows quasi-exponentially for $2 - 3.5$ hr, and then remains quasi-steady, oscillating around a mean value. It is also visible that the higher amplitude disturbances have larger periods, which confirms previous observations on the weakly dispersive properties of shear waves (Oltman-Shay et al., 1989). Although they differ in some details, the similarity between our results and
Figure 1: Time series of $\eta$, $\bar{U}$ and $\bar{V}$ at $\lambda = 0.75$ and $\nu = 0.5$ from the present model simulations (upper three plots) and Özkan-Haller and Kirby (1997) model simulations (lower three plots).

those of Özkan-Haller and Kirby is evident. We have also compared the present solution with that of Allen et al. (1996), and the agreement is not quite as good, which may be due to the rigid-lid assumption of Allen et al.. For brevity the results are omitted here.

Analysis of the results also shows that the shear wave propagation velocity $c_s$ is within the interval $0.5 < \frac{c_s}{V_M} < 0.54$, where $V_M$ is the maximum of the initial longshore current profile. The low-frequency oscillations ($T \approx 2$ hr) are the same in ours and Özkan-Haller and Kirby's results.

It is interesting to analyze the effect the shear wave motion produces on the mean longshore current. The initial current forms a quasi longshore uniform flow with the longshore current profile as plotted in Fig. 2. However, the shear waves cause a dispersion of momentum, which will modify the background time-mean longshore current profile relative to the profile maintained by the forcing and turbulent mixing. This is illustrated in Fig. 2, where we plot the initial cross-shore profile of the longshore current at $\nu = 0.5$ (solid line), versus the current profile obtained by time-averaging $V$ over the entire period of simulation ($t = 12$ hr), (dashed line). The maximum of
the time-averaged longshore current is approximately 20% smaller than that of the initial distribution. This result is similar to the results of Özkan-Haller and Kirby (1997).

3.2 - Longshore varying barred beach

Weak longshore forcing gradient

As a second example we analyze the nearshore currents over a periodically longshore varying barred beach. The longshore bottom perturbation is characterized by a slight depression in the bar crest, similar to the formation of a rip-channel (Fig. 3), located at the centerline of the computational domain. The bottom topography used in the present example is similar to the barred beach often encountered at the FRF experimental station in Duck, NC (e.g., Thornton and Kim, 1993). Details of the analytical expression for the bathymetry are given by Sancho and Svendsen (1997). The governing equations, closure submodels, and relevant parameters are given by equations (1)-(6). For simplicity and brevity, we again consider (below-trough) depth-uniform currents only. It turns out that the dispersive mixing caused by depth varying currents will somewhat reduce the development of the shear waves. This more complex situation was analysed in Sancho and Svendsen (1997). The initial condition for the simulations is a “cold start”, and the short-wave forcing is “ramped” smoothly until it reaches a steady forcing.

The relevant parameters that define the bathymetry and domain size are the crest to shoreline distance $l_c = 120$ m, and the domain lengths in the cross-shore and longshore directions, $l_x = 4 l_c$, and $l_y = 16 l_c$, respectively. The depth at the crest of the longshore uniform section of the bar is $h_c \approx 1.18$ m, and at the rip-channel is just 10% deeper. The width of the rip-channel is $w_r = 0.84 l_c$ (100 m), and the numerical grid spacings are $\Delta x \approx 4.24 h_c$ (5 m) and $\Delta y \approx 8.48 h_c$ (10 m).

First, we choose the incident wave conditions so that intense wave breaking occurs
along the entire bar, including over the rip channel, starting just before the bar crest, (at $x/l_c = 2.75$). The waves then propagate over the bar-trough without breaking before a second breaking occurs nearer the shoreline. This results in a nearly longshore uniform wave forcing. In numbers, the wave height at the seaward boundary ($x = 0$) is $H_0 = 0.9 \, h_c$ (1.06 m), the incident wave angle is $\alpha_{m0} = 7.5^\circ$ with the shore normal direction $x$, the wave period is $T = 14.4 \sqrt{h_c/g}$ (5 s), and the breaking criterion $H_b/h_b = 0.78$ is used.

Time-averaged velocity vectors of the current field are shown in Fig. 4. The time-averaging is performed over a period of approximately 4 hr, after the flow reached near stationarity. The time-averaged velocity vectors show a slight variation of the flow at the region of the rip-channel ($y = 8 \, l_c$). The largest variations are observed, as expected, around the rip-channel, but are more pronounced slightly downstream of it due to the inertia of the flow. In fact, examination of the magnitude of the terms in the longshore momentum equation shows that it is a combination of a steady and a fluctuating component of the advective accelerations that are responsible for the divergence the flow around the rip-channel, and the existence of currents in the
trough, respectively. Away from the rip-channel it turns out that the wave-induced shoreward mass flux is locally balanced by the return current (undertow).

The results show that even a small rip-channel is able to disturb the otherwise longshore uniform flow, although, the existence of a rip-channel does not necessarily induce the formation of a rip-current. This turns out to be due to the fact that the wave field, as well as the mean surface elevation, are very homogeneous in the longshore direction. The (time-averaged) longshore current profile at any section exhibits the “classical” double-peaked distribution caused by the breaking over the bar and at the foreshore. There is, however, a significant current in the trough driven largely by the mixing generated by the shear waves.

The instantaneous nearshore current fields are, however, quite different from the time-averaged situation. Fig. 5 shows the instantaneous depth-averaged velocity vectors at four different times during the simulation. The first three pictures are at early stages of the computation, and show how the growth of shear waves starts at the rip-channel location. Looking consecutively at plots (a), (b) and (c) shear instabilities develop continuously at \( y = 8 l_c \), where the small channel is, and propagate downstream with the longshore current. In general, the shear wave celerity is equal to 0.45–0.65 of the maximum (time-averaged) longshore current, which is comparable to that suggested by field measurements (Dodd et al., 1992). Between subplots (c) and (d) there is a significant time lapse (3.6 hr), during which the predicted predominant wavelength (and period) of the shear waves increased considerably. This frequency downshift is similar to that observed by Özkan-Haller and Kirby (1997). Closer inspection of the dynamics of these motions indicates that the shear waves are more intense seaward and over the bar-crest.

Clearly the rip channel acts as a strong disturbance that instantly initiates almost fully grown shear waves. Similar computations over a longshore uniform barred beach (not shown) indicate that shear waves develop much slower in the absence of the rip-channel. The longterm properties of the shear waves are, however, identical to those of the results just presented, indicating that once shear instabilities have formed they are relatively independent of small topographic perturbations.

**Large longshore forcing gradient**

The previous example illustrated that a nearly longshore uniform mean flow can occur over a longshore varying beach. In order to further analyse the conditions for generation of rip currents we consider an incident wave field that is slightly different from the previous example, over the same bottom topography of Fig. 3. The initial wave height is chosen so that outside the rip channel wave breaking occurs over the bar crest, whereas no breaking occurs in the rip-channel \( y = 8 l_c \), (Fig. 6). The wave height is about 30% smaller at the seaward boundary than in the previous example. The incident wave angle and period are the same as before. The substantial differences in wave conditions over the rip-channel and the bar, induce strong longshore longshore variations of the forcing, in particular the pressure gradients. Note that although the wave model predictions may not be accurate, a similar trend in the wave height
Figure 5: Depth-averaged current vectors at four instants of the simulation for the case of weak longshore forcing gradient.
The resulting time-averaged (over a period of 2.1 hr) and depth-averaged currents are illustrated in Fig. 7, which shows that a rip-current has formed, with two circulation cells around it, centered at the bar-crest. (The domain has been extended offshore to $l_x = 6l_c$). The width of the rip increases slowly towards offshore, as the result of a small turbulent dispersion as well as the dispersion caused by fluctuations of the rip (explained below). Bottom friction is also responsible for the widening of the rip. Longshore currents flow towards the rip-channel at both sides of the rip, mainly driven by local longshore gradients of the mean surface elevation. The maximum velocity in the rip-current is $0.2 \sqrt{gh_c}$ ($0.70 \text{ m/s}$), which is about twice as large as the maximum longshore current.

The results in Fig. 7 contrast with those of Fig. 4. Nearly longshore uniform currents are, however, found at a distance $10l_c$ ($1200 \text{ m}$) from the channel axis.
Larger differences from longshore uniformity mainly occur near and downstream of the rip-channel. Through inspection of the magnitude of the terms in the momentum equations, we find that the longshore pressure gradient and nonlinear advective accelerations are quite important in the longshore momentum balance, whereas in the cross-shore direction, the radiation stress gradient is mostly balanced by the surface elevation gradient.

The flow for the present simulation is, however, also unsteady. In fact, the current velocities are very dynamic, as can be seen in one "snapshot" of the depth-averaged current velocities, shown in Fig. 8. We find that in the rip-current vortices are generated at each side (note the similarity between the patterns predicted here and those observed in Fig. 7 of Shepard et al., 1941). Initiation of shear wave motion is delayed. The motion is steady downstream of the rip-channel until \( y = 14 l_c \) and then shear waves start to form very rapidly over the longshore uniform section of the beach. Both the cross-shore and longshore velocities vary dramatically with the position, depending on whether this is located upstream or downstream of the rip-channel. We also see that shear waves approaching the rip channel from upstream are washed out to the sea by the rip current.

Inspection of the time series of the predicted velocities along the rip-channel indicates that the rip-currents are periodically unsteady. The most energetic periods of oscillation are seen to range between \( 400 < T < 450 \) s, but there are also appreciable variations in the time series at a much lower frequency. The higher frequency oscillations are associated with a meandering motion of the rip-currents, whereas the longer period variations are related to a "side-to-side" shift of the rip-current, and with the passage of vortices released by the unstable rip over a certain location. Similarly, at locations where shear instabilities have formed, the period of the shear waves is initially \( \sim 440 \) s, and later a frequency downshift occurs and the period becomes \( \sim 800 \) s.

We find that the rip-current exhibits several features common with the shear waves. In fact, a hydrodynamic instability mechanism is common to the two flow types: shear waves are an instability mechanism of the longshore currents (Bowen and Holman, 1989), and rip-currents can be considered an unstable jet (whose me-
Mechanics are given by, e.g., Drazin and Reid, 1982). Both mechanisms have been observed in field and laboratory conditions, either isolated or simultaneously (e.g., Sonu, 1972). For the present conditions, the formation of the rip-current over the rip-channel destroys the structure and shear waves do not pass it.

Multiple rip-channels

Lastly, we investigated the effect of the domain size by performing calculations in a longshore periodic domain of size $l_y = \frac{10}{3} l_c$ (400 m) and $l_y = \frac{20}{3} l_c$ (800 m). Rip channels were 400 m apart, and the short-wave input lead to flow conditions similar to those of Figs. 4 and 5. This gave exactly the same longshore periodicity, and the results from these computations were identical, thus, meaning that the predicted shear waves were not dependent of the computational domain size. However, computations with different distance between the rip channels gave different patterns of the shear waves, with different period and wavelength, though their speed of propagation remained the same. Hence, the local signature of the shear waves appears to depend on the distance between rip-channels.

In a final example we chose a larger periodic domain size, of length $l_y = 1600$ m. Within this computational domain, we placed four rip-channels with different distances apart. The results from this computation showed the prediction of very irregular shear waves. In fact, time series of the predicted motions indicated a wide spectrum of energetic frequencies, which is in closer resemblance with those observed under field conditions (Oltman-Shay et al., 1989). This suggests that the shear waves observed in nature may come from many different sources of disturbance.

4 - Conclusions

In this study we addressed the development of flow instabilities over longshore nonuniform barred beaches. It was found that shear waves can be triggered by small bottom perturbations (in the form of rip-channels) in an otherwise longshore uniform coast, but the shear wave average properties are nearly independent of these. Those properties are found to depend mainly of the background longshore current. Similarly, the distance between rip-channels also affects the shear waves dynamics.

A second important conclusion is that rip-currents not always form in the presence of rip-channels. Rip-currents may occur when short-wave conditions give rise to large longshore forcing gradients around the rip-channel such as changes in breaking conditions. In that situation, unstable rip-currents were predicted. Conversely, shear waves can be suppressed by the existence of rip-currents, and will then form far downstream of the rip-channel, seemingly away from the influence of the rip.

The results suggest that the longshore variability of a beach, over a considerable domain length, can play an important role in the prediction of the dynamics of steady and unsteady currents. Hence, care should be taken in the comparison of model to field results, when assuming longshore uniform conditions, or using too small model domains.

Trapped and Free-Wave Propagation in Channels and Harbours

João A. Santos¹ and D. H. Peregrine²

Abstract

Most of the literature on edge waves is only concerned with edge-wave propagation over a bottom that is uniform in the propagation direction. There is still little knowledge of what happens when the bottom topography changes suddenly, as in the presence of a cape, submarine valley or harbour.

This paper presents some results of our study on the wave motion in such places, where edge waves may be transmitted, reflected or radiated as free waves and thus may have an important role in determining the wave conditions in otherwise sheltered regions.

We send an edge wave along a coast with an alongshore uniform bottom profile and, at a given section change suddenly for another bottom profile. This study is carried out with a very simple model. The linearised shallow water equations are used in a wide channel with the simplest bottom profile that enables the existence of edge waves: a ledge close to the coast and a uniform depth offshore.

Introduction

Edge waves are common in the spectrum of waves at the surf zone, Huntley et. al. (1981) showed that these waves could be responsible for up to 30% of the energy in the longshore current spectrum measured at Torrey Pines beach, California, and are believed to be responsible by the formation of beach cuspatate patterns, (Guza and Inman 1975), and so they can play an important role in coastal morphology.

However, most of the references in the literature on this subject are only concerned with edge-wave propagation over bottom configurations that are uniform.

alongshore. To our knowledge the only exceptions are Smith (1974), where an asymptotic technique is used study the propagation of high frequency edge waves along coasts whose bottom geometry varies gradually, and Evans & Fernyhough (1995), where edge waves are found for a vertical coast with periodic bays at the boundary of a flat ocean.

When the longshore uniformity in the bottom geometry that enables the occurrence of edge waves disappears suddenly, due to the presence of a cape, a submarine valley or a harbour, this obstacle may cause the reflection of that energy, its transmission to the region after the obstacle, if edge waves can propagate there, or its release as free long waves. This is the objective of our study: to understand what happens when such discontinuities appear. We send an edge wave along a coast with an alongshore uniform bottom profile and, at a given section change suddenly for another bottom profile.

We solve these problems by using a very simple model: we have a wide channel, instead of the semi-infinite ocean, and use the simplest bottom profile that enables the occurrence of edge waves, a ledge close to one of the channel walls. The linearised shallow water equations are employed to evaluate the modes (trapped, freely-propagating and evanescent) in each of the regions into which the domain under study can be divided.

In spite of its simplicity the results produced by this model allow us to draw some conclusions on the energy distribution between trapped and free waves when those longshore discontinuities occur and to explain some difficulties in using physical models to model long waves reported by Dodd & Bowers (1995).

Methodology

To study the influence of a sudden variation of the longshore bottom profile on edge wave propagation, we send an edge wave along a straight coast formed by two or more stretches with uniform longshore profile. At a given section, where two stretches meet, a sudden change in the longitudinal bottom profile occurs.

Although the number of edge-wave modes for a given frequency and bottom geometry is limited, the number of the freely-propagating and evanescent modes that can be excited by such a discontinuity is not. For both there is a continuous spectrum in frequency. So, to make analysis easier we use a wide channel instead of the semi-infinite ocean, as shown in figure 1. This gives a discrete spectrum but implies that we must choose a sufficiently wide channel and, as we will show later, special care must be used when interpreting the results so obtained.

Many cross-shore bottom profiles support the existence of edge wave modes. We choose the simplest such bottom profile: a ledge close to the coast. This profile, unlike the plane beach profile of Eckart (1951) or Ursell (1952), makes the establishment of the dispersion relation a straightforward task. In addition to that, it is always possible, by adjusting the ledge dimensions, to get an edge wave mode in this geometry with similar behaviour to a similar mode propagating over other bottom profiles.
Because the region we are interested in is quite close to the shoreline and the waves long enough to have negligible vertical variation of the horizontal velocity, we use the linearised shallow water equations. Assuming a time harmonic variation of the free-surface elevation, \( \eta \), gives the following equation:

\[
\nabla^2 \eta + \frac{\omega^2}{gh} \eta = 0
\]

where \( h \) is the water depth, \( \omega \) the angular frequency of the wave and \( g \) the acceleration of gravity. Using this equation the dispersion relations for both the propagating (either trapped or free) and the evanescent modes in the channel with the ledge, figure 2, are evaluated.

Figure 1. Scheme of an edge wave with the simplifications adopted in this study

Figure 2. Channel with ledge
We scale the space quantities by the maximum channel depth, \( h_2 \), and the time quantities by \( \sqrt{h_2/g} \) and the following dispersion relation is obtained:

\[
\gamma \sqrt{\Omega^2 - K^2} \tan \left( \alpha \sqrt{\Omega^2 - K^2} \right) = \sqrt{\Omega^2 - K^2} \tan \left( \alpha - \beta \right) \sqrt{\Omega^2 - K^2} \tag{2}
\]

where \( \alpha = w/h_2 \) is the ledge width ratio, \( \beta = W/h_2 \) is the channel width ratio, \( \gamma \) is the depth ratio, \( \Omega = \omega \sqrt{h_2/g} \) is the dimensionless frequency (can be interpreted also as the ratio between the total water depth and the free-wave wavelength) and \( K = k h_2 \) is the dimensionless longshore wavenumber (or the ratio between the total water depth and the longshore wavelength). See figure 2 for definitions of depths and widths.

Each mode is defined by the number of zero-crossings in the \( y \)-variation of its free-surface profile. For a given frequency, the character of the modes produced by equation (2) depends on their dimensionless longshore wavenumbers, \( K \). For \( K^2 < 0 \) we have evanescent modes or, being more precise, we have non-propagating modes with an alongshore exponential variation of the free-surface elevation. We chose the sign of that variation such that it decays exponentially inside our domain. For \( 0 < K^2 < \Omega^2 \) we have freely propagating modes and for \( \Omega^2 < K^2 < \Omega^2 / \gamma \) we have trapped or edge-wave modes.

If the ledge occupies the whole width of the channel then \( \alpha = \beta \), \( \gamma = 1 \) and equation (2) gives the dispersion relation for a flat channel. In this case no trapped modes are possible in the channel.

In what follows, we are going to designate by “leaky modes” the free-propagating modes in the channel with ledge. Although this does not make sense for a ledge along a channel wall, since no energy can escape the channel walls, these freely propagating modes do constitute a sample (albeit not a evenly spaced one) of the leaky modes continuum that would be obtained for the same ledge at the coast of a semi-infinite ocean.

For a given mode, as the dimensionless frequency increases, its character changes from evanescent to freely-propagating and then to trapped. In the channel with ledge this change in character implies the concentration over the ledge of the zero crossings in that \( y \)-variation. So, the sinusoidal variation over both the ledge and the deep part of the channel, when the mode is evanescent, changes to sinusoidal both across and along the channel, for the “leaky” modes, and ends up as a sinusoidal variation over the ledge with an exponential decay away for the ledge in the deep part of the channel, when the mode is trapped.

The transition between the “leaky” and the trapped character occurs when \( K = \Omega \), or when the dimensionless frequency is such that

\[
\Omega = n \pi \sqrt{\gamma} / \left( \alpha \sqrt{1 - \gamma} \right) \tag{3}
\]

where \( n \) is the mode number. Since this expression is independent of the channel width it is also valid for a ledge along the cost of a semi-infinite ocean. In fact, when a mode becomes trapped the \( y \)-variation of the free-surface profile after the ledge is horizontal,
this can be seen at $\Omega = 5.236$ in figure 3 which shows how mode 2 changes with frequency. In this case we have a ledge with $\alpha = 0.4$ and $\gamma = 0.1$, in a channel with $\alpha / \beta = 0.05$, but it is clear that, for $\Omega = 5.236$, the shape of this mode, and the associated value of $K$, does not change when other channel widths, or even a semi-infinite ocean, are considered.

![Figure 3. Free-surface elevation for mode 2 trapped waves in channel with ledge. $\alpha = 0.4$, $\alpha / \beta = 0.05$ and $\gamma = 0.1$.](image)

The figure also indicates that for larger values of $\Omega$ the same insensitivity to channel width is likely. In this case the free surface after the ledge approaches the undisturbed mean water level and the $y$-coordinate of this coincidence varies with $\Omega$.

The superposition of all the modes in each of the uniform regions into which we can divide our domain and the enforcement of the continuity of both the free-surface elevation and of the mass flux across the boundaries between those regions allow us to define a set of equations whose solution provides the amplitudes for all the modes considered. This mode-matching technique is used to get all the results presented here.

The number of modes in each region into which the domain of the problem was divided was always 200. Since this is the total number of modes (trapped + "leaky" + evanescent, in channel with ledge, or freely-propagating + evanescent, in flat channel) and the number of propagating modes increases with the frequency, this means that high frequencies have less evanescent modes than low frequencies. However, in the frequency range considered, the number of evanescent modes was always larger than 100.

**The Beginning of the Ledge**

We started by studying the excitation of trapped waves by external incident waves at the beginning of the ledge. Our domain is made of a flat channel, for $x > 0$, and a
channel with ledge, for $x < 0$. A flat channel mode comes from $+\infty$ and meets the beginning of the ledge at $x = 0$.

Since the incident energy is uniformly spread across the channel and the ledge occupies only a small fraction of the channel width, one would expect no significant influence of the ledge on the wave propagation in this problem, being most of the energy transmitted to $-\infty$ in the "leaky" modes of the channel with ledge.

However, figure 4 shows that this is not true when the incident wave is a zero "flat channel" mode. In that figure the energy transmitted in the trapped modes of a channel with ledge, $\alpha = 0.4$, $\gamma = 0.1$ and $\alpha/\beta = 0.05$ (the same used in figure 3), is plotted for several values of the dimensionless parameter $\Omega \alpha$ and for three different "flat channel" modes meeting the beginning of the ledge: zero, five and ten. The curve for mode zero has jumps at some frequencies and the transmitted energy in trapped modes reaches, at those frequencies, quite high values. In fact, the important property is how close the "channel with ledge" modes are to the incident "flat channel" modes.

![Figure 4](image)

Figure 4. Total energy transmitted in trapped modes for different incident modes meeting the beginning of ledge in channel. $\alpha = 0.4$, $\alpha/\beta = 0.05$ and $\gamma = 0.1$.

We saw before, figure 3, that whenever a new trapped mode appears, the free-surface elevation in the deep part of the channel is horizontal. For this frequency the free-surface elevation of the trapped mode almost coincides with the zero-mode incident wave over the deep part of the channel and so most of the incident energy is transmitted in it towards $-\infty$. Then a jump appears in the associated curve for the transmitted energy in trapped modes.

Figure 3 shows also that, as frequency increases, the slope of the free-surface elevation in the deep part of the channel becomes more pronounced and the disturbance in the free-surface elevation narrows down to the region close to the ledge. Then the free-
-surface elevation of this mode is quite different from the zero-mode incident wave and the amount of energy transmitted in trapped modes decreases.

If, instead of trapped modes only, we look to all of the propagating modes in the "channel with ledge" domain, we observe a more gradual variation in the transmitted energy, figure 5. In fact, the sudden increase in the energy in trapped modes happens because the "leaky" mode that was carrying most energy becomes a trapped mode at the frequency where the jump occurs. As the frequency increases the energy in this trapped mode goes to zero (the only exception occurs for the zero mode) and the energy carried in the next leaky mode increases. Another interesting feature in figure 5 is the absence of energy transported in the other leaky modes when a leaky mode becomes trapped.

![Figure 5. Distribution of transmitted energy by several modes when zero-mode incident wave meets the beginning of ledge in channel. $\alpha = 0.4$, $\alpha / \beta = 0.05$ and $\gamma = 0.1$.](image)

A similar behaviour is observed when the incident wave is a flat channel mode different from zero. In this case the energy is transmitted mainly in "leaky" modes, because no trapped mode has a free-surface elevation that oscillates in the deep part of the channel. Assuming that the ledge does not occupy a significant fraction of the channel width, the mode that carries most energy is the one that has the same number of zero-crossings in the deep part of the channel as the incident mode. When the frequency increases, the zero-crossings of any given mode tend to concentrate over the ledge. This phenomenon makes the "leaky" mode that was carrying most energy increasingly different from the incident wave and the next "leaky" mode more similar to it. Then, even before becoming a trapped mode, the "leaky" mode that was carrying most energy loses it to the next leaky mode.
The End of the Ledge

We now look at what happens when a trapped wave meets the abrupt end of the cross-shore depth variation that enabled its existence. This problem is also used to illustrate the influence of the channel width on the results obtained.

We use the same geometry, i.e. a channel with ledge for \( x < 0 \) and no ledge for \( x > 0 \), to study what happens when a zero-mode trapped wave coming from \(-\infty\) meets a discontinuity in the ledge at \( x = 0 \).

Plotting the total energy reflected back in trapped modes for several values of the parameter \( \Omega \alpha \) we get figure 6. In all the curves there, each corresponding to a given value of the depth ratio, \( \gamma \), three regions with distinct behaviour can always be identified: a region in the low frequency range where most of the incident energy is transmitted to the flat channel; a region in the high frequency range where the reflected energy in trapped modes tends to the value that would be obtained in a channel where the ledge occupies the whole channel width, this means that at \( x = 0 \) we would have a depth discontinuity of \( \gamma \); and an intermediate region of high oscillations.

In the low frequency range the free surface elevation of the zero mode trapped wave, the incident wave, is almost horizontal and the phase velocity of this wave is quite close to the phase velocity of the zero mode in the "flat channel" part of the domain. Then all the energy can be transmitted to the region after the end of the ledge.

![Figure 6](image)

Figure 6. Influence of ledge depth ratio on reflected energy carried in trapped modes when zero-mode incident wave meets the end of ledge in channel. \( \alpha = 0.4, \alpha / \beta = 0.05 \).

In the high frequency range the free-surface elevation of the incident wave is concentrated over the ledge, being its phase velocity similar to the phase velocity of a zero mode wave in a flat channel whose the water depth equals the water depth over the
ledge. Since most of the energy in the "flat channel" part of the domain is transmitted in the zero mode, when the incident wave meets the end of the ledge this is similar to a free zero mode in a flat channel meeting a depth discontinuity $\gamma$ in such a channel. So, in the high frequency range, the amount of reflected energy in trapped modes depends on $\gamma$ only.

In the intermediate frequency range, where the response varies rapidly with frequency, the oscillations in the curves are found to be dependent on the channel width. This dependence is illustrated figure 7 where the reflected energy in trapped modes is presented for two different values of channel width, $\alpha / \beta = 0.05$ and $\alpha / \beta = 0.1$, for a channel with ledge with $\alpha = 0.4$ and $\gamma = 0.1$. When the channel width increases, for the same frequency range, more "leaky" modes appear in the channel and so more oscillations in the reflected energy curve can be observed. Actually whenever a "leaky" mode appears a sudden increase in that curve occurs while a new mode in the "flat channel" part of the domain is responsible for a sudden decrease in that curve. The reduction in the amplitude of those oscillations can be explained by wave radiation from the end of the ledge: the farther the channel wall the lower the amplitude of the radiated waves when reaching the far channel wall and so the smaller their influence on the reflected energy.

![Figure 7. Influence of channel width on reflected energy carried in trapped modes when zero-mode incident wave meets the end of ledge in channel. $\alpha = 0.4$, $\gamma = 0.1$.](image)

This strong dependence of the results on the channel width, in this frequency range, is not the best result for our initial assumption that a semi-infinite ocean could be replaced by a wide channel.

However, this does show how careful one must be when interpreting results from scale model tests where long waves are to be produced. Since long waves are difficult to
attenuate at the boundaries of the model, results from this kind of model may have a strong variability with the frequency of the incident wave.

In addition to that, this geometry is also appropriate for modelling wave propagation in narrow or enclosed seas.

A Square Bay

The last geometry presented is an interruption in the ledge produced by a square bay that opens perpendicularly to the coast and whose bottom is at the same level of the deep part of the channel. The channel has a ledge along the whole length except in the bay region.

We investigate what happens when a zero-mode incident trapped wave coming from $-\infty$ meets that discontinuity. It is expected that part of the energy shall be reflected back, part shall be radiated through the gap, part shall be transmitted to the region after the gap and that waves are excited in the bay.

The behaviour of the whole system is controlled by the ratio between the bay dimensions (width, $a$, and length, $b$) and the wavelength of the zero mode in the “flat channel” part of the domain since resonance may occur in the bay. So, the relevant non-dimensional parameters are $\Omega \mu$ and $\Omega \nu$, where $\mu$ is the non-dimensional bay width, $\mu = a/h_2$ and $\nu$ is the non-dimensional bay length, $\nu = b/h_2$.

Of course the dimensionless parameter $\Omega \alpha$ also plays a role in this behaviour because it controls the energy spreading across the channel and this does influence energy transmission across the interruption in the ledge.

This was clearly seen in one special case of the bay geometry we studied: a gap in the ledge (the bay length, $b$, is nil). We looked at the transmitted energy for several values of the gap width, $\mu$, for two values of the parameter $\Omega \alpha$, 5.06 and 0.63.

For $\Omega \alpha = 5.06$ the incident energy is concentrated over the ledge and the curve with the transmitted energy in trapped modes versus the gap width oscillates as if the ledge occupied the whole channel width. The amplitude of those oscillations decreases slightly as the gap width increases.

Figure 8 shows the contour lines of the free surface elevation for $\Omega \alpha = 5.06$ when the gap width equals 4.5 times the wavelength of the zero mode in the “flat channel” part of the domain. There we can see the oscillating mode excited inside the gap region and the energy being radiated from the end of the ledge. Some of this energy misses the ledge after the gap and is transferred into “leaky” modes at that part of the domain.

Something different happens for $\Omega \mu = 0.63$. Then the incident energy is not concentrated over the ledge and the amount of energy transmitted to the region after the gap decreases sharply with the gap width. It is difficult to identify any pattern in the oscillations of that curve.
Figure 8. Amplitude of free surface elevation when zero-mode incident wave, with $\Omega \alpha = 5.06$, in channel with ledge, $\alpha = 0.4$, $\gamma = 0.1$ and $\alpha / \beta = 0.05$, meets gap in the ledge, $\mu = 2.28$.

For the square bay we keep the dimensions of the domain constant, $\alpha = 0.4$, $\gamma = 0.1$, $\alpha / \beta = 0.05$, $\mu = \nu = 1.0$, and vary the dimensionless frequency of the incident wave, $\Omega$, such that the ratio between the bay width and wavelength of the zero mode in the “flat channel” part of the domain varied between zero and 1.2.

This variation of the incident wave frequency implies that $\Omega \alpha$ varies with the dimensionless parameter $\Omega \mu$ and so does the concentration over the ledge of the incident energy. The evolution, with the dimensionless parameter $\Omega \mu$, of the fraction of the incident energy transmitted in all the modes as well as the fraction transmitted in trapped modes is not smooth. There are many jumps and depressions related to the appearance of the several trapped and freely-propagating modes, as the frequency increases. That is why we focus only at the evolution, with $\Omega \mu$, of the free-surface elevation amplitude at three points at the far end of the bay:

- left: at the bay corner close to the end of the ledge, $x / h_2 = -0.5$ and $y / h_2 = -1.0$;
- center: at the middle at bay far end, $x / h_2 = 0.0$ and $y / h_2 = -1.0$;
- right: at the bay corner close to the beginning of the ledge, $x / h_2 = 0.5$ and $y / h_2 = -1.0$.

Figure 9, shows the amplitude of the free surface elevation at those points, with jumps and depressions due to the appearance of new modes in the channel. However, they cannot be mistaken for the sharp peaks on the same curves around $\Omega \mu = \pi$ and $\Omega \mu = 2\pi$ that are related to the occurrence of resonance at the bay.
Figure 9. Channel with ledge, $\alpha = 0.4$, $\gamma = 0.1$ and $\alpha / \beta = 0.05$, that is interrupted by square bay, $\mu = \nu = 1.0$. Amplitude of free surface elevation inside bay for zero-mode incident wave.

The oscillation modes excited at those frequencies have nodal lines perpendicular to the channel boundary and is shown in figure 10 a). These peaks do not coincide with an integer number of half wavelengths across the bay width (the natural frequencies of the bay) but are slightly above it.

Next to each of those sharp peaks, at a higher frequency, a broad peak can always be noticed in figure 9. It corresponds to the excitation of an oscillation mode that has nodal lines parallel to the channel axis, in addition to the nodal lines perpendicular to the channel axis, figure 10 b).

Figure 10. Amplitude of free surface elevation when zero-mode incident wave in channel with ledge, $\alpha = 0.4$, $\gamma = 0.1$ and $\alpha / \beta = 0.05$, meets gap in the ledge created by square bay, $\mu = \nu = 1.0$. a) $\Omega \mu = 3.320$ and b) $\Omega \mu = 4.206$
All these peaks imply an oscillation that involves the bay only. However, since the domain considered here is not semi-infinite but a wide channel, some of the energy radiated from the bay entrance is reflected at the far channel wall and may contribute to the build-up of the oscillation at the region in front of the bay. This could be the cause for the oscillation involving the whole channel around the bay area, shown in figure 11, associated to the sharp peak at $\Omega \mu = 0.759$. Further investigation of this case is continuing.

![Figure 11](image-url)

**Figure 11.** Amplitude of free surface elevation when zero-mode incident wave, with $\Omega \mu = 0.759$, in channel with ledge, $\alpha = 0.4$, $\gamma = 0.1$ and $\alpha / \beta = 0.05$, meets gap in the ledge created by square bay, $\mu = \nu = 1.0$.

**Conclusions**

We use a channel with a ledge along one of its walls to investigate the effects of a sudden change in the bottom geometry that enables the presence of trapped waves on the propagation of those waves.

The results obtained in this channel allow us to infer on the general trend of the response to similar problems in a semi-infinite ocean. However, in some parameter ranges they show a strong dependence on the channel width. The variability of the results with the dimensionless frequency $\Omega$, show how careful one must be when interpreting results from scale model tests where long waves are to be produced. Since long waves are difficult to attenuate at the boundaries of the model, the effect of the wave tank walls is similar to the far channel wall in our model.

A Boussinesq Model for Breaking Waves: Comparisons with Experiments

Jayaram Veeramony and Ib A. Svendsen

ABSTRACT: The paper describes results with a breaking wave model based on an extended set of Boussinesq equations. The wave breaking is described by accounting for the effect of vorticity generated by the breaking process. The vorticity field in the domain is obtained by solving the vorticity transport equation, which is based entirely on the Reynolds equations. In addition to the wave height decay and profile deformation predicted by earlier breaker models, the present model also provides information about the velocity profiles. The model results give good agreement with experimental data for wave height, setup and the velocity profiles. The cross-shore variation of the radiation stress calculated from the model results gives a good representation of the results from experimental data.

1. Introduction.

Recently, there has been an increased need for time-domain modelling of breaking waves. This stems from a need to accurately model the nearshore wave motion and circulation. Simulations of breaking waves have been performed by Lin and Liu (1998a, 1998b). They solved the Reynolds equations for the mean flow and the \( k - \epsilon \) equation for turbulent kinetic energy using the VOF method. The model results and experimental data were found to be in good agreement. The advantage of this type of modelling is that the flow details such as the turbulent intensities and the shear stresses can be directly evaluated from the model results. However, it takes about 48 hours of CPU time on a supercomputer to simulate one minute of real time for a two-dimensional case. As a
result, applications to practical cases are limited.

Hence, modelling of breaking waves using shallow water theories such as the non-linear shallow water equations or the Boussinesq equations remain of practical importance. To incorporate breaking in such models, a wave breaking criterion and an energy dissipation mechanism is necessary. The wave breaking criteria used in all models are semi-empirical in nature, as there are no general theoretical bases on which a wave can be assumed to start breaking.

There are several ways in which the energy dissipation can be included in the models. One method is based on the concept of an artificial eddy viscosity term which is introduced in the momentum equations (see for example Zelt 1991; Karambas and Koutitas 1992; Wei and Kirby 1995). The value of the eddy viscosity is calibrated with experimental data. With suitable choices for the eddy viscosity, very good approximations to the wave height data is obtained. The problem with this approach is that the velocity profile is not changed from the standard quadratic profile (or a higher order polynomial depending upon the order of the terms retained in the Boussinesq theory) because the flow is modelled as a potential flow. The eddy viscosity term is also not physically justified.

Another method uses the concept of a roller model first used by Svendsen (1984a, 1984b). In these breaking models, the roller rides on the front face of the wave at the speed of the wave (Brocchini et al. 1991; Schäffer et al. 1992; Schäffer et al. 1993). This introduces a change in the velocity profile once the waves break. The velocity is assumed to have a constant value in the roller region equal to about 1.3 times the wave speed. Associated with this change in velocity profile is an excess momentum flux, which simulates wave breaking. As before, comparisons with experimental data show that the results for the wave heights and setup can be modeled quite accurately although the flow is essentially modelled as a potential flow. However, physically, the velocity profile assumed in such models is unrealistic.

Svendsen et al. (1996) presented a model for surf zone waves by accounting for the vorticity present in the breaking waves. The vertical distribution of the vorticity was obtained by solving the vorticity transport equation. The boundary condition was prescribed at the mean water level and a finite-difference scheme was used to solve the vorticity equation. However, though consistent with classical Boussinesq theory, this approach misses the significant contributions of the vorticity generated in the roller region. Also, by using a finite-difference scheme, it turns out that the small water depths in the surf zone resulted in significant numerical errors while resolving the vorticity distribution. The model used in
this paper is based on the same general principles. However, the boundary condition for vorticity is prescribed at the lower edge of the roller which is physically much more accurate. Furthermore, the vorticity equation is solved analytically, thus avoiding the problems associated with numerical modelling. Also, enhanced dispersion characteristics have been used.

2. Governing Equations.

The governing equations are derived from the basic equations for conservation of mass and momentum. The derivation, which is an extension of the classical Boussinesq theory with the Ursell number $U = O(1)$, was given in Svendsen et al. (1996). The Ursell number is defined as the ratio between the two parameters $\delta = a_0/h_0$ and $\mu = k_0h_0$ where $a_0$, $h_0$ and $k_0$ are the characteristic wave amplitude, water depth and wave number respectively.

Then, the nondimensional depth integrated continuity equation is

$$\frac{\partial \zeta}{\partial t} + \frac{\partial Q}{\partial x} = 0$$

where $\zeta$ is the instantaneous water surface elevation and $Q$ is the volume flux.

The model uses the direct depth integrated version of the momentum equations, with the enhancement of the frequency dispersion suggested by Madsen et al. (1991), which is

$$\frac{\partial Q}{\partial t} + (h + \delta \zeta) \frac{\partial Q}{\partial x} + \delta \left( \frac{Q^2}{h + \delta \zeta} \right)_x - \mu^2 \left( B + \frac{1}{3} \right) h^2 (Q)_{xxt} - Bgh^3 \zeta_{xxx}$$

$$+ \delta (\Delta M)_x + \mu^2 (\Delta P)_{xxt} = 0$$

where

$$\Delta M \equiv \int_{-h}^{h} (u_r^2 - \bar{u}_r^2) \, dz$$

and

$$\Delta P \equiv \int_{-h}^{h} \frac{\partial^2}{\partial z \partial t} \int_{z}^{h} \frac{\partial}{\partial x} \int_{-h}^{h} (u_r - \bar{u}_r) \, dz \, dz \, dz$$

are the momentum signatures of breaking. In (3) and (4), the velocities are given by

$$u = \bar{u}_p + \frac{\mu^2}{2} \left( \frac{h}{2} - z \right) (h \bar{u}_p)_{xx} + \frac{\mu^2}{2} \left( \frac{h^2}{3} - z^2 \right) \bar{u}_{p,xx} + u_r + O(\mu^4)$$

$$u_r \equiv \int_{-h}^{z} \omega \, dz - \frac{\mu^2}{2} \int_{-h}^{z} \int_{-h}^{z} \omega_{xx} \, dz \, dz$$

where $\bar{u}_p$ is the depth-averaged velocity corresponding to the potential part of the flow (i.e. terms that do not include the vorticity) and $u_r$ is the rotational
part of the velocity which essentially represents the effect of breaking. ω is the vorticity.

Assuming a constant eddy viscosity, the vorticity transport equation and the boundary conditions read

\[
\frac{\partial \omega}{\partial t} = \nu \frac{\partial^2 \omega}{\partial z^2} + O(\delta, \mu^2) \tag{7}
\]

\[
\omega(z = \zeta_c, t) = \omega_s(x, t) \tag{8}
\]

\[
\omega(z = -h, t) = 0 \tag{9}
\]

\[
\omega(z, t = 0) = 0 \tag{10}
\]

where \(\zeta_c\) is the lower edge of the roller and \(\omega_s(x, t)\) is as yet unspecified. Noting that the terms involving breaking in (2) are \(O(\delta)\) and \(O(\mu^2)\), we keep only terms of \(O(1)\) in the vorticity transport equation.

The bottom boundary condition of zero vorticity is consistent with the assumption that breaking is the most important source of vorticity. At the free surface we can expect zero vorticity along the part of the surface which does not include the roller region. In the roller region, measurements from hydraulic jumps (Svendsen et al. 1998) show that the free surface vorticity will also be close to zero. However, strong vorticity is generated inside the roller region with a maximum occurring near the lower limit of the roller. We approximate the vorticity generated in this region by the vorticity between the surface roller and the region beneath.

In the Svendsen et al. (1996) version of of the model, \(\omega_s\) was specified along the mean water level rather than the lower limit of the roller. Though this is consistent with the Boussinesq assumptions, this turns out to be a major source of inaccuracy. Also, in the previous version of the model, the vorticity equations were solved using a Crank-Nicholson method. With the small water depths in the surf-zone, the numerical error due to the finite difference methods were also very large due to the necessity of a very fine discretization in \(z\), unless a very fine discretization in \(x\) and \(t\) was also used. These deficiencies have been eliminated in the present version by introducing the coordinate transformation \(\sigma = (h + z)/(h + \zeta_c)\) where \(\zeta_c\) is \(O(\delta)\). To \(O(\delta, \mu^2)\) this gives (7) with \(\sigma\) instead of \(z\). Solving (7)-(10) analytically gives

\[
\omega = \sigma \omega_s - 2 \sum_{n=1}^{\infty} G_n \sin n\pi\sigma, \tag{11}
\]
where

\[ G_n \equiv \frac{(-1)^{n+1}}{n\pi} \int_0^t \frac{\partial \omega_z}{\partial t} e^{n^2\pi^2\kappa(t-\tau)} \, d\tau. \]  

(12)

Using (11), the expressions for \( \Delta M \) and \( \Delta P \) are obtained.

3. Boundary conditions for vorticity.

Measurements of velocity in the roller region for breaking waves are not yet available inside the surf-zone. However, velocity measurements are available for hydraulic jumps with for the range of Froude numbers \( 1 \approx Fr < 2 \) (Svendsen et al. 1998; Lin and Rockwell 1994; Bakunin 1995) which is similar to Froude numbers for breaking waves. Breaking waves viewed in a coordinate system which moves at the wave speed have flow patterns around the roller region that are very similar to that observed in hydraulic jumps. The absolute velocities and the bottom boundary layer would of course be different under this coordinate transformation but the turbulent stresses, the surface profile and especially the vorticity are the same in a moving coordinate system.

Figure 1: Velocity profiles in three hydraulic jumps with Froude numbers 1.38, 1.46 and 1.56. Data is ‘•’, vorticity is ‘——‘ and the fit to the velocity is ‘— — —’. The total water depth at each location is ‘+’ and the location of the lower edge of the streamline is ‘o’ (from Svendsen et al. 1998)

Velocity measurements by Bakunin (1995) were available for Froude numbers of 1.38, 1.46 and 1.56, from which the vorticity distribution could be calculated. The details of the analysis of the data can be found in Veeramony and Svendsen
Figure 1 shows the variation of the horizontal velocity and the vorticity in the three jumps. The volume flux is also known for each jump condition from which the thickness of the roller is calculated, since the net volume flux through the roller region is zero. Figure 2a shows that the non-dimensional roller thickness is similar for all three cases. Therefore, the dimensionless roller thickness can be represented by the curve, obtained using a least squares fit to the data, shown in figure 2a.

\[ \zeta_c = 0.78 e^{x/l_r} \left( \frac{x}{l_r} - \frac{x^2}{l_r^2} \right) \]  

(13)

Figure 2: (a) The non-dimensional thickness of the roller for the hydraulic jumps: Data for Froude numbers 1.38 (o), 1.46 (x), 1.56(*) and least-squares fit (13). (b) Non-dimensional vorticity at the lower edge of the roller with the linear fit (— — —) and according to (14) (— — —).

Figure 2(b) shows the vorticity at the lower edge of the roller. Again, the non-dimensional values for all three cases are very similar, and the dimensionless \( \omega_s \) can be represented by

\[ \omega_s = 15.75 \left( 1 - \frac{x}{l_r} \right) \]

which is shown as the solid line in the figure. However, though physically realistic, the step discontinuity at \( x/l_r = 0 \) causes instabilities during the numerical evaluation of (12). To avoid this, we represent the vorticity by the expression
which is shown as the dashed line in figure 2b.

\[
\omega_s = 15.75 \left(1 - e^{40x/L'}\right) \left(1 - \frac{x}{L'}\right)
\]  

(14)

The expressions of \( \zeta_e \) and \( \omega_s \) from (13) and (14) are used in the solution (11) to the vorticity equation.

4 Comparison between model results and data.

The results from the model described in the previous section was compared to two sets of experiments with monochromatic waves. Wave heights and setup measurements for monochromatic waves are available from set of experiments by Hansen and Svendsen (1979). Wave shape and the velocity profiles below the wave trough are available from the measurements by Cox et al. (1995). Both experiments were conducted in wave flumes with plane beaches. The computational domain, shown in figure 3, is similar to the experimental domain. A fourth-order ABM method is used to solve the equations numerically. Permanent form waves corresponding to (2) is used as input to the model. At the offshore boundary, an absorbing-generating boundary condition similar to that developed by Van Dongeren and Svendsen (1997) is used. A sponge layer is used to absorb the waves in the constant depth section which represents the shoreline. The wave is assumed to start breaking once the steepness at any point on the wave front is larger than 20°. Once the waves start breaking on a plane beach, it does not stop until it reaches the shoreline. The value of the eddy viscosity \( \nu_t \) used in the model is 0.05\( h \sqrt{g h} \) for all comparisons.

4.1 Wave height and set-up comparisons.

The first set of comparisons is to the data from Hansen and Svendsen (1979). The experiments were conducted in a wave flume with a plain beach of slope 1:34.26. The water depth at the start of the slope was \( h_0 = 0.36 \) m. Seven tests
Table 1: Wave parameters from (Hansen and Svendsen 1979) at the toe of the beach were conducted in all. The wave heights and set-up for each case was measured at a number of locations. In this paper, comparisons will only be shown for three cases. Table 1 presents the wave period and the wave height at the start of the slope for each of the cases.

Figure 4 shows the comparison between the model results and the data for Case 1. The wave heights in the initial part of the shoaling region is represented well. As the waves get closer to breaking, the agreement between the model and data deteriorates. At the point of wave breaking, the difference between the two is very obvious. The reason for this discrepancy is that the present version of the potential part of the model is based on weakly nonlinear theory as in Madsen et al. (1997a, 1997b)

Though that can be improved, the emphasis of this study, however, is the modelling of the phenomena after breaking. A short while after the breaking has been initiated in the model, it is seen that the agreement is very good.

</tbody>
</table>

Figure 4: Comparison between model results (———) and data (○) from (Hansen and Svendsen 1979) of wave heights (a) and setup (b) for Case 1 in table 1.
An important gauge of the model performance is obtained from looking at the prediction of the set-up (figure 4b), which show good agreement between the model results and the experimental data. This suggests that the evaluation of such terms as the radiation stresses will also be accurate.

Figure 5: Comparison between model results and data from (Hansen and Svendsen 1979) of wave heights (a) and setup (b) for Case 2 ( — is model, o is data) and Case 3 ( — — — is model, x is data) in table 1.

Figure 5 shows the comparisons for Cases 2 and 3. Again, the model underestimates the wave height near the breaking region. On the other hand, the prediction of the set-up is consistently good. All this indicates that the flow properties in the surf-zone are being modelled correctly. To illustrate this further, the results from the model are compared to velocity data from breaking waves in the next section.

4.2 Velocity and surface elevation comparisons to data.

Velocity and surface elevation data were gathered by Cox et al. (1995). The experiments were conducted in a wave flume with a plain beach slope of 1:35. The wave height at the wavemaker was $H_0 = 11.5 \text{ cm}$ and the water depth at the start of the beach was $h_0 = 0.40 \text{ m}$. The wave period was $T_0 = 2.2 \text{ secs}$. Measurements of velocity in the vertical were taken at six locations given in table 2.

The first measuring line was outside the breaking region, the second was close to the breaking point and the last four were inside the surf zone. Comparisons
Table 2: Location of measuring lines for the data of (Cox, Kobayashi, and Okayasu 1995)

Line No. | L1  | L2  | L3  | L4  | L5  | L6  |
------- |-----|-----|-----|-----|-----|-----|
 h (cm) | 28.0| 21.14| 17.71| 14.29| 10.86| 7.43|

will be shown again for three cases inside the surf-zone.

Figure 6 show the comparisons at the still water depths of $h = 17.71\, cm$ (6a), $h = 14.29\, cm$ (6b) and $h = 10.86\, cm$ (6c). The $x$-axis in the figure is normalized by the wave period. The wave shape according to the model (---) does not have the saw-tooth shape seen in the data (-----) at any location in the surf zone. To obtain a saw-tooth profile for the wave in the surf-zone it is necessary to have full non-linearity at least up to the order of dispersion that is retained. As a result, the weakly non-linear Boussinesq model will perform significantly worse in this regard than, say, the non-linear shallow water (NSW) model, although the NSW equations retain less terms than the Boussinesq equations. The comparison between the velocity profiles predicted by the model (---) and that obtained from measurements (o) are also shown in figure 6. For the most part, the agreement between the two are excellent. An exception is near the toe of the wave face ($t/T = 0.2$) where the model tends to predict a positive velocity whereas the data shows negative velocities. The differences are clearly due to the differences in the predicted and measured surface profiles.

Figure 7 shows the vorticity field in a breaking wave. The contour lines of vorticity (7a) show that the vorticity produced in the roller region is convected downward and towards the back of the wave. The maximum value of the vorticity in the wave is close to the toe of the roller as is expected. On the other hand, along each vertical cross-section, it is only in the initial region of the roller that the maximum of the vorticity is close to the lower edge of the roller. Behind approximately the halfway point between the start of the roller and the end, the maximum of the vorticity is below the lower limit of the roller. This result is similar to that observed in the hydraulic jumps (Figure 1). Thus, this important feature of the vorticity distribution is captured by the model, even though only terms upto $O(1)$ are retained in (7)-(10).

The results of the model for $u$ and $\zeta$ are used to compute the radiation stress. The radiation stress in the cross shore direction is defined as

$$S_{xx} = \frac{1}{2} \rho \left( \bar{u}^2 - \bar{p}_D \right) dz + \frac{1}{2} \rho (\bar{\zeta} - \bar{\zeta})^2$$  \hspace{1cm} (15)$$

where the $\bar{()}$ denotes averaging over a wave period and $p_D$ is the dynamic pressure. To the lowest order of approximation that has been retained so far,
Figure 6: Comparison between model predictions and data from Cox et al. 1995 at $h = 17.71$ cm (a), $h = 14.29$ cm (b) and $h = 10.86$ cm (c) showing water surface elevations from model (---) and data (-----) and velocity profiles from model (-----) and data (o). The vertical lines (· · · · · ·) show the locations at which the velocities are compared.

Figure 7: (a) Contours of vorticity at $L_4$. (b) Vertical profiles of vorticity under the roller and behind the crest.
\( p_D \propto \rho w^2 \) where \( w \) is the vertical velocity.

Figure 8 shows the spatial variation of the dimensionless radiation stress defined as

\[
P \equiv \frac{S_{xx}}{\rho g H^2}.
\]

Linear theory predicts a constant value of \( P = 0.1875 \). Wave breaking in the model starts at \( x \approx 9.6 \text{ m} \). The value of \( P \) at the start of breaking is relatively low due to the peaky shape of the waves (see Svendsen 1984b for a detailed discussion). Svendsen and Putrevu (1993) presented results from experimental data for the normalized radiation stress, which shows considerable variation from one data set to another. However, all results have the same feature that the value of \( P \) starts at the breaker point with fairly low values, increases to a maximum and then decreases towards the shoreline. Although the results of the model do not show that \( P \) quite reaches the value predicted by linear wave theory, the same trend is observed.

![Figure 8: Spatial variation of the dimensionless radiation stress \( P = S_{xx}/(\rho g H^2) \). Wave breaking starts at \( x = 9.6 \text{ m} \). The sponge layer starts at \( x = 15 \text{ m} \).](image)

5 Conclusions.

The breaking model is an extension of the classical Boussinesq equations. The vorticity field in the domain is obtained by solving the lowest order vorticity transport equation, which is based entirely on the Reynolds’ equations. The boundary conditions for the solution for vorticity is parameterized using measurements from hydraulic jump. Comparisons with experimental data for
monochromatic waves show that the model performs well in the surf-zone. The wave heights are predicted reasonably accurately within the limitations of the form of the Boussinesq equations. The comparisons to the velocity profiles are especially good. The vorticity distribution calculated by the model agrees qualitatively with the results shown for hydraulic jump. The radiation stress in the cross-shore direction is calculated directly from the velocity field given by the model. The result is seen to agree qualitatively with that observed from other experiments.

NEARSHORE WAVE DYNAMICS SIMULATED BY
BOUSSINESQ TYPE MODELS

Ole R. Sørensen1, Per A. Madsen1, and Hemming A. Schäffer1

Abstract

This paper presents a numerical study of nearshore wave dynamics including the surf zone. Two different time-domain Boussinesq type formulations are applied for this purpose. The first model incorporates Padé [2,2] dispersion characteristics and lowest order nonlinearity. The second and more sophisticated model incorporates Padé [4,4] characteristics and higher-order nonlinearity in the dispersive terms. The models are validated on the shoaling and breaking of regular and irregular waves with and without an ambient current.

1. INTRODUCTION

Numerical models of nearshore wave hydrodynamics have developed rapidly in complexity over the last decade. Today, the most advanced Boussinesq type models offer an accurate representation of complicated processes such as triad wave interactions and wave-current interaction, while wave breaking of irregular waves and the resulting dissipation processes can be approximated by fairly simple but reasonably accurate descriptions. This allows for a study of a variety of complicated phenomena in the surf zone and in the swash zone.

In previous publications (e.g. Schäffer et al., 1993; Madsen et al., 1997a,b; Sørensen et al., 1998) we have studied and modelled surf zone dynamics such as the shoaling, breaking and runup of regular and irregular waves, the generation and release of low frequency waves, wave-induced rip-currents and circulation cells behind detached breakwaters. For this purpose we have until recently applied a time-domain Boussinesq model (I) in terms of the depth-integrated velocity and including lowest order nonlinearity and Padé [2,2] dispersion characteristics. The results obtained with this model have been satisfactory with a few exceptions. However, it has been clear for some time that this model underestimates the nonlinear shoaling...
near the break point. This shortcoming shows up in the wave height or wave crest variations and even more clearly in the evolution of nonlinear measures such as the skewness and asymmetry.

In this work we introduce a more sophisticated Boussinesq model (II) which includes higher-order nonlinearity in the dispersive terms as well as more accurate linear dispersion characteristics (Padé [4,4]-type). Both models (I and II) are applied in this study to investigate shoaling and breaking of regular and irregular waves on different bathymetries. The emphasis is on the evolution of higher-order statistics in terms of the skewness and asymmetry. Comparisons with physical experiments are presented for three cases. The effect of an opposing current on the shoaling and breaking of regular waves on a sloping plane beach is also investigated. Here we concentrate on validating the ability of the breaking model to predict the breaker depth and breaker height.

2. MODEL DESCRIPTION

The two different time-domain Boussinesq formulations considered in this work are described below. For simplicity we shall list the equations for a constant depth although the variable-depth terms were included in all computations. Both models are extended into the surf zone by the use of the so-called roller concept as summarized in Section 2.2.

2.1 Boussinesq formulations

Model I is formulated in terms of the depth-integrated horizontal velocity and it retains terms of order $O(\mu^2,\epsilon)$, where $\epsilon$ is a measure of the nonlinearity and $\mu$ is a measure of linear dispersion. The general two-dimensional equations valid on a sloping bottom were originally derived by Madsen & Sørensen (1992) and later extended to the surf zone by Madsen et al. (1997a,b). In one dimension and on a constant depth the equations read

\[
\frac{\partial \eta}{\partial t} + \frac{\partial Q}{\partial x} = 0 \quad (1a)
\]

\[
Q_t + \epsilon \frac{\partial}{\partial x} \left( \frac{Q^2}{h + \epsilon \eta} \right) + \epsilon R_x + (h + \epsilon \eta) \eta_x + \\
\mu^2 \left( \left( v_1 - \frac{1}{3} \right) h^2 Q_{xxr} + v_1 h^3 \eta_{xxx} \right) = O(\epsilon \mu^2, \mu^4) \quad (1b)
\]

where $Q$ is the depth integrated velocity, $h$ is the still water depth, $\eta$ is the surface elevation and $v_1 = -1/15$. This formulation is superior to the classical Boussinesq equations as it incorporates Padé [2,2] dispersion characteristics for pure waves, i.e. in the absence of current. We note that the $R$-term in (1b) represents the roller dynamics as described in Section 2.2.
Model II is formulated in terms of the horizontal velocity at a certain z/h-location and it retains terms of order $O(\mu^2, \epsilon^4 \mu^2)$. The general two-dimensional equations valid on a sloping bottom can be found in Madsen & Schaffer (1998a), and they have previously been solved in one-dimension by Madsen et al. (1996). In one dimension and on a constant depth the equations read

$$\eta_t + h \dot{u}_x + \mu^2 \left( \left( \alpha + \frac{1}{3} - \beta_1 \right) h^2 \dddot{u}_{xx} - \beta_1 h^2 \eta_{xxr} \right) + \epsilon (\eta \dot{u})_x +$$

$$\epsilon \mu^2 h^2 \frac{\partial}{\partial x} \left( \alpha \eta \dddot{u}_{xx} - \beta_1 (\eta \dddot{u})_{xx} \right) - \epsilon^2 \mu^2 \frac{h}{2} \frac{\partial}{\partial x} \left( \eta^2 \dddot{u}_{xx} \right) = O(\mu^4)$$

$$\epsilon^3 \mu^2 \frac{\partial}{\partial x} \left( \frac{1}{6} \eta^2 \dddot{u}_{xx} \right) = O(\mu^4)$$

(2a)

$$\dddot{u}_r + \eta_x + \mu^2 ((\alpha - \alpha_1) h^2 \dddot{u}_{xx} - \alpha_1 h^2 \eta_{xxr}) + \epsilon \left( \dddot{u}_x + \frac{R_x}{h + \epsilon \eta} \right) +$$

$$\epsilon \mu^2 \frac{\partial}{\partial x} \left( \alpha h \dddot{u}_{xx} - \frac{\alpha_1}{2} h^2 (\dddot{u})_{xx} + \frac{1}{2} h^2 (\dddot{u})_{xx} - h \eta \dddot{u}_{xx} \right) +$$

$$\epsilon^2 \mu^2 \frac{\partial}{\partial x} \left( - \frac{1}{2} \eta^2 \dddot{u}_{xx} + h \eta (\dddot{u}_x - \dddot{u}_xx) \right) +$$

$$\epsilon^3 \mu^2 \frac{\partial}{\partial x} \left( - \frac{1}{2} \eta^2 \dddot{u}_{xx} + \frac{1}{2} (\eta \dddot{u}_x)^2 \right) = O(\mu^4)$$

(2b)

where $\dddot{u}$ is the velocity in a specific z/h-location and

$$\alpha, \beta_1, \alpha_1 = \left( \frac{-3 - \sqrt{23/35} - 2 \sqrt{19/7}}{18}, \frac{28 - 2 \sqrt{133}}{126}, \frac{105 - 3 \sqrt{805}}{1890} \right)$$

(3)

Again the $R$-term in (2b) represents the roller dynamics as described in Section 2.2. Madsen & Schaffer (1998a,b) demonstrated that (2a-b) is Galilean invariant and that it incorporates Padé [4,4] dispersion characteristics for pure waves as well as for waves in currents. Furthermore, the characteristics for shoaling and wave-wave interaction are generally superior to the ones obtained by Model I.

Fig. 1 shows the accuracy of the second order transfer functions derived from the two different Boussinesq formulations. The individual transfer functions are scaled with the target solution of Stokes. We notice that Model II obviously contains the best nonlinear performance, while Model I significantly underestimates the transfer function for larger $kh$-values.
2.2 Breaker model based on the roller concept

Wave breaking is introduced in the Boussinesq equations on the basis of the surface roller concept for spilling breakers as described by Schäffer et al. (1993) and Madsen et al. (1997a, 1997b). The basic principle is that the surface roller is considered as a volume of water carried by the wave with the wave celerity. The influence of breaking on the governing equations is modelled by an additional momentum term originating from a non-uniform velocity profile due to the presence of the roller. This momentum term can be expressed as

$$R = \frac{\delta}{1 - \delta/d} (c - u)$$

Here $d$ is the total water depth, $\delta$ is the roller thickness, $c$ is the roller celerity, while $u$ is the depth-averaged velocity $(Q/d)$ in eq. (1b) and the velocity at a specific $z/h$-location in eq. (2b).

The instantaneous roller thickness at each point is determined based on a heuristic geometrical approach. Incipient breaking is assumed to occur when the local slope of the surface elevation exceeds an initial critical value, $\tan \phi_B$. During the
transition from initial breaking to a bore-like stage in the inner surf zone the critical angle is assumed to gradually change from $\phi_B$ to a smaller terminal angle $\phi_0$. Hence the instantaneous value of $\phi$ defining the toe of the roller depends on the age of the roller and is assumed to follow an exponential time-variation with a half time $t_{1/2}$. Locally, the roller is defined as the water above the tangent of slope $\tan \phi$. Prior to inclusion in the governing equations the roller thickness is multiplied by a shape factor. In Model I a constant factor of 1.5 is applied, while a shape factor which has a linear variation from 2 at the toe of the roller to zero at the back of the roller is applied in Model II. The latter modification of the shape factor was introduced because the previous formulation had a tendency to give small spurious oscillations near the back of the roller, when applied to the peaked wave profiles appearing with Model II.

For Model I all test cases in the present paper are modelled with a default set of breaking parameters $({\phi_B}, {\phi_0}, t_{1/2}) = (20 \text{ deg}, 10 \text{ deg}, T/5)$, where $T$ is a characteristic wave period. These parameters were given by Madsen et al. (1997a). However, the calibration of $\phi_B$ and to some extent $t_{1/2}$ is related to the accuracy of the computed surface elevation before the breaking occurs. As Model II incorporates more nonlinearity, the wave profiles computed by this model will generally contain a higher level of skewness and this will show up in particular near the breaking point. Therefore, the breaking parameters, which have been calibrated on the basis of Model I, have to be revised. In the present paper all simulations with Model II are performed with $({\phi_B}, {\phi_0}, t_{1/2}) = (32 \text{ deg}, 10 \text{ deg}, T/10)$.

The wave celerity, which is an important part of (4), is determined interactively from the instantaneous wave field using

$$c = -\frac{n_y}{n_x}$$

(5)
determined at the steepest point of each wave front.

3. Shoaling and breaking of regular and irregular waves

3.1 Regular waves on a plane sloping beach

Ting and Kirby (1994) presented measurements for spilling breakers on a plane sloping beach with a slope of 1/35 starting in a depth of 0.40 m. As input they generated regular waves with a wave period of 2.0 s and a wave height of 0.125 m. Fig. 2 shows the spatial variation of the crest and trough elevations and of the mean water level computed by the two different Boussinesq models. It is obvious that model II, which contains higher-order nonlinear terms, significantly improves the nonlinear shoaling up to the vicinity of the breaking point. This result is in accordance with the analysis from Fig. 1. The difference between the two model results is emphasized in Fig. 3, which shows the spatial variation of the skewness and asymmetry, and in Fig 4, which shows the computed wave profiles at the point of wave breaking. Again model II is seen to predict a much higher level of nonlinearity.
Figure 2  Spatial variation of wave crest elevation, wave trough elevation and mean water level for the test of Ting and Kirby (1994). (- - -) Model I; (——) Model II; (o) experimental data.

Figure 3  Spatial variation of the skewness and asymmetry for the test of Ting and Kirby (1994), (- - -) Model I and (——) Model II.
3.2 Irregular waves on a plane sloping beach

This test case is based on the laboratory measurements reported by Cox et al. (1991). Fig. 5 illustrates the experimental setup. The flume consists of a 10 m horizontal section with a water depth of 0.47 m and a 12 m section with a constant slope of 1/20. Measurements of the surface elevation are available at eleven locations (denoted WG1 to WG11) in still water depths of 47, 35, 30, 25, 20, 17.5, 15, 12.5, 10, 7.5 and 5 cm. The input waves are generated on the basis of a target spectrum of Pierson-Moskowitz type with a peak frequency of 1.0 Hz and a significant wave height of 6.45 cm.

Based on the peak frequency we find that $h/L_0 = 0.30$ ($L_0$ being the deep water wave length) at the offshore boundary and this makes the test very demanding for weakly dispersive Boussinesq models. Model I, which incorporates Padé [2,2] dispersion characteristics, is restricted to $h/L_0$ values less than approximately 0.5 and beyond this limit errors in the linear dispersion relation will exceed 5% (see Madsen et al., 1991). Hence an accurate representation of free waves at 2.0 Hz (two times...
the peak frequency) requires the water depth to be less than 0.25 m. For this reason model I does not cover the full domain of the experimental flume, but it is started at station WG4 in a depth of 0.25 m. Model II, on the other hand, incorporates Padé [4,4] dispersion characteristics, which are accurate for \( h/L_0 \) as high as 1.0. Hence this model is started at WG1 at a depth of 0.47 m. In both cases the following procedure is used to obtain the incoming wave conditions: First, the measured surface elevation at WG4 (model I) and WG1 (model II) is analysed by FFT. Second, a bandpass filter is applied to remove the energy on frequencies lower than \( f=0.4 \) Hz, and higher than \( f=3.0 \) Hz. Third, the remaining energy is synthesized back into a flux or a velocity boundary condition by the use of a second order pertubation theory corresponding to each of the model equations.

Fig. 6a-c show the measured and computed spatial variations of the significant wave height, the skewness and the asymmetry. For both models the predicted wave heights are in fairly good agreement with the measurements. From Fig. 6b we notice that the skewness computed by model I is seen to be significantly underestimated everywhere in the flume, while model II picks up the correct variation of this quantity. The skewness is a measure of the nonlinearity in the wave profile and we notice that the results obtained in Fig. 6b confirm the analysis of the transfer function to second harmonics as shown in Fig. 1. Fig. 6c shows the spatial variation of the measured and computed asymmetry. This quantity, which measures the forward pitching of the wave profiles, is almost zero up to the break point beyond which the value decreases drastically. The results obtained by model II are seen to be in almost perfect agreement with the measurements. This result is remarkable and it confirms that the time-domain surf zone Boussinesq model can provide an accurate prediction of the statistics of the wave shape under the combined influence of triad interactions and wave breaking.

Fig 7 shows the measured and computed energy spectra at three locations (WG7, WG9, WG11). Model II is seen to be in very good agreement with the measurements, while model I tends to underestimate the high frequency tail of the spectrum. As mentioned above, the input spectrum used for model I, did not contain energy for frequencies higher than 3.0 Hz. Hence, whatever is present beyond this frequency limit is generated by triad interactions. It is therefore not surprising that the high frequency tail is underestimated by model I.

### 3.3 Irregular waves on a barred beach

This case is based on the Delta Flume '93 laboratory experiment (Arcilla et al., 1994) which was conducted on a barred beach (Fig. 8d) using a Pierson-Moskowitz spectrum with peak frequency of 0.122 Hz and a significant wave height of 0.58 m. The procedure described in section 3.2 to obtain the incoming wave conditions is also applied here. Fig. 8a-c shows the computed spatial variation of the significant wave height, skewness and asymmetry for the two Boussinesq models. Again the two models predict almost the same variation of the wave heights while significant differences appear in the measures of the nonlinearity: Model I clearly underpredicts the skewness (as well as the asymmetry) while model II is in very good agreement with the measurements.
Figure 6 Irregular wave on a plane beach. Spatial variation of (a) the significant wave height, (b) skewness, (c) asymmetry. (- - -) Model I; (----) Model II; (o) Experimental data by Cox et al. (1991).
Figure 7  Surface elevation spectra at three locations. (---) Model I; (-----) Model II; (.....) Experimental data by Cox et al. (1991).
Figure 8  Irregular waves on a barred beach. Spatial variation of (a) the significant wave height, (b) skewness, (c) asymmetry and (d) bathymetry. (- - -) Model I; (——) Model II; (o) Experimental data by Arcilla et al. (1994).
4. Waves in an opposing current

Boussinesq model II is Galilean invariant in contrast to model I, and it provides Padé [4,4] dispersion characteristics with the correct Doppler shift in connection with ambient uniform currents (see e.g. Madsen & Schäffer, 1998a,b). In this work we have applied model II to study the phenomenon of wave breaking in adverse currents. We have focused on the experiments by Sakai et al. (1981) who investigated breaker types and breaker depth indices for a variety of opposing currents, beach slopes and deep water wave stepnesses. The experiments were performed in a 24 m long, 0.36 m wide and 0.80 m deep wave flume as shown in Fig. 9. In this paper we present results for the following cases: A beach slope of \( s = 1/30 \), regular waves with wave period of \( T = 1.2 \) s, wave heights in the interval between 0.009 m and 0.180 m and the current discharges of \( q = 0, 0.0169 \) m\(^2\)/s and \( 0.0297 \) m\(^2\)/s.

Fig. 10 shows the calculated breaker depth index \( h_B/L_0 \) as a function of the deep water wave steepness \( H_0/L_0 \). Here \( h_B \) is the still water depth at the break point, \( H_0 \) is the wave height in deep water and \( L_0 \) is the deep water wave length. We notice that the breaker depth clearly increases for increasing currents and that the model results are in good agreement with the measurements.

Sakai et al. (1988) presented empirical formulas for breaking conditions of shoaling waves on opposing currents. These were based on the extensive flume experiments by Sakai et al. (1981, 1984) and they give the ratio of the breaker depth, \( R_h \), with and without current and likewise for the breaker height, \( R_H \). Both ratios are given as function of a new parameter \( \gamma \) which accounts for the combined effect of the discharge, the incident wave steepness and the slope of the bed

\[
\gamma = q^*s^{1/4}(H_0/L_0)^{-1}
\]

(6)

where

\[
q^* = qg^{-2}T^{-3}
\]

(7)

In Fig. 11 the calculated values of \( R_h \) and \( R_H \) are compared with the empirical formulas by Sakai et al. (1988). It is seen that for the relative breaker depth the

A 2D MODEL OF WAVES AND UNDERTOW IN THE SURF ZONE

Brian A. O'Connor¹, Shunqi Pan¹, John Nicholson¹, Neil MacDonald¹
and David A. Huntley²

Abstract
This paper describes the details of a 2D model of waves and undertow in the surf zone. The model uses an assumed shape of the undertow velocity profile together with the wave energy equation, surface and near-bed shear stresses and the mass flux balance due to the wave drift, surface roller and undertow velocity to compute the cross-shore wave development, surface set-up/set-down and the vertical distribution of the undertow velocity at cross-shore sections. The numerical model has been tested against both laboratory and field data and produces good agreements.

INTRODUCTION

The wave period-averaged horizontal cross-shore velocity in the surf zone (known as the undertow) is of great importance to hydrodynamic and morphodynamic studies in this area, as it controls the on-off shore sediment transport. The undertow structure is characterized by a two-dimensional circulation in the vertical plane, which has an offshore component near the bed. This flow, which is driven by the shear stresses induced by the waves and water surface slope (set-up/down), and also by the roller in the breaker zone, contributes to the flux balance in conjunction with the wave drift and the roller in the breaker zone. Aspects of the undertow flow have been studied by many researchers, such as Stive and Wind (1982) for radiation stress and surface elevation; Svendsen (1984a) for wave height predictions; Svendsen (1984b) for mass flux and the undertow pattern; Deigaard et al (1991), Fredsøe & Deigaard (1992), Deigaard (1993) for the shear stress and turbulence distributions in the surf zone and Cox and Kobayashi (1997) and Dean (1998) for the undertow velocity profile. However, difficulty has been experienced in computing wave heights, shear stresses, water surface slope and undertow velocity

¹ Department of Civil Engineering, The University of Liverpool, Liverpool, L69 3BX, UK
² Institute of Marine Studies, University of Plymouth, Plymouth, PL4 8AA, UK
together using a single simple model. It was also found that the determination of the water surface slope was particularly difficult due to its significant effect on the computation of the undertow velocity profile and the mass flux balance at each cross-shore section.

During project CSTAB (O'Connor, 1996), which was a Liverpool University co-ordinated multi-disciplinary research project involving 10 institutes under the European Community MAST 2 Programme for examining the coastal processes on the Flemish Banks near Middelkerke and the adjacent coastline at Nieuwpoort, a 2D hydrodynamic and sediment transport model was developed to compute the wave decay, undertow flow and sediment transport in the surf zone. The hydrodynamics in the model was based on the solution of the wave energy equation, the force balance due to the shear stresses and the mass flux balance in the water column with an assumed shape of the undertow velocity profile. This paper describes details of the hydrodynamic model as well as the results of model tests against laboratory data (Stive and Wind, 1982; Kraus and Smith, 1994; Dette et al, 1994) and field data (O'Connor, 1996).

**THEORY AND METHODOLOGY**

Figure 1 shows the hydrodynamics associated with a typical beach profile with incident wave characteristics ($H_0$ and $T$) and initial bed level information ($Z_b$), where $x =$

![Figure 1 Schematic diagram of cross-shore hydrodynamics](image)

... shorewards coordinate; $z =$ vertical coordinate and $\eta =$ water surface elevation relative to the mean water level. The computation of the wave height in the cross-shore direction can be carried out using a one-dimensional wave energy equation together with an energy dissipation equation. However, the computed wave height is not correct unless the correct water surface slope is used. Therefore, additional conditions are needed in computing the surface elevation. It was found that by assuming a particular undertow velocity distribution over the flow depth, use could be made of the relations between the undertow...
velocity profile, the surface and near-bed shear stresses and the mass flux balance through the water column due to the wave drift, surface roller and undertow velocity to solve the problem (see Figure 2). The following sections describe details of the new approach.

1) Wave energy equation
To compute the wave height distribution in the cross-shore direction (see Figure 1), the following one-dimensional wave energy equation (Frederksø & Deigaard, 1992) was used:

\[ \frac{dE_f}{dx} = -\dot{D} \]  

(1)

where \( E_f \) = wave energy flux; \( x \) = cross-shore distance and \( \dot{D} \) = energy dissipation rate. In the breaker zone, the energy dissipation rate is calculated based on the energy loss in a hydraulic bore, which can be expressed as follows:

\[ \dot{D} = \frac{1}{T} \rho g d \left( \frac{H^3}{4d^2 - H^2} \right) \]  

(2)

where \( d \) = water depth; \( \rho \) = water density; \( g \) = acceleration of the gravity; \( H \) = wave height; \( T \) = wave period. For non-breaking waves, the wave energy dissipation due to the bed shear was taken into consideration. However, the energy dissipation for non-breaking waves is rather small by comparison with the conditions produced by breaking waves.

2) Surface and near-bed shear stresses
The wave period-averaged shear stresses at the water surface and near the sea bed in the surf zone contain contributions from the wave motion, the surface roller and the water surface slope. In the present model, expressions for the surface and near-bed shear stresses given by Deigaard (1993) were used:

\[ \frac{\tau_s}{\rho} = \frac{g}{8C} \frac{\partial}{\partial x} \left[ H^2 \right] C - \frac{\partial}{\partial x} \left[ \frac{AC}{T} \right] \]  

(3)

\[ \frac{\tau_b}{\rho} = \frac{3g}{16} \frac{\partial}{\partial x} \left[ \frac{H^2}{T} \right] - \frac{\partial}{\partial x} \left[ \frac{AC}{T} \right] g ds \]  

(4)

where \( \tau_s \) = wave period-averaged shear stress at the water surface; \( \tau_b \) = wave period-averaged shear stress near the sea bed; \( s \) = wave period-averaged surface slope; \( A \) = roller area given by \( A = 0.9H^2 \).

3) Mass fluxes
In the surf zone, mass transport occurs due to the wave drift, streaming and the surface roller if the waves are broken. By neglecting the flux due to the streaming, the fluxes due to wave drift and the surface roller can be expressed respectively as follows (Frederksø & Deigaard, 1992):
4) The vertical distribution of undertow velocity

Theoretical and experimental results suggest that the undertow velocity profile in the vertical direction can be described by the following equation:

\[ u = a \left( \frac{z - z_0}{d} \right)^2 + b \ln \left( \frac{z}{z_0} \right) \]  

where \( u \) = horizontal undertow velocity; \( z \) = vertical coordinate measured upwards from the bed; \( z_0 \) = height where the velocity is zero; \( a \) and \( b \) are arbitrary constants. It can be seen that the undertow velocity consists of two parts: a parabolic distribution representing the upper part of the flow and a logarithmic distribution representing the lower part of the flow. The assumed undertow profile was also confirmed by recent laboratory work of Cox and Kobayashi (1997).

By relating the assumed undertow velocity profile (Eq. 7) gradient to the surface and near-bed shear stresses and balancing the mass flux due to undertow with the mass fluxes due to the wave drift and the surface roller, the following expressions can be obtained:

\[ \tau_s/\rho = v_s \frac{\partial u}{\partial z} \bigg|_{z=d} \quad \Rightarrow f_1(a,b,s) = 0 \]  

\[ \tau_b/\rho = v_b \frac{\partial u}{\partial z} \bigg|_{z=z_0} \quad \Rightarrow f_2(a,b,s) = 0 \]  

\[ Q_u = \int_{z_0}^{d} u \, dz = Q_d \cdot Q_r \quad \Rightarrow f_3(a,b,s) = 0 \]

Solving Equations 8, 9 and 10 gives the constants \( a \) and \( b \) and the water surface slope \( s \). The mean water depth determined by the surface slope is then returned to the wave energy equation (Eq. 1) to give a better estimate of the wave height. The whole process is then repeated until a converged water surface is obtained. The flow diagram of the model is shown in Figure 3.
NUMERICAL MODELLING

A finite difference method was used to solve wave energy equation (Eq. 1). The wave height was computed at each node point in the cross-shore direction, while the undertow velocity profile was computed mid-way between the node points (in the cell). Saturation wave breaking criteria were used in the computation without considering the wave breaking transition length. In order to increase the resolution of the undertow velocity near the bed, a non-uniform vertical grid system was adopted with a finer grid size near the bed and a coarser grid size near the water surface.

The eddy viscosities at the water surface and near the sea bed, which are needed in Eq. 8 and Eq. 9 were computed by a mixing length approach so that:

$$v = l_{mix} u_*$$

where, $l_{mix}$ = mixing length; $u_*$ = shear velocity ($u_* = \sqrt{\tau / \rho}$). The mixing length increases linearly from zero at the bed up a maximum value of 0.19$d$ at a particular level and remains constant at the higher level (Fredsoe & Deigaard, 1992).

RESULTS

The model was tested against prototype-scale laboratory and field data for the water surface set-up/down, wave height and undertow velocity. The test results involved laboratory data collected by Stive and Wind (1982), Kraus and Smith (1994) in Supertank and Dette et al (1992) in the Large Wave Flume at Hannover University, as well as field data measured at Nieuwpoort beach on Belgian coast (O'Connor, 1996). It should be noted that the laboratory test cases involved monochromatic waves with normal incidence.

1) Stive and Wind (1982) data
The experimental data used in the model were obtained from tests conducted in a wave flume at the Delft Hydraulics Laboratory. The wave flume was 55 m long, 1 m wide and 1 m deep. The bed slope was 1:40 and the water surface elevation was measured by conductivity-type wave gauges. The wave height was 0.159 m with 1.79 s period and the offshore water depth was 0.7 m.
Figure 4 shows a comparison of the computed and measured surface elevations with an exaggerated scale of the water depth for the purpose of clarity. The model results agree well with measurements and the breaking point was also predicted satisfactorily.

![Graph showing computed and measured water surface elevations](image)

**Figure 4** Computed and measured surface elevation for Stive and Wind (1982) data

2) **Supertank data (Kraus and Smith, 1994)**

The Supertank Data Collection Project (Kraus and Smith, 1994) was conducted in a large wave flume 104 m long, 3.7 m wide and 4.6 m deep at Oregon State University. Among 20 major data collection runs, ST_G0 was a case with monochromatic waves (normal incidence). The incident wave height was 0.8 m, the wave period was 3.0 s and offshore water depth was 4.0 m.

The numerical model was run with 146 grid points and a step size of 0.61 m (2 feet), which covered a total length of 91.38 m (300 feet). Five data sets measured at various stages of this run were used to validate the model, two of which are presented in this paper; the other data sets are in similar accuracy to those presented herein.

Figures 5 and 6 show comparisons between computed and measured wave heights and undertow velocities respectively for Case S0414a. In this case, a nearshore bar was in an early stage of its development. The results given in Figure 5 show that the model produces good agreement for the wave height; the breaking point is also well predicted. However, only few measurement points were available for use in the comparison of the undertow velocity. Figure 6 shows general agreement of the computed undertow with the
measurements, but discrepancies can be seen, particularly in the areas near the bar and break point.

**Figure 5** Computed and measured wave heights for Supertank data (Case S0414a)

**Figure 6** Computed and measured undertow velocities for Supertank data (Case S0414a)
Figures 7 and 8 show comparisons between the computed and measured wave heights and undertow velocities respectively for Case S0418a. In this case, the bar was further developed compared with Case S0414a. Again, the computed wave heights shown in Figure 7 are in good agreement with the measurements and the position of the break point.

**Figure 7** Computed and measured wave heights for Supertank data (Case S0418a)

**Figure 8** Computed and measured undertow velocities for Supertank data (Case S0418a)
was predicted well. Similarly to the previously mentioned case, the undertow velocity computed by the model shown in Figure 8 agrees reasonably with the experimental data. Discrepancies between the computed and measured undertow velocities for both cases landwards of the bar are believed to be due to a vortex generated by plunging breakers. The present model is not capable of predicting undertow velocities in such detail. In Figures 6 and 8, the computed undertow is found to be in the opposite direction from that of the measurements at the measuring points near the surface offshore of the bar. This may be due to these measuring points being partially exposed to the air within the wave period leading to spurious wave period-averaged velocity measurements.

3) Large Wave Flume data (Dette et al, 1992)
Prototype-scale experiments were carried out in the Large Wave Flume in Hannover University in 1990 (Test series I) and 1991 (Test series II) (Dette et al, 1992) in a flume 320 m long, 5 m wide and 7m deep. One case (16109001) in Test Series I (1990) with monochromatic waves was used in the model test. The incident wave height was 0.7 m with a 4.0 s wave period. The offshore water depth was 2.0 m. The computations were carried out with 1 m grid size.

Figure 9 shows comparisons of the computed and measured wave heights and surface elevations. Good agreement is obtained for the surface elevation and the wave break point is also well predicted. The computed wave heights also agree well with the measured results, except the wave height at the point nearest to the shore. The reason for this discrepancy is unclear, but it could be due to downwash effects. It may also be due to long wave effects as described in recent investigations by Kamphuis (1998).

![Figure 9](image-url)  
**Figure 9** Computed and measured wave heights and surface elevations for Large Wave Flume data (16109001)
4) Field data - Nieuwpoort Beach (O'Connor, 1996)
Field data had been obtained during the CSTAB Project which took place on Nieuwpoort Beach, off the Belgian coast (O'Connor, 1996). As the present model is limited to dealing with monochromatic waves, the root-mean square value of wave height was used as a first approximation to the random waves measured on site. The following wave parameters were used in the model test for the field data: root-mean square wave height was 0.7 m, mean wave period was 4.0 s and offshore wave depth was 4.33 m. The computation was carried out with 1.0 m grid size.

Figure 10 shows a comparison of computed and measured wave heights. The results once again demonstrate that the model predicts the wave height satisfactorily. Realistic undertow velocities have also been obtained, but are not shown here, see O'Connor (1996).

CONCLUSIONS
A 2D wave and current model has been developed to compute the wave decay, water surface slope and the undertow velocity distribution in the surf zone. Results produced by the model show good agreement as regards both wave height and water surface elevation against the laboratory and field data. The undertow flow structure was also reasonably reproduced by the model. This model provides a simple and practical method for engineers to predict the wave characteristics and hydrodynamics in the surf zone.

Field Measurements of Undertow on Longshore Bars

Yoshiaki KURIYAMA

Abstract
Field measurements of undertow over longshore bars were conducted at Hazaki Oceanographical Research Station (HORS) on the Kashima coast of Japan facing the Pacific Ocean. The field measurements, other field measurements and large-scale experiments were compared with one-dimensional models for undertow; one of them was developed in this study. The comparisons showed that the present model well predicted the undertow velocities over longshore bars in the field, while a previous model calibrated with small-scale experiment data underestimated the velocities.

1. Introduction
The prediction of undertow velocity over a longshore bar is required for predicting the deformation of the bar, which breaks waves and reduces the wave energy to protect the beach as a submerged breakwater. The undertow velocity prediction over a bar is also required for designing offshore nourishment, which has been recently developed in the United States, Australia and Europe (e.g., McLellan and Kraus, 1991); nourished sediment forms an artificial bar and the prediction of the bar movement is essential for the offshore nourishment project.

Although many models for undertow have been developed and verified with experiment data on planar beaches (e.g., Svendsen, 1984; Stive and Wind, 1986; Svendsen and Hansen, 1988; Okayasu et al. 1988; Deigaard et al., 1991; Dally and Brown, 1995), only a few models have been verified with data on barred beaches in experiments (Okayasu and Katayama, 1992; Rakha et al., 1996) and in the field (Smith et al., 1992; Haines and Sallenger, 1994). In this study, hence, field measurements of undertow were conducted over longshore bars at Hazaki Oceanographical Research Station (HORS) and compared with one-dimensional models for undertow, which predict the depth-averaged undertow velocity below the wave trough level; one of the models was developed in this

study. The models were also compared with other data obtained over longshore bars in large-scale experiments and in the field. The purposes of this paper are to describe the field measurements at HORS and to show the comparisons of undertow velocities measured and predicted.

2. Field Measurements

Field measurements were conducted from January 29 to February 3, 1997 at HORS, which is a field observation pier of 427 m in length on the Kashima coast of Japan facing the Pacific Ocean; the location of HORS is shown in Figure 1. Cross-shore and longshore current velocities were measured with electro-magnetic current meters for thirty minutes every two hours at a sampling frequency of 5 Hz, and water surface elevations were measured with ultrasonic wave gages. Wave breaking positions and types, and the locations of rip currents were visually observed several times a day, and the beach profile along HORS has been measured daily every 5 m.

The locations of the measurement points are shown in Figure 2 with the beach profiles on January 31 and February 1; the reference level is the Hasaki datum level, which is equal to the low water level, and the tidal rage is 1.4 m. Seaward bar migration occurred on January 31, and the bar crest moved seaward about 50 m. Except for the bar migration, no significant beach profile changes occurred during the measurements. The measurement point where the seaward distance is 230 m (referred to as P230m) was located shoreward of the bar crest, while the measurement point of P290m was located seaward of the bar crest. The measurement point of P260m was located just seaward of the bar crest before the bar migration and shoreward of the bar crest after the bar migration.
The seaward bar migration on January 31 damaged the supporting systems of the current meters at all measurement points, and current velocities were not measured temporarily. At P260m, two current meters were installed on January 29 at D.L. -0.87 m and D.L. -1.37 m, and were reinstalled on February 1 after the damage at D.L. -1.09 m and D.L. -1.59 m. At P230m, one current meter was installed at D.L. -1.99 m and reinstalled at D.L. -1.90 m. Although at P290m, a current meter was installed at D.L. -1.72 m, the supporting system of the current meter was completely destroyed at 7 a.m. on January 31, and then current velocities were not measured any more.

Figure 3 shows the time series of significant wave height $H_{1/3}$, significant wave period $T_{1/3}$ and undertow velocity $V$ measured. The significant wave heights at the tip of HORS, where the water depth was approximately 6m, increased from 11 p.m. on January 30, reached about 2.6m at 8 a.m. on January 31, and then gradually decreased. Undertow velocities increased as the wave heights increased, and from February 1 fluctuated regardless of the wave height changes.

Nearshore currents during the measurements are considered to be uniform alongshore owing to two reasons mentioned below. First, in the visual observations conducted several times a day during the measurements, no rip currents were observed, and the breaker lines were linear alongshore. Second, the low-frequency components of cross-shore current velocities $v_{med} (<0.04 \text{ Hz})$ were not related to the undertow velocities as shown in Figure...
4; the low-frequency components were relatively constant although the undertow velocities significantly changed. Some field measurements showed that rip currents were intermittent events (Wright and Short, 1983; Short, 1985, Smith and Largier, 1995), and hence the low-frequency component of cross-shore current in or near a rip current is expected to be large. The constant low-frequency components of the cross-shore currents in Figure 4 suggest that the possibility of rip current during the measurements is low.

3. Numerical Model

The one-dimensional model of undertow developed here consists of a wave transformation model and an undertow model, and adopts a wave-by-wave approach, in which wave heights and undertow velocities are calculated for individual waves. The time-averaged undertow velocity for an irregular wave group is estimated with averaging the undertow velocities of individual waves weighted according to the wave periods.

3-1 Wave transformation model

The wave transformation model is based on the model developed by Kuriyama (1996). The shoaling of a wave is estimated with a shoaling coefficient proposed by Shuto (1974) with the consideration of wave nonlinearity.

The criterion on wave breaking is based on a formula proposed by Seyama and Kimura (1988). Because Seyama and Kimura (1988) proposed the formula on the basis of experimental data, Kuriyama (1996) introduced a dimensionless coefficient \( C_{br} \) to adjust the formula to field data. The criterion is expressed by the following equation with the wave height-water depth ratio at wave breaking \( \frac{H_b}{h_b} \), wavelength in deep water \( L_0 \), and beach slope \( \tan \beta \), which is defined here as the average slope in the area from 15 m shoreward of the definition point to 15 m seaward of the point.

\[
\frac{H_b}{h_b} = C_{br} \left[ 0.16 \frac{L_0}{h_b} \left[ 1 - \exp \left( -0.8 \pi \frac{h_b}{L_0} (1 + 15 \tan^{4/3} \beta) \right) \right] - 0.96 \tan \beta + 0.2 \right]. \tag{1}
\]

Energy dissipation of a wave in the surf zone is estimated with a periodic bore model used by Thornton and Guza (1983); the model is expressed by

\[
\frac{\partial E_w C_g}{\partial y} = \frac{1}{4} \rho g \frac{1}{T} \frac{(BH)^3}{h}, \tag{2}
\]

where \( E_w \) is the energy of wave motion, \( C_g \) is the group velocity, \( \rho \) is the sea water density, \( T \) is the wave period, \( H \) is the wave height, \( h \) is the water depth, and \( B \) is a dimensionless coefficient determining the amount of energy dissipation. Kuriyama and Ozaki (1996) investigated the coefficient \( B \) with the experiment data of Seyama and Kimura (1988), and
proposed the following equation:

\[ B = C_B \left\{ 1.6 - 0.12 \ln\left( H_0 / L_0 \right) + 0.28 \ln(\tan \beta) \right\}, \]  

(3)

where \( H_0 \) is the wave height in deep water, and \( C_B \) is a nondimensional coefficient introduced with the consideration of scale effect.

The wave height-water depth ratio at wave reforming \( H/L \) is set to be 0.35 based on field data obtained by Kuriyama and Ozaki (1996).

When a significant wave height and a period are given at an offshore boundary, a time series of water surface elevation for ten minutes having the JONSWAP type spectrum at the offshore boundary is numerically simulated with the given wave height and period. Then, with the zero-down crossing method, the time series is divided into individual waves, which are used in the calculation.

The incident directions of individual waves at the offshore boundary are determined with the given principal wave direction, the directional spreading function of Mitsuyasu-type and the spreading parameter estimated with the method of Goda and Suzuki (1975). When the spreading parameter exceeds 100, the individual waves are treated as unidirectional waves.

The root-mean-square wave height \( H_{rms} \) and the wave height \( H_{m0} \), which are defined with the root-mean-square of water surface elevation \( \eta_{rms} \) by

\[ H_{rms} = 2\sqrt{2} \eta_{rms}, \]  

(4)

\[ H_{m0} = 4.004 \eta_{rms}, \]  

(5)

are not directly estimated in the wave-by-wave approach. The values of \( H_{rms} \) and \( H_{m0} \), thus, are obtained with the relationship between \( H_{rms}/\eta_{rms} \) and a dimensionless parameter \( \Pi_{1/3} \), which has been propose by Goda (1983) for expressing wave nonlinearity. The parameter \( \Pi_{1/3} \) is expressed by Eq.(6), and the relationship between \( H_{rms}/\eta_{rms} \) and \( \Pi_{1/3} \), which has been obtained by Kuriyama (1996), is expressed by Eq.(7).

\[ \Pi_{1/3} = H_{1/3} / L_{1/3} \coth^{3} (2\pi h / L_{1/3}). \]  

(6)

\[ H_{1/3} / \eta_{rms} = 0.349 \ln \Pi_{1/3} + 4.648, \quad \Pi_{1/3} \geq 0.1, \]

\[ H_{1/3} / \eta_{rms} = 3.8, \quad \Pi_{1/3} < 0.1. \]  

(7)

In all calculations in this study, to minimize the error in the prediction of undertow velocity caused by the error in the prediction of wave height, coefficients \( C_L \) and \( C_B \) in Eqs. (1) and (3) were determined so that the predicted significant wave heights fit the measured values.
3-2 Undertow model

Undertow velocity of an individual wave $V_{ind}$ is estimated with the mass flux due to wave motion $Q_w$ and that due to surface roller $Q_r$.

$$V_{ind} = \frac{(Q_w + Q_r)}{d_{tr}}$$  

where $d_{tr}$ is the distance between the wave trough level and the bottom, and is obtained as $d_{tr} = h - H/2$.

The mass flux due to wave motion $Q_w$ is calculated with the wave celerity $C$, the water depth $h$, and the root-mean-square of water surface elevation of an individual wave $\xi_{rms}$ by the following equation proposed by Svendsen (1984).

$$Q_w = \left(\frac{C}{h}\right) \xi_{rms}.$$  

The value of $\xi_{rms}$ is estimated with the consideration of wave nonlinearity. With the parameter $\Pi$ expressing nonlinearity of an individual wave and data shown by Goda (1983), the relationship between $\xi_{rms}$ and $H$ was obtained; the parameter $\Pi$ and the relationship obtained are expresses by

$$\Pi = \frac{H}{L} \coth^3\left(\frac{2\pi h}{L}\right),$$

$$\xi_{rms} = 1/8H^2, \quad \Pi < 0.15,$$

$$\xi_{rms} = (1.668 \log \Pi + 4.204)^{-2}H^2, \quad 0.15 \leq \Pi < 3,$$

$$\xi_{rms} = 1/25H^2, \quad \Pi \geq 3.$$  

In the estimation of $Q_r$, the vertical distribution of the time-averaged velocity shown in the middle of Figure 5 is assumed. In previously proposed models (e.g., Svendsen, 1984), the vertical distribution shown in the left of Figure 5 is assumed; the time-average velocity in the roller is equal to $C$. Although just behind the front of the roller, the cross-shore velocity near the wave trough level sharply changes from shoreward velocity equal to $C$ to

![Figure 5](image-url)
seaward undertow velocity, the cross-shore velocity in the middle of the roller is considered to change gradually from the top to the wave trough level. Hence, the vertical distribution shown in the middle of Figure 5 is assumed in the present model, and accordingly the mass flux due to the roller is obtained from

$$Q_r = A_r C / (2L),$$

where $A_r$ is the area of the roller.

The area of the surface roller is estimated on the basis of two assumptions mentioned below.

1. The area of the surface roller fully developed is proportional to $H^2$.
2. Up to the point where the roller is fully developed, the roller develops without energy dissipation.

When the values of $A_{r1}$ and $A_{r2}$ are defined to be the roller areas obtained on the basis of the assumptions No.1 and No.2, respectively, the smaller value between $A_{r1}$ and $A_{r2}$ is assumed to be the area of the surface roller.

Even in the developing roller, some energy is dissipated. However, the amount of energy dissipation in the developing roller is considered to be smaller than that in the developed roller because turbulence in the developing roller is not fully developed. The amount of energy dissipation in the developing roller, hence, is assumed to be zero.

The area $A_{r1}$ is estimated with a dimensionless coefficient $C_A$ from

$$A_{r1} = C_A H^2.$$  

The area $A_{r2}$ is obtained from the following energy balance equation as Okayasu et al. (1990) and Dally and Brown (1995). In Eq.(14), however, the rate of energy dissipation is set to be zero.

$$\frac{\partial (E_w C_g)}{\partial y} + \frac{\partial (E_r C)}{\partial y} = 0,$$

$$E_r = \frac{1}{8} \rho c^2 \frac{A_{r2}}{L},$$

where $E_r$ is the energy of the roller having the triangle-shaped distribution of the time-averaged velocity above the wave trough level.

4. Calibration

In the present model, $C_A$ in Eq.(13) is a key coefficient for estimating the area of the surface roller. Hence, the model was calibrated with the field data of fourteen cases.
obtained at HORS from 11 p.m. on January 30 to 10 a.m. on February 2 in 1997, when the wave heights were large.

The offshore boundary was set at P600m. The beach profiles measured every day were used for those shoreward of the tip of HORS, and the beach profile surveyed on January 16, 1997 shown in Figure 6 was used for that seaward of the tip of HORS; according to Kuriyama (1996), the amount of beach profile changes seaward of the tip of HORS is considered to be small.

The wave heights at the offshore boundary were estimated from the wave data obtained at a water depth of about 23m offshore of Kashima Port; the location of the wave gage is shown in Figure 1. The wave directions at the boundary were calculated with the Snell’s law from the principal wave directions at P260m.

The value of $C_A$ optimal for all cases was 7. The value of $C_A$ optimal in each case, on the other hand, was related to the surf similarity parameter at the wave breaking position $\xi_b$. The parameter $\xi_b$ is estimated by

$$\xi_b = \tan \beta / (H_{1/3b} / L_{1/3o})^{1/2},$$

(15)

where $H_{1/3b}$ is the significant wave height at wave breaking position and $L_{1/3o}$ is the offshore wavelength corresponding to the significant wave period. The value of $H_{1/3b}$ was defined to be the maximum of the significant wave heights over a longshore bar, and was obtained from the calculation result of wave transformation. The beach slope used in Eq.(15) was the value at the point where $H_{1/3b}$ was defined.

Figure 7 shows the relationship between $C_A$ optimal in each case and $\xi_b$. There is a positive correlation between them as Deigaard et al. (1991) and Dibajnia et al. (1994) reported; the correlation coefficient is 0.61. The value of $C_A$ increased as $\xi_b$ increased, that is, the coefficient increased as the ratio of the plunging breaker increased.
The relationship between $C_A$ and $\xi_b$ obtained with the least square method is given by

$$C_A = 17.0 \log \xi_b + 24.7.$$  \hspace{1cm} (16)

5. Comparisons of Models with Measurements

Undertow velocities predicted with $C_A$ give by Eq. (16) and with $C_A = 7$ were compared with the values measured in the field. Because $\xi_b$ in the measurements ranged from 0.3 to 0.5, the values of $C_A$ larger than 12 and those smaller than 4 were set to be 12 and 4, respectively. The values predicted with a model that has been proposed by Stive and De Vriend (1994) and calibrated by Reneirs and Battjes (1997) were also compared with the measurements; the model will be referred to as the previous model.

Figure 8 shows comparisons for four cases of the fourteen cases used in the calibration. The significant wave heights, periods, principal wave directions $\theta$, water depths and mean water levels $\bar{h}$ at the offshore boundary, and $\xi_b$ in the four cases are listed in Table 1; the values of $\xi_b$ at the offshore boundary exceeded 100. As shown in Figure 8, the previous model, which has been calibrated with experiment data, underestimated the undertow velocities. Both models with $C_A$ agreed with the measurements, while the performance of the model with $C_A$ give by Eq. (16) was better than that of the model with the constant $C_A$.

The root-mean-square errors defined by

$$\varepsilon = \left( \frac{\sum (V_{\text{meas}} - V_{\text{pred}})^2}{\sum (V_{\text{meas}})^2} \right)^{1/2},$$  \hspace{1cm} (17)

where $V_{\text{meas}}$ and $V_{\text{pred}}$ are the undertow velocities measured and predicted, for the fourteen cases used in the calibration were calculated for the three models. The values of $\varepsilon$ for the previous model and the present models with $C_A = 7$ and $C_A$ give by Eq. (16) were 52%, 41% and 35%.

The models with $C_A$ give by Eq. (16) and with $C_A = 7$, and the previous model were also compared with the field measurement of DELILAH (Smith et al., 1992) and the large-scale experiments of Delta Flume '93 (Rakha et al., 1996). The data on October 19, 1990 in DELILAH and of the cases 1-b and 1-c in Delta Flume '93 were used for the comparisons. The wave heights, periods, principal wave directions and water depths at the offshore boundaries are listed in Table 2, where $T_p$ is the wave period at the spectral peak. The value of $s_{\text{max}}$ exceeded 100 on October 19 in DELILAH.

Figure 9 shows a comparison of the models and the measurement DELILAH. Although the previous model underestimated the velocities, both of the models with $C_A$

Figure 10  Comparisons of models with Delta Flume '93 experiments.

agreed with field data. Comparisons between the models and the measurements in Delta Flume '93 are shown in Figure 10. The previous model agreed with the measurements, while both models with $C_d$ overestimated the undertow velocities. However, the performance of the model with $C_d$ given by Eq.(16) was better than that of the model with the constant $C_d$.

6. Discussion

In the calibration of the present model of undertow, the time-averaged cross-shore
velocity was assumed to be vertically uniform below the wave trough level, and the undertow velocities measured with one current meter at P230m and those at P290m were used. As shown in Figures 3 and 8, differences of the undertow velocities measured with two current meters at P260m were small, and this suggests that the assumption is appropriate.

Through the comparisons between the models and the measurements, it is concluded that for predicting undertow velocities over a longshore bar in the field where water depth ranges from 1 m to 3 m, the model with $C_A$ given by Eq.(16) was better than that with $C_A=1$. The previous model, on the other hand, sometimes underestimated the undertow velocities in the field. Figure 11 shows a comparison between the undertow velocities measured in case 5 at HORS and those predicted with the present model having $C_A$ given by Eq.(16) and with a modified previous model that assumes no energy dissipation. The previous model with no energy dissipation still underestimated the undertow velocities, and this result seems to suggest that the assumption of the rectangular-shaped distribution of time-averaged velocity above the wave trough level, shown in the left of Figure 5, is inappropriate. The previous model, however, has good agreements against experiment data (e.g., Dally and Brown, 1995). The discrepancy seems to be attributed to scale effect; size of vortex and the development of the surface roller in the field are considered to be different from those in small-scale experiments. For developing a model applicable to a wide range of conditions, from a small-scale experiment to the field, further improvement of the models and calibrations with a wide range of data would be required.
7. Conclusion

Field measurements of undertow were conducted over longshore bars at Hazaki Oceanographical Research Station (HORS), and the field data were used for the calibration of the one-dimensional model developed in this study. The calibration showed that the parameter \( C_A \), which is the ratio of the area of the surface roller fully developed to the square of the wave height, had a positive correlation with the surf similarity parameter at the wave breaking position; the correlation is expressed by Eq.(16).

The field measurements, other field measurements and large-scale experiments were compared with one-dimensional models for undertow. The comparisons showed that the present model with \( C_A \) given by Eq.(16) well predicted the undertow velocities over the longshore bars, while a previous model calibrated with small-scale experiment data underestimated the velocities.

Application of an Undertow Model to Irregular Waves on Barred Beaches

Douglas L. Kennedy¹, Daniel T. Cox² and Nobuhisa Kobayashi³

ABSTRACT: An undertow model calibrated for regular waves on plane beaches is applied to predict the irregular wave induced undertow for both plane and barred beaches and for both laboratory and field data sets. The model combines a logarithmic profile in the bottom boundary layer with a conventional parabolic profile in the interior. The height and period of the irregular waves are represented by the local root-mean-square wave height and spectral peak period, and the measured mean volume flux below trough level is used as input to the model. The model is capable of predicting the undertow profiles both inside and outside the surf zone, provided that the empirical coefficient associated with the mean bottom shear stress is adjusted at each measuring line. The model appears to give reasonable predictions of the bottom boundary layer thickness and shear velocity, although these predictions could not be verified due to a lack of data. To develop a predictive undertow model, a simple relationship with an adjustable coefficient is applied to predict the measured volume flux below trough level using the local wave height and water depth. The calibration coefficients involved in the predictive model are not universal among the lab and field conditions possibly due to the effects of wave directionality and longshore currents in the field measurements which are neglected in this paper.

INTRODUCTION

Detailed sediment transport models require accurate prediction of the cross-shore currents or undertow. Most undertow models are based on the time-averaged, cross-shore momentum equation and are verified primarily with laboratory measurements of the undertow induced by regular waves breaking on smooth, plane slopes. Cox and Kobayashi (1996) showed the difficulties inherent in standard undertow models, including the difficulties in obtaining reliable estimates of all the terms in the time-averaged, cross-shore momentum equation. Furthermore, some of these models give no estimate of the undertow in the bottom boundary layer or the mean bottom shear stress. Recently, Cox

and Kobayashi (1997) developed a new undertow model without relying on the time-averaged momentum equation. They calibrated and verified the model using laboratory data of regular waves breaking on rough and smooth plane slopes. The model was found to give accurate predictions of the undertow profiles inside and outside the surf zone, provided that the empirical coefficient associated with the mean bottom shear stress was calibrated at each measuring line.

This paper extends their work by applying the model to predict undertow induced by irregular waves breaking over plane and barred beaches using both laboratory and field data. Additionally, this paper shows how the mean volume flux below trough level, which is an input to the model, may be predicted from the local root-mean-square wave height and water depth. This paper is organized as follows. The model is briefly summarized, and the data sets used for comparison are discussed. Comparisons are then presented for undertow profiles and the mean volume flux below trough level along with a discussion of the calibration coefficients and model sensitivity. The performance of the model is summarized at the end with a discussion of the implications of the coefficients.

UNDERTOW MODEL

The undertow model was presented in detail in Cox and Kobayashi (1997) and is summarized herein to facilitate the comprehension of the subsequent comparisons. The model combines a conventional parabolic profile in the interior with a logarithmic profile in the bottom boundary layer. The undertow \( u \) from the bottom to trough level is expressed as

\[
\frac{u}{\kappa} = \ln \left( \frac{z_b}{z_0} \right) \quad \text{for} \quad z_0 \leq z_b \leq \delta
\]

for smooth slopes typical of laboratory experiments, the roughness height is specified as \( z_0 = \nu / (9 \sqrt{\nu}) \) based on unidirectional flow where \( \nu \) is the kinematic viscosity.

For rough slopes in the absence of bed forms, \( z_0 = 2 d_{50} / 30 \) based on the analysis of regular waves breaking on a plane, rough slope where \( d_{50} \) is the median grain diameter. Estimates of \( z_0 \) for the field data are more difficult due to the presence of ripples and megaripples and are explained later.

An expression for the mean shear velocity \( \bar{u} \) in (1) is developed using the quadratic friction equation for the temporal variation of the bottom shear stress \( \tau_b \) given by

\[
\tau_b = \frac{1}{2} \rho f_b |u_b| u_b
\]

where \( \rho \) = fluid density; \( f_b \) = constant bottom friction factor; and \( u_b \) = instantaneous horizontal velocity at the bottom in the absence of the boundary layer. For normally
incident regular waves, \( u_b \) may be expressed as a sum of the sinusoidal wave component and the mean component \( \bar{u}_b \) and is given as

\[
u_b = U_b \cos(kx - \omega t) + \bar{u}_b \tag{4}\]

where \( k = \) local wave number; \( x = \) horizontal coordinate, positive onshore; \( \omega = \) angular wave frequency; and \( t = \) time. The amplitude \( U_b \) of the wave component in (4) is based on linear wave theory and is given as (e.g., Jonsson, 1966)

\[
U_b = \frac{H \omega}{2 \sinh(k \bar{h})} \tag{5}
\]

where \( H = \) local wave height, and \( \bar{h} = \) local water depth including the setup. Substituting (4) into (3) and taking the time-average with the assumption of a small current \((\bar{u}_b/U_b)^2 << 1\), the mean bottom shear stress \( \tau_b \) may be given as

\[
\tau_b \approx \frac{2}{\pi} \rho f_b U_b \bar{u}_b \tag{6}
\]

Defining the mean shear velocity by \( \frac{\bar{u}_b}{\bar{u}_t} = \bar{u}_b / \rho \) together with (6) yields

\[
\bar{u}_t = (C_\ast f_b U_b |\bar{u}_b|)^{1/2} \frac{\bar{u}_b}{|\bar{u}_b|} \tag{7}
\]

in which \( C_\ast = \) empirical coefficient calibrated later. It is noted that \( C_\ast \approx 2/\pi \) if (3) and linear wave theory are accurate enough to estimate the relatively small value of \( \bar{u}_t \), and it is further noted that the time-averaged bottom boundary layer is much less understood than the oscillatory bottom boundary layer.

The bottom friction factor \( f_b \) in (7) may be estimated for rough slopes as (Jonsson, 1966)

\[
\frac{1}{4\sqrt{f_b}} + \log \frac{1}{4\sqrt{f_b}} = \log \left( \frac{A_b}{k_s} \right) - 0.08 \tag{8}
\]

and for smooth slopes as (Kamphuis, 1975)

\[
\frac{1}{8.1\sqrt{f_b}} + \log \frac{1}{\sqrt{f_b}} = \log \sqrt{Re} - 0.135 \tag{9}
\]

where \( A_b = \) excursion amplitude given by \( A_b = U_b / \omega \); \( k_s = \) equivalent roughness taken as \( k_s = 30 z_0 \); and \( Re = \) Reynolds number defined as \( Re = U_b A_b / \nu \).

Assuming that the thickness of the undertow boundary layer is approximately equal to the thickness of the wave boundary layer, the boundary layer thickness \( \delta \) in (1) and (2) may be approximated by (Grant and Madsen, 1979)

\[
\delta = C_\delta \frac{\kappa (u_s)_{\text{max}}}{\omega} \tag{10}
\]

where \((u_s)_{\text{max}} = \) maximum shear velocity over the wave period; and \( C_\delta = \) empirical constant in the range \( 1 \leq C_\delta \leq 2 \) and is taken as \( C_\delta = 1.5 \) in this paper because the predicted results have been found to be insensitive to \( C_\delta \) in this range. The maximum shear velocity \((u_s)_{\text{max}} \) in (10) is estimated by taking the maximum of (3) using (4)
and employing the small current assumption used to derive (7). Substitution of this expression into (10) yields

\[ \delta = C_\delta \left( \frac{\kappa}{\omega} \right) \left\{ \frac{1}{2} f_b U_b \left( U_b + 2|\bar{u}_b| \right) \right\}^{1/2} \]  

(11)

The coefficient \( \alpha \) in (2) can be obtained by matching (1) and (2) at \( z = \delta \) which yields

\[ \alpha = \frac{1}{\delta^2} \left[ \frac{\bar{u}_+}{\kappa} \ln \left( \frac{\delta}{z_0} \right) - \bar{u}_b \right] \]  

(12)

To close the problem, the mean volume flux below trough level, \( Q_t \), is specified and is estimated from the measured undertow profile in this paper. The prediction of \( Q_t \) will be addressed separately at the end of this section. The volume flux is defined as

\[ Q_t = \int_{z_b}^{d_t} \bar{u} \, dz \]  

(13)

where \( Q_t \) is negative for the undertow \( \bar{u} \). Substituting (1) and (2) into (13) and solving for \( \bar{u}_b \) gives

\[ \bar{u}_b = \frac{1}{d_t} \left[ Q_t + \frac{\bar{u}_+}{\kappa} \delta - \frac{\alpha}{3} \left( d_t^3 + 2\delta^3 \right) \right] \]  

(14)

The solution of (1), (2), (7), (11), and (12) with (14) is termed Method 1.

In light of the uncertainty in estimating the relatively small \( \bar{u}_* \) using the time-averaging of the quadratic equation (3), a second method is proposed to estimate \( \bar{u}_* \) directly from \( \bar{u}_b \) without regard to the oscillatory wave velocity. Instead of (7), \( \bar{u}_* \) is assumed to be expressed as

\[ |\bar{u}_*| \bar{u}_* = \frac{1}{2} \bar{f} |\bar{u}_b| \bar{u}_b \]  

(15)

in which \( \bar{f} = \text{empirical friction factor for the undertow} \) assumed to be given by \( \bar{f} = C_f f_b \), where \( C_f \) is an empirical coefficient. It is noted that \( C_f = 1 \) if the friction factors \( \bar{f} \) and \( f_b \) for the undertow and wave induced velocity are the same. From (15), the mean shear velocity is given by

\[ \bar{u}_* = \sqrt{0.5C_f f_b \bar{u}_b} \]  

(16)

Since (16) does not require the small current assumption used in (7), \( (\tau_b)_{\text{max}} \) is derived from (3) without this assumption and is given as

\[ (\tau_b)_{\text{max}} = \rho [(u_*)_{\text{max}}]^2 = \frac{1}{2} \rho f_b (U_b + |\bar{u}_b|)^2 \]  

(17)

Substitution of (17) into (10) for the boundary layer thickness gives

\[ \delta = C_\delta \left( \frac{\kappa}{\omega} \right) \sqrt{\frac{f_b}{2} (U_b + |\bar{u}_b|)} \]  

(18)

In short, \( \bar{u}_* \) and \( \delta \) estimated by (7) and (11) in Method 1 are replaced by (16) and (18) in Method 2. Since \( C_\delta \) is fixed, each method has only one primary calibration coefficient: \( C_* \) for Method 1 and \( C_f \) for Method 2. These methods may not be satisfactory
physically, but they are necessary to estimate the mean shear velocity \( \bar{u} \), whose data appears to be limited, especially inside the surf zone.

The above undertow model developed originally for normally-incident regular waves may also be applied to normally-incident irregular waves by approximating the irregular waves by the equivalent regular waves based on the local root-mean-square wave height, \( H_{\text{rms}} \), and the spectral peak period, \( T_p \). The use of \( H_{\text{rms}} \) may be appropriate because the mean volume flux \( Q_t \) given by (13) is approximately proportional to the square of the local wave height as explained below. The choice of the spectral peak period is somewhat arbitrary, but this period is typically reported for irregular wave data. For field data, the cross-shore fluid motion under directional random waves may be approximated by that under normally-incident random waves if \( \theta_c^2 \ll 1 \) where \( \theta_c \) is the characteristic incident angle in radians. The assumption of \( \theta_c^2 \ll 1 \) is usually satisfied in the surf zone because of wave refraction. However, longshore currents may not be negligible even if \( \theta_c^2 \ll 1 \) and may affect the mean cross-shore bottom shear stress in view of the cross-shore sediment transport analysis using field data by Thornton et al. (1996). Consequently, the subsequent comparisons with field data will need to be interpreted bearing this limitation in mind.

The use of the measured volume flux \( Q_t \) below trough level implies that this undertow model predicts the undertow profile but cannot be used to predict the magnitude of the undertow. To address this shortcoming, an attempt is made to estimate \( Q_t \) from the local root-mean-square wave height, \( H_{\text{rms}} \), and local water depth, \( \bar{h} = (d + \bar{\eta}) \), where \( d \) = still water depth and \( \bar{\eta} \) = setup. The volume flux below trough level is approximated as

\[
Q_t \simeq \bar{U} d_t
\]

where \( \bar{U} = \) depth-averaged velocity estimated by

\[
\bar{U} \simeq C_u \sqrt{\frac{gh}{8}} \left( \frac{H_{\text{rms}}}{\bar{h}} \right)^2
\]

where \( g = \) gravitational acceleration, and \( C_u = \) empirical coefficient introduced herein to account for the roller effect. The roller effect is expected to increase the magnitude of \( \bar{U} \) inside the surf zone. Equation (20) with \( C_u = 1 \) can be derived from the time-averaged continuity equation together with the assumption of linear progressive long waves where \( H_{\text{rms}} \) is defined as \( H_{\text{rms}} = \sqrt{8\sigma} \) with \( \sigma = \) standard deviation of the free surface elevation. It is further noted that cross-shore variation in wave height and setup could be predicted using the time-averaged equations for momentum and energy.

**SUMMARY OF DATA SETS**

Table 1 summarizes the data sets used for comparison with the undertow model, indicating the literature cited, the data set name from each paper, and the abbreviation used in this paper. The data are comprised of both laboratory and field conditions, and the undertow is induced by irregular waves for all cases. The fifth through eighth columns indicate the quantities used to compute the surf similarity parameter given by

\[
\xi = \frac{\tan \alpha}{\sqrt{H_{\text{rms}}/L_p}}
\]
where $\alpha = $ local beach slope, and $L_p = $ local wavelength computed using linear wave theory with the peak period, $T_p$. For the first five cases, $\xi$ is estimated at the most seaward measuring line as shown in the subsequent figures. For the last two cases, $\xi$ is estimated at the fifth measuring line since the first four seaward measuring lines had a very gentle slope. The range of the surf similarity parameter for the seven cases listed in Table 1 is $0.22 < \xi < 0.44$, indicating spilling and plunging waves with little reflection of wind waves. It is noted that the definition of $H_{rms}$ for these data sets was not clearly stated in all cases. As a result, the values of $H_{rms}$ based on the standard deviation $\sigma$, the spectral method, and the zero-crossing method are assumed to be the same.

Note: P=Plane, B=Barred; S=Smooth, R=Rough

Cox and Kobayashi (1997) compared the undertow model to the measured undertow induced by regular waves on plane slopes in the laboratory. The first extension of this paper is to compare the model to laboratory undertow data for irregular waves on a plane slope (Sultan, 1995), and then for irregular waves on a triangular barred profile (Okayasu and Katayama, 1992). These laboratory tests were for normally incident irregular waves with no longshore current. The next extension is to compare the model to the field data of Smith et al. (1992) and Haines and Sallenger (1994). The field measurements were collected on a barred beach at the USACE Field Research Facility in Duck, North Carolina, under a fairly uniform bathymetry in the longshore direction (e.g., Smith et al., 1992). Although the longshore current was not reported in Smith et al. (1992), the peak incident wave angle measured counter-clockwise from shore normal was given as $\theta = -15$, -43, and +24 degrees at 8 m depth for SSP92-A, SSP92-B, and SSP92-C. Nevertheless, Smith et al. (1992) compared their undertow model for essentially normally-incident waves with these data sets apart from an empirical correction of $\cos \theta$ in (20) with $C_u = 2.4$.

Haines and Sallenger (1994) reported the magnitude and direction of the longshore current for HS94-A and HS94-B. For HS94-A, the magnitude of the longshore current was generally less than the cross-shore current, but the longshore current was not unidirectional. For HS94-B, the magnitude of the longshore current was approximately on
the same order as the cross-shore current and was unidirectional. Haines and Sallenger (1994) compared their undertow model for normally-incident waves with their data sets, excluding one data set with vigorous longshore currents. It is noted that none of the data sets mentioned above included detailed measurements of the undertow and shear stress in the bottom boundary layer.

UNDERTOW PROFILES

The undertow model is compared with the seven data sets listed in Table 1 using the measured volume flux below trough level to close the system of equations as described above. The volume flux is estimated by integrating a cubic spline fitted through the measured points. For both Method 1 and Method 2, the calibration coefficients are adjusted at each measuring line to give a best fit “by eye” to the data.

Table 2 lists the input parameters to the model at each measuring line for the data of Sultan (1995) where \( \eta_{tr} \) = negative trough elevation relative to the still water level which is used to calculate \( d_t = (d + \eta_{tr}) \). Since the trough level \( \eta_{tr} \) was not given in Sultan (1995), \( \eta_{tr} \) was taken as the elevation where the undertow changed sign from negative to positive below the still water level. This elevation corresponds roughly to \( 0.3H_{rms} \); and it is noted that the ratio of \( |\eta_{tr}/H| \approx 0.3 \) was found for the regular wave data of Cox and Kobayashi (1996), Nadaoka and Kondoh (1982), and Hansen and Svendsen (1984). Column 8 indicates the amplitude of the orbital velocity \( \bar{u}_b/U_b \) based on linear wave theory; and for the cases presented here, the small current assumption \( (\bar{u}_b/U_b)^2 < 1 \) used in (6) is reasonable. Column 9 gives the Reynolds number used to estimate the friction factor \( f_b \) in Column 10 using (9) for the smooth slope, which are in the range \( 0.8 \times 10^4 \leq Re \leq 4.1 \times 10^4 \) and \( 0.011 \leq f_b \leq 0.017 \).

Columns 11 and 12 give the calibration coefficients \( C_* \) for Method 1 and \( C_f \) for Method 2. \( C_* \) increases shoreward as was found in Cox and Kobayashi (1997) for the regular wave comparisons, but the variation in \( C_* \) from outside the surf zone to inside the surf zone is less pronounced for the irregular wave case. The magnitude of
$C_*$ is 0.1 which is much less than $(2/\pi) = 0.64$, indicating that (6) overpredicts the mean bottom shear stress as was found by Cox and Kobayashi (1997). $C_f$ generally decreases shoreward as was also noted in Cox and Kobayashi (1997); however, $C_f$ increases unexpectedly in the inner surf zone. Overall, the magnitude of $C_f$ is on the order of 1.0, indicating that $f \approx f_b$. Column 13 gives the values of $C_u$ in (20) which are discussed later in relation to the prediction of the volume flux below trough level.

Figure 1 compares the model predictions with the measurements of Sultan (1995). Trough level is indicated in the figure by the vertical extent of the model predictions. The horizontal extent from S1 to S12 is approximately 9 m. The figure indicates that the model predicts the measured undertow profile below trough level both outside and inside the surf zone for both methods with the coefficients adjusted at each measuring line. The boundary layer thickness is estimated by the model to be in the range $0.5 \leq \delta \leq 0.7$ cm, and the mean shear velocity is estimated to be in the range $-0.5 \leq \bar{u}_* \leq -0.2$ cm/s over the 12 measuring lines for Methods 1 and 2. These ranges indicate the difficulty in measuring the undertow and mean shear velocity in the bottom boundary layer in the laboratory. Figure 2 shows the model sensitivity to a 20% variation in $C_*$ in this figure, the adopted $C_*$ at each measuring line is shown by a solid line whereas $0.8 C_*$ and $1.2 C_*$ are shown by dashed and dash-dot lines, respectively. A similar variation in the undertow profiles is achieved for only a 5% variation in $C_f$, and the figure is not shown for brevity.

Figure 1: Model predictions for S95: Measured $\bar{u}$ (●); Predicted, Method 1 (----); and Predicted, Method 2 (-- --).

For the data of Okayasu and Katayama (1992), the local $H_{rms}$ is estimated by $H_s = \sqrt{2} H_{rms}$ where the significant wave height $H_s$ is taken from the significant crest and trough elevations, $(\eta_c)_s$ and $(\eta_t)_s$, reported in their paper. Figure 3 compares the model and data for both methods. In this figure, the horizontal extent from O1 to O6 is approximately 5 m, and the triangular bar consists of three linear segments. Figure 3 indicates that the model predicts the undertow profile over a barred bathymetry as well, apart from the scatter of data points at O6, provided that the coefficients are adjusted at each measuring line. For this case, the boundary thickness is estimated to be in the range $0.2 \leq \delta \leq 0.4$ cm, and the mean shear velocity is estimated to be in the range $-0.4 \leq \bar{u}_* \leq -0.05$ cm/s.
Figure 2: Model sensitivity for S95: Measured $\bar{u}$ (●); Predicted, Method 1 with adopted $C_\ast$ (——); Predicted, Method 1 with 0.8 $C_\ast$ (—•); and Predicted, Method 1 with 1.2 $C_\ast$ (—...).}

For comparisons with the data of Smith et al. (1992), the local $H_{rms}$ for each of the six measuring lines is obtained by a linear interpolation of the measured values in their paper. Although the local setup $\bar{h}$ was not measured, $\bar{h}$ was estimated in Smith et al. (1992), and the ratio of this estimated setup to the minimum local water depth was approximately 0.03 for the three cases. Therefore, $\bar{h}$ is neglected here, and the approximation $\bar{h} \approx \bar{d}$ is assumed for input in the undertow model. The trough level was also not reported, and the crude approximation of $r_j \approx 0.3 H_{rms}$ is used here. The relative roughness in (8) is found to be in the range $29 < \frac{\eta_{tr}}{\bar{h}} < 73$ for the three cases where the roughness height is assumed as $\nu_0 = 0.05 \text{ cm}$ and $k_s = 30 \nu_0 = 1.5 \text{ cm}$ for lack of data on bed forms. The Reynolds number is found to be in the range $2.1 \times 10^5 < Re < 7.8 \times 10^5$ for the field data. This range of relative roughness and Reynolds number indicates that the flow in the bottom boundary layer is rough turbulent even without the turbulence generated by wave breaking (Jonsson, 1966). The friction factor was found to be in the range $0.025 < f_b < 0.038$ which is larger than $f_b = 0.01$ specified in Smith et al. (1992) for their model comparisons. However, the use of a much smaller value for $\nu_0$ would reduce $f_b$. For example, $\nu_0 = 0.007 \text{ cm}$ would yield the range $0.012 < f_b < 0.016$.

For a given case, $C_\ast$ varies at each measuring line; but for a given measuring line, $C_\ast$ is fairly constant for the three cases. Compared to the laboratory cases with regular waves, there is less cross-shore variation in $C_\ast$ for a given case, although it is noted that the field measurements do not include the inner surf zone near the still water shoreline. The variation in $C_f$ at a given measuring line for the three cases is also small. The values of $C_\ast$ and $C_f$ for these field data are smaller than the corresponding values of $C_\ast$ and $C_f$ listed in Table 2 for the laboratory data of Sultan (1995). (Table 4 compares the average calibration coefficients for all cases listed in Table 1). The mean shear velocity $\bar{u}$ given by (7) and (16) depends on $C_\ast f_b$ and $C_f f_b$, respectively, instead of $f_b$ itself. The calibrated values of $C_\ast$ and $C_f$ depends on the adopted value of $\nu_0$ which affects $f_b$ somewhat, but the values of $C_\ast f_b$ and $C_f f_b$ remain approximately the same. In other words, the change of $\nu_0$ by a factor of 10 will change $f_b$, $C_\ast$, and $C_f$ by roughly a factor of 2.
Figure 3: Model predictions for OK92: Measured $\bar{u}$ (•); Predicted, Method 1 (—); and Predicted, Method 2 (— —).

Figure 4: Model predictions for SSP92-A: Measured $\bar{u}$ (•); Predicted, Method 1 with adopted $C_*$ ( ); and Predicted, Method 1 with $C_{*\text{ave}}$ ( — —).

Figure 4 compares the undertow model for Method 1 with the data of SSP92-A using $C_*$ calibrated at each measuring line and the average $C_*$ values for the three cases. The horizontal extent from A1 to A6 is approximately 100 m. Figure 4 indicates that the model predicts the undertow profile over a barred beach for field conditions, provided that the coefficients are adjusted at each measuring line. The values of $C_*$ are larger at A2 and A3 located immediately seaward and on the bar crest, respectively, whereas the values of $C_f$ do not change much across the barred beach. The agreement for Method 2 and for the two other cases SSP92-B and SSP92-C is similar, and the figures are not shown for brevity. For these field data, the boundary layer thickness is estimated to be in the range $4 \leq \delta \leq 11$ cm, and the mean shear velocity is estimated to be in the range $-2.1 \leq \bar{u}_s \leq -0.2$ cm/s. These values are much larger than the laboratory values estimated for S95 and OK92.

Similar to Smith et al. (1992), $\bar{u}$ and $\eta_{tr}$ were not given in the paper of Haines and Sallenger (1994), and the assumptions of $\bar{h} \simeq d$ and $\eta_{tr} \simeq 0.3 H_{rms}$ are made here as well. The roughness height is assumed as $\bar{z}_0 = 0.05$ cm, and the relative roughness is found to be in the range $88 \leq A_h/k_s \leq 180$. The Reynolds number is found to be in the
range $8 \times 10^5 \leq Re \leq 34 \times 10^6$, indicating rough turbulent flow in the bottom boundary layer (Jonsson, 1966). The cross-shore variations in $C_s$ and $C_f$ are small compared to the laboratory cases.

Figures 5 and 6 show the model agreement for HS94-A and HS94-B. The horizontal extent from A1 to A7 and from B1 to B8 is approximately 300 m. Substantial offshore migration of the bar occurred from October 11 (HS94-A) to October 12 (HS94-B) as explained in Haines and Sallenger (1994). The agreement is good for both methods and for both cases with the calibration coefficients adjusted at each measuring line. For these two cases, the boundary thickness is estimated to be in the range $11 \leq \delta \leq 17$ cm, and the mean shear velocity is estimated to be in the range $-1.5 \leq \overline{u_x} \leq -0.8$ cm/s. These ranges are similar to the field data of SSP92.

**VOLUME FLUX BELOW TROUGH LEVEL**

As an alternative to specifying the volume flux below trough level using the measurement, the local depth-averaged velocity $\overline{U}$ is estimated using (20) with the measured values of $H_{rms}$ and $\overline{h}$ at the same location. The predictability of the depth-averaged...
velocity is discussed in terms of the calibration coefficient $C_u$ which is obtained from (20) using the measured depth-averaged velocity given by $\bar{U} = (Q_t/d_{tr})$ together with the measured values of $H_{rms}$ and $h$. If the calibrated values of $C_u$ are fairly constant, (20) may be applied to predict $\bar{U}$. Furthermore, the calibrated values of $C_u$ can be used to assess the roller effect on $C_u$ since $C_u = 1$ assuming no roller effect.

The calibrated values of $C_u$ listed in Table 2 for S95 indicate that $C_u$ is on the order of 1 over most of the shoaling and surf zone. For S9 to S12 in the inner surf zone, $C_u$ is larger than 1, possibly due to the roller effect. The calibrated values of $C_u$ for OK92 are generally less than 1. It is possible that the value of $H_{rms}$ estimated from the significant crest and trough elevations reported by Okayasu and Katayama (1992) may not be very accurate. Noting that $\bar{U}$ is proportional to $H_{rms}^2$, this estimation error may have resulted in the unexpectedly small values of $C_u$ for OK92. On the other hand, the calibrated values of $C_u$ in for the field data of SSP92 are mostly on the order of unity and tend to be larger over the bar crest region and smaller in the bar trough region in view of the measuring line locations shown in Figure 4. The calibrated values of $C_u$ for HS94 are also on the order of unity for both cases, but $C_u$ tends to be smaller for HS94-A which had a smaller longshore current than HS94-B.

Table 3 summarizes the calibrated values of $C_u$. The value $\bar{C}_u$ indicated in the table is estimated for each data set by averaging the $C_u$ values over the measuring lines that have qualitatively similar locations in the cross-shore direction, namely outside the surf zone, the breaker zone, the bar-trough zone, and the inner surf zone. In general, Table 3 shows that $\bar{C}_u$ is closer to unity for the laboratory data sets of S95 and OK92 than for the field data sets of SSP92 and HS94. There appears to be no systematic variation of $\bar{C}_u$ in the cross-shore direction as may be expected from the effect of rollers associated with regular breaking waves. For the irregular wave data in the laboratory, the roller effect is not very pronounced; and $C_u = 1$ is a reasonable approximation. For the field data, $\bar{C}_u$ tends to be larger than unity, and the magnitude of the undertow velocities may have been modified by the wave directionality and alongshore variation of wave and current fields.

**CONCLUSIONS**

Existing undertow models based on a local balance of the horizontal momentum equa-
tion can predict the order of magnitude of the undertow if empirical parameters are calibrated for each data set. Moreover, the literature is divided among regular or irregular waves and laboratory or field conditions with each model typically calibrated for one of these condition only. Rarely is it shown whether the empirical input is universal. For example, Okayasu and Katayama (1992) used empirically adjusted representative wave heights to get reasonable agreement with a model which was calibrated in an earlier paper under similar laboratory conditions. Haines and Sallenger (1994) employed a vertically uniform eddy viscosity which varied at each measuring line, and they attempted to parameterize this variation using their field data only.

Table 4 summarizes the types of data sets considered in this paper and in Cox and Kobayashi (1997), listing the average calibration coefficients with the standard deviation given in parenthesis. These averages are crude in that they do not distinguish between breaking and nonbreaking waves, but they serve to indicate the variability of the coefficients for the different data sets. Table 4 indicates that $C_*$ and $C_f$ are similar for both regular and irregular waves in the laboratories. For all of the data sets, Method 2 using $C_f$ appears to be the most consistent in terms of the small standard deviation relative to the mean value. It was noted earlier in this paper and in Cox and Kobayashi (1997), however, that the predicted undertow is more sensitive to small changes in the calibration coefficient $C_f$ for Method 2 than $C_*$ for Method 1.

The consistency of the average values of $C_u$ between the two field data sets suggests that (20) with $C_u \approx 2$ might yield reasonable approximations of the depth-averaged undertow velocity $U$, but the standard deviation is 1.1 and fairly large. The values of $C_*$ and $C_f$ for the field data tend to be smaller than those for the laboratory data, but these values of $C_*$ and $C_f$ are affected somewhat by the adopted value of $z_0$ as well as by the presence of longshore currents. Furthermore, errors associated with use of the model where the volume flux and calibration coefficients are not known are approximately 100% or roughly a factor of 2.

Finally, the values of $C_*$ for all the data sets in Table 4 are definitely less than $C_*= (2/\pi) = 0.64$ based on (6). Consequently, (6) overpredicts the mean bottom
shear stress. The alternative equation (16) with \( \bar{f} = C_f f_b \) has been proposed by Cox and Kobayashi (1997) to mitigate the shortcomings of (6), but (16) is physically unsatisfactory because it neglects wave effects. Therefore, it may be concluded that the mean cross-shore bottom shear stress is poorly understood. The state of the art for the alongshore bottom shear stress in the surf zone is similar (e.g. Garcez Faria et al., 1998).

WAKE WASH OF HIGH-SPEED CRAFT IN COASTAL AREAS

Jens Kirkegaard1, Henrik Kofoed-Hansen1 and Berry Elfrink1

Abstract

In recent years fast ferries have been introduced on many ferry routes throughout the world. Particularly when operating in shallow waters and near the coast, the waves generated by these ferries give rise to conflicts with recreational use of beaches and coastal waters. Also the potential coastal erosion caused by a changed wave impact has been a matter of concern. The paper presents the results of studies carried out with the objective of providing an unbiased description of these wave phenomena, which has served as basis for a new legislation for regulation of fast ferry operation. The coastal erosion potential was studied and sediment transport simulations showed that the long-periodic ship-generated waves give rise to beach accretion and steepening of the cross-shore profile.

Introduction

It is known that the waves generated by high-speed craft (HSC) in shallow water are substantially different from the waves generated by conventional ships as a consequence of the higher speed and the size of these modern vessels. This results in different wave impact – also denoted wake wash – in coastal areas. It has been observed that HSC operating in the transcritical and supercritical speed range generate diverging waves in groups of both long-periodic and short-periodic waves. This paper primarily describes the long-periodic wave behaviour. Even though these waves are transient, they are similar to swell and thus may cause changes to beaches in areas not usually exposed to swell or severe local seas. Also the safety of nearshore recreational boaters may be reduced and

1 Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark, Fax: +45 45 76 25 67, e-mail: jkj@dhi.dk
the long waves may increase the risk for people bathing and fishing as the long-periodic waves reach the shore without warning.

Several HSC in the form of catamaran and monohull fast ferries have been introduced on ferry routes in Denmark. Due to the shallow waters conditions in Danish waters the wave effects along the coast were immediately recognized and received much attention. Similar experience has been found in a number of other countries, eg UK, Ireland, USA and New Zealand.

The paper present results and analysis of recent full-scale wake wash measurements from a few of these Danish ferry routes. The measurements have been supplemented by wave propagation modelling in order to develop methods to predict the areas of particular concern. These prediction methods are required in connection with planning of new ferry routes or alteration of present routes to obey new Danish regulation concerning fast ferry operation.

The results of the wake wash studies were included in a report by the Danish Maritime Authority (1997) together with other studies on the effect on the external environment, including noise, emissions, impact on birds and marine life and marine safety.

Wave Generation by High-Speed Craft

When a ship moves through the water, it makes waves and suffers wave resistance. Typically, an advancing ship generates a set of waves at both its bow and stern as a consequence of pressure gradients along the hull. For a ship moving steadily in water of uniform finite depth, the nature of the wash which it creates will closely depend upon two non-dimensionless parameters; the length-based Froude number, \( F'_n = \frac{V_s}{\sqrt{gL_w}} \), and the depth-based Froude number, \( F''_n = \frac{V_s}{\sqrt{gh}} \). Here, \( V_s \) is the ship speed, \( g \) is the acceleration due to gravity, \( L_w \) is a characteristic length of the ship and \( h \) denotes the water depth.

In the subcritical speed range (ie \( F''_n < 0.6-0.7 \)), the wave system consists of diverging and transverse waves in a restricted wedge-shaped Kelvin wake, where the cusp angle is about \( \pm 19.5^\circ \) and almost independent of the ship speed, see eg Kostyukov (1959) and Newman (1977). In this speed range, the wave period of the diverging waves is proportional to the ship speed (\( T \approx 0.27V_s \), \( V_s \) in knots). For depth-Froude numbers beyond 1 (supercritical speed range), the transverse waves disappear and the wave system is characterised by a Havelock-like wave pattern taken a convex form as illustrated in the aerial photograph shown in Figure 1. This is typically the case for HSC operating in coastal water. The divergent waves are now contained within an angle that depends on the speed of the ship. In the transcritical speed range (\( F''_n \approx 0.9-1.1 \)), transverse and divergent waves merge together into wave fronts nearly straight and perpendicular to the ship's course. High-amplitude waves are typically generated for speeds in this speed range. If also \( F'_n \approx 0.5 \), ie in the vicinity of the primary hump, where maximum wave resistance occurs, particularly high waves can be generated.
Figure 1. Aerial photograph of wave pattern generated at supercritical speed. The vessel speed is $V_s = 35$ knots and the water depth is $h = 13-14$ m. The Froude numbers are $F_{nh} \approx 1.5$ and $F_{nl} \approx 0.7$. The overall length of the catamaran is approximately 78 m.

Even though a considerable amount of theoretical and experimental research effort has been devoted to HSC operating within the transcritical and supercritical speed range, particularly in shallow water channels (e.g., Johnson, 1958), yet no simple methods exist for ship wave prediction similar to Sorensen and Weggel (1986), see also Weggel and Sorensen (1984). These are only applicable for subcritical ship speeds.

**Full-scale Measurements**

A number of comprehensive full-scale measurement programmes have recently been carried out at various locations in Denmark and abroad (e.g., Kalundborg Fjord, Lindholm Dyb, Tunø Harbour and Odden Ferry Terminal, Denmark, and in Derwent River and Norfolk Bay, Tasmania). One of the objectives was to evaluate the consequences of wake wash from high-speed ferries as well as for route planning in order to reduce environmental impacts. The measurement programmes covered various navigation conditions for the involved catamarans, which have a service speed of 35-45 knots. Also wake wash caused by conventional ferries having a service speed of about 17 knots was measured. The ship-generated waves were measured at various water depths (2 m to 25 m) and at various distances to the navigation track. A few results of the comprehensive measurement campaigns carried out in Kalundborg Fjord are presented and discussed in Kofoed-Hansen and Mikkelsen (1997), see also Kofoed-Hansen and Kirkegaard (1996) and Kirkegaard et al (1998).

**Wave generation**

The measurements show that a catamaran advancing with a supercritical speed generally generates a wave system characterised by groups of both short-periodic and long-periodic waves as illustrated in the time series of surface elevation shown in Figure 2a ($F_{nh} \approx 1.39$, $F_{nl} \approx 0.74$). It is seen that the long waves have periods in the range of 7-9 s and the short
waves 2-4 s. Figure 2b shows that in the subcritical speed range \((F_{nh} \approx 0.66, F_{nl} \approx 0.34)\), the wave period is approximately 5 s, which is in reasonable agreement with Kelvin’s classical theory. For a ship speed near the critical speed \((F_{nh} \approx 0.93, F_{nl} \approx 0.47)\), the generated long-periodic waves are high as expected. From Figure 2c, it is seen that the maximum wave height is approximately \(H_{max} \approx 1.3\) m.

In Figure 3, the relationship between the measured maximum wave height of the long-periodic wave component \((T > 5s)\) and the depth-Froude number is depicted. A realistic trend line is also indicated. All measured data have been adjusted so they correspond to a distance of approximately 700 m (~10 ship-lengths) from the navigation track using the trend line shown in Figure 4. Although the scatter of the data is relatively high, it is seen that the highest waves appear in the transcritical speed range. The critical Froude number is slightly smaller than the theoretical value of one, which is in agreement with experience from model tests and CFD calculations. For supercritical speeds, it is also seen that the wave height is less than in deep water (ie subcritical speed). The reason for this is a lower pressure due to an increased particle velocity between the ship hull and the seabed.

![Figure 2](image-url)

**Figure 2.** Time series of measured surface elevation generated by a HSC catamaran at Lindholm Dyb, Denmark. a) supercritical speed \((V_s = 36\) knots, \(h = 18\) m, \(F_{nh} = 1.39, F_{nl} = 0.74)\), b) subcritical speed \((V_s = 17\) knots, \(h = 18\) m, \(F_{nh} = 0.66, F_{nl} = 0.34)\), c) near-critical speed \((V_s = 24\) knots, \(h = 18\) m, \(F_{nh} = 0.93, F_{nl} = 0.47)\). The distance between the measurement buoy and the navigation track was approximately 300-400 m.
Figure 3. Maximum wave height of the long-periodic waves versus the depth-Froude number. The measured data (○○○) have been corrected to be valid in a distance of 700 m (~10 ship lengths) from the ship track. (—) indicates a trend line.

The influence of the distance from the navigation route on the maximum zero-crossing wave height, i.e., the wave decay due to diffraction, is illustrated in Figure 4. The figure shows the maximum wave height versus the perpendicular distance between the ship track and the Waverider buoy. The data are not affected by shoaling and refraction effects as the water depth is in the range of 10-30 m. It is seen that the wave decay is exponential, which is in agreement with Crapper (1984), page 125.

Figure 4. Maximum wave height of the long-periodic waves versus the distance from the ship track. The measured data (○○○) have been based on various field campaigns involving catamarans only. The trend line (—) is given by $H_{max} = 16r^{-0.55}$, where $r$ (in meters) denotes the distance from the track.
Usually ship-generated waves are assumed to be caused by the ship hull alone, and the wave formation from the propulsion system is neglected. Based on a number of recent model tests, however, Taatø et al (1998) concluded that the propulsion system on large HSC (water jets) may cause increased wave heights of 20-40 per cent compared to the bare hull.

Wave propagation and transformation
The wave height, and to some extent, the wave period change during the wave propagation due to diffraction of the short-crested waves as well as to nonlinear wave interactions and wave breaking. When the long-periodic transient waves reach shallow water, the nonlinear shoaling results in rapid growth of the waves which ultimately break, typically as plunging breaker, and may cause transient run-up on the beach.

The photographs shown in Figures 5 and 6 illustrate an example of an HSC-generated wave pattern under propagation towards the coast.

Figure 5. Photograph of wave pattern generated by a monohull fast ferry at Hundested, Denmark.

Figure 6. Photograph of a plunging breaker east to Gedser Harbour, Denmark. A monohull fast ferry generated the wash.
Figure 7 shows two time series of wake wash measured at 2-3 m water depth. The wave train shown on the left panel was caused by a passing HSC with its service speed, and the right panel shows the wake wash caused by the same HSC operated in the transcritical speed range. It clearly illustrates that very large transient waves may occur in shallow water without any warning and cause transient currents and run-up. The consequence of this type of wave impact is discussed in the next section.

Sediment Transport and Coastal Impact

As the waves approach the coastline, changes in wave shape, size and direction occur due to transformation mechanisms such as refraction, shoaling and breaking. Mass transport in the direction of wave propagation occurs due to the wave orbital motion and the surface rollers in the breaker zone. If the bed shear forces generated by the wave orbital motion exceed a critical value, transport of bed sediments is initiated.

**Long-shore sediment transport**

Oblique incident natural waves give rise to littoral currents in the surf zone driven by the radiation stress gradient. For ship-generated waves, the long-shore current is not established due to the short duration of the wave event. The usual large run-up of the ship waves, however, may give rise to a long-shore sediment transport in the swash zone due to the zigzag motion of the water and sediment particles. Under natural conditions, the bulk of the littoral transport occurs in the surf zone. The long-shore component of the sediment transport in the swash zone is small compared to the transport in the surf zone Elfrink (1997).

**Cross–shore sediment transport**

In natural waves the mass transport perpendicular to the coast is balanced by means of a return current driven by the sloping water surface, the wave set-up. The vertical
distribution of the shear stress under breaking and non-breaking waves was analysed by Deigaard and Fredsøe (1989) and Deigaard (1993).

In ship-generated waves the balance between onshore directed flow due to the mass transport and offshore directed flow due the sloping water surface is not established due to the relative short duration of the wave event. The mass transport occurs during the passing of breaking waves, the return flow occurs later. The response time depends on the distance from the shoreline. The result is that onshore velocities occur over the entire water column during the wave event. Offshore-directed velocities, to balance the net drift occur later after the passage of the wave train. During the passage of the wave train, the level of turbulence and the suspended sediment concentrations are higher than during the return flow period. Therefore a net onshore transport of sediment occurs.

In order to illustrate the sediment transport mechanisms, a number of simulations were performed with the model presented in Elfrink et al (1996). The model was specially customised in order to account for the non-equilibrium conditions with regard to the turbulence levels, the mean flow, and the suspended sediment concentrations. The time series of water surface elevation shown in Figure 7 (left panel) was used as boundary conditions. The wave transformation on a beach slope of 1:50 was simulated with a wave model based on the Boussinesq type equations presented in Madsen et al (1997). Figure 8 shows the simulated wave orbital velocity (upper panel) at a water depth of 0.65 m. At this water depth the waves are fully breaking. The calculated instantaneous sediment flux is also shown in Figure 8 (lower panel). It is noticed that the highest sediment fluxes occur under the wave crests and that the resulting sediment transport is directed onshore (positive values).

Coastal Impact
The run-up height is higher for the long-periodic ship-generated waves than for natural wind waves with the same height. Thus, the swash zone of the beach will become wider and higher due to the ship waves caused by HSC.

The simulations showed an increasing onshore sediment transport rate towards the shore. This gives rise to a tendency of steepening of the cross-shore beach profile and sediment accumulation in the run-up zone. If the total amount of wave energy originating from the ship-generated waves is of the same order of magnitude as the energy from natural waves, this can lead to permanent changes in the cross-shore profile. The profile-steepening is counteracted by the natural waves. If the wave conditions are dominated by natural waves, the impact of the ship-generated waves on the cross-shore profile is negligible.
Figure 8. Time series of simulated wave orbital velocity (upper panel) and sediment flux (lower panel) caused by waves generated by a HSC. The water depth is 0.65 m.

Criteria of Acceptable Wake Wash

To ensure safe navigation of small craft in shallow water and leisure activity the Danish Maritime Authority has per May 1997 issued a governmental order that requires the HSC owner/operator to document that the ship-generated waves do not exceed a prescribed criterion along the entire route. The wake wash criterion is presently formulated as

\[
H_h \leq 0.5 \sqrt{\frac{4.5}{T_h}}
\]  \hspace{1cm} (1)

where \(H_h\) is the maximum wave height (in meters) of the long-periodic waves having a mean wave period of \(T_h\) (in seconds). The criterion is applicable at a still water depth of 3 m. Assuming that the mean wave period of the long-periodic waves is approximately 9 s at 3 m of water depth, the criterion gives \(H_h = 0.35\) m. The background for this criterion is briefly described below, see also Kofoed-Hansen and Kirkegaard (1996).
Despite the fact that wash generated by HSC is substantially different from wash caused by conventional ships and ferries, the choice of criterion of acceptability must reflect a connection between these two types of wash, where the latter is generally accepted by the public. Characteristic measures such as wave energy, maximum wave height prior to breaking and wave run-up on the coast have been used tentatively in the formulation of a criterion. A criterion based on the maximum wave height immediately before breaking was originally suggested as the most reasonable choice because it is directly connected to public's experience at sea.

Based on analysis of experimental data, the original criterion was formulated as

\[ H_{\text{HSC}} \leq \beta_b \frac{T_c}{T_{\text{HSC}}} H_c \]

which is applicable at about 3 m of water depth and for wave periods longer than 4-5 s. \( H \) indicates a maximum wave height at 3 m of water depth and \( T \) the related wave period. Index HSC refers to a High-Speed Craft, whereas index c refers to a conventional ferry. The decision parameter, \( \beta_b \), is indicated in the equation \( H_{b,\text{HSC}} = \beta_b H_{b,c} \), where \( H_b \) is the wave height immediately before breaking. The criterion in Eq. (1) appears immediately by setting \( \beta_b = 1 \), \( H_c = 0.5 \text{ m} \) and \( T_c = 4.5 \text{ s} \), which may be taken as very rough estimate of wash caused by a conventional ferry (in Kalundborg Fjord, Denmark) at a distance of 1-2 km from the track. It should be mentioned that the criterion does not state how the wake wash will break on the coast. Even though the wave height is less than the above-mentioned limit at 3 m of water depth, the wave height can be considerably higher in water depths less than 3 m due to the shoaling.

Legislation, Regulation and Approval

The conflicts between the ferries on the one side and environmental and recreational interests on the other have prompted the Danish authorities to impose certain restrictions on the operation of HSC. With this objective the Environmental, Coastal and Maritime Authorities introduced new legislation in 1997. The legislation relates to environmental protection of the marine environment, coastal protection and safe navigation and take into account waves but also noise, emissions and disturbance of marine life.

It is now required that a shipping company shall obtain approval from the authorities before it establishes a high-speed ferry route operating on a Danish port or puts a new high-speed ferry into service on an existing route. With respect to wave impact, the shipping company shall document that the ferry on the proposed route does not exceed the wave height criterion described above.

Prediction of wake wash in coastal areas

A numerical model capable of calculating ship-generated waves, wave propagation and wave transformation in non-homogeneous media is the ultimate tool when new regulations and approval procedures are introduced for HSC. Today's CFD methods are used to
compute the wave field around ships advancing in deep or shallow water, but the wave propagation and transformation towards a coastline are seldom not considered, see Larsson (1997). Time-domain models based on depth-integrated Boussinesq type equations, eg Madsen and Sørensen (1990), can be justified for practical purposes in shallow water. As for conventional CFD models, the computational effort may be huge for large domain areas why approximate and efficient methods are needed in practice.

Based on the knowledge of the waves generated along the route, the ship-generated wave climate in larger coastal and shallow water regions can be assessed using a phase-averaged model describing the most important physical processes (including wave decay) the waves are undergoing during their propagation and transformation. An example of a model output is illustrated in Figure 9 showing the computed maximum wave height and the wave directions. The HSC is navigating along the edge of the model in direction of the arrow. The figure shows distinctive focusing of wave energy in a number of areas, which is in agreement with field observations on the site. Even though such types of models neglect the transient effect of the wash, they are extremely helpful in eg route planning of new and existing HSC routes.

Figure 9. Wave propagation and transformation in Kalundborg Fjord, Denmark. The contour values show the relative wave height defined as the local wave height divided by the wave height at the boundary (the navigation route). The direction of the arrows indicates the wave propagation direction.
Conclusions

Wake wash generated by HSC is markedly different from waves from conventional ships. Wave measuring programs have demonstrated that HSC generates diverging wave patterns consisting of groups of long-period waves and short-periodic waves. The long waves from large car-carrying fast ferries are typically of more than 9 s wave period. These waves have a relatively larger wave height growth during shoaling and wave refraction caused by sea floor irregularities appears in deeper water. The result is that the waves when reaching the shore may cause higher breaking waves and larger run-up than traditional ship waves and the breakers are more often plunging. The waves will arrive faster than ordinary Kelvin waves and particularly during calm weather conditions, people on the beach will not be prepared for a breaking wave appearing without any warning. This is a main reason for the public concern over wake wash from HSC.

The full-scale measurements have also confirmed the significance of the vessel speed versus water depth, expressed in the depth-based Froude number. When operating at near the critical Froude number (~ 1.0), the wave generation is maximum. HSC will operate at critical speed during acceleration and deceleration and due to depth variations several times during transit. It is important that passage of critical speed is carefully planned in order not to coincide with sensitive coastal areas.

Due to the different wave characteristics and the repeated exposure to groups of long waves some variation of coastal characteristics may be experienced near HSC routes. The effect is mainly a steepening of the beach face and grading of sediments. However, the effects of ordinary storm waves will typically dominate the general coastal development.

The inherent conflict between fast ferry operation and recreational use of Danish coastal waters due to wake wash have to be solved by the authorities. New legislation has been made to cope with this issue and today a shipping company has to demonstrate that wake wash does not exceed certain limits along the route and that the environmental impact is limited.

Acknowledgement

The studies described in this paper have primarily been financed by the Danish Maritime Authority, Cat-Link A/S and Scandlines A/S. The co-operation with staff members of DMA, the involved shipping companies and Danish Car Ferry Association is greatly appreciated. Thanks also to Karim A. Rahka, International Research Centre for Computational Hydrodynamics (ICCH), for performing the Boussinesq wave simulations used for the study of cross-shore sediment transport.

WAVE PROPAGATION DIRECTIONS UNDER REAL SEA STATE CONDITIONS

Joachim Grüne

Abstract

This paper deals with the analysis of wave propagation directions from wave climate measurements in field. A simple method is presented to analyse wave approach directions from signals of a current meter and a wave gauge in time domain. Results using this method of analyzation are demonstrated exemplarily with data from field monitoring.

Introduction

Wind waves coming in from deeper parts of the shelf in areas with extremely restricted water depths, keep their general three-dimensional characteristic with respect to the water particle movement. Even when the breaking wave crests seem to be transformed into a considerable two-dimensional behavior, the wave-induced velocities keep their three-dimensionality, however often with a distinct strengthening towards a main axis system.

It is well known, that wind direction and wave approach direction don’t agree necessarily in areas with restricted water depths like the wadden seas in the German Bight. This is due to the strong influence of the complex three-dimensional underwater topography on wave climate propagation. Thus, forecasting the wave propagation direction sometimes can be very difficult and a more detailed knowledge about wave approach on wadden seas is desirable.

In general, some different methods are used to evaluate wave approach directions. These methods depend on the type of sensors which are used for field measurements of wave climate and may be the following ones:

1 Dipl.-Ing., Senior researcher, Operation and Research Manager of Joint Central Institution "Coastal Research Centre" (FZK) of University Hannover and Technical University Braunschweig, Merkurstrasse 11, 30419 Hannover, Germany
- One method uses the analysis in time domain from two synchronously recorded signals of the velocity components from a two-component velocity sensor in horizontal plane (method A).

- Another method uses the analysis from three synchronously recorded signals: two signals of the components from a velocity sensor as in method A and additionally one signal of the surface elevation from a wave staff. This analysis is done either in frequency domain (method B) or in time domain (method C).

The evaluation of wave approach direction with analysis method A only works sufficiently for strongly orientated velocities, which seldom occur in real sea state wave climate.

About the evaluation with analysis method B it has been reported in a lot of previous papers. Analysing the co- and quad-spectra in frequency domain from data triplets of the two horizontal velocity components and the water surface elevation, the directional distribution and from this the main wave approach may be estimated. This method is very complex and in most papers the essential details of this method never are described.

The evaluation of wave approach from the same data triplets using an analysis in time domain (method C) is much more simple compared with such in frequency domain. In addition to the easy practicability this method has a clear physical sense. Due to these advantages this paper will be focussed on this method.

Field measuring locations and equipment

The data used for the estimation of wave approach direction were measured within a comprehensive field research program on wave climate and wave run-up. This program has been running in cooperation with the Regional State Board for Water Management (ALW Heide, supervision Dipl.-Ing. J. Gartner) of the State of Schleswig-Holstein for many years at 4 different locations at the landside borders of the wadden sea and in the Elbe river estuary in the German Bight. The data presented in this paper, are recorded at the wadden sea location Heringsand at the coastline of the Dithmarscher Küste, which is shown in Fig. 1. The field locations and the measuring equipments already were described in previous papers in connection with first results on wave run-up (Grüne, 1996) and on wave climate (Grüne, 1997 and Wang & Grüne, 1997).

At each of these locations roughly 1 km in front of the dykeline a support pile with the measuring sensors is installed. The surface elevations are estimated from the records of a pressure cell, using the 1st order theory with empirical transfer function. The velocity components are measured in horizontal plane with an electromagnetic two-component sensor. The sensors are connected by cables with a computer controlled recording system, which is placed in a shelter behind the dyke.
Definitions and modalities of analysing wave approach directions

As already mentioned, this paper is focussed on analysing wave approach directions in time domain, using a data triplet of surface elevation $\eta$ and two rectangular velocity components $V_y$ (normal to dykeline) and $V_x$ (parallel to dykeline) in a horizontal plane as shown in Fig. 2 schematically. An example of such a synchronously recorded data triplet is shown in Fig. 3, where the time histories of the signals of the wave gauge WP1 and the horizontal velocity components S1Y and S1X are plotted for a period of 95 seconds. This example will be used in this paper, to explain the analyzing method.
Fig. 2  Scheme of coordinate system of installed sensors

Fig. 3  Example of synchronously recorded wave and velocity data
The data of the two horizontal velocity components $V_x$ and $V_y$ as well as those of the surface elevation $\eta$, shown in Fig. 3, are recorded digitally with 10 Hz. With the data from the time period in Fig. 3 the vector course of the two velocity components is plotted in Fig. 4. This course plot seems to have a main direction roughly along the Y-axis. But using the least square correlation method alternating for both independent velocity components $V_x$ and $V_y$, a mean value from both regressions of $-39.8^\circ$ will be calculated. This method (one possibility for method A as mentioned before) will create mostly such similar failure results due to the fact, that the mean value from two independent regression lines each with a bad correlation tends always around 45 degrees. A comparison with the result from Fig. 8 ($A_w = -15.6^\circ$), which is evaluated with method C as explained later, indicates, that this method don’t lead to sufficient results.

![Fig. 4 Velocity vector course of velocity data S1X and S1Y from Fig. 3](image)

But nevertheless, the vector course data itself are very helpful for an evaluation of wave approach directions as demonstrated in Figs. 5 a and 5 b, which give a kind of anatomy of a data triplet in time domain. The time history of surface elevation data $\eta$ (WP 1) from Fig. 3 has been used to split the wavetrain in 17 consecutive waves, each labelled with continuous number 1 to 17. Wave crests and wave troughs of all 17 waves are marked and labelled with time. For this procedure the unsealed pressure data may be used, a transfer to real surface elevations is not necessary. Below the time history of the surface elevation the vector course with the two horizontal velocity components $V_x$ and $V_y$ is plotted separately for each wave event. The vector positions at the dividing troughs between each of the consecutive waves are connected with a dotted line.
Fig. 5 a Surface elevation and velocity vector course of consecutive waves
Fig. 5b Surface elevation and velocity vector course of consecutive waves
Comparing the vector plots of the separated waves in the wavetrain in Figs. 5 a and 5 b, one finds a more or less distinct changing of the approach direction of the water particles at each wave crest and wave trough, which is self-evident for pure two-dimensional waves. This leads to the evaluation of wave approach directions for real sea state conditions from the vector course data between wave crests and troughs. The wave approach directions for such a mode are defined in Fig. 6 schematically.

![Wave Propagation Diagram](image)

**Fig. 6** Definitions for wave approach directions

The definitions in Fig. 6 may be described as follows:

The direction $A_{TSC}$ is defined as mean direction between trough $T_s$ and crest $C$. $T_s$ is the trough at the start of the wave event according to the time and $C$ is the crest, both are identified from the surface elevation in time history. Troughs and crests are related to time. According to physical sense this means the oncoming rising front of the
wave. $A_{TsC}$ is determined as angle between normal direction (Y-axis of horizontal plane) and linear connection between vector course positions at trough $T_s$ and crest $C$, as defined in the lower part of Fig. 6, where the rules of sign for the directions $A_{TsC}$ and $A_{CTe}$ are defined as well. The vector course of the oncoming rising front is marked with a black arrow in all figures.

The direction $A_{CTe}$ is defined as mean direction between crest $C$ and trough $Te$, where $Te$ is the trough at the end of the wave event and this part of the vector course is marked with an open arrow in all figures.

$A_w$ is defined as the total approach direction of each wave event. $A_w$ is calculated as the mean value of $A_{TsC}$ and $A_{CTe}$. It must be noticed, that $A_{TsC}$ and $A_w$ have approximately the same directions as the main direction of wave propagation has, whereas $A_{CTe}$ has the opposite direction (see also the lower part of Fig. 6, where the rule of sign is defined).

The vector plots in Figs. 5a and 5b demonstrate the manifoldness of the vector course anatomy and its complexity. The vector course of event Nr. 1 in Fig. 7 (right plot) confirms, that nearly each small crest or trough of surface elevation (left plot) creates a significant changing of course direction, even within a defined wave event.

![Fig. 7 Example of a wave with complex velocity vector course](image)

Comparing all wave events in Figs. 5a and 5b one can find wave events, where the vector courses are as well straightened relatively strong within each wave event and the directions $A_{TsC}$ and $A_{CTe}$ don’t differ very much from each other (e.g. wave events...
Nevertheless, the mean directions $A_w$ differ from those events next to distinctly.

Furthermore there are wave events, where the direction of $A_{TsC}$ differ considerably from that of $A_{CTe}$, which means a changing of main direction within the wave event (e.g. Nr. 5, 8, 10, 14 and 15). From these events it is obvious, that mostly the chaotic vector courses may be created by the smaller waves between larger ones (e.g. event Nr. 8, 14 and 15).

All estimated approach directions from the test example in Figs. 5a and 5b with totally 17 consecutive wave events are plotted in Fig. 8. Significant differences between the different defined directions within one wave event only occur for the smaller waves like e.g. Nr. 8 and 15, as already mentioned before. The result for the mean approach direction ($A_w = -15.6^\circ$) is compared in Fig. 5 with the results, using method A with the mean value of two independent correlations with the digitally recorded (equidistant with 10 Hz) velocity data. The failure of using the components alone in such a manner is manifest.

![Fig. 8 Wave approach directions evaluated from the waves in Figs. 5a and 5b](image.png)

**First results**

As already mentioned, the evaluated approach directions of consecutive waves in a wave train have strong fluctuations. This comes out clearly in Fig. 9, where the evaluated values for $A_{TsC}$ and $A_{CTe}$ are plotted as time history for a period of 15 minutes, measured in field. But beyond a certain time period the mean values are relatively
constant. In Fig. 9 for example the fat line in the upper part stands for the \( A_{TSC} \) mean values of 9 consecutive time periods, each 100 seconds long. The differences compared with the mean value of the total period (\( A_{TSC} = 305.9° \)) are very small. It must be noticed, that in Fig. 9 and in all following figures the wave approach directions are transferred to the geodetic coordinate system with \( 0° = \text{North} \).

![Fig. 9 Fluctuations of \( A_{TSC} \) and \( A_{CTe} \) during a period of 15 minutes](image)

The values for \( A_{TSC} \) and \( A_{CTe} \) from the example in Fig. 9 are plotted as frequency distributions in Fig. 10. The mean values of \( A_{TSC} \) and \( (A_{CTe} + 180°) \) for the total period differ only 0.6 degrees from each other. The agreements with the calculated Normal distributions are quite good. The total range of fluctuation of the evaluated approach directions is roughly \( \pm 70° \) and the standard deviation is roughly 26°. The frequency distribution of the total wave approach directions \( A_w \) is plotted in Fig. 11. Similar wide sectors of fluctuation of wave approach were found for other measurements. With respect to the influence on wave run-up these results indicate, that a possible reduction on wave run-up values due to oblique wave approach should be smaller than expected by existing formulae, verified with long-crested sea state.

Results of wave approach directions measured during one storm surge event are given in Fig. 12 examplarily. The stillwater level SWL, the local wind direction \( R_g \), the local wind velocity \( U_0 \) and the measured wave approach directions \( A_w \) are plotted as time history. Each plotted point is the result (mean value) of one of the time periods, which have each a duration of 15 minutes and were recorded consecutively.

During this storm surge event the local wind velocities \( U_0 \) as well as the local wind directions \( R_0 \) were relatively constant, whereas the wave approach directions \( A_w \)
partly differ considerable from the wind directions $R_w$. It is well known, that in such areas the wave propagation direction is strongly influenced by the local morphology and that waves are even propagating against the wind, as far as they run along gullies. Thus, it must be expected, that the differences between wind direction and wave approach direction are mainly caused by the influence of the morphology. Comparing the time histories of the wind- and wave approach direction in Fig. 12 it can be stated, that the differences between both directions decrease with increasing water depth.
Fig. 12  Time histories of stillwaterlevel SWL, local winddirection $R_0$, local windvelocity $U_0$ and wave approach directions $A_w$ during a storm surge

From the morphological conditions around the location Heringsand in Fig. 1 it may be supposed, that the mean wave propagation directions during the rising and falling part of the storm surge stillwaterlevel are adjusted to the end of the main gully.

The influence of water depth comes out clearly in Fig. 13, where the difference between the wave approach direction and the local wind direction $A_w - R_0$ is plotted versus the stillwaterlevel SWL. The phaseshift $A_w - R_0$ decrease with increasing water depth, but with different order of magnitude for rising and falling part of the storm surge stillwaterlevel. The phaseshift of the falling part of the storm surge has roughly up to twice the value of that of the rising part, whereas in the summit range it tends to zero. The different phaseshift for rising and falling part may be explained partly by the general trend of tidal motion from South to North in this part of the German Bight. From the ongoing analysis similar results are found for other storm surge events, often
in a more complex shape, especially for storm surges with lower summits of stillwaterlevel. Furthermore it was found that the phaseshift also depends on the absolut winddirection and that gullies like the one at Stinteck location have strong influence. All results confirm the strong influence of the local morphology.

Conclusion

For the analysis of wave approach directions from triplet field data of surface elevation and horizontal velocity components a simple method is discussed with the aid of an example and first results are presented from measurements during a storm surge event. These results indicate the wide range of fluctuations of wave approach directions as well as the strong influence of morphological conditions on approach directions. This topic has to be investigated during the ongoing research work in more detail, especially with the data recorded at the locations in the Elbe river estuary.

On the Accuracy of Parabolic Wave Models

Hakeem K. Johnson¹ and Sanne Poulin²

Abstract

Errors in parabolic equation models (PEM) for wave refraction and diffraction are investigated by examining the case of waves propagating over a planar bathymetry for which the analytical solution is well known. The models investigated are: i) lowest order parabolic approximation (Simple method), ii) Padé approximation and iii) Minimax approximation models.

Errors in wave heights, wave directions, radiation stresses and resulting longshore currents are investigated analytically and by numerical tests using the parabolic equation model MIKE 21 PMS. The results indicate that, while the predicted wave directions are generally accurate, the wave heights, radiation stresses and longshore currents can contain significant errors depending on the parabolic approximation used.

Introduction

Parabolic equation models (PEM) for wave refraction/diffraction are frequently used in coastal engineering practice for the computation of wave parameters, radiation stresses and associated wave-induced nearshore currents in coastal areas. The PEM approach is attractive since it is computationally more efficient than the complete elliptic mild-slope model, and it provides useful engineering results for refraction/diffraction problems (in the absence of significant reflection) in the coastal area (Berkhoff et. al., 1982, Johnson et. al., 1994).

The parabolic equation model is derived as an approximation to the elliptic mild slope equation (derived by Berkhoff, 1972) governing the refraction, shoaling, diffraction and reflection of linear water waves propagating on mildly sloping bathymetry. The lowest order parabolic approximation is obtained by assuming a principal wave direction (x-direction) and neglecting backscatter. Kirby (1986) extended this approximation to allow waves propagating at large angles to the assumed principal direction. Many numerical models have been developed based on these approximations. One such wave model is the MIKE 21 Parabolic Mild Slope (PMS) model, which is based on the equations derived by Kirby (1986).

As a result of the underlying assumptions, PEM do not exactly reproduce the refraction coefficient for waves approaching the coast at an angle. This introduces errors in the nearshore wave heights and radiation stresses and, consequently, in the wave-driven longshore currents. The magnitude of the errors depends on the type of parabolic approximation.

In this paper, we attempt to quantify the errors and give suggestions for minimizing the influence of the errors in real applications. This is achieved by examining the simple case of wave propagation over straight and parallel depth contours for which an analytical solution exists.

This paper is broadly divided into two parts. In the first part, the PEM is used to derive evolution equations for wave heights and directions over straight and parallel contours. This is compared with the analytical solution, and thus the errors in the PEM are obtained. In the second part, results of numerical tests using MIKE 21 PMS are compared with the analytical solution in order to quantify the errors in the various parabolic approximations. Finally, some conclusions are derived regarding an optimal PEM for practical situations.

**Parabolic Equation Model**

The starting point for the analysis is the general parabolic equation derived by Kirby (1986) for linear waves in the absence of currents. Kirby removed the rapidly varying term from the mean free surface potential \( \phi \), to obtain a slowly varying complex function \( A \) (see Eq. 1), which is used as the primary variable in the parabolic equation

\[
\phi = A(x, y)e^{ik_0x} \tag{1}
\]

In Eq. 1, \( k_0 \) is a characteristic wave number, typically chosen as the average wave number along the y-direction, and x is the principal wave direction. Kirby obtained the parabolic equation given in Eq. 2.
\[ A_x + i(k_o - \beta_1 k)A + \frac{A}{2c_g}(c_g)_x + \frac{\sigma_1}{\omega c_g}(cc_g A_y)_y \]
\[ + \frac{\sigma_2}{\omega c_g}(cc_g A_y)_x + \frac{W}{2c_g}A = 0 \]  

(2)

where

\[ \sigma_1 = i \left( \beta_2 - \beta_3 \frac{k_o}{k} \right) + \beta_3 \left( \frac{k_x}{k^2} + \frac{(c_g)_x}{2k c_g} \right) \]  

(3)

\[ \sigma_2 = -\frac{\beta_3}{k} \]  

(4)

The subscripts \( x \), \( y \) respectively represent differentiation with respect to \( x \) and \( y \), \( i \) is the imaginary unit, \( k \) is the local wave number, \( c_g \) is the local group velocity, \( \omega \) is the circular wave frequency, \( \beta_1 \), \( \beta_2 \) and \( \beta_3 \) are the coefficients of the parabolic approximation, and \( W \) is a dissipation term (e.g. bottom dissipation, wave breaking). The \( \beta \)-coefficients are given in Table 1 for various parabolic approximations.

Table 1. Coefficients for various parabolic approximations.

The lowest order parabolic approximation is denoted as the Simple approximation in Table 1. The Minimax approximations minimize the error in the wave number over the entire aperture width associated with it. However, this does not preclude that the error for specific directions (within the aperture width) may be large.
Parabolic Equation Model for Straight and Parallel Depth Contours

The evolution equations for wave heights and directions are derived here for the case of straight and parallel depth contours and no dissipation ($W = 0$). The Cartesian coordinate system is chosen such that the y-axis is parallel to the coastline.

The mean free surface potential for plane, progressive waves can be written as:

$$\phi = A^*(x, y)e^{i\psi}; \quad \Psi = \int k \cos \theta \, dx + \int k \sin \theta \, dy$$

where $A^*(x, y)$ is the amplitude function (equals half of the wave height $H$) and $\Psi$ is the phase function. Combining Eqs. 1 and 5, the slowly varying mean surface potential can be expressed as:

$$A = A^*(x, y)e^{i(\psi - k_0 x)} = \frac{H}{2} (x, y)e^{i(\psi - k_0 x)}$$

Thus, the derivatives in Eq. 2 can be found as a function of $A^*(x, y)$ and $\Psi$. For example, $A_y$ is obtained as:

$$A_y = \left\{ A^*(x, y) \cdot i \Psi_y + A^* \right\} e^{i(\psi - k_0 x)}$$

For straight and parallel depth contours, the wave height $H$, wave number $k$, phase speed $c$, and group velocity $c_g$, are all constant along the contours (y-direction). Introducing these constraints and rearranging, Eq. 2 gives:

$$c_g \left( c_g \right)_x = \frac{\frac{(c_g^2)}{2c_g} - k \sigma_1 \sin^2 \theta - \frac{k^2 \sin^2 \theta}{\omega c_g} \sigma_2 \left( c_g^2 \right)_x}{1 - k \sigma_2 \sin^2 \theta}$$

Using Eq. 6, an expression for $A_x/A$ in terms of the wave height and phase can be written as:

$$\frac{A_x}{A} = \frac{H_x}{H} + i \left( \Psi_x - k_0 \right) = \frac{H_x}{H} + i \left( k \cos \theta - k_0 \right)$$

Equating the real and imaginary parts of Eq. 9 with those of Eq. 8, the following evolution equations for wave height $H$ and direction $\theta$ are derived from the PEM

$$\frac{H_x}{H} + \left( \frac{c_g}{2} \right)_x - 2\beta_3 \frac{S^2}{k^2} \frac{k_x}{(1 + \beta_3 S^2/k^2)} = 0$$
\[
\cos \theta = \left( \frac{\beta_1 + \beta_2 S^2 / k^2}{1 + \beta_3 S^2 / k^2} \right) \tag{11}
\]

where \( S = k \sin \theta \).

**Exact solution for straight and parallel depth contours**

The evolution equations for the exact solution are derived from Snell's law and the conservation of energy flux. According to Snell's law, \( k \sin \theta = \text{constant} = S \). This can be alternatively written as:

\[
\cos \theta = \sqrt{1 - \left( \frac{S}{k} \right)^2} \tag{12}
\]

Eq. 12 may be accurately approximated as (see Figure 1):

\[
\cos \theta = \left( \frac{\beta_1 + \beta_2 S^2 / k^2}{1 + \beta_3 S^2 / k^2} \right) \tag{13}
\]

![Figure 1. Approximate expressions for \( \cos \theta \) using \( \beta \) coefficients for Simple, Minimax 10° and Minimax 60° PEM.](image)

The conservation of energy flux equation is written as:

\[
H^2 c_s \cos \theta = \text{constant} \tag{14}
\]

Differentiating Eq. 14 with respect to \( x \), the exact evolution equation for the wave height is obtained as:
\[ \frac{H_x}{H} + \frac{(c_g)_x}{2c_g} + \frac{(\cos \theta)_x}{2 \cos \theta} = 0 \]  

(15)

Inserting Eq. 13 (using Minimax 60° coefficients, indicated by *) into Eq. 15, an almost exact evolution equation (Eq. 16) for wave height is obtained.

\[ \frac{H_x}{H} + \frac{(c_g)_x}{2c_g} + \frac{\beta_1^* \beta_1^* - \beta_2^*}{\left( \beta_1^* + \beta_2^* S^2 / k^2 \right) \left( 1 + \beta_3^* S^2 / k^2 \right)} \frac{S^2}{k^2} \frac{k_x}{k} = 0 \]  

(16)

Eq. 16 can be readily compared with the corresponding evolution equation from the PEM, Eq. 9.

Errors

Since Eqs. 11 and 13 are identical, it is clear that the errors in wave directions are small in PEM, as long as Eq. 13 is a good approximation to Eq. 12. This covers a wide range of directions (as shown in Fig. 1), even for the lowest order approximation. Thus, calculated wave directions from PEM would be generally accurate.

Comparing Eqs. 10 and 16, it is obvious that the PEM evolution equation for the wave height is different from the analytical solution, resulting in errors.

In order to relate the errors to physically meaningful properties such as the shoaling coefficient \( K_s \) and refraction coefficient \( K_r \), the wave height at an inshore location is written as:

\[ H = H_0 K_s K_r \]  

(17)

where \( H_0 \) is the wave height at an offshore location. Differentiating Eq. 17 with respect to \( x \) and dividing through by \( H = H_0 K_s K_r \) gives:

\[ \frac{H_x}{H} \cdot \frac{K_{s,x}}{K_s} \cdot \frac{K_{r,x}}{K_r} = 0 \]  

(18)

Comparing Eqs. 18 and 15, it is clear that the second term in Eq. 15 (and in Eqs. 10 and 16) is related to the shoaling coefficient, while the third term is related to the refraction coefficient. Thus, while the shoaling coefficient is exactly reproduced in PEM, the refraction coefficient in PEM contains some errors. The refraction terms in Eqs. 10 and 16 are reproduced below:

\[ \left[ \begin{array}{c} K_{1,x} \\ K_r \end{array} \right]_{\text{PEM}} = \frac{2 \beta_3 S^2 / k^2}{1 + \beta_3 S^2 / k^2} \frac{k_x}{k} \]  

(19)
\[
\frac{\left[ K_{r,x} \right]_{\text{exact}}}{K_r} = \left( \frac{\beta_2^* - \beta_1^* \beta_3^*}{\beta_1^* + \beta_2^* S^2 / k^2} \right) \frac{S^2 / k^2}{\left( 1 + \beta_3^* S^2 / k^2 \right)} \frac{k_x}{k}
\]

(20)

For waves approaching perpendicular to the coast \((\theta = 0)\), \(S = 0\), and both refraction terms are zero. Thus, in this special case, the wave heights in the PEM are calculated correctly, since there is no refraction. The same is true for constant water depth where \(k_x = 0\).

It is also seen that the refraction term in the parabolic equation model is identically zero for all angles if the Simple approximation is used, since \(\beta_3 = 0\). Thus, the Simple approximation does not account for refraction effects at all.

For oblique incidence (and varying depth), we define \(\lambda\) as the ratio of the refraction term in the PEM to that in the exact solution.

\[
\lambda = 2 \beta_3 \frac{\left( \beta_2^* + \beta_3^* S^2 / k^2 \right) \left( 1 + \beta_3^* S^2 / k^2 \right)}{\beta_2^* - \beta_1^* \beta_3^* \left( 1 + \beta_3^* S^2 / k^2 \right)}
\]

(21)

The ideal situation is \(\lambda = 1\). This corresponds to the case where the refraction term is exactly reproduced in PEM. For \(\lambda < 1\), the refraction term is underestimated in PEM (i.e. not enough refraction), while for \(\lambda > 1\), the refraction term is over-exaggerated (i.e. too much refraction). In the case of the Simple approximation, the refraction term is not reproduced at all, i.e. \(\lambda = 0\). In Figure 2, \((\lambda - 1)\) is shown as a function of wave direction \(\theta\) for various parabolic approximations given in Table 1 (except Simple).

![Figure 2](image-url)

Figure 2. Error in the refraction term as a function of incident wave direction for various parabolic approximations.
It is seen from Figure 2 that the Padé approximation gives the minimum error for small angles of incidence, 0° to 20°. For larger angles, the Minimax 50° or Minimax 60° give the minimum error on average.

Using Eq. 18, we write:

\[
\left( \frac{H_x}{H} \right)_{\text{PE}} = \left( \frac{K_x}{K_r} \right)_{\text{exact}} + \lambda \left( \frac{K_x}{K_r} \right)_{\text{exact}}
\]  

(22)

\[
\left( \frac{H_x}{H} \right)_{\text{exact}} = \left( \frac{K_x}{K_r} \right)_{\text{exact}} + \left( \frac{K_x}{K_r} \right)_{\text{exact}}
\]

(23)

Using Eqs. 22 and 23, the error in wave height obtained with the PEM at a distance \( \Delta x \) from the offshore location is obtained as:

\[
H_{\Delta x, \text{PE}} - H_{\Delta x, \text{exact}} = (\lambda - 1) H_0 \Delta x \left( \frac{K_x}{K_r} \right)_{\text{exact}}
\]

(24)

The refraction coefficient \( K_r = \sqrt{\cos \theta_i/\cos \theta_o} \), where \( \theta_i \) is the inshore wave direction which decreases towards the shore (with increasing \( x \)), hence \( (K_x)_r/K_r \) is always less than 0. Thus, it follows that if \( \lambda > 1 \), the inshore wave height will be underestimated (since the refraction effect is over-exaggerated). The converse is true for \( \lambda < 1 \). For \( \lambda = 1 \), the error is identically zero. However, there is no PEM that gives \( \lambda = 1 \) for any range of wave directions. For example, if Padé approximation is used, the parabolic equation model will overestimate the inshore wave heights for most wave directions (> 15°).

Radiation stresses

The next important question is what effect these errors have on wave-driven longshore currents calculated using the parabolic equation model. For straight and parallel depth contours, the important radiation stress gradient term for these currents is

\[
\left( \frac{\partial S_{xy}}{\partial x} \right)_{\text{exact}} = \sin \theta \frac{\partial E_g \cos \theta}{c} \frac{\partial x}{\partial x} = S_{xy} \left\{ \frac{2 H_x}{H} + \frac{(c_g \cos \theta)_x}{c_g \cos \theta} \right\}_{\text{exact}}
\]

(25)

Outside the surf zone (disregarding bottom friction), the right-hand side should be zero, since there is no dissipation. Performing the differentiation of the second term in the curly braces and rearranging, we obtain:

\[
\frac{1}{S_{xy}} \left( \frac{\partial S_{xy}}{\partial x} \right)_{\text{exact}} = 2 \left( \frac{H_x}{H} \right)_{\text{exact}} + \left( \frac{(\cos \theta)_x}{\cos \theta} \right)_{\text{exact}} + \left( \frac{(c_g)_x}{c_g} \right)_{\text{exact}}
\]

(26)
A similar expression is obtained for the parabolic equation model. The last term in Eq. 25 is the shoaling term, which is identical both in the exact and the parabolic case. The second term is the refraction term.

Using Eqs. 22 and 23, and remembering that \((\cos \theta_x) / \cos \theta = (K_r \lambda) / K_r\), the difference between the exact and the PEM expression for the radiation stress term is obtained as shown below:

\[
\frac{1}{S_{xy}} \left( \frac{\partial S_{xy}}{\partial x} \right)_{PEM} - \frac{1}{S_{xy}} \left( \frac{\partial S_{xy}}{\partial x} \right)_{exact} = \frac{H_x}{H_{PEM}} - \left( \frac{H_x}{H_{exact}} \right) + \frac{\left( \cos \theta_x \right)_{PEM}}{\cos \theta} - \left( \frac{\left( \cos \theta_x \right)_{exact}}{\cos \theta} \right)
\]

\[
= 2(\lambda - 1) \left( \frac{K_{r,x}}{K_r} \right)_{exact} + 2(\lambda - 1) \left( \frac{K_{r,x}}{K_r} \right)_{exact} = 4(\lambda - 1) \left( \frac{K_{r,x}}{K_r} \right)_{exact}
\]

Outside the surf zone, we therefore see that:

\[
\frac{1}{S_{xy}} \left( \frac{\partial S_{xy}}{\partial x} \right)_{PE} = 4(\lambda - 1) \left( \frac{K_{r,x}}{K_r} \right)_{exact}
\]

which is generally non-zero, meaning that currents are generated which should not be there. Only when \( S = 0 \) (or the depth is constant) is the right-hand side zero, as it should be, for all wave directions. The type of current generated depends on \( \lambda \). If \( \lambda > 1 \), \( \partial S_{xy}/\partial x < 0 \), and spurious currents are generated which may look realistic. On the other hand, when \( \lambda < 1 \), \( \partial S_{xy}/\partial x > 0 \) and clearly unrealistic currents are generated in the “opposite” direction to wave propagation.

In the following second part, numerical examples are presented in order to quantify the errors.

**Numerical Examples**

The parabolic approximations implemented in MIKE 21 PMS will now be compared with the analytical solution on a beach with straight and parallel depth contours. The slope is 1:50 and the water depth at the toe of the slope is 10m. The shore is parallel to the y-axis and the wave direction is measured from the x-axis. A monochromatic wave is considered, with wave height \( H=1m \) at 10m depth and wave period \( T=8s \).

The results in Figures 3 to 5 are shown as functions of the wave direction at the toe of the slope, for a location halfway up the slope, where the depth is 5m. Note that the errors generally increase with decreasing water depth. However, in very shallow water, when wave breaking becomes important, the energy dissipation due to wave breaking is likely to
be more important than the refraction error in the PEM. This aspect was not investigated in this study.

In Figure 3, the relative errors (in %) in the wave directions calculated using the parabolic equation model are shown. It is seen that the errors are less than 1%, even for directions as large as 70°. This confirms that wave directions are calculated accurately using the parabolic equation model.

Figure 3. Relative errors in wave directions at 5m depth.

In Figure 4, the corresponding relative errors in wave heights are shown. As expected, these errors are much larger, especially for the Simple approximation. For very large wave directions (directions > 50°), the Minimax 80° performs well, however, it produces much larger errors for smaller directions. Generally, the various approximations are very accurate (less than 5% error) for directions up to 50°.
Figure 4. Relative errors in wave heights at 5m depth.

Figure 5 shows the relative errors in the radiation stress term $S_{xy}$. Notice that it is not the radiation stress gradient that is shown. It is again seen, that the Simple approximation only works well for very small directions and that the Padé approximation and the Minimax $10^\circ-30^\circ$ approximations are almost identical. The errors for larger wave directions decrease with increasing aperture width in the Minimax approximation. However, the Minimax approximation with large aperture width (Minimax $70^\circ$, Minimax $80^\circ$) gives bigger errors than the other PEM for small wave directions.

Figure 5. Relative errors in the radiation stress term $S_{xy}$ at 5m depth.
Figure 6. Radiation stresses $S_{xy}$ as a function of distance towards the shore ($x$). The wave direction at the toe of the slope is 30°.

In Figure 6, $S_{xy}$ is shown as a function of the distance towards the shore ($x$) for the case where the wave direction at the toe of the slope is 30°. From this figure, we can see the magnitude of the gradient $\partial S_{xy}/\partial x$ that generates the false currents in the parabolic equation model. The Simple approximation has a large positive gradient, which gives clearly unrealistic currents. The Padé and the Minimax 10-30 approximations have very small gradients. These gradients will not generate significant currents. The higher Minimax approximations generate spurious currents in this case because the gradients are negative.

The magnitude of the currents can be seen in Figure 7 where the longshore current profiles are given for four cases. The first three show the performance of the Simple approximation, the Minimax 40° and the Minimax 80° approximation for an angle of incidence of 30°. The Minimax 40° approximation is very good in this case, there is almost zero current outside the surf zone, whereas the two others generate modest currents. The fourth case shows the current profile for the Simple approximation for the case of a large incident wave direction (60°). In this case, the false current offshore of the surf zone is seen to be of a significant magnitude compared with the surf zone current.
Conclusions

The investigations in this paper show that the predicted wave directions from PEM models are generally accurate. However, wave heights, radiation stresses and longshore currents predicted from PEM can contain significant errors depending on the parabolic approximation used. The error arises because of the inexact representation of the refraction coefficient in PEM.

In the examples given here, it was easy to quantify the errors and identify the false longshore currents. However, for a complex bathymetry as usually encountered in nature, it will generally not be as easy, and we must emphasize the importance of making a proper choice of parabolic approximation. Also, in real applications the incident wave field will be directional, and thus, what works for one wave direction may not work for another.

Definitely, the Simple approximation should not be used in cases where the waves approach at an angle. In most practical cases, using a Minimax 50° or 60° approximation should work well, since this gives, on the average, a small error in the refraction coefficient over a large range of wave directions (0° to 60°) that will normally be encountered in practice. For cases where the wave directions in the study area are known a-priori to be less than 30°, the Padé approximation is recommended.

A Refraction-Diffraction Model for Irregular Waves

Q. Gao¹, A.C. Radder²

Abstract

A numerical model for wave refraction and diffraction has been used to compute irregular waves. The model is based on the parabolic approximation, but, by combining with the perfect boundary condition, it is suitable for waves propagating with large incident angles. The irregular waves are modelled through linear superposition of wave components. In order to apply the model to field cases, however, the numerical computations were carried out with one representative frequency while retaining spectral representation of the directionality of waves. This approximation has been examined by the laboratory conditions of Vincent & Briggs; The model’s performances in the field cases were also investigated.

Introduction

Recently, two distinct wave models have been used to determine wave properties in two-dimensional near shore zones. One is the so-called parabolic wave model based upon the mild-slope equation, the other is the phase averaged model based on the balance equation for wave energy or wave action. Both models are implemented according to Eulerian approach of wave propagation and wave information is available at the mesh-points of a regular grid. The phase averaged model (for example see Holthuijsen et al. 1989, Holthuijsen et al. 1993), if fully discretized in frequency and direction domain, can trustworthy account for various physical processes such as wave generation, dissipation and nonlinear wave-wave interaction. While this greatly improves representation of the random, short-crested waves, the absence of diffraction in the governing equation can lead to inaccuracy in the case of waves with small directional spreading. The parabolic model (see, for example, Radder, 1979, Kirby & Dalrymple, 1983) not only contains the processes of wave transformation such as shoaling, refraction and diffraction, but also can include various other physical influences such as wave growth and dissipation (see Vogel et al. 1988), and the model can be easily implemented on nearshore area. However, the parabolic model has its inherent shortcomings: waves must propagate in one

¹ Researcher, Rijkswaterstaat, Institute for Inland Water Management and W&W Treatment/RIZA, Postbus 17, 8200AA, Lelystad, The Netherlands
² Senior Researcher, Rijkswaterstaat, National Institute for Coastal and Marine Management/RIKZ, Postbus 20907, 2500EX, The Hague, The Netherlands
principal direction, say x-direction, since the diffraction effect is restricted to y-direction; and the model deals only with regular waves. A numerical model for irregular waves has been developed which is based on the parabolic approximation and which is suitable for waves with large incident angle (see Gao et al. 1993). In the model a careful treatment of the lateral boundary condition was introduced to prevent the contamination from undesirable side effects (see also Dalrymple & Martin, 1992), it not only makes computation very efficient, but also leads the physical interpretation of the computed results straightforward.

The model has been applied to the laboratory cases with fully spectral form. The results compare well with the experiment of wave transformation over the elliptical shoal carried out by Vincent & Briggs (1989), which usually can not be handled properly by a phase averaged model. When the model is applied to the field cases, the computer effort will be very excessive. We will define a representative frequency, mean frequency of waves, instead of full discretization in frequency domain, while the spectral representation of the directionality of waves is still retained as we consider on the coastal area the directional spreading of waves more important than the spectral representation in the frequency domain. The improvement of the model has been found when it was applied to estuary Haringvliet (a closed branch of the Rhine estuary). The model has also been applied to the tidal area of Friesche Zeegat.

Model Equations

In case of an irregular wave field we consider wave components which make fairly large angle $\theta$ with the x-direction. The wide angle equation, that describes the transformation of wave potential $\phi(x,y)$, can be derived

$$\frac{1}{2k^2} \frac{\partial^2}{\partial y^2} \left( 1 - \varepsilon^2 \right) \frac{\partial^2}{\partial x^2} \phi = i k^2 \left( 1 + \varepsilon^2 \frac{\partial^2}{\partial y^2} \right) \phi$$  \hspace{1cm} (1.a)

with

$$P_e \equiv \frac{1}{2k^2} \left[ \sqrt{1 - \varepsilon^2} \left( \frac{\partial k}{\partial x} + \varepsilon \frac{\partial k}{\partial y} + \omega \right) \left( \gamma_d + \nabla \cdot \bar{U} \right) \right]$$  \hspace{1cm} (1.b)

where $\varepsilon = \sin \theta$; $\gamma_d$ is the dissipation coefficient of waves and $\bar{U}$ is the horizontally varying current; $c$, $c_g$ and $\omega_r$ are respectively wave phase velocity, group velocity and relative frequency; wave number $k$ can be calculated according to the linear dispersion relation. The relative frequency is related to the absolute frequency $\omega$ by

$$\omega = \omega_r + k \cdot \bar{U}, \quad \omega_r = \sqrt{gk} \tanh kh$$  \hspace{1cm} (1.c,d)

and the local effective depth

$$h(x,y) = d(x,y) + p_a \cdot H(x,y), \quad 0 \leq p_a \leq 1$$  \hspace{1cm} (1.e)
with \( d(x,y) \) indicating water depth and \( H(x,y) \) wave height. The dissipation coefficient \( \gamma_d \) can be easily represented, as formulated by Dingemans (1985) and Vogel et al. (1988). If the incident angle \( \theta = 0 \) and if there are no dissipation and current, eq. (1) is then reduced to the eq. (17) of Radder (1979).

Numerical representation of eq. (1) is the discretization of wave potential \( \phi \) in spatial domain \( (x,y) \), with \( x > 0 \) and \( 0 < y < y_b \). The discretization in a computational region forms \( M+1 \) rows in \( x \)-direction, with \( x_m = m \Delta x \) \( (m=0, 1, \ldots M) \), and \( N-1 \) columns in \( y \)-direction, with \( y_m = n \Delta y \) \( (n=1, 2, \ldots N-1) \). The equations for lateral boundaries have to be applied at \( n=0 \) and \( n=N \), to provide enough equations to solve for unknown \( \phi_{m,n} \). The solution of \( \phi_{m,n} \) is using the Crank-Nicolson method, which is an implicit scheme with second-order accuracy in both \( \Delta x \) and \( \Delta y \). The details can be found in Gao et al. (1993).

The model has no difficulty to compute two-dimensional spectral waves, with four independent variables \( x, y, \theta \) and \( f \). The only one dependent variable is wave potential \( \phi(x_m, y_m, \theta, f) \). The computation is as follows: one starts computation at up-wave boundary where \( x=0 \) and processes in \( x \)-direction, the computation in \( \theta-f \) domain is that one first solves the linear system of one component on a line in \( y \)-direction, then processes to next component. The computation can proceed to the next line only after that all wave components in \( \theta-f \) domain of a line have been determined.

As mentioned, a parabolic wave model requires lateral boundary conditions. An improper treatment of boundary can cause contamination in the computational domain. Therefore, a parabolic model requires a very large computational domain to avoid the contamination of the interesting area from the lateral boundaries, which leads to inefficiency in computation. A perfect transmitting boundary condition (see also Gao et al. 1993; Dalrymple & Martin, 1992) has been established to allow waves to transmit out or into the computational domain without reflection regardless its direction, crest curvature and the strength of the scattering.

The basis for such a boundary condition is that an exact description of waves in the shadow regions (outside of the computational domain) has to be obtained. To this end we assume in these regions that bottom has straight and parallel contour lines to \( y \)-direction and that wave dissipation depends only on \( x \), then eq. (1) can be solved analytically for wave potential \( \phi \). In practice, we use the differential form of wave potential at the lateral boundaries rather than an analytical one in order that it can be combined with the discretized form of eq. (1). The following equation, which is discretized in \( x \)-direction, can be derived

\[
\frac{\partial \phi^m}{\partial y} + k \sigma \phi^m = \frac{\partial \phi_{inc}^m}{\partial y} + k \sigma \phi_{inc}^m + k \sum_{i=0}^{m-l} \rho \left( \phi^i - \phi_{inc}^i \right) e^{-i \sum_{k=1}^{\infty} \delta (x_1) \Delta x} \tag{2}
\]

which is consistent with the discretized form of eq. (1) at the boundaries. Eq. (2) is the so-called perfect transmitting boundary condition, where \( \phi_{inc} \) is the incident wave which can be obtained numerically, coefficients \( \sigma \), \( \rho \) and \( \delta \) are given as follows:
\[
\delta(x) = \sqrt{1 - \varepsilon^2} (1 + iP_x), \quad \sigma = -i \frac{I}{\sqrt{\beta}} e^{\alpha\mu} \left[ J_\alpha(\mu) - i J_\alpha(\mu) \right] \tag{2.a,b}
\]

\[
\beta = \frac{\varepsilon^2}{1 - \varepsilon^2/2}, \quad \rho_0 = -i \frac{I}{\mu \sqrt{\beta}} \left[ Q(m\mu) - Q((m-1)\mu) \right] \tag{2.c,d}
\]

\[
\rho_i = -i \frac{I}{\mu \sqrt{\beta}} \left[ 2Q((m-i)\mu) - Q((m-1)\mu) - Q((m-1-1)\mu) \right] \tag{2.e}
\]

with

\[
\mu = \frac{1 - \varepsilon^2}{2 \sqrt{1 - \varepsilon^2}} \left[ \frac{1 - \varepsilon^2 (1 + \varepsilon^2)}{2 - i \varepsilon^2 P_x} \right] \Delta x \left( k + \int \frac{\partial k}{\partial x} \, dx \right) \tag{2.f}
\]

\[
Q(z) = z e^{ik\phi} \left[ J_\alpha(z) - i J_\alpha(z) \right] \tag{2.g}
\]

in which \(I=+1\) for left hand side boundary where \(y=y_b\) and \(I=-1\) for right hand side one where \(y=0\), \(J_0\) and \(J_1\) being respectively the zero- and first-order Bessel function. Combining the discretized form of eq.(1) with eq.(2) results a linear system with tridiagonal matrix, which can be solved very efficiently.

To illustrate the performance of the perfect transmitting boundary condition, we compared the numerical results of eq.(2) with a simple absorbing boundary condition, given by

\[
\cos \theta \frac{\partial \psi}{\partial x} + \sin \theta \frac{\partial \psi}{\partial y} = ikp_x \psi \tag{3}
\]

where \(\theta\) is the angle at which the plane waves propagate and \(p_x\) is taken to be 1. A test was carried out for monochromatic waves in water a basis of 500mx500m, with water depth decreasing from 10m at \(x=0\) to 5m at \(x=500m\). The incident waves have height 1 meter, period 8s and an angle 30° with x axis. The spatial resolution is \(\Delta x=5m\), \(\Delta y=7.5m\). In figure (1a) the computation was carried out with eq. (2) to be applied at both boundaries. The robustness of eq.(2) can easily be seen in left panel of figure 1, where waves are reasonably calculated across the whole computational line. Whereas in figure (1.b) we apply eq.(3) to \(y=0\), the boundary of outgoing waves, the distortion in wave field can be easily found.
Figure 1. The plane waves propagate at 30° angle over a shoaling bottom, where arrows indicate the angle at which the waves propagate, and solid line is the iso-line of wave height.

Comparison with The Results of Experiments by Vincent & Briggs

Vincent & Briggs (1989) carried out experiments to simulate regular and irregular random waves in a hydraulic model, which consists of an elliptical shoal and an array of wave sensors. For details of the experiments the reader is referred to Vincent & Briggs. The incident waves which were generated by the spectral wave maker are described by TMA spectrum

\[ E(f) = \alpha g^2 (2\pi)^{-4} f^{-5} \exp\left\{-1.25\left(\frac{f_p}{f}\right)^4 + \ln \gamma \exp\left[\frac{-(f-f_p)^2}{2\sigma_f^2 f_p^2}\right]\right\} \phi_d \]

\[ \text{with } \sigma_a = 0.07 \text{ if } f \leq f_p, \quad \sigma = \sigma_b = 0.09 \text{ if } f \geq f_p; \quad (4.1.a) \]

where \( \alpha \) is the Phillip's constant, \( f_p \) the peak frequency, \( \gamma \) the peak enhancement factor, \( \alpha \) the wave shape factor. The shallow water factor \( \phi_d \) is given by

\[ \phi_d = 0.5 \omega_d^2, \quad \text{if } \omega_d < 1; \quad \phi_d = 1 - 0.5(2 - \omega_d)^2, \quad \text{if } 1 \leq \omega_d \leq 2 \]

\[ \phi_d = 1, \quad \text{if } \omega_d > 2; \quad \text{with } \omega_d = 2\pi f \sqrt{h/g} \quad (4.1.b) \]

The directional spreading used in the experiments is the Fourier series representation for the wrapped normal function, which will be approximated in our computations by the following one

\[ D(\theta) = \frac{1}{2I_s} \cos^2(\theta_0 - \theta), \quad \text{with } I_s = \int_0^{\pi/2} \cos^2(\theta) d\theta \quad (5) \]

where \( s \) is the directional spreading parameter, \( \sigma_w = 10 \) of the Fourier representation for the directional spreading will be approximated by \( s = 20 \) of eq.(5) and \( \sigma_w = 30 \) by \( s = 4 \).
A very high resolution in $\theta$-$f$ domain requires excessive computer effort when the model is applied to field cases. To this end, an approximation will be introduced and the accuracy of it will be examined. We are going to define a representative frequency, mean frequency, to approximate the full discretization in frequency domain, while the spectral representation of directionality of waves will be retained. This can not only save the computational cost by one order or more, but also allow us to employ the expressions for wave dissipation and wave growth in the model easily. The representative period is defined as follows

$$f = \frac{1}{E_0} \int f E(f) df, \quad T = 1/f \quad \text{with} \quad E_0 = \int E(f) df.$$

(6)

To examine the performance of this approximation, we compare to the laboratory case N1 and B1 of Vincent & Briggs, where case N1 and B1 have respectively a narrow and broad directional spreading. For each case three computations were carried out with the numerical model. The first computation was carried out with fully spectral form; the frequencies vary from the minimum $f_1=0.5Hz$ to the maximum $f_{15}=1.5Hz$, with $\Delta f=0.071$; the directional sector is $120^\circ$ and angular resolution is $\Delta \theta=5^\circ$ for all cases. The second and third computations were carried out with or without dissipation due to wave breaking; we employ the approximation form of eq.(6), but still keep the directionality of the spectral waves. There are total $15 \times 25=375$ wave components per mesh point in the first computation and only 25 in the second and third computation. The input parameters are listed in table 1. The parameters in column 2, 3, 4, 5, 7 and 8 are those used in the first computation and those in column 2, 6 to 8 are used in the second or third computations. The computation consists an area of 20m by 23m and the numerical resolution in spatial domain is $\Delta x=0.1m$, $\Delta y=0.1m$.

Table 1 The parameters used by the numerical model.

From above computations the following points are to be worthy noted.

1. The model computes the waves in fully spectral form (discretized in both frequency and directional domain) of the laboratory situation with reasonably accuracy and small cpu cost (about 15 minutes on Pentium 90).
2. We find that the differences between the wave heights calculated by the fully spectral form and by the approximation form of eq.(6) are insignificant.
3. Along section 3 discrepancies are found between the computed and measured wave heights in the divergence zones, but the differences decrease for waves with the broad directional spreading.
4. Along section 7-9 of wave propagation direction, the computed and measured wave heights agree reasonably well.
5. It is not conclusive that one can improve the computed results by including wave dissipation in the model.
Figure 2a. Comparison between the computed and measured wave heights along the section 3 for case N1. The legends are given as follows: spe tr: wave heights computed with fully spectral form; meas: measured heights; appr: computed with the approximation of eq. (6); break: computed with dissipation due to wave breaking.

Comparison with Field Measurements

When approaching the shore region, the surface waves will be influenced by a number of factors. Except for wave shoaling and breaking, refraction and diffraction, wind will have a profound effect on waves in a region behind an island or breaker zone. In our model we adopt an empirical expression to account for wave growth due to wind effect (see also Vogel et al., 1988)

\[
y'' = -a y' + \frac{2c}{b} \frac{dH_s}{dx} \cos(\theta_s - \theta),
\]

where \( H_s \) is the significant wave height, \( U_w, \theta_w, \theta, \) and \( x_w \) are respectively wind speed and direction, wave direction and fetch, coefficient \( b=0.30 \) and \( a=0.009 \) were used in the following computations. As mentioned in the previous section we will use a representative period, the mean period, but still keep the directionality of spectral waves in the field cases of the estuary Haringvliet and tidal area Friesche Zeegat.

A. The estuary Haringvliet

The area was chosen to test the model because the wave data in this area is well documented (for details see Andorka Gal, 1995), and because the data set has been extensively used to test the performance of various wave models (see, for example, Vogel et al., 1988, Holthuijsen et al., 1989). The bathymetry of the estuary and the locations of the measurement are shown in figure 3. The computational area of the present model, which consists of an area of \( 13600m \times 12400m \), is considerably smaller than those mentioned; the directional sector is \( 120^\circ \). The spatial resolution is \( \Delta x=5m, \Delta y=10m \) and the angular resolution is \( \Delta \theta=15^\circ \), the directional spreading parameter is \( s=4 \) for all cases. There are total 9 wave components involved in one mesh point. The computations were carried out for the storm situation of 14-15 Oct. 1982. The directional wave buoy WAVEC (see figure 3 at location WA) provides significant wave height, mean wave direction and mean period as up-boundary.
conditions; these are listed in Table 2, along with wind and water level. The measured wave heights at other locations were used to check the accuracy of the model. The comparison between the computed and the measured wave heights are given in Table 3. Further the computed wave heights versus the measured ones are shown in figure 4.

### Table 3. Comparison of the measured and computed wave heights in Haringvliet.

To measure the performance of the model, we employ the following two statistical expressions, by which the larger waves can not dominate the error quantities; the first one is the relative root-mean-square-error, the second is the performance rate of the model, defined as follows:

$$
\varepsilon_{\text{rms}} = \sqrt{\frac{1}{N} \sum_{i=1}^{N} \left( \frac{H_{\text{CMP}}}{H_{\text{MEAS}}} - 1 \right)^2}
$$

$$
P_{\text{mdl}} = 1 - \frac{\sum_{i=1}^{N} \left( H_{\text{CMP}} - H_{\text{MEAS}} \right)^2}{\sum_{i=1}^{N} \left( |H_{\text{CMP}} - H_{\text{MEAS}}| + |H_{\text{MEAS}} - H_{\text{MEAS}}| \right)^2}
$$

(8.a,b)
where $H_{CMP}$ is the computed wave height and $H_{MKAS}$ the measured one. $H_{MFW}$ is the measured mean wave height. For the data set listed in Table 3 we have $\varepsilon_{rms} = 0.094$ and $P_{md} = 76\%$, these compare favourably to the model CREDIZ (Vogel et al., 1988), which has $\varepsilon_{rms} = 0.17$ and $P_{md} = 67\%$.

Figure 3 Bathymetry of the estuary Haringvliet and locations of the measurement, where the rectangle indicates the computational area.

Figure 4 Computed wave heights versus measured ones.

B. The tidal area Friesche Zeegat

The aim is to test the model in a situation of strong tidal current, up which waves propagate. The area was chosen because the wave data from measurements is available (see Dunsbergen, 1995), and tidal currents were calculated with a fair degree of detail. The bathymetry of the area, along with locations of measurement, is shown in figure 5. A shoal, located in the centre of the tidal channel, will shelter most onshore area from the incoming waves. The tidal current, as shown in figure 6a (for
flood case) and figure 7a (for ebb case), will also contribute to deflect the propagation direction of the incoming waves.

The weather situation was that a storm in the North Sea generated waves, which propagated into tidal area. The computations were carried out for the flood case at 06:00 M.E.T., Oct. 9, 1992 and the ebb case at 12:00 M.E.T. Oct. 9 1992 in a rectangular area of 22000m×16000m, the directional sector was taken to be 90°. The waves measured by WAVEC buoy at location S is used to provide the model with the up-wave boundary. The input parameters are given in Table 4, where the mean wave direction is the same as wind and is in nautical convention. The wave heights measured at other locations were used to check the performance of the model. The resolution was Δx=5m, Δy=10m and Δθ=15°, the directional spreading parameter s=6 is used for flood case and s=10 for ebb case. In these computations only 7 wave components per mesh point are used.

Table 5 The measured and computed wave heights for ebb and flood cases.
The comparison between the computed and measured waves is shown in table 5. For the flood case the rms error $\varepsilon_{\text{rms}}$ is 0.23, the performance rate $P_{\text{mdl}}$ is 97% and for the ebb case $\varepsilon_{\text{rms}}=0.27$, $P_{\text{mdl}}=69\%$. The computed wave fields are shown in figure 6b for the flood case and figure 7b for the ebb case. The following remarks are added here according to the computed results: The varying depth in the area of the tidal inlet deflects the propagation direction of the incoming waves, making them towards the shallow area. In such a situation it is hardly possible for monochromatic waves to penetrate through the channel and to arrive in the onshore region (south of tidal inlet). The computations also indicate that in the inlet region the tidal current has profound influence on the computed waves, whereas wind nearly dominates the waves in onshore region.

Figure 6a. Tidal current for flood case at 06:00 M.E. T., Oct. 9, 1992 in the area of Friesche Zeegat, where the rectangular line indicates the computational area.

Figure 6b. Computed waves for the flood case, where the iso-lines refer to the wave height and arrows indicate the mean wave direction.
Conclusions

The advantage of the parabolic model is that it can be used to compute wave transformation in a large horizontal domain, say, a region of several hundreds of wave length on one side. But when applied to field cases, the model often assumes the incoming waves to be monochromatic. The numerical model presented in this paper can be used to compute irregular waves and regular waves as well. The numerical results have been compared to a number of measurements from hydraulic models as well as field cases on coastal areas. We have the following conclusions: 1, The results show that the model is suitable for waves with large incident angle. 2, Through the linear superposition of regular waves, the model can be used to compute irregular waves; the performance of the model was reasonably good when it was applied to the laboratory cases of Vincent & Briggs. 3, The perfect boundary condition used in the numerical model can allow waves to transmit out or into the computational domain.
without causing disturbances in the computational domain, which also makes the
computation of waves very efficient. 4. The model can be used to compute waves in
field cases and it performs quite well when compared to the observations.

CALCULATION OF VELOCITY FIELD IN 3-D RANDOM WAVES
Yu-xiu Yu* and Ning-chuan Zhang**

ABSTRACT

A method simply treating the governing equation for 3-D wave-motion is proposed in this paper. The Euler's velocity in whole depth can be directly calculated with this method if the wave free surface is given. For the linear waves the wave surface is determined from given directional spectrum (Yu, et al. 1991) or other wave surfaces at near locations with an inversion method proposed in this paper. For the nonlinear waves the wave surface can be determined with the method proposed by Dommermuth and Yue (1987). These methods proposed by authors are tested and verified with numerical simulation, model test or field observation data.

1. INTRODUCTION

The sea wave is a three-dimentional random process. An understanding of the kinematics of waves is critical to the understanding of many processes in the sea from the forcing on structures to nearshore sediment transport. In general the velocity field of sea waves is three dimentional, random, and nonlinear. Due to the complexity of this problem, some scientists only considered its three-dimentionality and random property and the direct linear superposition method was used to calculated the velocity. Others emphasized its nonlinearity and the higher-order unidirectional wave theories were used. Forristall et al (1978) showed that even linear wave theory with directional spereading of wave energy predicts storm wave kinematics of the subsurface flow better than higher-order unidirectional wave theories. But the direct linear method greatly overestimate crest velocities near the surface (Donelan, 1992). Some methods, for example the coordinate stretching method and the extrapolation method were proposed to correct the direct linear method and the results of former are smaller than that of the latter. The measured kinematics in the crests of random waves is bounded by these two modified linear models.

* Professor, The State Key Laboratory of Coastal and Offshore Engineering, Dalian University of Technology (DUT), Dalian 116024, China
** Associate Professor, Dept. of Civil Eng. DUT, Dalian 116024, China
(Roderbusch and Forristall, 1982). More recently, Donelan (1992) proposed a new method based on the linear superposition of a sum of freely propagating wave-trains and assume that shorter waves ride on longer ones. But the effect of nonlinearity is not considered yet in this method.

Methods used for the calculation of velocity field in irregular waves fall into two general categories, global and local approximations. The local method attempt to find separate solutions to the governing equations that fit sequential windows in time of the given record, rather than attempting to find a single solution that fits an entire record. The amount of computation work is large.

Prislin and Zhang (1997) presented a newly-developed deterministic methodology for decomposition of nonlinear short-crested irregular waves up to second order in wave steepness into a characteristic set of free-wave components. Based on the decomposed free-wave components, the Directional Hybrid Wave Method (DHWM) allows for prediction of wave properties other than measured and at different locations including wave crests.

Dommermuth and Yue (1987) developed a numerical method for modelling nonlinear gravity waves which is based on the Zakharov equation/mode-coupling idea but is generalized to include interactions up to an arbitrary order $M$ in wave steepness. This method was used to calculate the deformation of a travelling wave (Dommermuth, et al. 1987). In this paper, an inversion method is proposed to determine the wave surface from other wave surfaces at near locations, then it is used as the boundary condition to derive the wave kinematics in 3-D random waves with Dommermuth’s idea.

2. NUMERICAL INVERSION OF 3-D RANDOM WAVE SURFACE

The single direction per frequency model (Yu et al. 1991) is used to describe the 3-D random wave surface at point $(x,y)$:

$$\eta(x,y,t) = \sum_{m=1}^{M} \sum_{i=1}^{I} a_{mi}\cos(\omega_{mi}t + k_{mi}(xcos\theta_i + ysin\theta_i) + \epsilon_{mi})$$

(1)

$$a_{mi} = \sqrt{2S(\omega_m,\theta_i)d\omega_m d\theta_i}$$

(2)

where $M$ and $N$ are the division numbers of frequency and direction respectively; $a_{mi}$, $\omega_{mi}$, $k_{mi}$ and $\epsilon_{mi}$ are amplitude, frequency, wave number and random initial phase of the component waves; $S(\omega,\theta)$ is the directional spectrum.

Usually, if the directional spectrum is given, the 3-D wave surface can be obtained with Eqs. (1) and (2). It also can be measured. But sometimes we can not measure the wave surface at structure position. In this case, an inversion method is proposed to determine the wave surface from other wave surfaces at near locations. The wave surface can be expanded as a Fourier Series:

$$\eta(x,y,t) = \sum_{j=1}^{J} (A_j\cos\omega_j + B_j\sin\omega_j)$$

(3)

where $A_j$ and $B_j$ are the Fourier coefficients. If the length of the wave data is $L$, then
$A_j = \frac{2}{L} \sum_{l=1}^{L} \eta(x, y, t_l) \cos \omega t_l dt$

$B_j = \frac{2}{L} \sum_{l=1}^{L} \eta(x, y, t_l) \sin \omega t_l dt$

Eq. (3) can be rewritten as

$$\eta(x, y, t) = \sum_{j=1}^{J} a_j \cos(\omega t + \beta_j)$$

$$a_j = \sqrt{A_j^2 + B_j^2}$$

$$\beta_j = \arctan(-B_j/A_j)$$

Comparing with Eq. (1) we can get the total phase

$$\beta_j = k_j(x \cos \theta_j + y \sin \theta_j) + \epsilon_j$$

If the wave surfaces $\eta(x, y, t)$ are measured at $I$ points and $I \geq 3$, the total phase for each surface can be obtained

$$\beta_j = k_j(x \cos \theta_j + y \sin \theta_j) + \epsilon_j$$

In these equations, only the directions, $\theta_j$, and the initial phase $\epsilon_j$ of component waves are unknown and they can be obtained from any two equations in principle. For example, from points 1 and 2 (Fig. 1) one can get

$$\theta_{12} = \alpha_{12} + \cos^{-1}\left[\frac{\beta_j - \beta_{j'}}{k_j D_{12}}\right]$$

But in Eqs. (5) and (8), both arctangent and arccosine are multi-value function. Moreover, some component wave's directions are nearly parallel to the line 1-2 and the Eq. (7) for points 1 and 2 is invalid for these component waves. Therefore, at least three measured points are necessary. For each pair of measured point, two equations form a simultaneous equations and the values of $\theta_j$ and $\epsilon_j$ can be obtained for each component wave except the invalid condition. In general, for $n$ pairs of measured points.

$$\theta_j = \frac{1}{n} \sum_{k=1}^{n} \theta_{jk}$$

Then the wave surface at any point can be calculated with Eq. (1) if the wave field is homogenous.

The numerical simulation, the physical simulation and the field wave data are used to examine this method. Five wave gages of vertical line type arranged in T-type array (Fig. 2a) were used in the field observation (Liu and Yu, 1995). The wave data were recorded simultaneously for 1200 seconds every hour and the time interval, $\Delta t$, is 0.25s. Fig. 2(b) shows an example of the comparison of wave surfaces between field data at point 1 and the numerical inversion result form these at
points 2, 3, 4 and 5. It shows that this method is successful and its precision is dependent on the length of data, $N\Delta t$, the distance, $R$ from measured points to predicted point and the spatial homogeneity of wave field. According to the numerical simulation result, when $R/L_\alpha = 1.0$, number of points $N \geq 2000$, when $R/L_\alpha = 10$, $N \geq 3000$ and when $R/L_\alpha = 20$, $N \geq 4000$, where $L_\alpha$ is the significant wave length. But in nature, the wave field is not exactly homogenous, so the validity of this method is limited to a few wave length from the measurement sites.

(b) Fig. 2 A comparison of wave surfaces between field data (-----) and numerical inversion (-----)

3 CALCULATION OF VELOCITY FIELD

3.1 Governing Equations

The irrotational wave motion of a homogeneous, incompressible and inviscid fluid is considered. The origin is located at the mean water level and the vertical axis $z$ is positive upward. The wave flow can be described by a velocity potential $\phi(x,y,z,t)$ such that within the fluid $\phi$ satisfies Laplace’s equation:

$$\Delta \phi = \frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} = 0$$  \hspace{1cm} (10)

where $x, y, z, t$ denote the coordinate $x$ of boundary between water and land at time $t$. $\eta(x,y,z,t)$ is the free surface of wave. For determining the velocity potential, the following boundary conditions should be satisfied.

Kinematics condition at bottom

$$\left. \frac{\partial \phi}{\partial z} \right|_{z=-h} = 0$$  \hspace{1cm} (11)

Kinematics condition at free surface

$$\left. \frac{\partial \phi}{\partial x} \right|_{x=\eta} = \frac{\partial \eta}{\partial t} + \frac{\partial \eta}{\partial x} \left. \frac{\partial \phi}{\partial x} \right|_{x=\eta} + \frac{\partial \eta}{\partial y} \left. \frac{\partial \phi}{\partial y} \right|_{x=\eta}$$  \hspace{1cm} (12)

Dynamic condition at free surface

$$\left. \frac{\partial \phi}{\partial t} \right|_{x=\eta} + g\eta + \frac{1}{2} (\nabla \phi \cdot \nabla \phi)_{x=\eta} + \frac{\rho_U(x,y,z,t)}{\rho} = 0$$  \hspace{1cm} (13)

with $x \to \infty$ or $y \to \infty$ or $z \to \infty$, $\phi(x,y,z,t)$ and $\eta(x,y,z,t)$ are finite.
Initial condition
\[ \eta(x, y, t) \big|_{t=0} = \eta_0(x, y) \]
\[ \nabla \phi(x, y, z, t) \big|_{t=0} = \nabla g(x, y, z) \] (14)
(15)
where \( \nabla g(x, y, z) \) denote the initial velocity potential and it should satisfy the irrotational condition. It is very difficult to solve Eq. (10) directly to study the wave kinematics and some simplification is necessary.

3.2 Simplified Treatment Method

Dommermuth and Yue (1987) presented an approximate model for wave motion. The velocity potential at wave surface is defined as (Zakharov, 1968):
\[ \phi^*(x, y, t) = \phi(x, y, \eta(x, y, t), t) \] (16)
where, \( \eta(x, y, t) \) denotes the free surface. In terms of \( \phi^* \), the kinematic and dynamic boundary conditions on the free surface are respectively
\[ \eta + \nabla \phi^* \cdot \nabla \eta - (1 + \nabla \eta \cdot \nabla \eta) \phi_4(x, y, \eta, t) = 0 \]
\[ \phi^* + g \eta + \frac{1}{2} \nabla \phi^* \cdot \nabla \phi^* - \frac{1}{2} (1 + \nabla \eta \cdot \nabla \eta) \phi_4^2(x, y, \eta, t) = 0 \] (17)
where \( \vec{r} = (x, y) \) is the position vector, \( \nabla = \left( \frac{\partial}{\partial x}, \frac{\partial}{\partial y} \right) \) denotes the horizontal gradient.

The initial conditions at wave surface are
\[ \phi(x, y, 0) = q_1(x, y) \] (18)
\[ \eta(x, y, 0) = q_2(x, y) \] (19)
where \( q_1(x, y) \) and \( q_2(x, y) \) are given.

If the wave elevation, \( \eta(x, y, t) \) and the velocity potential at free surface, \( \phi^*(x, y, \eta, t) \) are expressed with the Fourier integral which satisfy the continuous equation and the bottom boundary condition, Eq. (17) is expressed as the equations concerning Fourier amplitude and these equations are solved by a perturbation method, whose key idea is that \( \phi_4(x, y, \eta, t) \) is to be expressed as the function of \( \phi \) and \( \eta \). Dommermuth and Yue (1987) assumed that \( \phi \) and \( \eta \) are \( O(\epsilon) \) quantities, where \( \epsilon \), a small parameter, is a measure of the wave steepness. We consider a consistent approximation up to and including a given order \( M \) in \( \epsilon \), and write \( \phi \) in a perturbation series in \( \epsilon \).

The surface vertical velocity
\[ \phi_4(x, y, \eta, t) = \sum_{m=1}^{M} \sum_{K=0}^{M-m} \frac{\eta^K}{K!} \sum_{n=1}^{N} \phi_n^{(m)}(t) \frac{\partial^{K+1} \phi_n(x, y, 0)}{\partial \xi^K} \] (20)
Substitute (20) into (17) and yields the final result
\[ \eta + \nabla \phi^* \cdot \nabla \eta - (1 - \nabla \eta \cdot \nabla \eta) \left( \sum_{m=1}^{M} \sum_{K=0}^{M-m} \frac{\eta^K}{K!} \sum_{n=1}^{N} \phi_n^{(m)}(t) \frac{\partial^{K+1} \phi_n(x, y, 0)}{\partial \xi^K} \right) = 0 \]
\[ \phi^* + g \eta + \frac{1}{2} \nabla \phi^* \cdot \nabla \phi^* - \frac{1}{2} (1 + \nabla \eta \cdot \nabla \eta) \phi_4^2 \]
\[ \left( \sum_{m=1}^{M} \sum_{K=0}^{M-m} \frac{\eta^K}{K!} \sum_{n=1}^{N} \phi_n^{(m)}(t) \frac{\partial^{K+1} \phi_n(x, y, 0)}{\partial \xi^K} \right)^2 = 0 \] (21)
Where \( (\quad)^m \) denote a quantity of \( O(\epsilon^m) \), \( \phi_n^{(m)} \) is called modal amplitude, \( \phi_n(x, y, 0) \) is given as follows:
\[ \psi_n = \frac{\cosh k_n(z + d)e^{ik_n d}}{\cosh k_n d} \]  
where \( k_n \) is the wave number of \( n \)th characteristic wave. The modal amplitude, \( \phi_n^{(m)}(t) \) can be treated as the function of \( \phi \) and \( \eta \) and can be obtained by solving successively at increasing order the following equations:

\[
\begin{align*}
\sum_{n=1}^{N} \phi_n^{(1)}(x, y, 0) &= \phi' \\
\sum_{n=1}^{N} \phi_n^{(m)}(x, y, 0) &= \sum_{n=1}^{N-1} \frac{y}{k!} \frac{\partial}{\partial x} \left( \sum_{n=1}^{N} \phi_n^{(m-k)}(x, y, z) \right) \bigg|_{z=0} \\
m &= 2, 3, \ldots, M
\end{align*}
\]  
(23)

Eq. (21) is the generalization to Mth order in wave steepness, \( \epsilon \) of perturbation equations. For the finite \( \epsilon \), Dommermuth (1987) had proven that \( |\psi_n(x, y, \eta_{\text{max}})/\psi_n(x, y, \eta_{\text{min}})| \) will rapidly increase along with \( n \) increasing. It means that the perturbation equation will exactly consistent converge to the original equation.

For treating the three dimensional problem with both nonlinear and randomness the following model are proposed.

3.3 Wave Motion Equation under Known Wave Surface

When the surface elevations of a random wave are known, among two boundary condition equations at free surface only the potential function \( \phi \) is to be determined. so we can choice either the kinematics boundary condition or the dynamic boundary condition as the boundary condition at known free surface. Thus the problem of solving velocity field under known wave surface is transformed into the boundary-value problem of Laplace equation in a given area, \( x_1 \leq x \leq x_2; y_1 \leq y \leq y_2; -d \leq z \leq \eta(x, y) \) as Fig. 3 shown.
In given area, this boundary-value problem can be divided into two parts:

Part 1. Solve the surface protential function, \( \psi(x, y, t) \) at free surface. Using Dommermuth's expression method, substituting (20) into (12), one can get the governing equation:

\[
\eta_i = \sum_{m=1}^{N} \sum_{k=0}^{K} \sum_{n=1}^{N} \eta^{(m)}_n (t) \frac{\partial^{k+1} \psi_n (x, y, z)}{\partial x^{k+1}} \bigg|_{z=0} - \eta_{x} \frac{\partial \psi}{\partial x} - \eta_{y} \frac{\partial \psi}{\partial y} \tag{24}
\]

Part 2. In the given area, solve the Laplace equation given as Eq. (10). Their boundary conditions are

At bottom \( z = -d \), as same as Eq. (11)

At free surface \( z = \eta \), use the results in Part 1. The potential function at surface is used as the first kind of boundary condition.

At four profiles of \( x = x_1, x = x_2, y = y_1 \) and \( y = y_2 \) it is given directly by the linear potential function:

\[
\phi(x, y, z, t) = \sum_{m=1}^{N} \sum_{i=1}^{I} a_{m,i} \cos k_m (x \cos \theta_i + y \sin \theta_i) + \omega_m t + \epsilon_m \tag{25}
\]

As we know the accuracy of linear theory is enough except at where close free surface. If the computation area is large enough, the effect of the linear error on the computed results at the center point of this area can be negligible.

3.4 Numerical Method

The governing equation is solved with a finite difference method. Because the simplified governing equation is very simple, any special treatment is not needed for its computation.

3.4.1 Computing potential function at free surface.

At a given time the wave surface elevation, \( \eta(x, y, t) \) and the linear potential function \( \phi(x, y, t) \) are given so that the modal amplitude, \( \phi^{(m)}_n (t) \) of velocity potential satisfies the Dirichlet boundary condition. Because the calculation range is \( z \leq 0 \), so the amplitude \( \phi^{(m)}_n (t) \) in the range of computational cuboid can be given with a pseudospectral method (Gottlieb and Orszag, 1977). The basic of the pseudospectral method is the Fourier series expansion of periodic function and the Chebyshev polynomial expansion of a general function and the expansive coefficients are obtained with FFT. Here the FFT is done for wave number \( k \) (for frequency in general). In each order of solving process, the number of \( k \) requested is equal to that of Fourier item.

For calculate \( \phi (x, y, t) \), considering the nonlinear interaction between the component waves of different period, the order of the perturbation, \( M \) should be four. In this case, from Eq. (20) one can get:

\[
\phi (x, y, t) = \sum_{s=1}^{N} e^{is\tau} \left\{ \phi_1 (k_s \tanh (k_s d) + \eta k^2 + \frac{\eta^2}{2} k^2 \tanh (k_s d) + \frac{\eta^4}{6} k^4_d) \right. \\
+ \phi_2 (k_s \tanh (k_s d) + \eta k^2 + \frac{\eta^2}{2} k^2 \tanh (k_s d)) \\
+ \phi_3 (k_s \tanh (k_s d) + \eta k^2 + \phi_4 (k_s \tanh (k_s d)) \right\} \tag{26}
\]
Then calculate $\phi$ at discrete points with iterative method.

3.4.2 Calculate $\phi$ in the given area.

3.4.3 Matching the boundary conditions

At the boundary between free surface and four profiles of $x=x_1$, $x=x_2$, $y=y_1$ and $y=y_2$ the boundary conditions are not continuative. Because the potential function at free surface is obtained by Eq. (24) and those at four profiles are given by linear wave theory. The Lagrange's insertion formula is used to matching the boundary conditions. For the deep water take the bottom boundary at $z=-d/2$ and the potential function is also given by linear theory, it is in harmony with that at four profiles.

3.4.4 Solve difference equation group

The successive overrelaxation (SOR) method is used to solve the difference equation. The relaxation factor is equal to 1.5.

3.5 Reliability Examination of Numerical Method.

3.5.1 Errors due to linear boundary conditions

A regular wave is considered, its $H=15\text{cm}$, $T=1.5\text{s}$ and depth $d=41.3\text{m}$. Two boundary conditions are artificially constructed, one is a linear boundary and at the boundary between wave surface and four profiles, the boundary conditions are matching with Lagrange's insertion. Another is taken as $\phi_0(z) \cdot G(z)$ and the definition of $G(z)$ is shown in Fig. 4(a). The computational parameters are perturbation order $M=3$, Fourier truncation number $N=16$. Computation area $x_1=0$, $x_2=2.0\text{m}$, node spacing $\Delta x=0.05\text{m}$, $\Delta z=0.01\text{m}$. Fig. 4(b) shows that the potential functions $\phi(i,j)$ at different depth obtained from linear boundary condition are in agreement with that obtained from another boundary condition beyond the eighth node. So it is concluded that for calculating the potential function at the center of area $2 \times 2\text{m}$ the linear boundary condition is available with enough accuracy.

![Fig. 4 Errors due to linear boundary condition](image)

3.5.2 The effect of perturbation order number $M$

Taking $M=1, 2, 3$ and $4$ respectively calculate the velocity $v_x$ in a regular
wave as above mentioned at $x = 1.0m$, $z/d = -0.25$. As Fig. 5 shows that the velocity for $M=3$ is almost the same as that for $M=4$ and even if $M=2$ its result is acceptable.

![Fig. 5 Comparison of calculation results with different $M$ for velocity $V_x$](image)

3.5.3 Comparison between numerical calculation and wave theories

The linear theory, 2nd Stokes and 3rd Stokes wave theories and the numerical method are used to calculate the velocity $V_x$ respectively in a regular wave. The results show that at the crest phase the velocity $V_x$ calculated by numerical method is almost the same as that from 3rd Stokes wave theory.

3.6 Velocity Field in 3-D Random Waves—Model Test

The velocity field in regular wave, unidirectional random wave and 3-D random wave were experimentally studied in the State Key Laboratory of Coastal and Offshore Engineering, Dalian University of Technology, China. The wave basin is 55m long, 34m wide and 1.3m deep. The multi-directional wave-maker consists of 70 independent segments of 0.4m wide. Wave absorbers were placed along the basin walls to prevent wave reflection from the walls. A wave gage array consisted of 8 X 8 gages was set 6.5m apart from the wave plate. The gage spacings were about 0.25m. An Acoustic Doppler Velocimeter (ADV) was put near the center of the wave gage array to measure three flow velocity components. The data of wave elevations and velocities were acquired simultaneously by computer. The sampling interval was 0.05s and the data length is 512—1024 (regular waves), 4096 (unidirectional waves) and 8192 points (3-D random waves). The water depth was kept 0.413m. The velocities were measured at $Z = -0.303m$, $-0.196m$, $-0.109m$ and $-0.018m$ respectively. For the last case, the ADV was out of water at trough phase.

The JONSWAP spectrum, $\gamma = 3.3$ and the Mitsuyasu-type spreading function, $G_0 \cos^\nu \frac{\theta}{2}$, was used to simulate the 3-D random waves with the Single Direction Per Frequency Model (Yu et al., 1991). $H_\frac{1}{3} = 0.047 \sim 0.145m$, $T_H \frac{1}{3} = 1.09$~
1. 88s. The measured directional spectrum was estimated by the Bayesian Approach (Hashimoto et al., 1987). The numerical inversion method was used to obtain the wave surface at ADV's position from the wave surfaces at 5 near locations. Then it was used to calculate the velocities and compared with the measured ones by ADV.

Fig. 6 shows an example of the comparison between calculated and measured velocity histories in an oblique 2-D random wave. Two velocity histories are agreeable each other.

The example of the comparison between the calculated and measured velocities \( v_x, v_z \) in a 2-D random wave at the position \( z = -0.018 \text{m} \) is shown in Fig. 7. Two sets of velocity history are agreeable. But for the trough phase, the ADV is out of the water so the measured velocities are equal to zero.

For the 3-D random waves the example of the comparison between the measured and calculated velocities is shown in Fig. 8. The wave spreading parameter, \( s = 50 \). The velocities are measured at the position 0.304m above bottom. Two sets of velocity history are basically consistent. In this case the accuracy of velocity calculation is also dependent on that of the wave surface inversion.

3. 7 Effects of nonlinearity on velocity

For the unidirectional wave, the direct linear method and Donelan's linear method (1992) are used to calculate the velocities at different depth and their results are compared with that by the nonlinear numerical method. Their ratios are shown in Fig. 9. The measured results are also shown in this figure by closed circles. It is found that when \( z/d < -0.25 \) all of three methods can predict the available velocities which is close to the measured ones. But when \( z/d \rightarrow 0 \) two linear
methods over-predict the velocities. For 3-D waves, the general variation tendency is the same as for 2-D waves.

Fig. 10 shows the comparison between calculated and measured velocities \( v_x \) and \( v_y \) at wave crest for 3-D random wave. The linear method overestimate the velocities and the nonlinear numerical method predict the velocities closed to measured ones.

4. CONCLUSIONS

A numerical method calculating the 3-D velocity field under a given random wave surface directly by the governing equations is proposed in this paper. It is verified with the experimental study that this method can predict 3-D velocities at different locations including wave crest with high accuracy. The direct linear method usually greatly overestimates the crest velocities near the surface.

The wave surface needed for velocity calculation can be numerically simulated from directional spectrum or determined from other wave surfaces at near locations with an inversion method proposed in this paper. The inversion method is verified with model test and field data.

The effects of nonlinearity of waves on the velocities at positions near still water level are not negligible. The experimental results show that this effect of 2-D waves is more than that of 3-D waves and this effect on vertical component velocity is more than that on horizontal component velocity.

ON THE REFLECTION OF SHORT-CRESTED WAVES IN NUMERICAL MODELS

Michael Brorsen and Jacob Helm-Petersen

Abstract

The paper concerns the reflection performance of so-called 'sponge' layers, which are used to model partially reflecting (porous) structures in a numerical model domain. Various compositions of sponge layers and their performance with respect to wave reflection, main direction of propagation, and directional spreading have been investigated. The numerical model used in this study was a finite difference model based on the time-dependent mild-slope equation. Comparisons are made with reflection measured in physical experiments with short-crested waves. The results obtained so far indicate that in several cases partial reflection of short crested waves can be described satisfactorily in numerical models by use of sponge layers.

Introduction

An accurate modelling of reflection may be of great importance when the wave disturbance in a harbour is estimated by use of a numerical model.

In order to obtain a correct partial reflection from a porous structure under arbitrary wave conditions, it is necessary to set up a 3D numerical model to describe the flow in the porous structure. This would lead to a computational effort that normally cannot be afforded in a practical investigation of wave disturbance in a harbour.

Models based on depth integrated flow equations are nearly always applied in practical investigations of wave fields in order to reduce the computational effort. Typical examples of depth integrated equations are Boussinesq equations or mild-slope equations.

In models based on Boussinesq equations it is rather easy to model the depth integrated flow in a porous structure with vertical front. Terms describing the

1Hydraulics & Coastal Engineering Laboratory, Dept. of Civil Engineering
Aalborg University, Sohngaardsholmsvej 57, DK-9000 Aalborg
dissipation are included in the governing equations, and dissipation as well as reflection can be modelled rather accurately in such numerical models, at least in case of head on waves (Madsen and Warren, 1984). A major drawback of these models is the necessary substantial computational effort, and some 'tuning' is normally still necessary to obtain a correct reflection coefficient.

Models based on mild-slope equations may demand much less computational effort, especially if partial reflection could be modelled by implementation of a simple boundary condition for the surface elevation or the velocity potential at the structure. With such a type of boundary condition one has to specify the reflection coefficient beforehand and this demands an estimate of the yet unknown wave steepness. In principle an iterative approach is therefore necessary.

Furthermore, it is not straightforward to obtain an analytical boundary condition which combines good performance with respect to the angle of incidence of the waves and easiness of implementation into the numerical model see e.g. Behrendt (1986) and Dingemans (1997).

The present paper concerns the reflection performance of so-called 'sponge' layers, which are used to model partially reflecting (porous) structures in the numerical model domain. The applied sponge layer technique was first described by Larsen and Dancy (1983). This technique is very easy to implement into finite difference models and has been used extensively to model open boundaries, i.e. boundaries where the goal is no reflection at all.

Various compositions of sponge layers and their performance with respect to wave reflection, main direction of propagation, and directional spreading have been investigated with models based on the finite difference method.

Attention has also been paid to the effects due to the discretization of an oblique structure with straight front in a finite difference model. Here an oblique structure means a structure, where the front of the structure is not aligned with a grid line in the model domain. For such a structure the straight front will be discretized into shorter pieces in the numerical model which might influence the reflection from the structure. Comparisons are made with reflection measured in physical experiments with short-crested waves (Helm-Petersen, 1994).

Numerical model

The numerical model was based on the time-dependent mild-slope equation, see e.g. Kirby et al. (1992) and Dingemans (1997). In this equation the vertical dependence is extracted from the velocity potential \( \phi(x, y, z, t) \) according to

\[
\phi(x, y, z, t) = f(z, h) \cdot \varphi(x, y, t)
\]

(1)

where

\[
f(z, h) = \frac{\cosh k(z + h)}{\cosh kh}
\]

(2)

Here \( \varphi(x, y, t) \) is the velocity potential at \( z = 0 \), \( h \) is the local still water depth, \( k \) is the local wave number and \( z \) a vertical co-ordinate.
Assuming small variations in the seabed topography (mild slopes) and first order wave theory leads to the model equations

\[ \eta = -\frac{1}{g} \varphi_t \]  

and

\[ \eta_t + \frac{\partial}{\partial x} (A \varphi_x) + \frac{\partial}{\partial y} (A \varphi_y) - B \varphi = 0 \]  

where

\[ A(x, y) = \frac{1}{2k} \left[ 1 + \frac{2kh}{\sinh(2kh)} \right] \tanh(kh) = \frac{c c_g}{g} \]  

\[ B(x, y) = \frac{k}{2} \left[ 1 - \frac{2kh}{\sinh(2kh)} \right] \tanh(kh) = \frac{\omega^2 - k^2 c c_g}{g} \]  

and \( \omega \) is the circular frequency, \( c \) is the phase velocity and \( c_g \) is the group velocity.

If equation (3) is substituted into equation (4) the result is the hyperbolic time-dependent mild-slope equation. This equation is able to handle refraction, shoaling, diffraction and reflection of linear, irregular waves provided that the sea state can be described by a narrow frequency spectrum (Dingemans, 1997) with a dominant carrier frequency \( \tilde{\omega} \).

In this study the numerical solution was based on an explicit finite difference discretization of equation (3) and equation (4). The computational domain was divided into quadratic boxes, and central differences were used for spatial as well as time derivatives. Both \( \eta \) and \( \varphi \) were calculated at the center of each box (but at different new time levels, \((n + 1/2) \Delta t\) and \((n + 1) \Delta t\), respectively) from the discretized equations:

\[ \frac{\eta_{i,j}^{n+1/2} - \eta_{i,j}^{n-1/2}}{\Delta t} \approx B_{i,j} \varphi_{i,j}^n \]

\[ \frac{A_{i+1,j} - A_{i-1,j}}{2\Delta x} \cdot \frac{\varphi_{i+1,j}^n - \varphi_{i-1,j}^n}{2\Delta x} \]

\[ -A_{i,j} \frac{\varphi_{i-1,j}^n - 2\varphi_{i,j}^n + \varphi_{i+1,j}^n}{(\Delta x)^2} \]

\[ \frac{A_{i,j+1} - A_{i,j-1}}{2\Delta y} \cdot \frac{\varphi_{i,j+1}^n - \varphi_{i,j-1}^n}{2\Delta y} \]

\[ -A_{i,j} \frac{\varphi_{i,j-1}^n - 2\varphi_{i,j}^n + \varphi_{i,j+1}^n}{(\Delta y)^2} \]  

(7)

\[ \eta_{i,j}^{n+1/2} = -\frac{1}{g} (\varphi_t)_{i,j}^{n+1/2} \approx -\frac{1}{g} \frac{\varphi_{i,j}^{n+1} - \varphi_{i,j}^n}{\Delta t} \]  

(8)

In each time step \( \eta_{i,j}^{n+1/2} \) was first calculated by equation (7) and then \( \varphi_{i,j}^{n+1} \) was calculated by equation (8).
Fully reflective boundaries were modelled by forcing the flow to be zero between the two boxes on each side of the boundary. This was obtained by setting the values of $\varphi$ at the two boxes to be equal.

Partially reflective boundaries were modelled by use of sponge layers. A reduction factor $\mu < 1$ is specified for each box in the sponge layer. In each time step the surface elevation, $\eta$, was calculated in each box within the entire domain. Hereafter, also at each time step, the $\eta$-values in sponge layers are multiplied by the corresponding $\mu$-factors. Thus energy was extracted from the system. The width (no of boxes) of a sponge layer, denoted $W_s$, and the $\mu$-values corresponding to a desired reflection coefficient were found by trial and error for head on waves in a numerical wave flume.

The factor $\mu$ was found from the expression

$$\mu = \frac{1}{(a - 1)(\frac{n}{N})^b + 1}$$

where $n$ (the type of the sponge box) is an integer between 1 and $N$, $a$ and $b$ are constants. Open boundaries were modelled by sponge layers where the type $n$ was varied linearly from the beginning of the sponge layer to the boundary of the computational domain. The reflection coefficient from such a layer was typically only a few percent if the width of the sponge layer was approximately 2 times the wave length corresponding to the peak frequency of a sea state.

A single summation wave generation model (Miles, 1989) was applied to generate the short crested sea state. Hence each wave component had a unique frequency, whereas several wave components were travelling in the same direction. This can be expressed as

$$\eta(x, y, t) = \sum_{l=1}^{L} \sum_{m=1}^{M} A_{lm} \cos(\omega_{lm}t - k_{lm}(x \cos \theta_m + y \sin \theta_m) + \phi_{lm})$$

where

$$\omega_{lm} = 2\pi f_{lm}$$

$$= 2\pi(M(l - 1) + m)\Delta f + 2\pi f_{\min}$$

$$A_{lm} = \sqrt{2S(f_{lm})H(f_{lm}, \theta_m)M\Delta f \Delta \theta}$$

$$\theta_m = (m - 1)\Delta \theta - \theta_{\max}$$

$\phi_{lm}$ is a random phase, $S(\cdot)$ and $H(\cdot)$ are the wave energy spectrum and the directional spreading function, respectively.

The waves were generated in the numerical model by the method described in Larsen and Dancy (1983) by adding or removing volume along a gridline, referred to as the wave generation line. In order to generate a single wave component

$$\eta_I = a \sin(kx' - \omega t + \varphi)$$

$$= a \sin(k \cos \theta x^* + k \sin \theta x^* - \omega t + \varphi)$$
travelling in the direction $\theta$, see Figure 1, the necessary volume to be added at each generation box at each time step was calculated from equation

$$\Delta \eta = \frac{2 c_e \eta_l \cos \theta \Delta t}{\Delta x}$$

(16)

where $c_e$ is the energy velocity defined (Suh et al., 1997) as

$$c_e = \frac{\bar{\omega}}{\bar{c}} \sqrt{1 + \frac{\bar{c}}{\bar{c}_g} \left( \frac{\bar{\omega}}{\bar{\omega}_g} \right)^2 - 1}$$

(17)

Here the overbar is associated with the applied carrier frequency.

Analysis of data

Directional spectra were estimated by use of the software package PADIWA (1997), which is based on the Bayesian Directional Spectrum Estimation Method - BDM (Hashimoto and Kobune, 1988). This method estimates the spreading function $H(f, \theta)$, and the directional spectrum $S(f, \theta)$ was found from

$$S(f, \theta) = H(f, \theta) S(f)$$

(18)
From Figure 2 it is seen that waves propagating in directions between 0° and 180° were incident waves, and waves propagating in directions between 180° and 360° were reflected waves. Having estimates of $H(f, \theta)$ in $K$ directions at each frequency, the main propagation directions for incident and reflected waves, see Figure 2, were found from

$$\theta_{o,I}(f) = \sum_{k=1}^{K/2} \theta_k H(f, \theta_k) \Delta \theta - 90°$$  \hspace{1cm} (19)$$

$$\theta_{o,R}(f) = 270° - \sum_{k=K/2+1}^{K} \theta_k H(f, \theta_k) \Delta \theta$$  \hspace{1cm} (20)$$

and the variances of the directional spreading functions from

$$\sigma^2_{\theta,I}(f) = \sum_{k=1}^{K/2} (\theta_k - \theta_{o,I}(f))^2 H(f, \theta_k) \Delta \theta$$  \hspace{1cm} (21)$$

$$\sigma^2_{\theta,R}(f) = \sum_{k=K/2+1}^{K} (\theta_k - \theta_{o,R}(f))^2 H(f, \theta_k) \Delta \theta$$  \hspace{1cm} (22)$$

The frequency dependent reflection coefficient (defined as the ratio between wave heights) was found from

$$R(f) = \frac{S_R(f)}{S_I(f)}$$  \hspace{1cm} (23)$$

and the total reflection coefficient from

$$C_R = \frac{S_I(f) + S_R(f)}{S_I(f) + S_R(f)} R(f)$$  \hspace{1cm} (24)$$

**Numerical simulations**

In all simulations the following setup was applied:

- computational domain : 120 x 208 boxes
- box size : $dx = dy = 0.125$ m
- water depth : $h = 0.61$ m
- Jonsnap frequency spectrum ($\gamma = 3.3$), significant wave height $H_s = 0.10$ m and peak period $T_p = 1.5$ secs. Energy outside the frequencies $0.66 f_p$ and $2 f_p$ was cut off
- Mitsuyasu spreading function i.e.

$$H(f, \theta) = \text{const} \cdot \cos^{2s}(\frac{\theta - \theta_0}{2})$$ with $s = 15$ ($\Rightarrow \sigma_{\theta,I}(f) = 20°$)
- time step: $dt = 0.05 \text{ sec}$
- short-crested sea: 220 wavelets
  (20 frequency bands ($L = 20$) each with 11 directions ($M = 11$))
- the sponge layer coefficients were calculated by equation (9) with $a = 1.3$, $b = 1.8$ and $N = 50$.

Figure 3: Model setup. Structure with stepped front (1:3), $C_R \approx 55\%$.

Different types and placement of structures were investigated, but the wave generation line and the 2 fully absorbing sponge layers were in all simulations situated as shown in Figure 3. In case of oblique structures an additional sponge layer with $W_s = 2$ and types 50 and 35 was applied at the left boundary of the domain.

In all simulations surface elevation time series were sampled at 10 positions in a $0.5 \times 0.5 \text{ m}$ grid placed parallel with the front of the actual structure at a distance of 1.25 m, see Figure 3. These time series provided the data for the reflection analysis. The elevation time series were sampled with a frequency of 10 Hz, i.e. every second time step and the duration of each time series was 18 minutes.

The applied setup of measuring positions is not considered optimal, but was chosen in order to get the same setup which was used in similar physical experiments (Helm-Petersen, 1994). In these physical experiments reflection coefficients from a breakwater with a vertical, porous front were determined by use of the same type of analysis applied in the present numerical simulations.

The estimation of the directional spectrum was based on subseries having a duration of 25.6 secs corresponding to a spectral resolution of $\Delta f = 0.039 \text{ Hz}$. The directional resolution was chosen to $5^\circ$ corresponding to $K = 72$ directions.
Structures with straight front

In those cases the structure was parallel with the wave generation line. The following reflection conditions were simulated:

- fully reflective front
- partially reflective front, $C_R \approx 85 \%$, corresponding to a sponge layer with $W_s = 1$ and $n = 20$ or $\mu = 0.95$
- partially reflective front, $C_R \approx 55 \%$, corresponding to a sponge layer with $W_s = 3$ and $n = 20, 25, 35$ corresponding to $\mu = 0.95, 0.92, 0.86$

The results from these simulations are shown in Figures 4 – 7.

![Figure 4: Reflection coefficients. Numerical models with straight front and physical model (Helm-Petersen, 1994).](image)

![Figure 5: Main propagation angles. Numerical model with straight front, $C_R = 100\%$.](image)
Structures with stepped front

The oblique structures were forming angles of 9.5° (1:6), 18.4° (1:3) or 26.6° (1:2), respectively, with the computational grid. Hence the discretized front of the models were stepped. The model setup for a structure forming an angle of 18.4° (1:3) with the computational grid is shown in Figure 3. The following conditions were simulated for the three oblique structures:

- fully reflective front.
- partially reflective front, \( C_R \approx 55 \% \), \( W_s = 3 \).

The setup of the sponge layers are shown in Figures 8–9, and the results from these simulations are shown in Figures 10–14.

Discussion of results

For a structure having the front aligned with a grid line in the model domain it was found that sponge layers provide a very reasonable reflection of short-crested
Figure 8: Structure with stepped front (1:6), $C_R \approx 55\%$, $W_s = 3$.

Figure 9: Structures with stepped front, $C_R \approx 55\%$, $W_s = 3$.

Figure 10: Reflection coefficients. Structures with \textit{stepped} front, fully reflective.
waves. The variation of the total reflection coefficient \( C_R \) with the angle of incidence (main propagation direction) was the same in the numerical and in the physical model in case of a partially reflective front, see Figure 4. Furthermore the main propagation directions of the waves was reflected into directions corresponding to Snell’s law, see Figures 5-7. This was also found in the physical experiments. Some deviation between the specified and measured main incident angles are seen for angles larger than 20-30°. In the numerical simulations it was only possible to generate wavelets propagating at angles of approximately 65° from the line of generation and therefore the directional spectrum had to be truncated at angles where considerable energy was present. This might be the main cause to the deviation between the specified and measured main incident angles.

Also in case of oblique structures with a straight front discretized into a stepped front it was found that sponge layers provide a very reasonable reflection of short-crested waves. The total reflection coefficient \( C_R \) was modelled correctly up to
approximately 20°’s angle of incidence (main propagation direction) in the numerical model. For larger angles the variation of $C_R$ in the numerical simulations had the correct trend, but $C_R$-values from numerical simulations were somewhat larger than the corresponding $C_R$-values from the physical experiments, see Figure 11. The main propagation direction of the waves was also in case of stepped fronts reflected into directions corresponding to Snell’s law, see Figures 12–14. Due to the oblique structure larger angles of incidence could be obtained, but also in these simulations some deviations between specified and measured main incident angles were seen. Average values of the relative directional spreading, defined as $\sigma_{rel} = \sigma_{\theta, R}/\sigma_{\theta, I}$, are shown in Table 1. It is seen that simulations with partially reflective structures having $C_R \approx 55\%$ typically had a relative spreading $\sigma_{rel} \approx 1.25$. A relative spreading larger than one is to be expected for a partially reflective structure, and in physical experiments with vertical fronts having $C_R \approx 55\%$ (Helm–Petersen, 1994) $\sigma_{rel} \approx 1.20$ was found.

Conclusions

The 3D reflection performance of sponge layers applied in numerical models has been investigated considering short-crested waves. In general the results from the numerical simulations compare well to results from physical experiments carried

model. Coastal Engineering, Volume 8, pp. 73-93.

Abstract: A horizontally two-dimensional, time dependent numerical model for obliquely incident shallow water waves with arbitrary incident angles is developed to predict the temporal and spatial variations of the free surface elevations and fluid velocities on inclined coastal structures. As a first attempt, use is made of periodic lateral boundary conditions, which limits the computations to regular waves on the slope of alongshore uniformity. The numerical method and the seaward and landward boundary algorithms are fairly general and expected to be applicable to irregular waves as well. The computed results for plunging waves on a rough 1:3.5 slope with the incident angles in the range of 0° – 80° are presented.

Introduction

The three-dimensional hydrodynamics processes on and around coastal structures are little known in comparison to the nearshore hydrodynamics on sandy beaches. As a result, no predictive model is available to predict breaking waves and induced currents on and around these inclined structures.

The available data are still limited because the experiments in directional wave basins to examine the effects of incident wave angles and directionality on design variables such as wave runup (De Wall and Van der Meer 1992) and wave reflection (Isaacson et al. 1996) were conducted mostly for straight structures on horizontal bottom. In addition, since these experiments include more design parameters and are much more time-consuming than unidirectional wave flume experiments, measurements are normally limited to free surface oscillations at several locations and do not provide detailed understanding of oblique wave dynamics on steep rough slopes.

Existing time-dependent models for waves on inclined coastal structures are limited mostly to normally-incident waves as reviewed by Kobayashi (1995). Liu et al. (1995) solved the finite-amplitude, shallow-water equations numerically to predict solitary wave runup around a circular island with a 1:4 side slope. Kobayashi and Karjadi (1996) and Kobayashi et al. (1997) developed numerical models for oblique irregular waves with small incident angles but these models can not be used to examine the...
effects of incident wave angles on the important quantities for the design of coastal structures.

In this paper, a two-dimensional, time-dependent numerical model for finite-amplitude, shallow-water waves with arbitrary incident angles is developed to examine the effects of incident wave angles on oscillatory and time-averaged wave characteristics on a steep rough slope. As a first attempt, use is made of periodic lateral boundary conditions. Consequently, computations are limited to regular waves on the slope of alongshore uniformity. Incident nonlinear waves at the toe of the slope are specified as input to the model. Reflected waves are predicted at the toe of the slope to examine the height, shape, angle and phase shift of reflected waves as a function of the incident wave angle. Computed waterline oscillations are analyzed to obtain wave runup, setup and run-down as a function of the incident wave angle. Furthermore, the computed spatial and temporal variations of the free surface elevation and horizontal velocities are analyzed to elucidate the detailed wave mechanics on the steep rough slope.

Numerical Model

The normalized depth-integrated continuity and horizontal momentum equations in shallow water may be expressed in the conservative vector form as

\[
\frac{\partial U}{\partial t} + \frac{\partial E}{\partial x} + \frac{\partial F}{\partial y} + G = 0
\]

with

\[
U = \begin{bmatrix} h \\ hU \\ hV \end{bmatrix}; \quad E = \begin{bmatrix} hU \\ hU^2 + h^2/2 \\ hUV \end{bmatrix}; \quad F = \begin{bmatrix} hV \\ hUV \\ hV^2 + h^2/2 \end{bmatrix};
\]

\[
G = \begin{bmatrix} 0 \\ h \frac{\partial^2 z_b}{\partial x^2} + f(U^2 + V^2)^{1/2} U \\ h \frac{\partial^2 z_b}{\partial y^2} + f(U^2 + V^2)^{1/2} V \end{bmatrix}
\]

where the symbol are depicted in Fig. 1 with the prime indicates the physical variables; \( x' \) = horizontal coordinate taken to be positive landward with \( x' = 0 \) at the toe of the slope; \( y' \) = horizontal coordinate parallel to the toe alignment and taken to be positive in the downwave direction; \( h' \) = water depth; \( U' \) = depth-averaged cross-shore velocity; \( V' \) = depth-averaged alongshore velocity; \( g \) = gravitational acceleration; \( \eta' \) = free surface elevation above the still water level (SWL). The vertical coordinate \( z' \) is taken to be positive upward with \( z' = 0 \) at SWL. The bottom elevation is located at \( z' = z_b' \) with \( z_b' = (\eta' - h') \) and the spatial variation of \( z_b' \) is assumed to be known.

The normalized variables without the primes in (1) and (2) are defined as

\[
t = \frac{T'}{T''}; \quad x = \frac{x'}{\sigma H''}; \quad y = \frac{y'}{\sigma H''}; \quad U = \frac{U'}{\sqrt{gH''}}; \quad V = \frac{V'}{\sqrt{gH''}}
\]

\[
h = \frac{h'}{H''}; \quad \eta = \frac{\eta'}{H''}; \quad z_b = \frac{z_b'}{H''}; \quad f = \frac{1}{2} \sigma f_b'; \quad \sigma = \frac{T'' \sqrt{gH''}}{H''}
\]

where \( T'' \) and \( H'' \) = incident wave period and height, respectively; \( f_b' \) = bottom friction factor which is allowed to vary spatially; and \( \sigma \) = ratio of the horizontal and vertical
length scales which is assumed to satisfy $\sigma^2 \gg 1$ in shallow water (e.g., Kobayashi and Wurjanto 1992).

Equation (1) is solved numerically to compute the temporal and spatial variations of $h$, $U$ and $V$ where $E$, $F$ and $G$ depend on $U$ only for given $z_b$ and $f$. The mean water depth $\bar{h}$ and the mean velocities $\bar{U}$ and $\bar{V}$ are then obtained by time-averaging the computed $h$, $U$ and $V$ where the overbar indicates time-averaging.

To interpret the computed spatial variations of $\bar{h}$, $\bar{U}$, and $\bar{V}$, the time-averaged continuity and momentum equations are derived from (1)

$$\frac{\partial}{\partial x}(\bar{h}U) + \frac{\partial}{\partial y}(\bar{h}V) = 0$$

(5)

$$\frac{\partial}{\partial x}(S_{xx}) + \frac{\partial}{\partial y}(S_{xy}) + \bar{h}\frac{\partial \bar{\eta}}{\partial x} + \tau_{bx} = 0$$

(6)

$$\frac{\partial}{\partial x}(S_{xy}) + \frac{\partial}{\partial y}(S_{yy}) + \bar{h}\frac{\partial \bar{\eta}}{\partial y} + \tau_{by} = 0$$

(7)

with

$$S_{xx} = \bar{h}U^2 + \frac{1}{2}(\eta - \bar{\eta})^2$$

$$S_{xy} = \bar{h}UV$$

$$S_{yy} = \bar{h}V^2 + \frac{1}{2}(\eta - \bar{\eta})^2$$

(8)

$$\tau_{bx} = f(U^2 + V^2)^{1/2}U$$

$$\tau_{by} = f(U^2 + V^2)^{1/2}V$$

(9)

where $S_{xx}$, $S_{xy}$ and $S_{yy}$ = time-averaged momentum fluxes similar to radiation stresses (Longuet-Higgins 1970); and $\tau_{bx}$ and $\tau_{by}$ = time-averaged bottom shear stress in the $x$ and $y$-directions. The accuracy of the time-dependent numerical model is checked using (5)-(7) with (8) and (9) because the computed $h$, $U$ and $V$ must satisfy the corresponding time-averaged equations.

The derivation of the depth-integrated energy equation corresponding to (1) is similar to that of Kobayashi and Wurjanto (1992). The time-averaging normalized
energy equation corresponding to (1) may be expressed as

\[
\frac{\partial}{\partial x}(F_x) + \frac{\partial}{\partial y}(F_y) = -D_f - D_B
\]

with

\[
F_x = hU\left[y + \frac{1}{2}(U^2 + V^2)\right] ; \quad F_y = hV\left[y + \frac{1}{2}(U^2 + V^2)\right] ; \quad D_f = f(U^2 + V^2)^{1.5}
\]

where \(F_x\) and \(F_y\) = time-averaged energy flux per unit width in the \(x\) and \(y\)-directions, respectively; and \(D_f\) and \(D_B\) = time-averaged rate of energy dissipation per unit horizontal area due to bottom friction and wave breaking, respectively. The dissipation rate \(D_B\) is related to the vertical variations of horizontal velocities and shear stresses outside the bottom boundary layer which are not predicted in this two-dimensional model. As a result, \(D_B\) is computed using (10) with (11) for the computed \(h\), \(U\) and \(V\) using (1). The computed \(D_B\) must be positive or zero.

The computer program is developed using the MacCormack method (MacCormack 1969) which has been used successfully for the computation of two-dimensional transient open channel flow with bores (Chaudhry 1993). The finite difference grid of constant grid size \(\Delta x\) and \(\Delta y\) is used to solve (1). The values of \(\Delta x\) and \(\Delta y\) must be small enough to resolve the rapid spatial variation of the wave motion on the slope. The initial time \(t = 0\) is taken to be the time when the incident wave train arrives at the seaward boundary and there is no wave action in the computation domain. The waterline in the numerical model is defined as the location where the instantaneous water depth \(h\) equals a small value \(\delta\), which is taken as \(\delta = 10^{-3}\) in the subsequent computation. The time step size \(\Delta t\) varies for each time step and determined using an approximate numerical stability criterion proposed by Thompson (1990).

It is very difficult to specify incoming waves through the lateral boundaries into the computation domain and allow outgoing waves to propagate out of the computation domain without any numerical reflection from the lateral boundaries. As a first attempt, the periodic lateral boundary conditions are used here, although these conditions are appropriate only for regular waves on the slope of alongshore uniformity. For the periodic lateral boundaries, the nodes along the lateral boundaries are treated as the interior nodes.

The seaward boundary of the numerical model is located at the toe of the slope along the \(y\)-axis as shown in Fig. 1. In the region \(x \leq 0\), the bottom is assumed to be horizontal so that a regular wave theory on the horizontal bottom may be used to specify the normalized incident wave train \(\eta_i(t, y)\) at \(x = 0\) in the following form:

\[
\eta_i(t, y) = F_i(p) \quad \text{at} \quad x = 0
\]

with

\[
p = t - \lambda y \quad ; \quad \lambda = \frac{T' \sqrt{g H' \sin \theta_i}}{L'}
\]

where \(F_i\) = periodic function with respect to the phase \(p\) such that \(F_i(p + 1) = F_i(p)\); \(L'\) = dimensional incident wavelength; \(\theta_i\) = incident wave angle as shown in Fig. 1; and \(\lambda = \text{inverse of the normalized alongshore wavelength}\). The alongshore wavelength, \(L'/\sin \theta_i\), is constant on the slope of alongshore uniformity because of Snell's law (e.g.,
Dean and Dalrymple 1984). The function \( F \) depends on the wave theory used for a specific application. To satisfy the initial conditions of no wave action in the region \( x \geq 0 \), use is made of \( \eta_i = tF_i \) for \( 0 \leq t < 1 \) and \( \eta_i = F_i \) for \( t \geq 1 \). To satisfy the periodic lateral boundary conditions, the computation domain width is taken as \( 0 \leq y \leq \lambda^{-1} \).

The seaward boundary algorithm for obliquely incident and reflected waves is not well established because no unique direction of propagation for characteristic variables exists for multidimensional hyperbolic equations including (1) (e.g., Thompson 1990). Several algorithms including that of Van Dongeren and Svendsen (1997) were tried to produce the periodic wave motion on the slope which satisfies the time-averaged equations (5)-(7). In addition, the computed reflected wave train must become periodic and propagate along the \( y \)-axis in a manner similar to (12). The algorithm satisfying these requirements is developed using the method of cross-shore characteristics.

A smoothing procedure is applied to damp numerical high-frequency oscillations which may appear at the rear of the steep front of a breaking wave. Use is made here of the relatively simple procedure described in Chaudhry (1993). The procedure of the numerical method and boundary conditions is described in detail in Kobayashi and Karjadi (1999).

**Computed Wave Motions on Steep Slope**

The developed two-dimensional model becomes practically the same as the one-dimensional model of Kobayashi et al. (1987) for normally-incident waves which was compared with the large-scale riprap tests reported by Ahrens (1975). Since there are no appropriate data available to verify this two-dimensional model, test 18 of Ahrens (1975) is used as an example in this paper. The computation results for test 12 with surging waves are presented in Kobayashi and Karjadi (1999).

For test 18, the riprap slope was 1:3.5; the still water depth at the toe of the slope, \( d' = 4.57 \) m; the incident wave period \( T' = 4.2 \) s; the incident wave height \( H' = 1.01 \) m; the median mass of the riprap, \( M_{50} = 34 \) kg; and the density of the riprap, \( \rho_a = 2710 \) kg/m\(^3\). The nominal diameter of the riprap defined as \( D_{n50} = (M_{50}/\rho_a)^{1/3} \) was \( D_{n50} = 0.232 \) m. The test was limited to normally incident waves with \( \theta_i = 0 \). Computation is also made for the incident wave angle \( \theta_i = 10^\circ, 20^\circ, 30^\circ, 40^\circ, 50^\circ, 60^\circ, 70^\circ \) and \( 80^\circ \). The ratio \( \sigma \) of the horizontal and vertical length scales defined in (4) is \( \sigma = 13 \), which satisfies the shallow water assumption of \( \sigma^2 \geq 1 \). The surf similarity parameter given by \( \xi = \sigma \tan \theta / \sqrt{2\pi} \) is \( \xi = 1.5 \). The Ursell number \( U_r = 5.7 \) and the incident wave \( \eta_i(t', y') \) at the seaward boundary is computed using the Stokes second order theory (Kobayashi and Karjadi 1994). The bottom friction factor \( f_b' \) is taken as \( f_b' = 0.3 \) (Kobayashi et al. 1987). The damping coefficient \( \kappa \) for smoothing high-frequency numerical oscillations is taken to be very small (\( \kappa = 0.01 \)) so as to minimize the numerical dissipation, although the numerical high-frequency oscillations become more visible as shown in Figs. 2 and 3 later.

The computation domain is taken as \( 0 \leq x \leq 1.95 \) and \( 0 \leq y \leq \lambda^{-1} \) except for \( \theta_i = 0 \) because \( \lambda = 0 \) for \( \theta_i = 0 \). For \( \theta_i = 0 \), use is made of the value of \( \lambda \) corresponding to \( \theta_i = 10^\circ \). The number of nodes in the \( x \) and \( y \)-directions are taken as 162 and 161,
Figure 2: Spatial variations for free surface elevation $\eta$ at time $t = 9, 9.25, 9.5, 9.75$ and 10.

respectively. The time step size $\Delta t$ is on the order of 0.0003. The computation is made for $0 \leq t \leq 10$ and the time-averaging is performed for the last wave period $9 < t \leq 10$.

In the following, the computed results for $\theta_i = 40^\circ$ are presented as an example. Fig. 2 shows the spatial variations of the free surface elevation $\eta$ at time $t = 9, 9.25, 9.5, 9.75$ and 10 for $\theta_i = 40^\circ$. The computed spatial variations at $t = 9$ and 10 are identical because the periodicity is established before $t = 9$. In the region of no water with $h = (\eta - z_b) = 0$, use is made of $\eta = z_b$ to depict the bottom elevation $z_b$ of the slope. Fig. 2 indicates the oblique waves breaking and propagating along the slope.

Fig. 3 shows the temporal variations of $\eta$, $U$ and $V$ at $x = 0, 0.35, 0.71, 1.16$ and 1.40 along the cross-shore line at $y = 1.35$ where $\lambda^{-1} = 2.73$ for $\theta_i = 40^\circ$. The waterline at SWL is located at $x = 1.20$. The lower limit of the free surface elevation $\eta$ at $x = 1.16$ and 1.40 corresponds to the bottom elevation $z_b$ at those locations. The cross-shore velocity $U$ at $x = 1.16$ and 1.40 indicates wave uprush ($U > 0$) of a short duration and wave down-rush ($U < 0$) of a longer duration. The longshore velocity $V$ at $x = 1.16$ and 1.40 becomes more unidirectional ($V > 0$) because the large longshore velocity occurs only during the short wave uprush. Fig. 3 also shows that the computed wave motion becomes periodic after a few waves unlike the longshore velocity $V$ on a gentle smooth slope (Kobayashi and Karjadi 1994).

Fig. 4 shows the cross-shore variations of the maximum, mean and minimum values of $\eta$, $U$ and $V$ during the last wave period $9 < t \leq 10$. The root-mean-square (rms) values of the oscillatory components $(\eta - \bar{\eta}), (U - \bar{U})$ and $(V - \bar{V})$ are the standard deviations of $\eta$, $U$ and $V$, which represent the oscillatory wave motion intensity.
Figure 3: Temporal variations of free surface elevation \( \eta \), cross-shore velocity \( U \), and longshore velocity \( V \) at five cross-shore locations.
Figure 5: Cross-shore variations of time-averaged momentum quantities.

Figure 4: Cross-shore variations of maximum, root-mean-square, mean, and minimum values of $\theta$, $U$, and $V$. 
The quantities shown in Fig. 4 are uniform alongshore. The 1:3.5 slope indicated by the solid straight line is added in the top panel to indicate the swash zone of wave uprush and down-rush on the slope. The rms wave intensity decreases landward in the swash zone. The largest $U$ occurs near the still waterline while the largest $\eta$ and $V$ occur seaward of the still waterline. The mean cross-shore velocity $\bar{U}$ is negative and represents the cross-shore return current. The mean alongshore velocity $\bar{V}$ is the wave-induced longshore current which becomes as large as the standard deviation of $V$ in the swash zone on the steep rough slope. The longshore current can become dominant on a gentle smooth slope (e.g., Kobayashi and Karjadi 1994).

The computed alongshore volume flux $\bar{h}V$ is uniform alongshore. The time-averaged continuity equation (5) requires $\bar{h}U = 0$ to satisfy the no flux condition into the impermeable slope. The computed cross-shore volume flux $\bar{h}U$ satisfies this requirement.

The cross-shore variations of the momentum fluxes $S_{xx}$, $S_{xy}$ and $S_{yy}$ are depicted in Fig. 5, which also shows the bottom shear stresses $\tau_{bx}$, $\tau_{by}$ and the time-averaged momentum equations (6) and (7). $S_{xx}$ increases landward and decreases in the swash zone, whereas $S_{yy}$ and $S_{xy}$ is approximately constant seaward of the swash zone. The bottom shear stresses are important in the swash zone where the zone of $\tau_{bx} < 0$ and $\tau_{by} > 0$ corresponds approximately to the zone of $\bar{U} < 0$ and $\bar{V} > 0$ shown in Fig. 4. The computed time-averaged quantities are uniform alongshore. There is a small residual on the right hand side (RHS) of (6) and (7) due to the numerical dissipation, although the numerical damping coefficient $\kappa = 0.01$ is very small. For surging waves, the residuals for (6) and (7) were practically zero (Kobayashi and Karjadi 1999).

Fig. 6 shows the cross-shore variations of the time-averaged energy fluxes $F_x$ and $F_y$ and the time-averaged energy dissipation rates $D_f$ and $D_B$ due to bottom friction and wave breaking, respectively. The computed values of these quantities are uniform alongshore. Fig. 6 indicates that $D_B$ is maximum at the location where $\eta$ and $V$ are maximum as shown in Fig. 4. The cross-shore and alongshore energy flux $F_x$ and $F_y$ decreases in the swash zone.
The reflected wave profile \( r(t,y) \) along \( x = 0 \) is obtained as \( r = (r - r_i) \) with \( r \) and \( r_i \) being the computed free surface elevation at \( x = 0 \). All the computed time series \( r_i \) and \( r \) at the 161 nodes along \( x = 0 \) for \( 0 \leq t \leq 10 \) are plotted as a function of \( p = (t - \lambda y) \) in Fig. 7. The 161 time series of \( r_i \) do not coincide for \(-1 \leq p < 1\) because of the adjustment of \( r_i \) to satisfy the initial conditions of no wave action in the computation domain. The reflected wave profile \( r \) becomes periodic with respect to \( p \) after a few waves. This implies that the alongshore wavelengths of the incident and reflected waves are the same where \( \lambda \) for the incident waves is defined in (13). If the incident and reflected wavelengths are the same, \( \sin \theta_i = \sin \theta_r \) where \( \theta_r = \) reflected wave angle. This assumption is generally adopted to separate incident and reflected waves using linear wave theory (e.g., Isaacson et al. 1996).

The reflection coefficient \( r \) and the phase shift \( \phi_r \) are estimated to examine their variations with respect to \( \theta_i = 0^\circ - 80^\circ \). The estimation of \( r \) and \( \phi_r \) is based on the periodic portions of \( r_i \) and \( r \) shown in Fig. 7. The reflection coefficient \( r \) is defined here as the ratio of the standard deviation of \( r_i \) to that of \( r \). The phase shift \( \phi_r \) is obtained as the shift of the crests of the incident and reflected wave profiles plotted as a function of \( (t - \lambda y) \). For \( \theta_i = 40^\circ \), the incident and reflected waves are in phase as shown in Fig. 7, where the phase shift remains the same by adding an integer to \( \phi_r \).

Fig. 8 shows the computed values of \( r \) and \( \phi_r \) as a function of \( \theta_i \). The computed values of \( r = 0.056 \) for \( \theta_i = 0^\circ \) is compared with available empirical formulas. The formula of Seelig and Ahrens (1995) predicts \( r = 0.18 \) for the rough impermeable slope assumed in the present computation. On the other hand, the formula of Davidson et al. (1996) predicts \( r = 0.08 \). The computed reflection coefficient \( r \) in Fig. 8 increases from \( r = 0.056 \) for \( \theta_i = 0^\circ \) to \( r = 0.32 \) for \( \theta_i = 80^\circ \). Most of the regular wave data by Isaacson et al. (1996) indicated the increase of \( r \) with \( \theta_i = 0^\circ - 60^\circ \). As for the phase shift \( \phi_r \), Sutherland and O’Donoghue (1998) proposed two empirical formulas for the range \( 0^\circ < \theta_i < 60^\circ \). These formulas can be expressed as \( \phi_r = 2.5(\cos \theta_i)^{0.71} \) and \( \phi_r = 2.2(\cos \theta_i)^{0.625} \) for this specific case and are plotted in Fig. 8. The computed phase shifts are almost within the empirical curves for \( 0^\circ \leq \theta_i \leq 60^\circ \).

The waterline elevation \( Z_r \) above SWL is defined as the free surface elevation measured by a hypothetical wire placed at a vertical distance of \( \delta_r \) above the bottom and parallel to the slope in the cross-shore direction. Since the nominal stone diameter was 23.2 cm, use is made of \( \delta_r = 0.4, 2 \) and \( 4 \) cm which may represent the possible range of the roughness of the irregular bottom surface. All the computed time series of \( Z_r \) along the 161 cross-shore lines for \( 0 \leq t \leq 10 \) are plotted as a function of \( p = (t - \lambda y) \) for \( \delta_r = 0.4, 2 \) and \( 4 \) cm. Fig. 9 shows that the computed waterline oscillations become periodic after a few waves. The normalized alongshore wavelength of the waterline oscillations on the slope is the same as the incident alongshore wavelength \( \lambda^{-1} \) at \( x = 0 \). This indicates the validity of Snell’s law for obliquely incident waves on the slope of alongshore uniformity. Fig. 9 also indicates that wave down-rush with a thin layer of water is sensitive to the wire height \( \delta_r \).

The periodic portions of \( Z_r \) are used to obtain the maximum, mean, minimum and standard deviation and values of \( Z_r \). The maximum \( Z_r \) is the wave runup \( R_u \), which is shown in Fig. 10, and the minimum \( Z_r \) is the wave rundown. The wave runup \( R_u \) is not sensitive to \( \delta_r = 0.4 - 4 \) cm. The computed value of \( R_u \) for \( \theta_i = 0^\circ \) is 1.05 in comparison
Figure 7: Incident and reflected wave profiles as a function of shifted time \((t - \lambda y)\).

Figure 8: Reflection coefficient \(r\) and phase shift \(\phi_r\) as a function of incident wave angles \(\theta_i\) in degrees.
Figure 9: Waterline elevations $Z_r$ for water depth $s' = 0.4, 2$ and $4$ cm as a function of shifted time $(t - \lambda y)$.

$R_u = 1.06$ observed visually in test 18 by Ahrens (1975). The empirical relationship shown in Fig. 10 is based on the runup reduction factor $\gamma = R_u(\theta_i)/R_u(\theta_i = 0^\circ)$ proposed by De Wall and Van der Meer (1992). For unidirectional irregular waves, $\gamma = 1$ for $0^\circ \leq \theta_i \leq 10^\circ$, $\gamma = \cos(\theta_i - 10^\circ)$ for $10^\circ \leq \theta_i \leq 63^\circ$, and $\gamma = 0.6$ for $63^\circ \leq \theta_i \leq 80^\circ$. The decrease of the computed regular wave runup with the increase of $\theta_i$ is consistent for small $\theta_i$ but larger for large $\theta_i$. On the other hand, Fig. 11 shows the wave runup $R_u$, the mean waterline elevation $\overline{Z_r}$, the standard deviation $\sigma_r$, and the wave run-down $R_d$ for $s' = 2$ cm. The computed $R_u$, $\overline{Z_r}$ and $R_d$ decrease with the increase of $\theta_i$, whereas the standard deviation of $Z_r$ representing the intensity of the waterline oscillation about the mean $\overline{Z_r}$ remains approximately constant. Correspondingly, the value of $(R_u - R_d)$ remains approximately constant.

Conclusions

A two-dimensional, time-dependent numerical model for finite-amplitude, shallow-water waves with arbitrary incident angles is developed to provide an additional tool for the design of coastal structures. The utility of this numerical model is to obtain the detailed wave motions in the vicinity of the still waterline which are difficult to
The time-averaged continuity, momentum and energy equations are used to check the accuracy of the numerical model as well as to examine the spatial variations of the time-averaged quantities. For the computed plunging waves, the energy dissipation rate due to wave breaking is significant as shown in Fig. 6. This dissipation appears to have produced the residuals in (6) and (7) as shown in Fig. 5. The computed reflected waves and waterline oscillations are shown to have the same alongshore wavelength as the incident waves.

The numerical model will need to be compared with new experiments that will
include the temporal and spatial variations of the free surface elevation and velocities. It is also essential to generalize the lateral boundary algorithm for irregular waves. An algorithm similar to the seaward boundary algorithm used here might be applied if the incident waves at the lateral boundaries could be specified as input.

ALES Shallow-Water Flow Solver with Non-Hydrostatic Pressure: Wave Applications

J. G. Zhou and P. K. Stansby

Abstract

A shallow-water flow solver with non-hydrostatic pressure in σ coordinates has been developed to include effects due to the moving grid, referred to as the ALES approach. The formulation is outlined for 2D vertical plane problems and tested against experimental data for wave flows over plane beds, bars and trenches. Agreement with experiment is generally good and the importance of non-hydrostatic pressure and moving-grid terms is demonstrated.

Introduction

Conventional shallow-water flow models based on hydrostatic pressure can provide accurate results for many engineering problems. However, the model will not be accurate for problems in which there is significant gradient of either bed topography or free surface. A recent study by Stansby and Zhou (1998) has shown that the influence of non-hydrostatic pressure on current flow over a trench with bottom slope greater than 1:5 can be significant. The solver developed for non-hydrostatic pressure applies also to wave flows. Accurate predictions of wave flows including viscous/turbulence effects are of importance in coastal and ocean engineering projects such as harbors, channel dredging, pipeline trenching and storm-surge barriers. In this paper, we present a shallow-water flow solver to predict waves over a plane bed, a trapezoidal trench and a bar and compare with experimental data. The model is based on the unsteady Reynolds-averaged Navier-Stokes equations in ALE (Hirt, 1970) description which is able to account for the moving mesh with non-hydrostatic pressure. The equations are solved in the σ coordinate system and the eddy viscosity is calculated using the standard $k - \epsilon$ model. The method is referred to as ALES. The computations are also compared with the model with hydrostatic pressure alone.

Flow Model

The unsteady Reynolds-averaged Navier-Stokes equations for incom-
pressible flow in a 2-D vertical plane can be written with the ALE description for incompressible flow, with the Boussinesq assumption for the time-averaged Reynolds stress in $\sigma$ coordinates as

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \quad (1)$$

$$\frac{\partial (hu)}{\partial t} + \frac{\partial (huu)}{\partial x} + \frac{\partial (\omega u)}{\partial \sigma} - w_g \frac{\partial u}{\partial \sigma} = -g h \frac{\partial \eta}{\partial x} - \frac{h \partial \bar{p}}{\rho \partial x}$$

$$+ h \frac{\partial}{\partial x} \left( v_e \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial \sigma} \left( \frac{v_e}{h} \frac{\partial u}{\partial \sigma} \right) \quad (2)$$

$$\frac{\partial (hw)}{\partial t} + \frac{\partial (huw)}{\partial x} + \frac{\partial (\omega w)}{\partial \sigma} - w_g \frac{\partial w}{\partial \sigma} = -\frac{1}{\rho \partial \sigma} \frac{\partial \bar{p}}{\partial \sigma}$$

$$+ h \frac{\partial}{\partial x} \left( v_e \frac{\partial w}{\partial x} \right) + \frac{\partial}{\partial \sigma} \left( \frac{v_e}{h} \frac{\partial w}{\partial \sigma} \right) \quad (3)$$

$$\frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x} \int_{-1}^{0} h u d\sigma = 0 \quad (4)$$

where $x$ is the horizontal coordinate and $\sigma$ the vertical dimensionless coordinate defined below; $\eta$ is the water surface elevation above horizontal datum; $h$ is water depth; $u$ and $w$ are the velocity components in the horizontal and vertical directions; $\omega = h d\sigma / dt$ (defined below); $w_g$ is the grid velocity in the vertical direction; $g$ is the gravitational acceleration; $\bar{p}$ is the non-hydrostatic pressure; $\rho$ is the fluid density; $v_e$ is the eddy viscosity; where

$$\sigma = \frac{z - \eta}{h}, \quad \omega = w - u \left( \sigma \frac{\partial h}{\partial x} + \frac{\partial \eta}{\partial x} \right) - \left( \frac{\partial h}{\partial t} + \frac{\partial \eta}{\partial t} \right)$$

$\omega = 0$ when $\sigma = -1$ or $\sigma = 0$, corresponding to the bed and the free surface. The continuity equation (1) is not transformed into $\sigma$ coordinates because the non-hydrostatic pressure is calculated in real space.

The eddy viscosity $v_e$ is defined by the standard $k - \epsilon$ equations (Rodi, 1993), which can be written in $\sigma$ coordinates as

$$\frac{\partial (hk)}{\partial t} + \frac{\partial (huk)}{\partial x} + \frac{\partial (\omega k)}{\partial \sigma} - w_g \frac{\partial k}{\partial \sigma} = h \frac{\partial}{\partial x} \left( \frac{v_e}{h} \frac{\partial k}{\partial x} \right)$$

$$+ \frac{\partial}{\partial \sigma} \left( \frac{v_e}{h \sigma k} \frac{\partial k}{\partial \sigma} \right) + hP - h \epsilon \quad (5)$$
\[
\frac{\partial (h\epsilon)}{\partial t} + \frac{\partial (h\epsilon u)}{\partial x} + \frac{\partial (\omega \epsilon)}{\partial \sigma} - w_g \frac{\partial \epsilon}{\partial \sigma} = h \frac{\partial}{\partial x} \left( \frac{\nu_\epsilon}{\sigma} \frac{\partial \epsilon}{\partial x} \right) \\
+ \frac{\partial}{\partial \sigma} \left( \frac{\nu_\epsilon}{h \sigma} \frac{\partial \epsilon}{\partial \sigma} \right) + h c_{1\epsilon} \frac{\epsilon}{k} P - h c_{2\epsilon} \frac{\epsilon^2}{k} 
\]

(6)

Solution of the Equations

Spatial discretization is in finite-volume form on a staggered mesh following Stansby (1997). For a cell \( i, k \) the equations (2)-(4) can be discretized in time from time level \( n \) to \( n + 1 \) with time step \( \delta t \), as

\[
\frac{\eta_{i}^{n+1} - \eta_{i}^{n}}{\delta t} + \frac{\partial}{\partial x} \int_{i-1}^{i} \left[ h_{i}^{n} \left[ \theta u_{i,k}^{n+1} + (1 - \theta) u_{i,k}^{n} \right] d\sigma = 0 \right. 
\]

(7)

\[
\frac{\eta_{i}^{n+1} - \eta_{i}^{n}}{\delta t} + \frac{\partial}{\partial x} \int_{i-1}^{i} \left[ h_{i}^{n} \left[ \theta u_{i,k}^{n+1} + (1 - \theta) u_{i,k}^{n} \right] d\sigma = 0 \right. 
\]

(8)

\[
\frac{\eta_{i}^{n+1} - \eta_{i}^{n}}{\delta t} + \frac{\partial}{\partial x} \int_{i-1}^{i} \left[ h_{i}^{n} \left[ \theta u_{i,k}^{n+1} + (1 - \theta) u_{i,k}^{n} \right] d\sigma = 0 \right. 
\]

(9)

The equations (7)-(9) are solved for \( \eta \) efficiently by the conjugate gradient method. Similarly, Eqs. (5) and (6) are discretized and solved.

The continuity equation (1) can be used to derive an equation for non-hydrostatic pressure in real space as

\[
a_{P} p'_{P} = a_{EP} p'_{E} + a_{WP} p'_{W} + a_{VP} p'_{V} + a_{DP} p'_{D} \\
+ a_{EUP} p'_{EU} + a_{EDP} p'_{ED} + a_{WUP} p'_{WU} \\
+ a_{WP} p'_{UDP} + a_0 
\]

(10)

in which \( p' \) is the correction of the no-hydrostatic pressure. The coefficients such as \( a_{P} \) and the details are described by Stansby and Zhou (1998).
The σ mesh is refined near the bed and surface as in Stansby (1997).

Results

1. Wave over a plane bed

A wave over a plane bed is simulated. A mesh of 600x20 cells is used with $\delta x = 0.1 \text{ m}$, $\delta t = 0.05 \text{ s}$, and $h_0 = 1.0 \text{ m}$. The period $T$ is 4 s. The amplitude of uniform sinusoidal velocity at inflow is $U_0 = 0.2 \text{ m/s}$. Fig. 1 shows velocity vectors at $t = 100 \text{ s}$. Clearly, regular waves are propagating along the channel.

![Figure 1: Wave over a plane bed](image)

2. Wave over a bar with small side slope

The progressive wave considered here is the same as that studied experimentally by Beji et al. (1992). The wave flume is sketched in Fig. 2. The wave height is 2.0 cm and the period $T$ is 2.0 s. A mesh of 320x21 cells is used with $\delta x = 0.1 \text{ m}$ and $\delta t = 0.005 \text{ s}$. For the inflow boundary conditions, $U_0 = 0.09 \text{ m/s}$ which generates a wave of 2.01 cm height and $h_0 = 0.4 \text{ m}$.

![Figure 2: Sketch of the wave flume](image)
Results after 17.5 s are shown in Figs. 3-5 with experimental data, showing good agreement. Results from the $\sigma$ model without incorporating the moving grid are also plotted in Fig. 5. It is clear that the ALES model is superior to the $\sigma$ model.

Figure 3: Comparison between model and experiment of the wave profile at station 1

Figure 4: Comparison between model and experiment of the wave profile at station 3

3. Wave over a bar with steep side slope

Here a progressive wave over a bar with steep slope is considered. The flume is the same as that in the experiment by Ohyama et al. (1995) and is sketched in Fig. 6. The wave height is 5.0 cm and the period $T$ is 2.01 s. A mesh of 600x21 cells is used with $\delta x = 0.1$ m and $\delta t = 0.005$ s. $U_0 = 0.2$ m/s generates a wave of 5.006 cm height and $h_0 = 0.5$ m. Results are presented after 33 s.
Figure 5: Comparison between model and experiment of the wave profile at station 5

![Comparison between model and experiment of the wave profile at station 5](image)

Figure 6: Sketch of experimental arrangement for wave over a bar with steep side slope

![Sketch of experimental arrangement for wave over a bar with steep side slope](image)

A comparison between experimental data and computations for station 3 is depicted in Fig. 7. The figure shows that the agreement is good. The results from the standard $\sigma$ model are also plotted in the figure for comparison. Again, this shows that the ALES model is superior due to the incorporation of grid velocity

4. Comparison with hydrostatic model

In order to show the difference between the results predicted with and without non-hydrostatic pressure, a wave over a trench with the same geometry as described by Alfrink and van Rijn (1983) is simulated. A mesh of 170x20 cells is used in the numerical computation with $\delta x = 0.1 \, m$, $\delta t = 0.01 \, s$, $U_0 = 0.2 \, m/s$ and $h_0 = 0.2 \, m$. The period $T$ is 3 s. Comparison of the surface...
Figure 7: Comparison between model and experiment of the wave profile at station 3

Figure 8: Comparison of surface profiles at $t = 20$ s with and without non-hydrostatic pressure: dashed line denotes the surface from hydrostatic pressure model

profiles is shown in Fig. 8.

5. A wave flow over a trench

A current over a trench has been investigated numerically and experimentally (Alfrink and van Rijn, 1983; Basara and Younis, 1995; Stansby and Zhou, 1998). No experimental studies of wave flow over a trench have been reported in the literature to our knowledge. However, this is an important problem in coastal engineering and is investigated numerically here. The trench used is the same as that investigated experimentally for a current (Alfrink and van Rijn, 1983) and is sketched in Fig. 9. A mesh of 170x30 cells is used in the numerical computation with $\delta x = 0.1$ m, $\delta t = 0.01$ s, $U_0 = 0.08$ m/s and $h_0 = 0.2$ m. The wave height is $h_w \approx 0.2h_0$ and the period $T$ is 1 s. The streamlines are shown at $t = 20$ s in Fig. 10. The reflection coefficient is $K_r \approx 0.38$ and the transmission coefficient is $K_t \approx 0.44$, estimated after 4 wave crests have passed the trench. As comparison, a current over the trench
is shown in Fig. 11 (Stansby and Zhou, 1998).

6. A wave/current flow over a trench

Waves often occur in combination with a current. Here a wave/current flow over the same trench is simulated. To retain the same wave height, \( U_0 = 0.2 \text{ m/s} \) and inflow boundary condition for velocity \( u \) is specified as

\[
u_{in} = \frac{u_* \log_e \left( \frac{30.0(z - z_0)}{k_s} \right)}{k_s} + U_0 \sin(2\pi t/T) \tag{11}
\]

where \( u_* = 0.033 \text{ m/s}, \kappa = 0.4, k_s = 0.002 \text{ m} \) and \( z_0 = 0.00067 \text{ m} \). This gives wave height \( H = 0.038 \text{ m} \) and mean current velocity \( \bar{u} \approx 0.387 \text{ m/s} \).

Fig. 12 shows the streamlines at \( t = 8.4 \text{ s} \). At this moment, there is clearly separation in the trench. There is also flow separation in the trench when \( t = 8.7 \text{ s} \) as shown in Fig. 13. However, separation appears to disappear when \( t = 8.9 \text{ s} \) as shown in Fig. 14. This highly unsteady separation is in contrast to the stable separation in a steady current (see Fig. 11) and attached flow in a wave alone.

Conclusions

In this paper, we present the application of the ALES model to wave flows. The results have shown that the ALES model is more accurate than the conventional shallow-water flow model in \( \sigma \) coordinate. When there is significant variation in either free surface or bed topography, the effect of the non-hydrostatic pressure on flows should not be ignored.

Linear and Nonlinear Modeling of Long Waves Propagating around Channel Bends

By Aimin Shi¹ and Michelle H. Teng², M. ASCE

Abstract

In the present study, the transmission and reflection of long waves traveling through right-angled channel bends of constant depth and width are investigated by using numerical simulation based on the linear and nondispersive long wave equations. The present linear results are compared with the results obtained by Shi, Teng and Wu (1998) based on the weakly nonlinear and dispersive Boussinesq equations. The objective is to examine the difference between linear and nonlinear modeling of long waves propagating through curved channels.

Introduction

It is of practical interest to coastal engineers to understand how tides and other long ocean waves are transmitted and reflected through curved river inlets and harbors. In the past, several excellent studies were carried out on the related subject including the studies by Rostafinski (1976) on long acoustic waves in curved ducts, by Webb and Pond (1986) on Kelvin waves in channel bends, and by Kirby, Dalrymple and Kaku (1994) on short water waves through wide channel bends. Most of the previous studies were based on the linear wave theory and focused on waves propagating through smoothly curved channels, except in Miles' (1947) pioneer study where analytical solutions were obtained for linear acoustic waves traveling through sharp-cornered 90°-bends. Miles' solution is valid for long waves propagating in relatively narrow ducts whose width is less than half the wavelength.

In recent studies by Shi and Teng (1996), Shi, Teng and Wu (1998), the previous analytical studies were extended to investigate the propagation of a solitary wave through both smoothly curved and sharp-cornered 90°-bends by using numerical simulation based

¹ Researcher, Environmental Fluid Dynamics Research, Jamesburg, NJ 08831, USA.
² Associate Professor, Department of Civil Engineering, University of Hawaii at Manoa, Honolulu, HI 96822, USA.
on Wu's (1981) weakly nonlinear and dispersive Boussinesq equations. Solitary waves propagating through various narrow and wide channel bends were studied. Two parameters, namely, the bending curvature and the ratio of channel width \(b\) to effective wavelength \(\lambda_e\), were found to be the dominant factors that affect the transmission and reflection of a solitary wave through curved channels. For solitary waves traveling through sharp-cornered 90°-bends, the transmission (reflection) coefficient, i.e., ratio of the leading transmitted (reflected) wave amplitude along the channel centerline to the initial wave amplitude, was found to depend on a single dimensionless parameter, namely, \(b/\lambda_e\). Quantitatively, the transmission (reflection) coefficient was found to decrease (increase) as \(b/\lambda_e\) increases. Based on the numerical results, empirical power laws for predicting the transmission and reflection coefficients as functions of \(b/\lambda_e\) were obtained. For solitary waves traveling through smooth channel bends, the initial wave was observed to be almost completely transmitted in both narrow and wide bends with little backward reflection.

In the present study, the same cases studied in Shi, Teng and Wu (1998) will be revisited by applying the linear nondispersive long wave equations. The objective is to investigate the difference between linear and nonlinear modeling of long waves propagating through channel bends.

Governing Equations

In the recent study of Shi, Teng and Wu (1998), the numerical simulation of long waves propagating through curved shallow water channels of constant depth was based on the generalized weakly nonlinear and dispersive Boussinesq model (i.e., the gB model)

\[
\begin{align*}
\zeta_t + \nabla \cdot [(h + \zeta) \nabla \phi] &= 0 \\
\phi_t + \frac{1}{2} (\nabla \phi)^2 + \zeta - \frac{h^2}{3} \nabla^2 \phi_t &= 0
\end{align*}
\]

where \(\zeta\) is the wave elevation relative to the unperturbed water surface, \(h (=1)\) the water depth, \(\phi\) the depth-averaged velocity potential, \(t\) time, and \(\nabla = (\partial_x, \partial_y)\) with \(x, y\) being the spatial coordinates in the longitudinal and lateral directions, respectively. All the variables are in dimensionless form, with length scaled by \(h\), and time by \(\sqrt{h/g}\). The boundary conditions were unperturbed water surface at \(x = \pm \infty\), and zero normal velocity at the channel walls.

In the present study, the following linear and nondispersive long wave equations

\[
\begin{align*}
\zeta_t + h \nabla^2 \phi &= 0 \\
\phi_t + \zeta &= 0
\end{align*}
\]
are applied along with the same boundary conditions as described above.

The long waves studied are solitary waves whose initial wave profile and speed are given by (Teng 1997, Teng and Wu 1992, Shi, Teng and Wu 1998):

$$\zeta(x,t) = \frac{\alpha \text{sech}^2 \beta(x-x_0-ct)}{1+\alpha \tanh^2 \beta(x-x_0-ct)}$$ (5)

$$c = \left\{ \frac{6(1+\alpha)^2}{\alpha^2 (3+2\alpha)} [(1+\alpha) \ln(1+\alpha) - \alpha] \right\}^{1/2}$$ (6)

where $\alpha$ is the wave amplitude, $\beta = \left[3\alpha / 4(1+0.68\alpha)\right]^{1/2}$, $c$ the wave speed, and $x_0$ the initial wave position. Here the effective wavelength $\lambda_e$ of a solitary wave is defined as the wavelength within which the wave elevation $\zeta$ is greater than 1% of the amplitude $\alpha$. Based on (5), $\lambda_e$ can be calculated by

$$\lambda_e = \frac{2}{\beta} \ln \frac{(1+0.01\alpha)^{1/2} + 0.99^{1/2}}{(0.01+0.01\alpha)^{1/2}}$$ (7)

Numerical Results

In Shi, Teng and Wu (1998), the Boussinesq model (1), (2) was solved by using an iterative predictor-corrector finite difference scheme (Wang, Wu and Yates 1992) to simulate the propagation of solitary waves through 90°-channel bends. The numerical results for solitary waves traveling through sharp-cornered 90°-bends revealed an interesting phenomenon that in a narrow channel bend, the initial wave is almost completely transmitted with little reflection, while in a wide channel, the amplitude of the reflected wave becomes much greater than the transmitted wave. It was also found that the transmission and reflection coefficients depend on only one dimensionless parameter, namely, the ratio of channel width $b$ to wavelength $\lambda_e$. This implies that, when studying long wave transmission and reflection through channel bends, whether a channel is “wide” or “narrow” is judged by comparing the channel width with the wavelength, rather than with the water depth. Based on the numerical results, empirical power laws for predicting the transmission and reflection coefficients through sharp-cornered 90°-bends were obtained as

$$\frac{\alpha_T}{\alpha} = \begin{cases} 1, & 0 < b/\lambda_e < 0.2 \\ 0.28(b/\lambda_e)^{-0.72}, & 0.2 \leq b/\lambda_e < 1.0 \end{cases}$$ (8)

$$\frac{\alpha_R}{\alpha} = \begin{cases} 1.19(b/\lambda_e)^{0.9}, & 0 < b/\lambda_e < 0.4 \\ 0.58(b/\lambda_e)^{0.14}, & 0.4 \leq b/\lambda_e < 1.0 \end{cases}$$ (9)
where $\alpha$ is the initial wave amplitude, and $\alpha_r$ and $\alpha_s$ are amplitudes of the leading transmitted and reflected waves, respectively. For solitary waves traveling through smoothly curved channel bends, it was found that the waves are almost completely transmitted with little backward reflection in both narrow and wide channels.

In the present study, the linear and nondispersive long wave equations (3), (4) are solved by using the 4th-order Runge-Kutta scheme. The scheme is first tested on solitary waves traveling in a straight channel where closed-form solution (5), (6) exists. Our results show that after a solitary wave travels for about 60 water depths, the amplitude changes by only 0.1%. The accuracy of the numerical simulation is also examined by monitoring the mass and energy conservation at each computational step. Both the Runge-Kutta scheme and the scheme by Wang et al. (1992) are found to conserve mass and energy accurately. In all the simulations, including the cases involving waves traveling through sharp-cornered channel bends, the maximum errors in mass and energy conservation are 1.2% and 4.2% with Wang et al.'s scheme in solving the nonlinear Boussinesq model, and 2.2% and 1.9% with the Runge-Kutta scheme in solving the linear wave equations.

Numerical results of a solitary wave of initial amplitude $\alpha = 0.3$ propagating through a sharp-cornered 90°-bend of width $b = 5$ are shown in Fig. 1 (linear results) and Fig. 2 (nonlinear results). Figures 1 (a) and 2 present the two-dimensional wave field at different time instants based on the linear and nonlinear results, while Fig. 1 (b) and (c) show the detailed comparison between the linear (dashed line) and nonlinear (solid line) results for transmitted and reflected wave profiles along the channel centerline. From these results, we observe that, the Boussinesq model can predict more detailed (e.g., Fig.1 (a) and Fig.2, near the sharp corner) and more realistic (e.g., Fig.1 (c), the transmitted wave profile) wave features than the linear wave equations. In addition, there are some quantitative differences between the two models in predicting the transmitted and reflected wave amplitude and speed. The linear wave equations predict a slightly smaller (larger) transmitted (reflected) wave amplitude, and a slower speed which is expected. Despite these small differences, the linear and nonlinear wave models are seen to be fundamentally consistent with each other in predicting the transmission and reflection of solitary waves propagating through sharp-cornered channel bends. This consistency is further shown in Fig. 3 (a) and (b) where numerical results from fifteen simulations involving different initial wave amplitude and different channel width are plotted together. In this figure, the connected solid and dashed lines are based on the least-square fitting of the numerical data points, and the solid line also represents the empirical power laws given by (8) and (9). We can see that, similar to the nonlinear results based on the Boussinesq model, the data points for the transmission (and reflection) coefficient based on the linear and nondispersive model (3) and (4) also fall along one curve when plotted against $b/\lambda_c$, hence revealing the same similarity parameter that governs the phenomenon.

The linear results for a solitary wave of initial amplitude $\alpha = 0.3$ traveling through a smooth 90°-bend of width $b = 5$ are presented in Fig. 4 (a) and (b). Comparing with the nonlinear results (Shi, Teng and Wu 1998, Fig.9 (a), p.171), we find that the nonlinear
and dispersive Boussinesq model again provides more detailed wave features, such as the lateral wave variation in the trailing region, than the linear model. In addition, based on the linear equations, the back of the transmitted wave is slightly steeper than the front of the wave, which is less realistic than the wave profile predicted by the Boussinesq model (see comparison in Fig.4 (b)). Nevertheless, both models predict that for long waves traveling through smoothly curved channels, the initial wave is almost completely transmitted with little backward reflection. In addition, the values for the leading transmitted wave amplitude predicted by the two models are quite consistent.

In our numerical simulation, the wave speed based on both models is calculated. Here we define the average wave speed as the total longitudinal distance traveled along the channel centerline divided by the corresponding travel time. Detailed numerical results on the wave speed of an initial solitary wave of $\alpha = 0.3$ traveling in different curved channels are presented in Table 1. These results show that the linear waves travel with critical wave speed, slower than the nonlinear waves, which is consistent with the wave theory.

Table 1. Comparison between wave speeds based on the linear and nonlinear models

Conclusion

For long waves propagating through smooth and sharp-cornered channel bends, it is found that the weakly nonlinear and dispersive Boussinesq model and the linear nondispersive long wave equations are fundamentally consistent with each other in predicting the amplitude of the leading transmitted and reflected waves. Beyond this fundamental consistency, we also find that the Boussinesq model can predict slightly more detailed wave features and more realistic wave profiles.

Mass Transport of Progressive Edge Waves: A Comparison between the Full and Shallow-Water Wave Theories

K. M. Mok¹ & Harry Yeh²

¹Member of ASCE

Abstract

The differences between the full and shallow-water wave theories for edge waves are reviewed. Detailed comparisons between the solutions of the second-order mass transport velocities within the laminar boundary layer obtained through the two theories are carried out for the first three edge-wave modes. The results clearly show that the error of the shallow-water approximation is larger as the mode number gets larger, and/or the beach slope gets steeper. It is also found that the magnitude of shallow-water approximation error increases in the offshore direction first, then it decreases as the distance approaches further offshore due to the energy decay in that direction. The affecting area of the shallow water approximation is relatively larger for the longshore transport than for the cross-shore transport in higher-mode edge waves. The significant differences between the full and shallow water-wave solutions in the near shore region identified in the present study issue a warning to the modellers of coastal hydrodynamics and nearshore topography, who utilize the shallow water approximation.

Introduction

Edge waves, the waves trapped near the shoreline on a uniformly sloping beach due to wave refraction, were discovered by Stokes (1846). The crest of Stokes' edge wave on a plane beach is perpendicular to the shoreline, it propagates along the shore with the wave amplitude decaying exponentially offshore. Other edge wave modes, besides the Stokes mode, were found by Eckart (1951) through the shallow water-wave theory and Ursell (1952) through the full water wave theory.

The assumptions associated with the full water wave theory are inviscid and homogeneous fluid, irrotational fluid motion, constant pressure on the free surface, negligible surface tension effect, and only gravity as the restoring force. For the shallow-water wave theory, the assumptions are the same as the full water theory with further simplification; the vertical fluid acceleration is neglected which means that the pressure variation with depth within the fluid domain is hydrostatic, and the horizontal component of the velocity field is uniform over the whole depth. With these assumptions, the problem formulated with the shallow water approximation is reduced to two-dimensional by the depth-integration. The mathematical descriptions of a mode-n progressive edge wave through the shallow water theory (Eckart, 1951) are

\[\phi_s = \frac{a_n g \beta}{\omega} \exp(-k_n y') L_n(2k_n y') \sin(k_n x - \omega t),\]

\[\eta_s = a_n \beta \exp(-k_n y') L_n(2k_n y') \cos(k_n x - \omega t),\]

with the dispersion relation,

\[\omega^2 = gk_n (2n + 1)\beta,\]

where \(n\) is a non-negative integer \((n = 0, 1, 2, 3, \ldots)\) representing the offshore mode number, \((x, y', z)\) are the Cartesian coordinates of the alongshore, horizontally offshore and vertically upward directions (the shoreline is at \(y' = 0\) and \(z = 0\), \(\phi\) is the velocity potential, \(\eta\) is the displacement of the water surface from the equilibrium position, \(a_n\) is the wave run-up amplitude on the beach, \(\beta\) is the beach sloping angle from the horizontal, \(\omega (= 2\pi/\text{wave period})\) is the angular frequency and \(k (= 2\pi/\text{wavelength})\) is the wavenumber in the longshore direction, and \(L_n(\bullet)\) is the Laguerre polynomial of order \(n\), which is defined as

\[L_n(s) = \frac{e^s}{n!} \frac{d^n}{ds^n} (e^{-s} s^n).\]

The counterparts of (1) to (3) by the full water wave theory (Ursell 1952) are

\[\phi = \frac{\alpha_n g \beta}{\omega} \left[\exp\left(-k_n y' \cos\beta + k_n z \sin\beta\right) \right.\]

\[+ \sum_{m=1}^{n} A_{mn} \left\{\exp\left[-k_n y' \cos(2m-1)\beta - k_n z \sin(2m-1)\beta\right] \right.\]

\[+ \exp\left[-k_n y' \cos(2m+1)\beta + k_n z \sin(2m+1)\beta\right]\left[\sin(k_n x - \omega t)\right],\]

\[\eta = \alpha_n \left[\exp(-k_n y' \cos\beta) + \sum_{m=1}^{n} A_{mn} \left\{\exp(-k_n y' \cos(2m-1)\beta) \right.\right.\]

\[+ \exp(-k_n y' \cos(2m+1)\beta)\right\}\cos(k_n x - \omega t),\]

\[A_{mn} = (-1)^m \prod_{j=1}^{m} \frac{\tan(n - j + 1)\beta}{\tan(n + j)\beta},\]
and $\alpha_n$ is a constant. The corresponding dispersion relation is given by
\[ \omega^2 = g k_n \sin((2n + 1)\beta). \]  
Ursell (1952) further showed that the number of possible trapped modes depends upon the beach sloping angle $\beta$ with the maximum mode number $n$ (a non-negative integer) satisfying
\[ (2n + 1)\beta \leq \frac{\pi}{2}. \]  

Stokes mode which is also called the mode 0 corresponds to $n = 0$, and edge waves with $n \geq 1$ are termed higher-mode edge waves. It is noted that Eckart's (1951) solution does not give any limitation to the value of the mode number $n$ for a given beach slope; i.e. one cannot distinguish between the trapped modes and those that radiate energy offshore; as $n \to \infty$, the shallow-water wave solution corresponds to the perfectly reflected cross-shore wave (Whitham, 1976) which is obviously not a (trapped) edge-wave mode. To show the discrepancies between the full water-wave solution and the shallow-water wave approximation, Yeh (1986) plotted the surface profiles obtained by the two theories for the first three modes ($n = 0, 1, 2$) on a beach of $15^\circ$ ($\beta = \pi/12$) slope as shown in figure 1. He showed that the full water-wave and the shallow-water wave solutions have good agreement for the mode-0 edge wave, but the two solutions deviate from each other as either $n$ or $y'$ increases; these deviations reflect the failure of the shallow-water wave

![Figure 1](image)

**Figure 1.** Offshore surface profiles of various edge-wave modes with $\beta = \pi/12$; (a) $n = 0$, (b) $n = 1$, (c) $n = 2$. ——— full theory; ———— shallow-water approximation.
approximation as \( y' \to \infty \) (in deep water). A more general comparison of the water-surface profiles predicted by the full water-wave solution and the shallow water-wave approximation can be demonstrated qualitatively by plotting the normalized difference \( \varepsilon \) for a range of beach slope and offshore distance:

\[
\varepsilon = \frac{\eta_s}{\eta_{s, y'=0}} - \frac{\eta}{\eta_{y'=0}}.
\] (10)

Figure 2 shows the difference \( \varepsilon \) for the mode-0, mode-1 and mode-2 edge waves. It is noted that the plot range of the beach slope \( \beta \) is determined by (9). The \( \varepsilon = 0 \) plane represents the perfect agreement between the two theories. It is clearly shown that the deviation of \( \varepsilon \) from the zero plane increases both with the beach slope and the mode number. These deviations indicate the failure of the shallow water approximation in deep water. Quantitative comparison of the water surface as shown in figure 2 is given by Mok (1995b) who plotted the contour maps of the difference \( \varepsilon \) for the mode-0, 1, and 2 edge waves.

Figure 2. Differences on the water-surface elevation between the full water-wave theory and the shallow-water wave approximation for the (a) mode-0, (b) mode-1, (c) mode-2 edge waves.
In the natural beach environment, various field observations show that edge waves with the mode number less than 5 could be significant nearshore (Munk, Snodgrass & Gilbert, 1964; Huntley & Bowen, 1973; Huntley, 1976; Huntley, Guza & Thornton, 1981; Oltman-Shay & Guza, 1986). Due to the rhythmic characteristics of edge waves in the longshore direction, they can be related to many nearshore morphological features such as the formation of systematically spaced rip currents, nearshore circulation (Bowen & Inman, 1969), crescentic bars, some rhythmic topographical patterns nearshore (Bowen & Inman, 1971; Holman & Bowen, 1982), and beach cusps (Bowen & Inman, 1971; Guza & Inman, 1975; Huntley & Bowen, 1978; Guza & Bowen, 1981). The effects of edge wave on the coastal topography are due to its time-averaged Lagrangian mass-transport velocities (wave induced currents). Even if the magnitude of the induced current might be small, incipience of sediment detachments from the bottom might be caused by the disturbance such as turbulence induced by wave breaking. Then, the fate of the detached sediments might be controlled by the minute-but-persistent time-averaged wave induced currents, and eventually change the sea-bed topography.

Due to simplicity, many of the previous edge-wave mass-transport models (e.g. Bowen & Inman (1971) and Holman & Bowen (1982)) are based on the shallow-water wave theory and the transport velocity is evaluated only at the outer edge of the boundary layer. The question remained is “How much error will the shallow-water approximation introduce to the mass-transport velocity?”. In the present study, the second-order mass-transport velocity at the outer edge of the bottom laminar boundary layer derived based on the full water-wave theory is compared with that obtained by the shallow-water-wave theory to identify the differences.

Mass Transport at the Outer Edge of the Bottom Boundary Layer

According to the thin laminar boundary layer theory, the flow field within the bottom viscous layer is driven by the outer irrotational oscillatory flow which is described by the velocity potential. A comparison between (1) and (5) shows that the shallow water solution has the vertical (z-direction) structure of the irrotational flow field removed due to the depth integration operation. This approximation is acceptable when the beach slope or the mode number is small as the vertical structure of the flow field depends on the sine of these two parameters (see (5)). Nevertheless, when the beach slope or the mode number becomes large, the failure of the shallow water approximation is apparent. When the shallow water approximation introduces error into the forcing (the outer irrotational flow field) of the bottom boundary layer, it will pass the error down to the induced second-order mass transport velocity.

Using the full water-wave solution of the velocity potential (5) with the coordinates rotated by the beach slope $\beta$,
Mok & Yeh (1998) and Mok (1992) derived the second-order mass-transport velocity within the thin laminar bottom boundary layer for all modes of progressive edge waves propagating along a uniformly sloping beach. Their solutions are evaluated at the outer edge of the boundary layer here to give the longshore and cross-shore mass-transport velocities \( \bar{u}_L, \bar{v}_L \),

\[
\bar{u}_L = (\alpha_n g)^2 \left( \frac{k_n}{\omega} \right)^3 \left\{ \frac{3}{2} [\exp(-k_n y) + 2 \sum_{m=1}^{n} A_{mn} \exp[-k_n y \cos(2m\beta)]] \right. \\
+ \left. \sum_{m=1}^{n} A_{mn} \sin^2(2m\beta) \exp[-k_n y \cos(2m\beta)] \right\},
\]

\[
\bar{v}_L = -\left( \alpha_n g \right)^2 \left( \frac{k_n}{\omega} \right)^3 \left\{ \exp(-k_n y) + 2 \sum_{m=1}^{n} A_{mn} \cos(2m\beta) \exp[-k_n y \cos(2m\beta)] \right\} \\
+ \left[ \sum_{m=1}^{n} A_{mn} \sin^2(2m\beta) \exp[-k_n y \cos(2m\beta)] \right],
\]

where, the coordinates \((x, y, z)\) are measured longshore, offshore along the bottom and perpendicular to the beach. Based on the mass-transport velocity solutions at the outer edge of the boundary layer given by Hunt & Johns (1963) and the velocity potential given in (1), the second-order mass-transport velocity for progressive edge waves can also be estimated by the shallow-water wave theory. The mass-transport velocities in the longshore and cross-shore directions are, respectively,

\[
\bar{u}_{Ls} = (\alpha_n g)^2 \left( \frac{k_n}{\omega} \right)^3 \frac{1}{4} \left\{ 5 \exp(-k_n y') [L_n(2k_n y')]^2 \right. \\
- \left. \frac{3}{k_n^2} \exp(-k_n y') L_n(2k_n y') \frac{d^2}{dy'^2} [\exp(-k_n y') L_n(2k_n y')] \right\},
\]
\[
\left. + \frac{2}{k_n^2} \left( \frac{d}{dy'} \right) \left[ \exp(-k_n y')L_n(2k_n y') \right]^2 \right) \]
\[
\frac{-1}{v_{Ls}} = \left( a_{ng} \beta \right)^2 \left( \frac{k_n}{\omega} \right)^3 \frac{1}{4k_n} \frac{d}{dy'} \left[ \exp(-k_n y')L_n(2k_n y') \right] .
\]
\[
\left\{ \exp(-k_n y')L_n(2k_n y') \right\} - \frac{3}{k_n^2} \frac{d^2}{dy'^2} \left[ \exp(-k_n y')L_n(2k_n y') \right] \}
\]

Comparison between the Full and Shallow-Water Wave Solutions

Since the coordinate \( y' \) for the shallow-water wave solution is measured horizontally offshore and the coordinate \( y \) for the full water-wave solution is along the beach bottom, the mass-transport velocities calculated by the shallow-water wave solution are evaluated at position \( y' \) but plotted against the corresponding \( y \) location \( (y = y' \cos \beta) \) in order to be compared with the full water-wave solution. To show the characteristics of the longshore and cross-shore mass transport velocities of progressive edge waves and to be consistent with Yeh's (1986) comparison, the mass-transport velocity profiles obtained by the two theories on a beach of \( \pi/12 \) slope is plotted to view the differences. The \( \beta = \pi/12 \) selection restricts the discussions only on the mode-0, mode-1 and mode-2 edge waves according to (9). For both longshore and cross-shore mass-transport velocities of a mode-0 edge wave, the full and shallow-water wave solutions agree with each other (the differences are indistinguishable so that the results are not presented). However, as the mode number becomes larger, the differences appear. Figure 3 shows the longshore and cross-shore mass-transport velocities of a mode-1 edge wave, respectively. It is shown that the differences between the full and shallow-water wave solutions are small. For the longshore transport (figure 3a), the shallow-water wave solution is slightly larger at \( k_{1y} < 1.68 \) and smaller at \( k_{1y} > 1.68 \) than the full water-wave solution. For the cross-shore transport (figure 3b), the two solutions agree qualitatively. The main differences between them are the locations of the zero mass-transport (zero-crossing) and the offshore locations of the local minimum and maximum. In general, the locations of the zero-transport, local minimum and local maximum predicted by the shallow-water wave theory occur closer to the shore than those predicted by the full water-wave theory. Figure 4 shows the longshore and cross-shore mass-transport velocities of a mode-2 edge wave, respectively. The differences between the full and shallow-water wave solutions are evident. The main differences are the offshore locations of the local minima, local maxima and zero crossings; the shallow-water wave theory still predicts those locations closer to the shore than the full water-wave theory does.

Further general comparisons between the two theories are carried out for the longshore and cross-shore mass transport velocities by plotting the normalized difference.

\]

(17)

The comparison scheme is to assume that both of the solutions have the same magnitude at the shoreline and see how they deviate from each other as the beach slope and the offshore distance increase. Figure 5 shows the differences \( \Delta u_L \) and \( \Delta v_L \) for a mode-0 edge wave. It is noted that the error chart is valid for both the longshore and cross-shore transports due to the similar offshore structure that they possess. Each line in figure 5 represents the longshore (or cross-shore) transport difference between the two solutions (full and shallow) on beaches of various slope \( \beta \). For a given beach slope, the magnitude of the error increases offshore from zero to a local maximum then it decreases. The increase of error in the offshore direction at location near the shore reflects the failure of the shallow water approximation due to the increasing water depth. The maximum error of a mode-0 edge wave occurs at \( k_0y < 0.5 \) for the entire range of beach slope \( (\beta \leq \pi/2) \).

Figure 5. Error chart of the longshore (or cross-shore) transport between the full and shallow-water wave theories for a mode-0 edge wave on various beach slopes.
The decrease of the relative error at further offshore location is due to energy decay in that direction; i.e. the magnitude of the mass-transport velocity is small at location far offshore due to the exponential decay and therefore the relative error between the two solutions becomes small there. On the other hand, the relative error between the two solutions increases with the increasing beach slope for a given offshore location \( k_0 y \). This characteristic clearly indicates the effects of the water depth. As the water depth at a fixed offshore location becomes larger with the larger beach slope, the error of the shallow water approximation becomes larger. In fact, this behaviour is expected to be the same for the other edge-wave mode and will not be addressed again in the following discussions for the higher-mode edge waves.

For a mode-1 edge wave, the variation of the error for longshore and cross-shore transports differs. Figure 6 shows the longshore-transport difference \( \Delta u_L \) of a mode-1 edge wave. For the shown beach-slope range, the errors increase offshore from zero to local maxima at \( 0.5 < k_1 y < 0.8 \), then it decreases offshore to local minima at \( 2.0 < k_1 y < 2.7 \). The magnitudes of the local maxima are larger (about 1.7 times for the case of \( \beta = \pi/6 \)) than the local minima. Nevertheless the magnitude of the error decreases gradually at \( k_1 y > 2.7 \). Again, the increase of error in the offshore direction at location near the shore reflects the failure of the shallow water approximation due to the increasing water depth.

![Figure 6](image_url)  
*Figure 6. Error chart of the longshore transport between the full and shallow-water wave theories for a mode-1 edge wave on various beach slopes.*
depth while the decrease of error at location further offshore \((k_1y > 2.7)\) is due to the energy decay as discussed earlier. For the cross-shore mass transport comparison, figure 7 shows the difference \(\Delta v_L\) for a mode-1 wave. Similar to the longshore transport, the magnitudes of the cross-shore transport errors increase in the offshore direction with formation of local minima and maxima at \(0.1 < k_1y < 0.2\) and \(2.2 < k_1y < 3.0\), respectively. However, the magnitudes of the local minima are much larger (about 7 times for the case of \(\beta = \pi/6\)) than the local maxima. This significant magnitude difference is caused by the rapid decay of the cross-shore transport velocity in the offshore direction (see figure 3b). Comparing the longshore and cross-shore transport error variation (figures 6, 7), it is clear that the error introduced by the shallow water approximation has a relatively wider offshore coverage for the longshore transport than for the cross-shore transport. Again this is due to the different offshore energy decaying rates of the two transport velocities as shown in figure 3. Note that the complexity of the offshore variation and the existence of local maxima, minima and zero crossings are due to the intersection of the two solutions at various offshore locations (see figure 3).

For the mode-2 edge wave, variation of the error is similar to that of a mode-1 edge wave qualitatively but with more complexity. Detailed description of the comparison is not given for the mode-2 edge wave. Figures 8 and 9 show the longshore-

![Figure 7](image.png)

transport difference $\Delta u_L$ and the cross-shore transport difference $\Delta v_L$ for a mode-2 edge wave, respectively. Generally, the error still increases with the beach slope and the offshore distance and forms local maxima and minima. The affecting area of the shallow water approximation is still larger for the longshore transport than for the cross-shore transport.

![Error chart of the longshore transport between the full and shallow-water wave theories for a mode-2 edge wave on various beach slopes.](image)

**Figure 8.** Error chart of the longshore transport between the full and shallow-water wave theories for a mode-2 edge wave on various beach slopes.

**Conclusions**

Due to its simplicity, many edge-wave mass-transport models are based on the shallow-water approximation. The use of the shallow-water approximation seems reasonable if the beach slope is mild, or only relatively low-mode edge waves are considered. The present study shows that the significant differences between the full and shallow water-wave solutions as the beach slope gets steeper, the distance is farther from the shoreline, or the mode number gets larger issue a warning to the modellers of coastal hydrodynamics and nearshore topography, who utilize the shallow water approximation. Even the present comparison of the two solutions are carried out for mass transport located at the outer part of the boundary layer, it should be noted that there may be major drawbacks on the usage of the mass transport velocity at this location to model the nearshore topography formation. According to Mok's (1995a) experimental verification
and discussions on Dore's (1975) mass transport solution for the Stokes progressive edge wave, the cross-shore transport is bidirectional; the transport is in the inshore direction near the bottom of the boundary layer, while it is in the offshore direction in the upper part of the boundary layer. Evidently, using only the mass-transport velocity at the outer edge of the boundary layer may give an incomplete picture or even misleading prediction of the edge waves' influences on the coastal regions.

Coherent Motions in the Bottom Boundary Layer under Shoaling and Breaking Waves

Daniel T. Cox¹ and Nobuhisa Kobayashi²

ABSTRACT: Laboratory measurements of the instantaneous horizontal and vertical velocities induced by regular waves spilling on a rough, impermeable slope were analyzed to elucidate the nature of turbulence generated in the bottom boundary layer and by wave breaking. In the bottom boundary layer outside the surf zone, both the absolute shear stress $|r'|$ and the turbulent kinetic energy $k'$ exhibited intermittent behavior where the instantaneous values were often several times greater than the phase-averaged values. The motions occurred with the passing of each regular wave, however, and the phase-averaged values described the turbulent fluctuations reasonably well. A quadrant analysis showed that the turbulent velocities $u'$ and $w'$ were strongly correlated and oriented in either the first and third quadrants with $u'w' > 0$ during the acceleration phases or in the second and fourth quadrants with $u'w' < 0$ in the deceleration phase. The Reynolds stress contributions for this unsteady flow case depended strongly on the phase. Inside the surf zone, $|r'|$ and $k'$ were marked by intense, intermittent events which did not occur with the passing of each wave and which were roughly two orders of magnitude larger than the phase-averaged values. This intermittent motion extended into the wave bottom boundary layer. Near trough level, the intermittent events were phase-dependent, and the intense motion was primarily in the fourth quadrant. Near the bottom, the intermittent events were less phase-dependent. A preliminary analysis of the intensity and duration of the intermittent events indicated that coherent events occurred for about 10% of the record and accounted for approximately 50% of the motion, whereas intense events occurred for about 2% of the record and accounted for approximately 20% of the motion. These statistics clearly indicated that the intense, coherent events were intermittent and infrequent but contributed significantly to the magnitude of the absolute shear stress and turbulent kinetic energy.

INTRODUCTION

Progress in understanding nearshore sediment suspension has been aided by the development of concentration sensors with high temporal resolution based on either optic or acoustic principles. Using these techniques, researchers have shown that nearshore sediment suspension is characterized by intermittent events and that these events, particularly inside the surf zone, can not be explained simply in terms of the free surface.

elevation or local wave-induced horizontal velocity. A number of mechanisms have been put forward to explain the intermittent behavior of nearshore sediment suspension [e.g., Jaffe et al., 1984; Beach and Sternberg, 1988; Nadaoka et al., 1988; Hanes, 1991; Hay and Bowen, 1994]. Coherent fluid motions, such as bursting events in the boundary layer and large eddies produced by wave breaking, are plausible mechanisms but have received little attention due to a lack of suitable measurements, particularly estimates of the instantaneous vertical turbulent velocity, momentum flux and kinetic energy in the nearshore. In light of this, this paper identifies intermittent, coherent fluid motions under regular waves in three areas: (1) outside the surf zone and inside the bottom boundary layer where turbulence is generated at the boundary, (2) inside the surf zone in the interior region below trough level and above the bottom boundary layer where turbulence is generated primarily by wave breaking and (3) inside the surf zone and inside the bottom boundary layer where both mechanisms may be important. The term "bottom boundary layer" used in this paper is in reference to the wave bottom boundary layer which was shown to exist inside the surf zone [e.g., Cox et al., 1996].

EXPERIMENT

The nature of nearshore turbulence generated in the bottom boundary layer and by wave breaking is investigated using a laboratory flume since repeatability of the wave condition allows the turbulent signal to be extracted by phase-averaging. The experiment was conducted in a 33 m long, 0.6 m wide, and 1.5 m deep wave flume with a 1:35 impermeable slope, corresponding to a dissipative beach. A physical bottom roughness was added to the slope to increase the boundary layer roughness and boundary layer thickness so that the bottom boundary layer would be fully rough turbulent for non-breaking waves. The roughness was prepared by gluing sand grains with a median grain diameter of \( d_{50} = 1.0 \) mm to Plexiglas sheets and then taping these sheets over the entire slope. The adopted roughness in this small-scale experiment would correspond to gravel on a natural beach if geometric similitude were applied.

Six measuring lines were established, noted L1 to L6, and their cross-shore position relative to the spilling breakers can be described as follows: L1 was in the shoaling region seaward of breaking, L2 was at the break point defined as the onset of aeration in the tip of the wave crest, L3 was in the transition region where the wave changed from organized motion to a turbulent bore, and L4 to L6 were in the inner surf zone where the saw-toothed wave shape was a well-established turbulent bore. The free surface elevation, \( \eta \), was measured at each measuring line using capacitance-type wave gages with a sampling rate of 100 Hz. The horizontal, cross-shore velocity, \( u \), and the vertical velocity, \( w \), were measured at a number of elevations at each measuring line by a fiber-optic laser-Doppler velocimeter (LDV). The effective sampling rate was in excess of \( 1 \times 10^3 \) data points per second, and the data were reduced by band averaging to a sampling rate of 100 Hz. The flume was filled with fresh water to a depth of 0.4 m in the flat section of the tank, and regular waves were generated with a wave period of \( T = 2.2 \) s. Fifty regular waves were measured at each elevation, and the turbulent signal was extracted by phase-averaging.

Table 1 summarizes the measuring line locations and elevations. The second column indicates the horizontal coordinate, \( x \), for each measuring line which is defined positive onshore with \( x = 0 \) at L1, where L1 was 9.8 m from the still water shoreline. The third
column indicates the depth \( d \) below the still water level to the top of the Plexiglas sheet. The fourth column indicates the phase-averaged wave height \( H \). The fifth column indicates the range of measuring elevations analyzed near the bottom with the number of elevations given in parenthesis. The vertical coordinate \( z_m \) is defined positive upward with \( z_m = 0 \) on the bottom at each measuring line. The thickness of the wave bottom boundary layer is estimated to be approximately 1 cm based on the maximum shear velocity and angular wave frequency which is consistent with observations for this data set [Cox et al., 1996].

The sixth column indicates the range of measuring elevations in the interior region outside the bottom boundary layer to trough level with the number of elevations given in parenthesis. The seventh column indicates the range of the dropout rate for all elevations at each measuring line. The dropout rate is expressed as a percent and is typically low (less than about 2%), except near trough level for L3 and L4 due to aeration by the bores. Statistics presented in this paper were compared extensively using two types of time series, one in which the dropouts were excluded and a second in which the dropouts were replaced by a linear interpolation of the nearest points. For all elevations except those immediately below trough level at L3 and L4, there was no significant difference in the statistics using the two types of time series. In this paper, only the time series in which the dropouts were replaced by a linear interpolation are presented for clarity. As summarized in Table 1, the data set consists of a total of 86 measuring elevations from the bottom to trough level over six measuring lines. The following sections present the instantaneous and phase-averaged turbulence using three representative elevations: L2 at \( z_m = 0.30 \) cm inside the bottom boundary layer outside the surf zone, L5 at \( z_m = 7.10 \) cm in the interior region inside the surf zone, and L5 at \( z_m = 0.30 \) cm inside the bottom boundary layer inside the surf zone.

### INSTANTANEOUS AND PHASE-AVERAGED TURBULENCE

The instantaneous free surface elevation, \( \eta \), and the horizontal and vertical velocities, \( u \) and \( w \), were phase-averaged over the fifty waves. The turbulent signals were defined as the difference of the instantaneous signals and phase-averaged signals and are expressed

\[
\eta' = (\eta - \eta_a), \quad u' = (u - u_a), \quad \text{and} \quad w' = (w - w_a)
\]

where the subscript \( a \) denotes a phase-averaged quantity and the prime denotes a turbulent quantity. The phase-averaged quantities include both the organized wave-induced motion and the mean motion. The instantaneous turbulent momentum flux may be defined \( \tau' = \rho = -u'w' \) where \( \rho \) is the
fluid density and $\tau'_a$ is the phase-averaged Reynolds shear stress. The absolute value of the phase-averaged Reynolds shear stress, $|\tau'_a|$, is normally related to the concentration of suspended sediments at the bed or to the pick-up of bottom sediments. This approach may be reasonable if $|\tau'_a|$ represents most of the fluctuations in $|\tau'|$. The notation of $\tau' = -u'w'$ without the assumed constant $\rho$ is used in this paper for simplicity. The instantaneous turbulent kinetic energy per unit mass $k'$ is also of interest since it is not clear whether suspended sediments near the bed respond to $|\tau'|$ or $\kappa'$. Since the cross-tank component of velocity, $v$, was not measured for this experiment, the turbulent kinetic energy per unit mass in this paper is defined as $k' = (u'^2 + w'^2)/2$ which is less than the actual $k'$ including the contribution of $v'^2$.

Figure 1 shows the temporal variations of the instantaneous and phase-averaged free surface elevation, horizontal and vertical velocities, absolute shear stress, and turbulent kinetic energy for L2 at $z_m = 0.30$ cm for $20 \leq t/T \leq 25$ where $t$ is time with $t = 0$ at the beginning of the 50 waves. The instantaneous and phase-averaged free surface elevation $\eta$ and $\eta_a$ in Figure 1a are difficult to distinguish and indicate the repeatability of the wave form. The wave shows strong asymmetry in both the horizontal and vertical planes. Figures 1b and 1c show the instantaneous and phase-averaged horizontal velocities, $u$ and $u_a$, and vertical velocities, $w$ and $w_a$. The phase-averaged horizontal velocity is dominant and much larger than the horizontal turbulent fluctuation. This assumption of a relatively weak turbulent intensity in a locally steady flow has been used in the analysis of surf zone turbulence [George et al., 1994]. The phase-averaged vertical velocity $w_a$ is small at this elevation and throughout most of the water column except near trough level, and the vertical turbulent fluctuation is dominant $w'$ in comparison to $w_a$. Note that $u$ and $w$ were measured simultaneously and that the LDV and wave gage were synchronized to the wavemaker signal. Since multiple runs were repeated at the same measuring line, however, the velocity and free surface measurements presented in this figure and in Figure 2 are not synoptic.

Figures 1d and 1e show the instantaneous and phase-averaged variations of the absolute shear stress, $|\tau'|$ and $|\tau'|_a$, and turbulent kinetic energy, $k'$ and $k'_a$. Both $|\tau'|$ and $k'$ exhibit intermittent behavior where the instantaneous values are often several times greater than the phase-averaged values. Nevertheless, this motion occurs with the passing of each wave, and the phase-averaged values describe the turbulent fluctuations reasonably well with the following features: relatively low turbulence in the trough, an increase with the approaching wave crest (acceleration) which continues with the passing of the wave crest (deceleration). Elevations in the range $0.20 \leq z_m \leq 1.10$ cm exhibited similar behavior. Elevations for $z_m > 1.10$ cm above the bottom boundary layer outside the surf zone show very little turbulent motion [e.g., Cox et al., 1994].

Figure 2 is similar to Figure 1 but for L5 inside the surf zone in the interior region at $z_m = 7.10$ cm where turbulence is generated by wave breaking. Comparison of $\eta$ and $\eta_a$ in Figure 2a shows the variability of the free surface inside the surf zone, particularly at the roller region on the crest of the wave. Inspection of the entire record $0 \leq t/T \leq 50$ did not reveal any large deviations in the instantaneous time series from the phase-averaged time series in the trough region, however. On the other hand, Figures 2b and 2c show intense, coherent motion in the horizontal and vertical velocities at $t/T \approx 21$ and $t/T \approx 24$. Inspection of the entire record $0 \leq t/T \leq 50$ for this elevation and for
Figure 1: Temporal variation of (a) $\eta$, (solid) and $\eta_a$ (dash-dot); (b) $u$, (solid) and $u_a$, (dash-dot); (c) $w$, (solid) and $w_a$, (dash-dot); (d) $|r'|$, (solid) and $|r'|_a$, (dash-dot); and (e) $k'$ (solid) and $k'_a$ (dash-dot) in the range $20 < t/T < 25$ for L2 at $z_m = 0.30$ cm.
the other elevations inside the surf zone indicates that these intense turbulent events are intermittent, that they do not occur with the passing of each wave, and that the motions extends into the bottom boundary layer. The intense turbulent velocity fluctuations are of the same magnitude as the phase-averaged horizontal velocity, and the motion generally occurs with the passing of a wave crest and spreads downwards.

Figures 2d and 2e show the instantaneous and phase-averaged absolute shear stress and turbulent kinetic energy. Similar to L2, $|\tau'|$ and $k'$ are well correlated. However, $|\tau'|$ and $k'$ are an order of magnitude larger than in the bottom boundary layer outside the surf zone. Since the intense motion does not occur with each wave, this motion is more intermittent and can not be explained in terms of the phase-averaged quantities. In the bottom boundary layer inside the surf zone, the motion is characterized by intense, intermittent turbulence generated by wave breaking and less intense but more frequent turbulence generated at the boundary (Figure not shown).

Figures 3a–c show smoothed spectra of $k'$ and $k'_a$ at the representative locations. The spectral densities are plotted as a function of the frequency, $f_*$, normalized by the wave period $T = 2.2$ s. The spectra of $k'_a$ were computed using phase-averaged time series repeated over 50 waves. All spectra were computed with detrended time series and were smoothed using band-averaging with 20 degrees of freedom. Figure 3a shows that the spectrum of $k'$ can be reasonably well represented by the spectrum $k'_a$, and that the low frequency components are small outside of the surf zone. Figure 3b shows that the spectrum of $k'_a$ describes a small portion of the $k'$ spectrum at the fundamental harmonic. Figure 3c shows that the spectrum $k'$ is poorly represented by the spectrum $k'_a$ inside the bottom boundary layer inside the surf zone. Figures 3b and 3c also show large low frequency components which are due to the intermittent nature of the eddies generated by wave breaking. The spectra for $|\tau'|$ and $|\tau'|_a$ are similar to those shown in Figure 3. These observations of small low frequency motion outside the surf zone and large low frequency motion inside the surf zone are consistent with observations of sediment suspension in a wave flume under regular waves [Dally and Barkaszi, 1994].

**QUADRANT ANALYSIS**

In this section, a quadrant analysis is used to identify coherent motions in the instantaneous turbulent velocity time series. For unidirectional flow in the marine atmospheric boundary layer, Boppe and Neu [1995] used the quadrant technique to identify coherent motions and to quantify the bursting process. Associated with the bursting process are “ejections” where low speed fluid is brought up from the boundary layer and “sweeps” where high speed fluid rushes down from the outer layer. For unidirectional flow, motion in the second quadrant where $u' < 0$ and $w' > 0$ corresponds to ejections and motion in the fourth quadrant where where $u' > 0$ and $w' < 0$ corresponds to sweeps. Both ejections and sweeps contribute positively to the Reynolds stress since $\tau'/\rho = -u'w'$.

Figure 4 shows quadrant plots of $u'$ and $w'$ at 20 phases for the entire 50 waves in the range $0 \leq t/T < 50$ for L2 at $z_m = 0.30$ cm. The time in the first quadrant for each panel indicates the phases for which the data were plotted. For example, $t_a/T = 0.05$ indicates that the data plotted in that panel correspond to all data in the range $0 \leq t_a/T < 0.05$ over the fifty waves where $t_a/T$ is the normalized phase.
Figure 2: Same as Figure 1 for L5 at $z_m = 7.10$ cm.
over one wave period. The four horizontal bars plotted along the vertical axis indicate (from top to bottom) the phase-averaged free surface elevation, $\eta_a$; the phase-averaged horizontal velocity, $u_a$; the local acceleration of the horizontal velocity, $\partial u_a / \partial t$; and the vertical gradient of the horizontal velocity $\partial u_a / \partial z$. The plotted values of $\eta_a$, $u_a$, $\partial u_a / \partial t$, and $\partial u_a / \partial z$ in each panel were averaged over that interval and were scaled by the maximum absolute value of the phase-averaged variable shown in the lower right of the figure. Temporal and spatial derivatives were estimated using a centered finite difference. The scaling is such that the maximum absolute value of the phase-averaged variable is equal to the upper limit of $u'$ on the abscissa of that figure. For example, $\eta_a = 13.5$ cm would correspond to $u' = 15$ cm/s in Figure 4. Although the phase-averaged variables may be difficult to interpret quantitatively in this figure, they give a useful qualitative comparison of the relative phases of these important variables.

In Figure 4, the top horizontal bar indicates that the wave crest occurs at $t_a / T = 0.65$, and the wave height decreases until reaching a minimum near $t_a / T = 0.40$. Comparison of the first and second bars indicates that $\eta_a$ and $u_a$ are generally in phase. The undertow is small compared to the maximum wave-induced velocity, $|u_a| / |u_{a,\text{max}}| \approx 0.14$. The third horizontal bar indicates that local deceleration of the flow starts at $t_a / T = 0.65$, is a minimum at $t_a / T = 0.70$, and deceleration continues until $t_a / T = 0.35$. At $t_a / T = 0.40$, the flow accelerates and reaches a maximum acceleration at $t_a / T = 0.55$. The bottom horizontal bar indicates that the vertical gradient of the horizontal velocity reaches a minimum at $t_a / T = 0.50$ and a maximum at $t_a / T = 0.70$. This gradient is large at this elevation compared to the elevations above the bottom boundary layer, and this gradient is not in phase with either the horizontal velocity or the local acceleration.

Figure 4 shows that the turbulent motion is most intense during periods of large local acceleration ($t_a / T = 0.55, 0.60$) and large local deceleration ($t_a / T = 0.65, 0.70, 0.75$). In the trough region, both the turbulent motion and the fluid acceleration is small. The horizontal and vertical velocity fluctuations are of similar magnitude and are generally much smaller than the phase-averaged horizontal velocity. Perhaps the most striking feature of Figure 4 is that the turbulent motion is strongly correlated and oriented in either the first and third quadrants with $u'u' > 0$ during the acceleration phases or in the second and fourth quadrants with $u'u' < 0$ in the deceleration phase.

Figure 3: Spectral densities of $k'$ (solid) and $k'_a$ (dash-dot). NDOF = 20.
This indicates that unidirectional flow results such as estimates of the Reynolds stress contributions can not be extended directly for oscillatory flow. The Reynolds stress contributions for this unsteady flow case depend strongly on the phase.

Similar to Figure 4, Figure 5 shows quadrant plots at 20 phases for L5 at $z_m = 7.10$ cm. The wave crest and maximum phase-averaged horizontal velocity occur at $t_a/T = 0.75$. The undertow is large, $|u_a|/u_0 \simeq 0.25$, and the vertical gradient of the horizontal velocity is small compared to L1 at $z_m = 0.30$ cm. The largest fluctuations of $u'$ and $w'$ occur after the passage of the wave crest and in the trough region ($t_a/T = 0.95, 1.0, 0.05, 0.10, 0.15, 0.2$). For the quadrant plots in this range, the large fluctuations occur primarily in the fourth quadrant, corresponding to sweeps where high speed fluid ($u' > 0$) rushes downward ($w' < 0$) due to wave breaking. The phase-averaged horizontal velocity is generally positive in this range $u_a > 0$, but because the undertow is strong, $u_a$ can become negative even when $\eta_a > 0$. The instantaneous values of $u'$ and $w'$ during sweeps can be as large as $|u_a|_{max} = 26.18$ cm/s in Figure 5.

**INTENSE COHERENT EVENTS**

An analysis on the intensity and duration of the intermittent turbulent events is presented here similar to that by Jaffe and Sallenger [1992] for suspended sediments. Coherent events are defined in this paper when the magnitude of $|\tau'|$ or $k'$ exceeds a critical value. Since setting the critical values is somewhat subjective, the following procedure adopted from Jaffe and Sallenger [1992] was used. A coherent event was defined as $|\tau'| \geq (m + \sigma)$ where $m$ is the mean of $|\tau'|$ over the entire 50 waves at that elevation and $\sigma$ is the standard deviation. An intense event was defined as $|\tau'| \geq (m + 3\sigma)$. This analysis was also used to detect events in $k'$ where coherent events are defined as $k' \geq (M + \sigma_k)$ and intense events are defined as $k' \geq (M + 3\sigma_k)$ where $M$ is the mean and $\sigma_k$ is the standard deviation of $k'$ at that elevation. It is noted that the wave phase is not considered in this simplified analysis. Figure 6 illustrates the procedure with a portion $|\tau'|$ in the range $20 \leq \frac{t}{T} \leq 25$ for L5 at $z_m = 7.10$ cm. The lower dash-dot line shows the threshold $(m + \sigma)$ for the coherent events, and the upper dash-dot line shows the threshold $(m + 3\sigma)$ for the intense events. The corresponding detection of coherent events and intense events are shown by the solid lines above the $|\tau'|$ time series.

Statistics of coherent events and intense events for $|\tau'|$ and $k'$ were computed for all elevations listed in Table 1. Table 2 compares the statistics of $|\tau'|$ and $k'$ at L1 and L2 outside the surf zone. Statistics shown in this table are averages of the first four elevations near the bottom $z_m = 0.20, 0.25, 0.30,$ and $0.40$ cm since these elevations were fairly similar in terms of $m$, $\sigma$, and $n_1/n$. In this table, $n_1$ is the number of coherent events out of a total number of data points, $n = 11000$, for which $|\tau'| \geq (m + \sigma)$; and $m_1$ is the average value of $|\tau'|$ for the coherent events. The second column essentially indicates the duration of the coherent event as a percent of the total record, $(n_1/n) \times 100$; and the third column indicates the percent of the motion contained in the coherent events in relation to that in the entire time series, $\left[\frac{n_1}{m_1}\right]/\left(\frac{nm}{m}\right) \times 100$. The subscript "3" indicates statistics computed using the definition of intense events, and the capital letters are used to distinguish coherent events and intense events computed using $k'$. In general, the statistics for the coherent events and intense events are similar for definitions based on $|\tau'|$ or $k'$. However, from L1 to L2, $(n_1/m_1)/(nm)$ and $(N_1/M_1)/(nM)$ are similar but $(n_3/m_3)/(nm)$ and $(N_3/M_3)/(nM)$ increase by approximately 15%, indicating
Figure 4: Quadrant plots at 20 phases for L2 at $z_m = 0.30$ cm. Figure explained in text.

that the magnitude of the intense events increases landward before breaking.

Table 3 lists the statistics of coherent events and intense events inside the surf zone. The statistics were averaged from $z_m = 0.20$ cm to trough level for all elevations at L3 to L6, and the standard deviations are given in parenthesis. The average statistics for L4, L5, and L6 in the inner surf zone are remarkably similar and suggest that it should be possible to parameterize the intense, coherent motion inside the surf zone. The average statistics for L3 in the transition region are different from those in the inner surf zone, and this suggests that the statistics could also vary with breaker type.

Tables 2 and 3 shows that coherent events and intense events are of short duration, occurring for approximately 10% and 2% of the record, respectively, but contain a large portion of the turbulent motion, approximately 50% and 20%, respectively.

CONCLUSIONS

In the bottom boundary layer outside the surf zone, the phase-averaged horizontal velocity is dominant and much larger than the horizontal turbulent fluctuation. The phase-averaged vertical velocity is small, and the vertical turbulent fluctuation is dominant. Both $|r'|$ and $k'$ exhibit intermittent behavior where the instantaneous values are often several times greater than the phase-averaged values. The motions occur with the passing of each regular wave, however, and the phase-averaged values described the turbulent fluctuations reasonably well. In the interior region below trough level inside the surf zone, the horizontal and vertical velocity records showed intense, intermittent turbulent events that did not occur with the passing of each wave. The intense turbulent fluctuations were of the same magnitude as the phase-averaged horizontal velocity. The instantaneous quantities of $|r'|$ and $k'$ could not be explained in terms of the phase-averaged quantities. The intermittent turbulent events extended into the bottom boundary layer inside the surf zone. The infrequent but intense turbulence generated by wave breaking is an order of magnitude larger than the turbulence generated locally at the boundary.

Spectra of $k'$ showed that the low frequency motion is small outside the surf zone and that the low frequency motion due to the intermittent turbulence from wave breaking increases inside the surf zone. Spectra of $k'$ are reasonably well represented by spectra of $k'_a$ outside the surf zone and poorly represented by spectra of $k'_a$ inside the surf zone. This conclusion was the same for the spectra of $|r'|$ and $|r'|_a$.

A quadrant analysis was used to show the relative contributions to the Reynolds stress as a function of wave phase. In the bottom boundary layer outside the surf zone, the turbulent motion was strongly correlated and oriented in either the first and third quadrants with $u'w' > 0$ during the acceleration phases or in the second and fourth quadrants with $u'w' < 0$ in the deceleration phases. In the interior region below trough level inside the surf zone, large fluctuations occurred primarily in the fourth quadrant, corresponding to sweeps where high speed fluid rushed downward due to wave breaking. These large motions did not occur with each wave but were phase-dependent near trough level. Near the bottom, the large motions were less dependent on phase and may be related to a more random arrival of eddies in the bottom boundary layer. The horizontal turbulent fluctuations increased relative to those outside the surf zone, whereas the vertical turbulent fluctuations were similar.

To analyze the intensity and duration of the intermittent turbulent events, two thresholds were used to distinguish coherent events and intense events. The analysis showed that coherent events occurred for about 10% of the record and accounted for approximately 50% of the turbulent motion. Intense events occurred for about 2% of the record and accounted for approximately 20% of the turbulent motion. These statistics indicated that coherent and intense events are infrequent but contribute significantly to the magnitude of $|r'|$ and $k'$ and possibly the suspension of bottom sediments.

These results are based on one experiment of regular laboratory waves spilling on a fixed, rough bottom. Further work with plunging waves, irregular waves, and movable beds will be necessary to generalize these conclusions. Nevertheless, this is an important step to show that instantaneous turbulence even for regular waves are dominated by
intense, intermittent events. Furthermore, this may explain difficulties in correlating suspended sediment concentrations and transport rates to phase-averaged or ensemble-averaged horizontal velocities. Parameterization and prediction of the intense events is left for further work but would likely be beneficial in developing predictive models for sediment suspension inside the surf zone.

EXPERIMENTAL STUDY ON NON-LINEAR WAVE BOUNDARY LAYERS

Hitoshi Tanaka¹, Hiroto Yamaji² and Ahmad Sana³

Abstract

A mechanical generation method of an asymmetric oscillatory flow has been proposed by the authors (Tanaka et al., 1997, 1998), though, its applicability to an actual experiments has not been thoroughly examined yet. In the present study, laboratory experiments are carried out for an asymmetric oscillatory flow in a U-shaped oscillating tunnel to make comprehensive investigation on the validity of the generation method under both laminar and turbulent condition using air and water respectively as working fluid.

Introduction

In numerous experimental studies on oscillatory boundary layers, a U-shaped oscillating tunnel has been effectively utilized in place of a wave flume (e.g., Jonsson, 1963). Use of this type of facility enables us to generate oscillating motion with the period almost similar to prototype wave motion. Most of the existing experimental facilities are, however, restricted to sinusoidal oscillation, equivalent to fluid motion induced by linear waves. In reality, waves are generally asymmetric more or less due to non-linear effect. In order to generate corresponding asymmetric oscillatory flow in a U-tunnel, it requires a highly expensive sophisticated equipment to control the piston movement, the reason being for scarcity of the experiments in this regard. For example, Nadaoka et al. (1994, 1996) and Ribberink and Al-Salem (1994) performed some experiments by using a computer-controlled piston system to study the characteristics of asymmetric oscillatory boundary layers.

Recently, the authors have proposed a rather simple and inexpensive piston mechanism, by which an asymmetric oscillation simulating fluid motion under non-linear waves is produced mechanically, and preliminary experiments have already been done using this generation method (Tanaka et al., 1997, 1998). However, number of experimental cases performed using this system is too limited to judge whether or not it works in actual experiments under various conditions. In the present study, the applicability of this generation method is examined at low and high Reynolds numbers.

Mechanical Generation of Asymmetric Oscillatory Flow

The schematic description of the piston mechanism to generate asymmetric oscillatory motion is shown in Fig. 1. According to Tanaka et al. (1997, 1998), time-variation of the velocity induced by the piston system is

\[ \frac{U}{U_c} = \frac{(b_* - 1)(b_* \cos \omega t - 1)}{(b_* - \cos \omega t)^2} \]  

where \( U \) is the horizontal velocity, \( U_c \): peak velocity of \( U \) during wave crest, \( \omega \) is the angular frequency (\( =2\pi/T \), \( T \): wave period ), \( t \) is the time, \( b_* = b/a \) and the definitions of \( b \) and \( a \) are found in Fig. 1.

Time-variation of the velocity given by Eq.(1) is plotted in Fig.2, where \( A_s \) denotes the asymmetry of the velocity variation defined as (Dibajnia and Watanabe 1992, Ribberink and Al-Salem 1994)

\[ A_s = \frac{U}{U_c+U_t} \]  

and \( U_t \) is the magnitude of the trough velocity. Since the velocity variation of Eq.(1) is symmetric about the crest, only the first half of the wave cycle is shown in Fig.2. The dotted lines with open circles in Fig.2 denotes the first-order solution of cnoidal wave theory given by

\[ \frac{U}{U_c} = \text{cn}^2 \left( \frac{2Kt}{T}; k \right) \]  

where \( \text{cn} \) is the Jacobian elliptic function with modulus \( k \), \( K \) is the complete elliptic integral of the first kind, and the bar denotes time average. In the above equation, the asymmetry of the velocity is more predominant with the increase of \( k \), whereas the asymmetry of Eq.(1) is dependent on \( b_* \). These two parameters governing the asymmetry can be correlated as follows (Tanaka et al., 1997, 1998). According to Eq.(3), \( A_s \) defined by Eq.(2) is

\[ A_s = \frac{1}{k^2} \left( 1 - \frac{E}{K} \right) \]  

where \( E \) is the complete elliptic integral of the second kind of modulus \( k \). On the other hand, the expression for \( A_s \) induced by the present generation system is obtained from Eq.(1).

\[ A_s = \frac{b_* + 1}{2b_*} \]  

Thus, by equating Eqs.(4) and (5), we obtain

\[ \frac{1}{k^2} \left( 1 - \frac{E}{K} \right) = \frac{b_* + 1}{2b_*} \]  

Figure 3(a) shows how \( A_s \) varies with the change of \( k^2 \) calculated from Eq.(4), whereas Fig.3(b) denotes the relationship between \( b_* \) and \( k^2 \) obtained from Eq.(6). Figure 3(c) is drawn to show the relationship between \( q \) and \( k^2 \).

Figure 2 shows a comparison between Eq.(1) and Eq.(2) thus correlated. In Fig.2, it is seen that Eq.(1) and the exact solution of the cnoidal wave theory, Eq.(3), show surprisingly excellent agreement, especially at smaller values of \( A_s \). Theoretical treatment of Tanaka et al. (1997, 1998) revealed that Eq.(1) can be derived from Eq.(3) using an approximate formula for the elliptic function in the form of infinite product in terms of nome, \( q (=\exp(-\pi K'/K)), K'(k) = K(\sqrt{1-k^2}) \).
Fig. 1 Mechanical generation method of an asymmetric oscillatory movement proposed by Tanaka et al. (1997, 1998)

Fig. 2 Time-variation of free-stream velocity
Fig. 3 Relationship between $A_s$, $b_*$, $q$ and $k^2$
Furthermore, Tanaka et al. (1997, 1998) correlated $b_*$ with Ursell number, $U_r$, as follows:

For $U_r < 90$:

$$b_* = \frac{32\pi^2}{3U_r} + \tanh^{4/3}\left\{\left(U_r / 70\right)^{3/4}\right\}$$  \hfill (7)

For $U_r > 90$:

$$b_* = \frac{1}{8} \left[ 1 - \frac{1}{\sqrt{3U_r}} \right]$$  \hfill (8)

in which the definition of Ursell number is

$$U_r = \frac{HL^2}{h^3}$$  \hfill (9)

where $H$, $L$, and $h$ are the wave height, the wave length and the water depth, respectively.

Figure 4 shows the accuracy of the approximate formulae, Eqs (7) and (8), in which the exact relationship is obtained from Eq. (10). (Shuto, 1974)

$$k^2K_l^2 = \frac{3}{16} U_r$$  \hfill (10)

For designing an actual oscillating facility, Eqs (7) and (8) can be used to determine $b_*$ of piston system for a given Ursell number. Meanwhile, if $A_s$ value is given instead of $U_r$ as an experimental condition, corresponding $b_*$ value is easily computed from Eq. (5).

$$b_* = \frac{1}{2A_s - 1}$$  \hfill (11)

Fig 4 Relationship between $b_*$ and Ursell number
Experimental Set-up and Experimental Condition

The present experiments were performed in a U-shaped oscillating tunnel with smooth walls seen in Fig. 5 and Photo 1. The vertical risers of the tunnel were connected to the piston movement system described in the previous section. The velocities were measured with the help of a one-component fiber-optic laser doppler velocimeter (LDV) in forward scatter mode.

Table 1 shows the experimental conditions for the experiments presented herein. In this table, $R_\delta$ is the Reynolds number defined in terms of the crest velocity and the Stokes layer thickness.

$$R_\delta = \frac{U_s \sqrt{2\nu/\omega}}{\nu}$$

where $\nu$ is the molecular viscosity of the fluid.

As to the present days, the critical Reynolds number in case of asymmetric oscillatory boundary layer has not been studied in detail. As a first approximation, the value for purely sinusoidal oscillatory boundary layers may be considered to be applicable. According to an experimental study of Hino et al. (1976), transition from laminar to turbulence occurs around $R_\delta = 550$ in a sinusoidal wave boundary layer. It may be thus anticipated that Case 1 may be in laminar regime, whereas Case 2 may be turbulent, although the representative velocity in the definition is different between sinusoidal and asymmetric oscillatory flow.

Experimental Results and Discussions

**Case 1**

Figure 6(a) shows the temporal variation of velocity at the axis symmetry in the wind tunnel. It is seen that the measurement and the theory, Eq.(1), shows excellent agreement.

The open and closed circles in Figs. 6(b) and 6(c) show the profile of measured mean velocity in horizontal direction. The solid lines denote an analytical solution for laminar asymmetric oscillatory flow expressed in terms of Fourier series (Schäffer and Svendsen, 1986).

$$u = \sum_{n=1}^{\infty} \left[ a_n \{ \sin n\omega t - \exp(-\beta_n z)[\sin(n\omega t - \beta_n z)] \} + b_n \{ \cos n\omega t - \exp(-\beta_n z)[\cos(n\omega t - \beta_n z)] \} \right]$$

where $a_n, b_n$ are the coefficients obtained by Fourier analysis of the measured free stream velocity, $\beta_n$ is the Stokes layer thickness for each harmonics,

$$\beta_n = \sqrt{n\omega/2\nu}$$

and $z$ is the vertical coordinate taken positive upward from the wall surface. In the
Fig. 5 Experimental set-up

Photo 1 Piston system
Fig. 6 Velocity profile in a wind tunnel
present computation, the total number of terms in Eq.(13), \( m \), is 5 to achieve sufficient accuracy. It is seen that the agreement between the measurement and the theory in Fig.6 is excellent, suggesting the validity of the present generation system.

Figure 7 depicts the time-variation of the wall shear stress from the experiment and the laminar theory,

\[
\tau_0(t) = \rho \sum_{n=1}^{m} \sqrt{n\omega V} \left\{ a_n \sin(n\omega t + \frac{\pi}{4}) + b_n \cos(n\omega t + \frac{\pi}{4}) \right\}
\]

(15)

In the experiment, \( \tau_0(t) \) is evaluated by multiplying the measured near-wall velocity gradient to the kinetic viscosity of the fluid. It is seen that the time-variation of the measurement shows reasonable agreement with the theory, although small difference is seen near the peak. As may be recalled, in case of purely sinusoidal wave boundary layer in laminar flow regime, shape of the wall shear stress is also sinusoidal, but there exit a phase difference of \( \pi / 4 \) between free-stream velocity and \( \tau_0 \). It may be noted that from Eq.(15) that following the same basic principle, every component of the wall stress has a phase lead of \( \pi / 4 \) from the corresponding velocity component. But after the addition of these components with different frequency, the shape of the resultant wall shear stress profile is altogether different from the corresponding free-stream velocity over the wave cycle.

Judging from Figs.6 and 7, it can be concluded that the present generation system works very well for the use of wave boundary layer experiment under non-linear waves.

![Fig.7 Time-variation of bottom shear stress](image-url)
Case 2

During the experiment with water as working fluid, it was observed that the temporal free-stream velocity showed slight deviation from Eq.(1). Therefore, it was necessary to open both the valves on top of the risers in order to get the velocity in close agreement with the theory (Fig.8(a)). The velocity profile thus obtained is shown in Fig.8 at selected phases. The laminar solution, Eq.(13), is also plotted in Figs.8(b) and 8(c) along with numerical solution based on $k-\epsilon$ model. Among various versions of $k-\epsilon$ model, Jones and Launder's (1972) low-Reynolds number model is employed in the present study, based on Sana and Tanaka's (1996) comparative study of the existing models. Detailed computation method is already described elsewhere (Tanaka and Sana, 1994, Sana and Tanaka, 1996).

In contrast to Fig.6, the experimental result in Figs.8(b) and 8(c) shows distinct difference from the laminar solution. The velocity profile at the beginning of deceleration phase ($t/T=0.0$) shows better agreement with $k-\epsilon$ model prediction, especially where the velocity overshooting occurs. But during the course of deceleration, it seems that the model fails to cope with the flow situation. During deceleration, both of the experiment and model show logarithmic behavior, although the boundary layer thickness is different each other. As the flow proceeds to acceleration in the trough phases, the model predictions begin to conform to the data very well. In the next deceleration phase during the trough phase ($t/T=0.5-0.7$), the model prediction is satisfactory. During the next acceleration phase ($t/T=0.8-0.9$), an excellent agreement is found between prediction of the model and the experimental data.

Figure 9(a) depicts turbulence intensity measured in an oscillating tunnel. As may be observed around $t/T=0.5$, turbulence is generated with time near the wall, yet with a lower rate as compared to that in crest period around $t/T=0.1$. During the trough period, the contours are almost horizontal, suggesting small variation in the turbulence intensity in that region. This is distinct difference from sinusoidal boundary layer and in accordance with what might be anticipated on the basis of the flat free-stream velocity during trough period, where the behavior similar to a steady flow should be observed. The contour plot obtained from the model prediction is shown in Fig.9(b). Since the model provides the total turbulent kinetic energy $k$, x-direction fluctuating component $u'$ is obtained using Nezu's (1977) expression to correlate $k$ and $u'$ in a steady open channel flow. It is seen that the $k-\epsilon$ turbulence model can very well reproduce the fluctuating velocity near the wall.

Conclusions

The following conclusions can be drawn from this experimental study on non-linear wave boundary layers:

(1) It is confirmed that the generation method of an asymmetric oscillatory flow proposed by Tanaka et al. (1997, 1998) can be effectively utilized in a laboratory experiment for both air and water as working fluid.

(2) The low-Reynolds number $k-\epsilon$ model by Jones and Launder (1972) shows good performance to predict mean velocity profile except decelerating phases under wave crest. As for turbulence intensity in x-direction, the overall agreement is satisfactory between the model prediction and experimental data.

A 2-DV NUMERICAL SOLUTION FOR THE TURBULENT WAVE BOUNDARY LAYER UNDER BREAKING WAVES

Nguyen The Duy¹, Tomoya Shibayama² and Akio Okayasu³

Abstract

This paper presents a numerical solution for the bottom boundary layer (BBL) in the surf zone. The upper boundary of the BBL is determined through the solution of a breaking waves model. Different turbulence models have been tested to determine the distribution of turbulent kinetic energy, energy dissipation and eddy viscosity in the BBL. Finally, the vertical profiles of horizontal velocity can be found out through the solution of the governing equations of the BBL.

Introduction

A quantitative study of the hydrodynamics of the bottom boundary layer (BBL) is necessary for determining precisely the near-bottom shear stress, a major driving force in predicting the transport of sediment in coastal areas. Various studies on the mechanics of the wave boundary layers under non-breaking condition have been reported in the literature (e.g. Kajura 1968, Kamphuis 1975, Grant and Madsen 1979, Trowbridge and Madsen 1984, Larson 1995, etc.). Under breaking waves, however, development in the study of the BBL has been limited because of the following unsolved or unsatisfactorily solved problems.

(1) The free stream velocity at the upper edge of the BBL, an important boundary for solving BBL flow, still cannot be determined properly by available 1-D or 2-DH breaking wave models. Outside the BBL, it is necessary to solve a 2-DV breaking wave model in order to determine directly the upper boundary condition of the BBL from computed vertical profile of water particle velocity. For this purpose, the breaking waves model presented by Duy et al. (1996), Duy and Shibayama (1997) has been applied in the present study.

(2) The effect of turbulence induced by waves breaking on the turbulence structure of the BBL is still not understood adequately. In this study, it is assumed that in

¹ Dr. Eng., Dept. of Civil Eng., Ho Chi Minh University of Technology, 268 Ly Thuong Kiet, Q.10, Ho Chi Minh City, Vietnam.
² Dr. Eng., Professor, Dept. of Civil Eng., Yokohama National University, Hodogaya-ku, Yokohama 240, Japan.
³ Dr. Eng., Assoc. Prof., Dept. of Civil Eng., Yokohama National University, Hodogaya-ku, Yokohama 240, Japan.
case of a surf zone formed by spilling breakers, the transfer of turbulence from the upper layer to the BBL is negligible and therefore the turbulence production resulted from shear is dominant in the BBL.

(3) The lack of reliable measured velocity data that can be used for verifying a BBL model in the surf zone.

**Model formulation**

At each time level of computation, a three-step procedure is utilized to solve the 2-DV flow equations for the BBL. This solution procedure is illustrated in the flow diagram below.

![Flow diagram of solution procedure.](image)

- In the first step, the breaking waves model is solved for the water domain outside the BBL (the upper layer) to determine the wave variables in 2-DV plane such as water surface, pressure field and velocity field. The result of this solution provides the values of velocity vectors at the upper boundary of the BBL.

- In the second step, turbulence structure of the BBL is investigated through the solution and comparison of the following turbulence models: eddy viscosity model, $k$-model and $ke$-model. From this solution, it is possible to find out the distribution of eddy viscosity, turbulent kinetic energy and energy dissipation inside the BBL.

- In the final step, the results obtained from the previous two steps are used as input data to solve the governing equations for the BBL. From which, the velocity field in the BBL can be determined.

The governing equations and boundary conditions used in the second and third step of the solution procedure are described briefly as follows.

---

**TURBULENCE MODELS**

- $k$, $e$, $v$ 

**BBL FLOW EQUATIONS**

- $(u, w)$ 

**BREAKING WAVES MODEL**

- $v_p, P, (u, w), \zeta$ 

**FLOW DIAGRAM**

- $t = t + \Delta t$
In a 2-DV plane, the flow in the BBL can be modeled by the following equations

\[
\frac{\partial u}{\partial t} + \frac{\partial \nu}{\partial z} = 0 \tag{1}
\]

\[
\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + w \frac{\partial u}{\partial z} - \frac{1}{\rho} \frac{\partial \tau_{xx}}{\partial z} = \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} \tag{2}
\]

where \((u, w)\): Reynolds-averaged velocity vector; \(\tau_{xx}\): Reynolds shear stress; \(u_e\): free stream velocity. The momentum term due to turbulent motion can be expressed as

\[
\frac{1}{\rho} \frac{\partial \tau_{xx}}{\partial z} = \nu_T \left( \frac{\partial u}{\partial z} + \tau_{zz} \frac{\partial \nu}{\partial z} \right) \tag{3}
\]

In (2), the momentum terms on the right hand side are the forcing function reflecting the process of water motion in the region outside the BBL. Along the edge of the BBL, these momentum terms can be determined by using the 2-DV turbulent flow model for breaking waves developed by Duy et al. (1996).

The boundary conditions for the BBL equations are introduced in the following.

\[
u = 0, \ w = 0 \quad \text{for} \quad z = 0 \tag{4}
\]

\[
u \to u_e, \ w \to w_e \quad \text{for} \quad z \to \infty \tag{5}
\]

and at the seaward and shoreward boundary (side boundaries), a logarithmic distribution is assumed for the vertical profile of horizontal velocity in the BBL.

\[
u = u_e \ln(C_1 z + C_2) \quad \text{for} \quad x = 0 \text{ or } x = x_{\text{max}} \tag{6}
\]

in which the constants \(C_1\) and \(C_2\) are determined by using the boundary conditions (4) and (5)

\[
C_1 = \frac{e - 1}{\delta} \tag{7}
\]

\[
C_2 = 1 \tag{8}
\]

where \(\delta\) is the thickness of the BBL and \(e\) the natural logarithmic base.

At the side boundaries, the vertical velocities are determined by substituting Eq. (6) into the mass conservation, Eq. (1), and then solve for \(w\).

In addition to the above boundary conditions, it is necessary to know the distribution of the eddy viscosity in the BBL to solve (1) and (2). Three different solutions of the eddy viscosity are investigated in the present study.

In the first solution, the following equation of the eddy viscosity, or also known as the eddy viscosity model, is applied for the entire boundary layer thickness (e.g., Kajura 1968, Grant and Madsen 1979)

\[
\nu_T = \kappa u_e z \tag{9}
\]

where \(\kappa\) is the Karman constant (\(\kappa=0.4\)), \(z\) the vertical elevation from the bottom and \(u_e\) the friction velocity

\[
u = \sqrt{f_w u_{\text{em}}^2} \tag{10}
\]
where $f_v$ is the wave friction factor and $u_{	ext{em}}$ the maximum horizontal velocity at the upper boundary of the BBL. Eq. (10) expresses a linear distribution of the eddy viscosity inside the BBL. In fact, this time-invariant eddy viscosity has been originally developed to simulate non-breaking wave boundary layers.

The second solution of the eddy viscosity is based on the transport equation for turbulent kinetic energy, or the $k$-equation, which in a 2DV-plane reads

$$\frac{dk}{dt} = \frac{\partial}{\partial x} \left( \nu_T \frac{\partial k}{\partial x} \right) + \frac{\partial}{\partial z} \left( \nu_T \frac{\partial k}{\partial z} \right) + \frac{\text{PROD}}{\rho} - c_2 \frac{k^{\frac{3}{2}}}{l_d}$$

(11)

in which

$$\frac{dk}{dt} = \frac{\partial k}{\partial t} + \frac{\partial (uk)}{\partial x} + \frac{\partial (wk)}{\partial z}$$

(12)

PROD is the turbulence production, $c_2$ a constant, and $l_d$ the length scale of turbulence

$$l_d = \kappa \sqrt[4]{c_2} z$$

(13)

In the $k$-equation, the eddy viscosity is determined by the following expression

$$\nu_T = l_d \sqrt{k}$$

(14)

Under breaking waves condition, the turbulence production in the BBL can be assumed to be resulted from two different sources: one is the transfer of breaker-generated turbulence from the upper layer to the BBL, denoted by $\text{TRANS}$, and one is caused by shear inside the BBL.

$$\text{PROD} = \text{TRANS} + \rho \nu_T \left( \frac{\partial u}{\partial x} \right)^2$$

(15)

In case of spilling breakers, as mentioned above, it may be reasonable to assume that

$$\text{TRANS} \rightarrow 0 \quad \text{for} \quad z \rightarrow 0$$

(16)

Therefore, the turbulence production resulted from shear is dominant in the BBL, and Eq. (15) becomes

$$\text{PROD} = \rho \nu_T \left( \frac{\partial u}{\partial x} \right)^2$$

(17)

The boundary conditions for the $k$-equation are

$$k = \frac{1}{\sqrt{c_2}} \nu_T \frac{\partial u}{\partial z} \quad \text{for} \quad z = \frac{k_N}{30}$$

(18)

and

$$\frac{\partial k}{\partial z} = 0 \quad \text{for} \quad z \rightarrow \infty$$

(19)

in which $k_N$ is the bed roughness.

Eq. (18) is derived by assuming that there is local equilibrium between production and dissipation close to the bottom. Eq. (19) is based on the assumption (16), i.e. there is no flux of turbulent kinetic energy at the upper boundary.
At the side boundaries, a uniform distribution of turbulent kinetic energy in the $x$-direction is assumed.

The third solution of the eddy viscosity is based on the transport equations for turbulent kinetic energy and dissipation, or the $k\varepsilon$-equations, which in a 2DV-plane reads

$$\frac{dk}{dt} = \frac{\partial}{\partial x} \left( \frac{\nu_T}{\sigma_k} \frac{\partial k}{\partial x} \right) + \frac{\partial}{\partial z} \left( \frac{\nu_T}{\sigma_k} \frac{\partial k}{\partial z} \right) + \nu_T \left( \frac{\partial u}{\partial x} \right)^2 - \varepsilon$$  \hspace{1cm} (20)

$$\frac{d\varepsilon}{dt} = \frac{\partial}{\partial x} \left( \frac{\nu_T}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial x} \right) + \frac{\partial}{\partial z} \left( \frac{\nu_T}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial z} \right) + c_{1\varepsilon} \frac{\nu_T}{\varepsilon} \left( \frac{\partial u}{\partial x} \right)^2 - c_{2\varepsilon} \frac{\varepsilon^2}{k}$$  \hspace{1cm} (21)

$$\nu_T = \frac{c_\mu k^2}{\varepsilon}$$  \hspace{1cm} (22)

where $\sigma_k$, $\sigma_\varepsilon$, $c_{1\varepsilon}$, $c_{2\varepsilon}$ and $c_\mu$ are empirical constants.

The boundary conditions for the $k\varepsilon$-equations are

$$k = \frac{1}{\sqrt{c_2}} \nu_T \frac{\partial u}{\partial z} \text{ for } z = \frac{k_N}{30}$$  \hspace{1cm} (23)

$$\frac{\partial k}{\partial z} = 0 \text{ for } z \to \infty$$  \hspace{1cm} (24)

$$\varepsilon = \left( c_2 \right)^{\nu_4} \frac{k^{3/2}}{\kappa z} \text{ for } z = \frac{k_N}{30}$$  \hspace{1cm} (25)

$$\frac{\partial \varepsilon}{\partial z} = 0 \text{ for } z \to \infty$$  \hspace{1cm} (26)

And similar to the $k$-equation, uniform distributions of $k$ and $\varepsilon$ in the $x$-direction are also assumed at the side boundaries.

In the second and third step of the solution procedure (Figure 1), the governing equations and corresponding boundary conditions are solved by the finite difference method, using a fully implicit scheme. On a sloping bottom, in order to establish a linear numerical mesh in which the grid lines are parallel to the coordinates axes, the $(x,z)$ domain is transformed to the $(\xi,\eta)$ domain as shown in Figure 2.

![Figure 2. Coordinates transformation for numerical solution.](image)

The functional relationship between the $(x,z)$ and $(\xi,\eta)$ coordinates systems is expressed by
\[ x = \xi \cos \theta - \eta \sin \theta \]  
\[ z = \xi \sin \theta + \eta \cos \theta \] 
(27)  
(28)

From (27) and (28), the Jacobian matrix of the transformation can be determined as follows

\[
J = \begin{bmatrix}
\frac{\partial \xi}{\partial x} & \frac{\partial \xi}{\partial z} \\
\frac{\partial \eta}{\partial x} & \frac{\partial \eta}{\partial z}
\end{bmatrix} = \begin{bmatrix}
\cos \theta & \sin \theta \\
-\sin \theta & \cos \theta
\end{bmatrix}
\] 
(29)

The first derivatives of the velocity components in the computational domain are then determined by the chain rule, using the Jacobian matrix (29)

\[
\begin{bmatrix}
\frac{\partial u}{\partial x} & \frac{\partial u}{\partial z} \\
\frac{\partial w}{\partial x} & \frac{\partial w}{\partial z}
\end{bmatrix} = \begin{bmatrix}
\frac{\partial \xi}{\partial x} & \frac{\partial \xi}{\partial z} \\
\frac{\partial \eta}{\partial x} & \frac{\partial \eta}{\partial z}
\end{bmatrix} \begin{bmatrix}
\frac{\partial u}{\partial \xi} & \frac{\partial u}{\partial \eta} \\
\frac{\partial w}{\partial \xi} & \frac{\partial w}{\partial \eta}
\end{bmatrix}
\] 
(30)

while the time derivative \( \frac{\partial}{\partial t} \) remains unchanged in the transformed domain.

**Numerical results**

Some numerical results of the present model are compared with the laboratory data of Cox et al. (1996). In this experiment, an extensively detailed measurement of surf zone hydrodynamics was reported for the case of a spilling breaker. The velocity profiles were measured at different locations in a surf zone by using a laser-Doppler velocimeter. At each location, 30 measuring points were set along the vertical line, of which 10 points were located in the near-bottom area. In the experiment, the wave period was 2.2 s, the water depth in the constant depth section was 0.4 m, and the wave height was 17.10 cm at breaking. The 1:35 bottom slope was filled with natural sand of 1.0 mm median grain diameter. The boundary layer thickness was found to be approximately 1 cm in this experiment.

![Figure 3. Locations of measuring lines in the surf zone.](image)

In Figure 3, according to the experimental observation, section A is in the transition region where the wave form goes from organized motion to a turbulent bore; and sections B and C are in the inner surf zone where the saw-toothed wave shape is a well-developed turbulent bore.

Figure 4 shows a result obtained in the first step of the solution procedure (Figure 1), that is the time series of horizontal velocity at different positions outside the BBL which are computed by the breaking waves model of Duy et al. (1996). In this figure, the variable \( X \) denotes horizontal distance from the shoreline of the still water, subscript "b" denotes the breaking point, and \( z^b \) is the vertical elevation from the
Figure 4. Time series of water surface elevation $\zeta$ and horizontal velocity $u$.

The comparisons show that the model is capable of simulating the deformation of the velocity profiles as wave propagates shoreward and of producing the high nonlinearity of the velocity profiles in shallow water area. As a general tendency, in the transition region (section A), the model results overestimate the peak values of horizontal velocity at elevations far away from the bottom. At sections in the inner surf zone (sections B and C), reasonable agreements are obtained between the simulated and measured velocities.

In the second step of computational procedure, the turbulence structure of the BBL is examined through the solutions of different turbulence models.

Figure 5 presents the water surface computed by the breaking waves model and the distribution of turbulent kinetic energy in the BBL computed by the $k$-equation. The wave decay due to energy dissipation in the surf zone can be observed from the surface elevations at different phases. At each phase, it can be seen that the developing cores of $k$ are originated from the bottom and correspond to the locations of wave crests at the water surface. And as wave moves shoreward, the magnitude of $k$ decreases gradually. This distribution pattern of $k$ may be caused by the following: (1) the assumption that turbulence production resulted from shear is dominant in the BBL, and
Figure 5. Distribution of turbulent kinetic energy in the bottom boundary layer in a surf zone (solution of the $k$-equation)
Figure 6. Distribution of turbulent kinetic energy in the bottom boundary layer in a surf zone (solution of the $k\varepsilon$-equations).
(2) the effect of the upper boundary, which is expressed by the forcing function on the right hand side of Equation (2).

Figure 6 also presents the distribution of turbulent kinetic energy in the BBL for different phases, but from the solution of the $ke$-equations. Very similar distributions of $k$ can be seen for the solutions of the $k$-equation and the $ke$-equations. Quantitatively, the differences in $k$ magnitude between the above two models are less than 5%.

The numerical results of turbulent kinetic energy are compared with laboratory data as shown in Figure 7. The time series of $k$ at different positions in the BBL again indicate that the results of the $k$-equation and the $ke$-equations are very similar. The comparison with laboratory data shows that the agreement between computed and measured values is not good around the peak of $k$. At other phases of the wave period, reasonable agreements are obtained.

Figure 7. Time series of turbulent kinetic energy in the bottom boundary layer.

Figure 8 also plots a result of the $ke$-equations, that is the distribution of energy dissipation, $\varepsilon$, in the BBL. Similarly to the distribution of $k$, zones of large energy dissipation are also originated from the bottom and correspond to the locations of wave crests at the water surface. This means that large dissipation occurs where there exists high turbulent kinetic energy. The magnitude of energy dissipation is smaller at locations closer to the shoreline. With known distributions of $k$ and $\varepsilon$, the distribution of eddy viscosity in the BBL can be determined as shown in Figure 9.

With known distribution of the eddy viscosity, Equations (1) and (2) can be solved to determine the velocity field in the BBL. Figure 10 presents the computed vertical profiles of horizontal velocities inside the BBL corresponding to different distributions of the eddy viscosity. There are certain differences between these three velocity profiles. However, they exhibit the similar features as follows: (1) when the flow
Figure 8. Distribution of energy dissipation in the bottom boundary layer in a surf zone (solution of the $k\varepsilon$-equations).
Figure 9. Distribution of eddy viscosity in the bottom boundary layer in a surf zone (solution of the $k e -$ equations)
changes direction, the near-bottom velocity always turns before the free stream velocity, both in the increasing and the decreasing stages of the water surface; this indicates a phase difference between the near-bottom velocity and the free stream velocity, a typical feature of oscillatory boundary layers that has been also observed for non-breaking waves, (2) as a result of the nonlinearity and asymmetry of the time variation of the water surface and the free stream velocity in the surf zone, the velocity amplitude of the shoreward flow is larger than that of the seaward flow, and (3) the velocity amplitude is largest at certain elevation inside the BBL, not at the upper edge of the layer. The comparison with laboratory data show that the numerical model is capable of predicting reasonably the velocity profiles inside the boundary layer for most phases of the wave period. However, at the phases when the velocities of the seaward flow reach their maximum values, the slope of the measured velocity profile at the area very close to the bottom tends to decrease and the present model fails to predict such change.

For the specific comparison shown in Figure 10, the calculation of the standard deviations indicates that when solving equations (1) and (2) with the eddy viscosity computed by the k-model, best agreement is obtained between the simulated velocity profiles and laboratory data.

Conclusions

Under breaking waves condition, the flow inside the BBL was modeled by solving numerically the 2-DV governing equations for the bottom boundary layer for the entire surf zone. The comparisons with laboratory data show that the numerical model is capable of predicting reasonably the distribution of turbulent kinetic energy as well as the velocity profiles inside the boundary layer for most phases of the wave period.

WAVE MODELLING IN THE WISE GROUP

L. Cavaleri and L.H. Holthuijsen

ABSTRACT

The WISE group is a group of investigators who have agreed to jointly (i) study the physical processes affecting waves in shallow water, (ii) develop numerical codes to explicitly represent these processes in operational models and (iii) verify these wave models in real coastal conditions. The group meets once per year in Europe or North America to discuss progress and coordinate future plans. Since the first meeting in 1993, interesting results have been obtained in all of the three aspects, including operational third-generation spectral wave models for shallow water (one of which has been released in public domain).

INTRODUCTION

When in 1992 the highly successful third-generation wave model WAM for ocean applications (WAMDI group, 1988; Komen et al., 1994) was completed, several members of the WAM group turned their attention to coastal regions where of course they encountered coastal engineers with their large diversity of wave models notably the second-generation HISWA model (Holthuijsen et al., 1988). In the following year, these WAM members and members of the HISWA group and others met and decided to jointly approach the study of Waves In Shallow water Environments (WISE). In this first meeting the WISE group agreed to develop (operational) wave models for coastal regions in which all relevant physical processes would be represented explicitly. Three tasks were correspondingly defined: (i) to study the physical processes affecting waves in shallow water, (ii) to develop numerical codes to represent these processes in operational models and (iii) to verify these wave models in real coastal conditions. We wish to emphasize that the WISE group does not necessarily exhaust all the activities in the field. However, it includes a fairly large and comprehensive part of it.

THE WISE GROUP

The WISE group is an informal group of some 50 active members (individuals) from some 15 countries, mostly from Europe and N. America but also from Australia, Japan, S. America and the Middle East. The home institutions of these members are both public and private with a wide range of interests from applied research to daily marine operations (e.g., ministries, harbour authorities, army & navy, universities, research institutions, consultants). The WISE group as a whole is coordinated by the present authors. The group meets once every year, alternating between Europe and N. America. Meetings were held in Thessaloniki (Greece, 1993), Ensenada (Mexico, 1995), Venice (Italy, 1996), San Francisco (USA, 1997) and Leuven (Belgium, 1998). The next meeting shall convene in Annapolis (USA, '99). The WISE group has three working groups corresponding to the above three tasks. Each group communicates and coordinates common interests (e.g., joint funding, exchange of visiting scientists and students, computer codes and observational data). During the meetings, scientific and operational progress in each group is reported in plenary meetings which are also used to discuss common interests such as large-scale joint efforts, funding opportunities and sharing of data and computer codes. The WISE meetings are organized in a very informal way, without any written report or proceedings, and with an open continuous discussion during and after the individual presentations. The latest findings are regularly shown at the meeting for constructive discussion about future steps. The WISE group as such is not funded by any agency but some (subgroups of) WISE members are funded contingent on their participation in the WISE group and their willingness to share results with other WISE members.

SHALLOW-WATER WAVE MODELS

Two families of numerical wave models can be used effectively in shallow-water. These are (a) phase-resolving models which are based on vertically integrated, time-dependent mass and momentum balance equations and (b) phase-averaged models, which are based on a spectral energy (or action) balance equation. The phase-resolving models require a spatial resolution that is a small fraction of the wave length. They are therefore limited to relatively small areas of the order of a dozen wave lengths (i.e. order of 1 km). The phase-averaged models do not require such fine resolution so that they can be used in much larger areas, the limitation being the size of the ocean basin (with the conventional resolution of 50 - 100 km for ocean applications). The reason for using both models is that some processes cannot be adequately handled in one or the other. For instance, diffraction and triad wave-wave interactions can at present not or only approximately be modeled in phase-averaged models whereas wind-generation cannot be modeled in phase-resolving models with any operational feasibility. Since the first WISE meeting in 1993, the role of these types of models in the group has evolved. The interest of most WISE members is aimed at the region between the deep ocean and the surf zone (it includes islands, shoals, tidal flats and estuaries; e.g., Fig. 1). This has resulted in a support-oriented role of the phase-resolving models (source of basic results) and an operationally-oriented role for the phase-averaged models (source of operational products). It must be emphasized that this evolution in the WISE group does not distract from the operational importance of the phase-resolving models in small-scale areas where they may well perform better than any phase-averaged model (in particular when diffraction is important).
Phase-averaged energy balance models are often formulated in terms of the two-dimensional energy density varying in spectral space, geographic space and time, $E(\sigma, \theta; x, y, t)$. The energy balance can then be written as (e.g. Hasselmann et al., 1973):

$$\frac{\partial}{\partial t} E + \frac{\partial}{\partial x} c_x E + \frac{\partial}{\partial y} c_y E + \frac{\partial}{\partial \sigma} c_\sigma E + \frac{\partial}{\partial \theta} c_\theta E = S$$

(1)

The first term in the left-hand side of this equation represents the local rate of change of energy density in time, the second and third term represent propagation of energy in geographical space (with propagation velocities $c_x$ and $c_y$ in $x$- and $y$-space, respectively). The fourth term represents shifting of the relative frequency due to (time) variations in depths (with propagation velocity $c_\sigma$ in $\sigma$-space). The fifth term represents depth-induced refraction (with propagation velocity $c_\theta$ in $\theta$-space). The expressions for these propagation speeds can be taken from linear wave theory (e.g., Mei, 1983; Dingemans, 1997). Interactions with ambient currents are readily included by extending all of these propagation speeds consistent with linear wave theory and by replacing energy density in the balance equation by action density (defined as the energy density $E$ divided by the relative frequency $\sigma$). This formulation is for Cartesian coordinates. It is readily changed into a formulation in spherical coordinates for applications on oceanic scales. The term $S (= S(\sigma, \theta))$ at the right hand side of the action balance equation is the source term in terms
of energy density representing the effects of generation, dissipation and nonlinear wave-wave interactions.

The most important phase-resolving models are Boussinesq models. These are essentially wave propagation models without source terms and they are commonly formulated in terms of the surface elevation and some depth-averaged velocity (the long-wave equations corrected for the vertical velocity distribution), e.g.:

\[
\frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x} \left\{ (h + \eta)u_x \right\} + \frac{\partial}{\partial y} \left\{ (h + \eta)u_y \right\} = 0
\]

\[
\frac{\partial u_x}{\partial t} + u_x \frac{\partial u_x}{\partial x} + u_y \frac{\partial u_x}{\partial y} = -g \frac{\partial \eta}{\partial x} + \sum C_x
\]

\[
\frac{\partial u_y}{\partial t} + u_x \frac{\partial u_y}{\partial x} + u_y \frac{\partial u_y}{\partial y} = -g \frac{\partial \eta}{\partial y} + \sum C_y
\]

in which \( \eta \) is the sea surface elevation, \( h \) is mean water depth, \( u_x \) and \( u_y \) are the depth averaged velocity components in x- and y-direction respectively, \( g \) is gravitational acceleration and \( \sum C \) is the sum of all correction terms to represent effects of the vertical velocity distribution. Some Boussinesq models include processes of dissipation by adding particular boundary conditions at the surface, notably a roller to represent depth-induced breaking (e.g. Schäffer et al., 1993).

Recent developments which integrate the two approaches of the energy balance and the Boussinesq models are reported below.

ACHIEVEMENTS

Most of the progress in task (i) of WISE has come from the phase-resolving models, providing input for the development of the phase-averaged models. The most fundamental development here has been an explicit formulation for the evolution of wave phases in shallow water which can be used in energy balance models. It involves the introduction of the bispectrum. Representing the random surface elevation in the Boussinesq equations as the sum of a large number of harmonic components with complex amplitudes eventually leads to evolution equations for amplitudes and biphases (or the bispectrum). The bispectrum \( B(\sigma_1, \sigma_2) \) is defined as the Fourier transform of the third-order correlation function \( R(\tau_1, \tau_2) \), analogous to the definition of the energy density spectrum \( E(\sigma) \) which is defined as the Fourier transform of the second-order correlation function \( R(\tau) \):

\[
E(\sigma) = \int_{-\infty}^{\infty} R(\tau) \exp(-i\sigma \tau) d\tau
\]

\[
B(\sigma_1, \sigma_2) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R(\tau_1, \tau_2) \exp[-i(\sigma_1 \tau_1 + \sigma_2 \tau_2)] d\tau_1 d\tau_2
\]

where \( \tau, \tau_1, \) and \( \tau_2 \) are time lags. The essence of the bispectrum is that it represents the coupling between triads of wave components with phases \( \varphi_i, \varphi_m \) and \( \varphi_{i+m} \). Madsen and Sørensen (1993) thus obtained a discrete spectral version of the (phase-resolving) Boussinesq model which explicitly formulates the triad wave-wave interactions. In deep water these interactions can be ignored but in shallow water they often generate a
secondary, high-frequency peak in the wave spectrum. This spectral Boussinesq model is phase-resolving in the sense that the phases of the wave components are an integral part of the formulation (in contrast to the random-phase assumption in phase-averaged models). Because of its spectral nature, it allows a blending with phase-averaged models in a hybrid approach: the energy balance equation (partially dependent on the biphases) can be supplemented with a phase evolution equation (which in turn depends on the energy spectrum). The first step in implementing this explicit formulation of triad interactions in a phase-averaged model was taken by Eldeberky and Battjes (1995). They used an approach somewhat similar to the discrete interaction approximation (DIA) of the quadruplet wave-wave interactions of Hasselmann et al. (1985) for deep water. Eldeberky and Battjes consider only self-self triad interactions for unidirectional waves in their model (the lumped triad approximation, LTA, Eldeberky, 1996) and they avoided the use of an explicit phase-evolution equation by locally estimating the biphase \( \varphi_i + \varphi_{im} - i\varphi_{im} \) from the local wave steepness and local relative water depth (Ursell number). The next step, i.e. to fully blend the spectral energy balance model with a bispectral model has been taken by Herbers and Burton (1997). They explicitly compute the biphase and the energy density of short-crested waves on a plane beach in the absence of generation and dissipation. It should be relatively straightforward to expand this propagation model to arbitrary bathymetry. But adding source terms to represent the effect of generation and dissipation of wave energy on the biphase seems difficult.

Another phase-resolving model, the mild-slope equation (Berkhoff, 1972) is the basis for attempts to include diffraction in phase-averaged models. The essence is that diffraction modifies the conventional dispersion relationship from the linear wave theory and consequently the refraction term in the phase-averaged models (the propagation velocity \( c_\theta \) in \( \theta \)-space, Booij et al., 1997; Rivero et al., 1997):

\[
c_\theta = \frac{c_g}{k} \frac{\partial k}{\partial m} + \frac{c_g}{2(1 + \delta)} \frac{\partial \delta}{\partial m}
\]

where \( \delta = \nabla (c_g \nabla a) / k^2 c_g a \) and in which \( k \) is the separation constant (e.g. Dingemans, 1997), determined from linear wave theory with \( \sigma = g k \tanh kd \) (normally referred to as the wave number \( 2\pi/L \) where \( L \) is the wave length but not in this context where the difference is essential). The phase speed is \( c \), the group velocity is \( c_g \) and \( m \) is the direction normal to the wave direction. The first term in the right-hand side of Eq. (4) is the conventional refraction representation and the second term is obviously the diffraction addition in terms of the amplitude \( a \) of a harmonic wave. A spectral formulation of diffraction (i.e. in terms of energy or action density) is not available. Since the second-order derivatives in the expression for \( \delta \) are linear in amplitude, an ad-hoc approach would be to replace the amplitude by the square root of energy density \( E = E(\sigma, \theta) \) per spectral wave component \( \delta = \nabla (c_g \nabla E) / k^2 c_g \sqrt{E} \). Preliminary attempts to compute diffraction in this way are being made (Booij et al., 1997; Rivero et al., 1997), but an adequate numerical formulation has not yet been developed.

Progress with phase-averaged modelling in this task (i) as been mostly in depth-induced breaking. It has been observed in laboratory conditions (e.g., Battjes and Beji, 1992; Vincent et al., 1994) that depth-induced wave breaking of waves with a unimodal spectrum hardly affects the shape of the spectrum (the changes in spectral shape are mostly due to triad wave-wave interactions). This has led to a simple spectral version
(Eldeberky and Battjes, 1995) of an earlier expression for the overall dissipation of waves breaking in shallow water that is based on a bore model (Battjes and Janssen, 1978; Thornton and Guza, 1983). Outside the WISE group Elgar et al. (1997) have shown with a detailed analysis of observations that the dissipation is often proportional with the square of the frequency. But the effect of this on the spectrum seems often to be masked by the simultaneous effects of triad wave-wave interactions (Chen and Guza, 1997). More observations in the surf zone will further contribute to the understanding of this phenomenon.

In task (ii) the main progress has been achieved with new numerical codes of phase-averaged models and adaptations of the WAM code. A serious problem with the codes of phase-averaged ocean wave models such as the WAM model (but also similar third-generation models such as the WAVEWATCH model, Tolman, 1991) for applications in shallow water is that their numerical schemes are explicit. This implies that they are subject to the Courant criterion of numerical stability: the time step in the computations is limited by the spatial resolution of the model. In open ocean applications this is usually not a problem (the spatial resolution is of the order of 100 km and the propagation time step is of the order of 15 min). For coastal applications however this is a problem because the required spatial resolution is often of the order of 100 m or less and the corresponding time step would be about 10 s or less in water of 10 m depth. This is operationally unacceptable and new ways for integrating the energy balance have to be found. One successful optimization has been to use a larger time step for integrating the physical processes than for wave propagation (the WAVEWATCH model, Tolman, 1991; the WAM model, Luo et al., 1997). This permits reasonably efficient computations down to a spatial resolution of about 1 km (in particular on vector machines, as these models vectorize well). Another attempt is being made with a hybrid scheme: piecewise propagation along rays between grid points (in the TOMAWAC model of Benoit et al., 1996). This numerical scheme is unconditionally stable but time steps larger than corresponding to the spatial resolution (i.e. $\Delta t > \Delta x/c_p$) ignore the variations in the physical processes at that spatial resolution since spatial variations in the processes are not considered within the time step $\Delta t$. This approach is therefore still subject to the Courant criterion (for reasons of spatial resolution of the physical processes rather than numerical stability). An implicit scheme that avoids the stability problem has been developed by Booij et al. (1996) in their SWAN model. It sweeps through the computational area in four 90° quadrants with an upwind scheme that is unconditionally stable and does not suffer from the limitation of the hybrid approach. However, the present implementation is based on a first-order, upwind scheme which is rather diffusive. This seems acceptable for small-scale regions (25 km or less) but it needs to be replaced by a higher-order scheme for larger scales. It operates on arbitrarily small spatial resolution (varying from 1 km to 10 m in field conditions to 0.1 m in laboratory conditions). A third-order upwind scheme is presently being developed in SWAN for Cartesian and spherical coordinates (which would allow long-distance propagation over the oceans). The TOMAWAC model and the SWAN model are extensions of the WAM model in the sense that they supplement the processes that are represented in the WAM model (Cycles 3 and 4 of that model) with the LTA of the triad wave-wave interactions, spectral depth-induced wave breaking and several options for bottom friction. Vectorization has not been considered in the design of SWAN as it is aimed at relatively small (nonvectorizing) computers. Like the WAM model, to all
The wave models often need coupling to other models, either to be driven by models such as atmospheric and circulation models or to drive other models such as circulation models (with wave induced radiation stresses) and morphodynamic or ecological models. Also, some wave models need to be nested into other wave models to achieve high-resolution results or to shift to other physical processes (e.g. to include diffraction). Work in these aspects is being carried out at several levels in the WISE group. From a scientific point of view the effect of wind variations in coastal regions is being investigated by coupling coastal atmospheric models with coastal wave models (in particular orographic and boundary-layer effects along mountainous coastlines and behind barrier islands). The effects of tidal currents on the coastal wave climate are similarly investigated by coupling coastal wave models with tide-driven coastal circulation models.

To numerically accommodate such interactions with circulation models, the TOMAWAC model is formulated on a triangular grid and the SWAN model has recently been adapted to operate on a non-orthogonal curvi-linear grid. To carry out computations from large scale to small scale, the SWAN model can be nested into the WAM model (SWAN accepts output directly from the WAM model; Luo and Flather, 1997). To pre- and post-process the input and output of such sets of models (both numerically and graphically), dedicated tools are being developed based on ARCINFO (Kaiser, 1994), ARCVIEW and MATLAB.

In task (iii) a number of fairly large field campaigns has been carried out with very useful results. A most interesting field campaign was carried out in nearly ideal shallow-water generation conditions in Lake George in Australia (e.g. Young and Verhagen, 1996). The observations of this campaign provide much needed characteristics of the wind-induced growth of waves in limited water depth. It has already served (and will continue to do so) to verify or calibrate models of the WISE group. Several other large field campaigns have been executed off fairly open coasts along the east coasts of the USA and England and along the rather convoluted coast in the north of the Netherlands and Germany. It is expected that the wave models of WISE members will be verified against these observations. Such verification has already been carried out for the SWAN model (Figs. 2 and 3). The rms-error of the significant wave height and mean wave period computed with SWAN in these (and other, similar) conditions was typically about 10% of the incident values (note that locally the relative error can be much larger as the local waves may be much lower).
Fig. 2 Significant wave height and mean wave direction (unit vectors) computed with the SWAN model in the Norderneyer Seegat (Germany, see Fig. 1; six buoy locations indicated). Significant wave height contour line interval 0.5 m.

Fig. 3 The significant wave height and mean wave period in the Norderneyer Seegat (Germany, see Fig. 1) observed at the six buoy locations of Fig. 2 and computed with the SWAN model.
OUTLOOK

Although considerable progress has been made in the WISE group over the last few years, several basic aspects are still unresolved and the verification of the existing computer codes has been rather limited. Moreover, the numerical quality of the present codes pose unnecessary constraints on their operational applicability. With the present and future R&D programs of WISE members, these aspects will improve. In addition, relatively new model technology such as real-time data assimilation based on buoy and satellite observations will be introduced in the forecasting of waves in coastal regions. The outlook for these developments is optimistic because both in Europe and in the USA, funding is available to continue research and development at an increased pace. With the release of the SWAN model in the public domain, next to the WAM model, these developments can be concentrated in two widely available, supplementary computer codes.

ACKNOWLEDGEMENTS

The achievements in the WISE group are a credit to individual members who, we hope, have benefited from the discussions and interactions with other members. The group as a whole proceeds with its own momentum which we, as chairmen, hope to maintain with our logistical efforts.

A Long Term Wave Hindcast System Using ECMWF Winds

Yoshio Hatada¹ and Masataka Yamaguchi²

Abstract

A long-term shallow water hindcast system for the evaluation of wave climate is applied to consecutive computation of nearshore waves over a period of 9 years from 1986 to 1994 at 6 wave measurement stations of the Pacific coast of Japan. The data of the wind fields was acquired from the ECMWF wind data sets. Comparison between hindcasts and measurements is made for wave climate represented by not only significant waves and mean wave direction but also frequency-integrated directional wave energy and directional spectrum in addition to time variation of significant waves and mean wave direction. The conclusion is that the newly-revised system is fairly useful for a reasonable and computationally efficient evaluation of the wave climate at the level of spectral representation.

Introduction

Evaluation of long term wave conditions over several years, the so called wave climate, is of great importance for the mitigation of wave-induced disasters such as beach erosion and so on. The authors (1990, 1991, 1992, 1993, 1995, 1997) developed a long term shallow water wave hindcast system which makes it possible to consecutively follow wave conditions over several years with reasonable accuracy. Applicability of the system was verified by close agreement between computations and measurements for time series and climatic characteristics of significant waves and mean wave direction over 2 to 8 years at several locations around the coasts of Japan.

The system consists of a wind estimation model and a wave estimation model. Wind estimation is due to the application of the Bijvoet model (1957), in which input data are atmospheric pressure data obtained every 3 hours at irregularly-distributed points on the weather charts. Accordingly, tremendous efforts are required to acquire atmospheric pressure data sets, which make it

practically impossible to extend data sets over several years, and the accuracy of the estimates at the Pacific coast of Japan in the cases of complicated wind fields associated with movement of intense typhoons and low systems is not high owing to the use of a simple wind model.

This paper presents a revised system for the estimation of wave climate around the coasts of Japan by using wind data sets provided by ECMWF (European Centre for Medium-range Weather Forecasts) for atmospheric pressure data sets in the former system as input conditions. Wave hindcasting is conducted over 9 years (1986-1994) at 6 wave measurement stations in the Pacific coast of northern Japan. In order to investigate the validity of the system, wave climates represented by not only significant waves and mean wave direction but also frequency-integrated directional wave energy and directional spectrum in addition to time variations of significant waves are compared with those obtained from measured wave data.

**Description of the System**

1. **Wind Estimation**
   
   Wind data at a height of 10 m ($U_{10}$, $\theta_w$) is gathered from uninitialized analysis surface wind data sets in ECMWF/TOGA Advanced Operational Analysis Surface and Diagnostic Fields Data Sets. This is hereafter called the ECMWF wind data. The ECMWF wind data is provided every 6 hours on a spherical grid system with a space resolution of 1.125 degree for a period of Jan. 1, 1986 to Sept. 16, 1991 and with a space resolution of 0.5625 degree for a period of Sept. 17, 1991 to Dec. 31, 1994. The wind data with a time resolution of 6 hours is bilinearly interpolated onto a Cartesian grid system with a grid size of 80km set on the Northwestern Pacific Ocean area over a period of 9 years from Jan. 1, 1986 to Dec. 31, 1994.

2. **Wave Estimation**
   
   A shallow water wave prediction model (Yamaguchi et al., 1987), which traces the change of directional spectrum along a refracted ray of each component focusing on a hindcast point is applied for long-year wave hindcasting in order to save computer processing time. The model belongs to a decoupled propagation model classified into the first generation. The source function consists of linear growth term by the Phillips mechanism, exponential growth term by the Miles mechanism and energy dissipation term by opposing winds, bottom friction and pseudo-viscosity. Energy dissipation due to wave breaking is evaluated by imposing the limitation of a saturated spectrum.

   Wave ray is traced on the nesting grid system composed of the Northwestern Pacific Ocean with a medium grid size of 5 km and a small sea area surrounding the hindcast point with a fine grid size of 1 km. At the land boundary, the directional spectrum is set at zero. At the open boundary, the directional spectrum is given, which is obtained from the product of a modified Pierson-Moskowitz spectrum using local wind speed and the $\cos^3 \theta$ type angular spreading function using local wind direction. In the wave hindcast, 25 frequency components ranging from 0.04 to 0.5 Hz and 19 to 37 directional components,
determined by taking into account angular width of a wave window at each hindcast point, are employed.

Figure 1 shows the grid system used in the wave computation and location of 6 wave hindcasting points. The use of a nested grid system with high topographical resolution yields a reasonable estimate of waves in coastal sea water. Wave hindcast points are 5 coastal stations such as Sendai-shinko (water depth \( h=20 \text{m} \)), Soma \((h=16\text{m})\), Onahama \((h=19\text{m})\), Hitachinaka \((h=30\text{m})\) and Kashima \((h=23\text{m})\), and an offshore station of Iwakioki \((h=154\text{m})\). Wave measurements at 6 stations have been conducted by the Second District Port Construction Bureau of the Ministry of Transport, Japan. These stations constitute some parts of NOWPHAS (Nationwide Ocean Wave information network for Ports and Harbours) managed by the Port and Harbour Research Institute of the Ministry of Transport. The measured data (Coastal Development Institute of Technology, 1992-1995) and analyzed results for wave climate (Kobune et al., 1988-1991, Nagai et al., 1992, Nagai et al., 1993-1996) have been published as annual reports. Coastal stations where measurement data of significant waves and mean wave direction are acquired are located within a distance of 1 to 2 km from

Figure 1. Medium and Fine Grid Systems of the Northwestern Pacific Ocean, Contour Plot of Water Depth and Location of Wave Hindcast Points
the coast. The offshore station Iwakioki, where measurement data of not only significant waves but also directional spectra and frequency-integrated directional energy using a multi-gauge array are acquired, is located 42 km off the Pacific coast in the Tohoku district of northern Japan. In wave hindcasting, the ECMWF wind data over the area with a time resolution of 6 hours is linearly interpolated every 1 hour on time domain and then is bilinearly interpolated onto a wave ray of each component.

Verification of the System

(1) Wind Climate

Figure 2 shows the comparison between ECMWF analysis winds and measured winds for monthly-averaged wind speed and occurrence rate of wind speed over 10 m/s, and directionally-grouped occurrence rate of wind speed over 10 m/s at Buoy 21001 of the Japan Meteorological Agency. A close agreement between analyzed and measured data is obtained, in spite of the discrepancy that analyzed data tends to indicate a slightly stronger concentration to the NW direction than does the measured data. But there is a possibility that the measured data at the buoy may be used in the data assimilation of the ECMWF analysis winds. In this case, a close agreement would be a natural result.

Figure 2. Comparison of Analysis Data and Measurement Data for Monthly-Variations of Mean Wind Speed and Occurrence Rate of Strong Winds, and Yearly-Average of Directionally-Grouped Occurrence Rate of Strong Winds

(2) Time Variations of Significant Waves and Mean Wave Direction

Comparison between computed and measured results was conducted for the time variations of significant wave height $H_m$, significant wave period $T_m$ and mean wave direction $\bar{\theta}$ over a period of 9 years from 1986 to 1994 at 6 measurement stations. Two examples of the comparison over 3 months in summer at the offshore station (Iwakioki) and at the coastal station (Onahama) are given in Figure 3. Calm sea states associated with low swell continue in summer except for some less frequent periods of passage of typhoons. The system generally reproduces the measured time variations of waves with reasonable accuracy,
Figure 3. Comparison between Hindcast and Measurement for Time Variations of Significant Waves and Mean Wave Direction over 3 Months.

Figure 4. Scatter Diagram between Hindcast and Measurement for Significant Waves and Contour Plot of Relative Occurrence Frequency in a Segment of Wave Height at 3 Stations.
although a slight overestimation is observed for the typhoon period.

Figure 4 illustrates some examples of the scatter diagrams between hindcast and measurement for individual significant wave height obtained every 2 hours over 9 years and the contour plot for relative frequency of data contained in a small segment of wave height. Individual data gathers and distributes almost symmetrically around the line indicating a perfect correlation, but the tendency of somewhat excess evaluation to higher waves is found at both Iwakioki and Onahama. It may be said that the hindcasted wave height follows the measured wave height fairly well, taking into account complicated wind and wave fields in an open ocean area, in which case the correlation coefficient $\rho_H$ ranges from 0.80 to 0.83.

(3) Wave Climate for Significant Waves and Mean Wave Direction

Various kinds of mean wave statistics for representing wave climate are obtained from the time series of computed and measured wave data. Figure 5 shows the comparison for monthly averages of significant waves and occurrence rate of high waves greater than 2 m at 6 wave measurement stations. The system evaluates well a general pattern of the seasonal change of the wave climate in the Pacific coastal area of northern Japan, in which high wave conditions associated with frequent passage of intense low pressures occur in spring and autumn, and comparably calm sea states continue in summer. In detail, the system tends to overestimate the occurrence rate of higher waves and to underestimate the wave period in winter particularly at coastal stations. The former results may be caused by the still insufficient grid resolution of 1 km used for the coastal sea area. The latter may be explained as a result of wave computation in a restricted area with artificial open boundary. In winter and in the latter half of autumn, strong landward northwesterly monsoon winds prevail frequently and regularly over the area. Consequently, waves hardly grow by landward winds at coastal sea areas because of the short fetch condition, but low swell-like waves with a longer period propagate from the Pacific Ocean. This means that waves with lower height and longer period reach the coastal area in these seasons. The system may not give a proper estimate for the arrival of low swell-like waves probably due to the above-mentioned reason.

Histograms of wave height grouped every 0.5 m at 6 stations are compared in Figure 6. The system produces well the overall distribution of the histograms for measurement data. But the system tends to underestimate the occurrence rate in the highest rank and the second highest rank, and to overestimate the occurrence rate in the other ranks. Figure 7 indicates the comparison of hindcast and measurement for correlation between wave height and wave period. A higher correlation between wave height and wave period is observed at the offshore station (Iwakioki) where wind waves reach from all directions. This results in the contourlines extending in the right-upward direction. At 5 coastal stations where onshore winds do not give rise to the growth of wind waves and low swell-like waves reach in monsoon seasons, the contourlines show a flatter distribution compared to those at the offshore station. The system yields general features in the correlation diagrams, although each contourline in the hindcast is situated on the shorter period side to the one in the measurement because of underestimation for low swell-like waves.
Figure 5. Comparison of Hindcast and Measurement for Monthly Variations of Mean Significant Waves and Occurrence Rate of High Waves

The directionally-grouped occurrence rates of high waves over 2 m at 6 stations are given in Figure 8. Close agreement between hindcast and measurement is found at the offshore station and 3 coastal stations. At 2 coastal stations (Hitachinaka and Kashima), the distribution in the hindcast indicates counterclockwise deviation from the one in the measurement by a directional
Figure 6. Comparison of Hindcast and Measurement for Histograms of Wave Height

Figure 7. Comparison of Hindcast and Measurement for Correlation between Wave Height and Wave Period
Figure 8. Comparison of Hindcast and Measurement for Directionally-Grouped Occurrence Rate of High Waves Exceeding 2 m

segment (22.5 degree). The reason is not clear, but an insufficient topographical resolution in the nearshore wave computation may contribute to the small discrepancy. While the wave window for high waves at the offshore station has a wider directional range, the wave window at the coastal stations becomes narrower by the presence of the surrounding land topography and the effect of wave refraction during propagation. The system reproduces fairly well the change of the
directional distribution of mean wave direction associated with the propagation from the offshore area to the coastal area.

(4) Wave Climate for Directional Energy and Directional Spectrum

As mentioned above, directional spectra have been analyzed using wave data measured over long years with a multi-gauge array at the offshore station (Iwakioki) by a group of the Port and Harbour Research Institute of the Ministry

Figure 9. Comparison of Hindcast and Measurement for Monthly-Averaged Directional Energy
of Transport (Nagai et al., 1993, Shimizu et al., 1996). Figure 9 illustrates the comparison of hindcast and measurement for monthly mean of frequency-integrated directional wave energy $E(\theta)$ of every 2 hours for the period of 1989 to 1990, in which the measurement data is analyzed by Nagai et al. (1993) using the BDM (Bayesian Directional spectrum estimation Method) proposed by Hashimoto (1987). In winter, directional energy is concentrated in directional ranges of E to NE, and in spring, it has two peaks at the S and NE directions. In summer, directional energy for the S direction is greatly augmented with the passage of intense typhoons, and in autumn, predominant directional energy ranges from E to SE directions. The seasonal change of directional energy is highly correlated with the weather conditions in the concerned sea area. It may be said from the comparison that a gross feature of the seasonal change is reasonably evaluated with use of the present system except for the insignificant difference in directional distribution of each month.

Figure 10 shows the evaluation and measurement (Shimizu et al., 1996) for directional spectrum $E(f, \theta)$, normalized frequency-integrated directional energy $E(\theta)$ and frequency spectrum $E(f)$ averaged over 7 years, in which the value of the contour line for analyzed directional spectrum was not given in their report. Directional spectrum is analyzed with use of EMEP (Extended Maximum Entropy Principle method) proposed by Hashimoto et al. (1993). General patterns of directional spectrum distribution, directional energy distribution with two peaks and frequency spectrum distribution are rather similar in both results based on the hindcast and measurement.

In order to have a closer look at the applicability of the system, comparison of the spectral informations mentioned above is made at each month. Figure 11 shows examples of monthly-averaged spectral characteristics representing each season. In February, a peak of directional energy is seen in the NE direction, but another peak of directional energy in the S direction is slightly overestimated. In May, the hindcast seems to indicate a clockwise shift of peak direction by a directional segment compared to the analysis. In August, the mutual correspondence seems to be acceptable, but in November, directional range with high energy is

![Figure 10](image-url)
Figure 11. Comparison of Hindcast and Measurement for Monthly-Averaged Directional Spectrum, Directional Energy and Frequency Spectrum
somewhat narrower in the hindcast than in the analysis. In addition, directional energy from W to SW direction is underestimated through all seasons. In spite of such discrepancy observed in detail, the overall pattern of the directional distribution of wave energy in the hindcast is in reasonable agreement with that in the analysis. This may lead to the conclusion that the present system is amply applicable for the estimation of long-term wave climate at the level of spectral representation.

**Conclusions**

Consecutive wave computations over 9 years were carried out at 6 wave measurement stations near the Pacific coast of northern Japan by using a long term wave hindcasting system. Close correlation between hindcast and measurement emphasizes that a newly-revised system, in which the ECMWF wind data sets are incorporated as input data is fairly useful for reasonable and efficient evaluation of the wave climates represented by not only significant waves and mean wave direction but also directional spectrum and its frequency-integrated directional wave energy.

NUMERICAL SIMULATIONS OF DIRECTIONALLY SPREAD SHOALING SURFACE GRAVITY WAVES

Françoise BECQ\textsuperscript{1}, Michel BENoit\textsuperscript{4}, Philippe FORGET\textsuperscript{2}

Abstract
The study aims at investigating the non-linear triad interaction process affecting shoaling surface gravity wave fields in shallow water areas. Attention is specifically paid to analyse the effects of these second-order non-linearities on the directional distribution of incident waves. A stochastic approach was chosen to model the triad interaction process. Three source terms have been implemented in the spectral wave model TOMAWAC developed at the Laboratoire National d'Hydraulique (LNH). The model results are compared to the laboratory data of Nwogu (1994).

1. Introduction:
This work focusses to the study of the non-linear interactions between triplets of waves which occur in the nearshore zone. These non-linearities, of lower order than the four wave interactions, are usually considered as the main exchange mechanism for wave energy of an irregular wave train towards sub- (long waves) and super-harmonics (bound higher order waves) (e.g. Freilich and Guza, 1984). The strength of these near-resonant interactions is governed by the phase mismatch between the bound and free wavenumbers. As for decreasing water depth the waves tend to become non-dispersive, the phenomenon is enhanced towards the shore. The effect of the transfer of energy associated with near-resonant wave interactions is not only distortions of the frequency spectrum, but also modifications of the directional spreading of energy. Elgar et al. (1993) observed that directionally bi-modal wave spectra can give rise to a new directional peak. This implies that both collinear and non-collinear triad interactions are important. Boussinesq equations have been extensively used to establish evolution equations for the amplitudes and phases of unidirectional waves propagating over a mildly sloping bottom. The models (e.g. Freilich and Guza (1984), Madsen and Sorensen (1993)) are able to correctly reproduce the generation of harmonics. The quality of the results incited us to extend the deterministic model of Madsen and Sorensen (1993) to bidimensional situations. The model is presented in part 2.

\textsuperscript{1}EDF - Laboratoire National d'Hydraulique, 6 quai Watier, 78400 Chatou, FRANCE
\textsuperscript{2}L.S.E.E.T Université de Toulon et du Var, BP 132, 83957 La Garde, FRANCE
Alternatively, stochastic (phase-averaged) models are more useful to predict the evolution of directional wave spectra. The shallow water three-waves interaction process is simulated by including a source term in the energy balance equation. From the works of Zakharov et al. (1992), Eldeberky et al. (1996) proposed a directionally coupled source term. Some misbehaviours of this non-linear model were pointed out by the authors. We studied more particularly the problem of energy conservation and the ability to generate new directional peaks (which was not demonstrated in Eldeberky, 1996). For practical applications, Eldeberky et al. (1996) recommended the use of the parametrized LTA (Lumped Triad Approximation) model proposed by Eldeberky and Battjes (1995) and Eldeberky (1996). This model has been applied in the wave propagation model SWAN developed at Delft University of Technology (Ris, 1997). The LTA model is characterised by the restriction to self-self interactions leading to a great computational efficiency. From the 2D spectral deterministic equation presented in §2, we developed a new stochastic model. To solve the classical problem of closure, we used the works of Holloway (1980) who assumes that the sum over fourth-order moments draws some contribution from third-order moments through a coupling coefficient interpreted as a broadening of the resonance condition. The three formulations for phase-averaged models are presented in part 3. They are implemented in the spectral wave model TOMAWAC developed at the LNH (Benoit et al., 1996) and they have been compared to the experimental laboratory results presented by Nwogu (1994) (§4).

2. DETERMINISTIC APPROACH:
Deterministic Boussinesq (SB) model:
Starting from their extended Boussinesq equations, Madsen and Sorensen (1993) derived a set of deterministic evolution equations for the amplitudes and phases of unidirectional waves propagating over a mildly sloping bottom. We extended the model to bidimensional situations by use of the 2D Boussinesq equations of Madsen and Sorensen (1992):

\[
\frac{\partial \zeta}{\partial t} + \mathbf{v} \cdot \mathbf{P} = 0
\]

\[
\frac{\partial \mathbf{P}}{\partial t} + \left[ \frac{\mathbf{P}}{h + \zeta} (\nabla \cdot \mathbf{P} + (\mathbf{P} \cdot \nabla) \frac{\mathbf{P}}{h + \zeta}) + g(h + \zeta) \nabla \zeta - \left( B + \frac{1}{3} \right) h^2 \nabla \left( \nabla \cdot \frac{\partial \mathbf{P}}{\partial t} \right) \right]
\]

\[
- \frac{h}{6} \left( \nabla \cdot \frac{\partial \mathbf{P}}{\partial t} \right) \mathbf{h} - \frac{h}{6} \nabla h \cdot \nabla \left( \frac{\partial \mathbf{P}}{\partial t} \right) - \frac{h}{6} \nabla h \otimes \left( \nabla \otimes \frac{\partial \mathbf{P}}{\partial t} \right)
\]

\[
-Bgh^2 \left( \nabla h \cdot \nabla \right) (\nabla \cdot \zeta) - Bgh^2 \left( \nabla \cdot \nabla \zeta \right) \mathbf{h} - Bgh^2 \nabla \mathbf{h} \nabla \nabla \zeta = 0
\]

where \( \zeta \) is the free surface elevation, \( \mathbf{P} \) is the depth-integrated velocity and \( h \) is the water depth. These equations include a linear parameter \( B \) which improves the dispersion properties and the shoaling mechanisms associated with the model. The optimal value \( B=1/15 \) was obtained by the authors by a fit to the reference linear shoaling coefficient predicted by the Stokes first-order theory. The standard form of the Boussinesq equations can be recovered by setting \( B=0 \).
The extended Boussinesq equations are combined into one single equation. For this, the partial derivative in time of the continuity equation is substracted to the partial derivative in space of the momentum equation. This leads to:

\[ L = M + N \]  

where:

\[ L = \zeta_n - gh \nabla \cdot \nabla \zeta + Bgh^2 \nabla \cdot \left( \nabla (\nabla \cdot \zeta) \right) - \left( B + \frac{1}{3} \right) h^2 \nabla \cdot \left( \nabla \zeta_n \right) \]  

\[ M = g \nabla h \cdot \nabla \zeta + (2B+1)h \nabla h \cdot \nabla \zeta_n - 5Bgh^2 \nabla h \cdot \nabla \left( \nabla \cdot \zeta \right) + \frac{h}{6} \nabla h \left( \nabla \otimes \nabla \tilde{p} \right) \]  

\[ N = \nabla \cdot \left[ \frac{\tilde{p}}{h + \zeta} \left( \nabla \cdot \tilde{P} \right) + \left( \tilde{P} \cdot \nabla \right) \frac{\tilde{p}}{h + \zeta} \right] + g \nabla \cdot \zeta \cdot \zeta + g \zeta \nabla \cdot \zeta \]  

\( L \) contains the lowest order and dispersive terms, \( M \) represents the effects of slowly varying depths on the wave propagation and \( N \) models the non-linear effects due to wave coupling. Now, the equation is transformed into the spectral domain. \( \zeta \) is written as a discrete Fourier series:

\[ \zeta(x, y, t) = \sum_{p=-\infty}^{\infty} A_p(x, y) \exp \left[ i \left( \omega_p t - \psi_p(x, y) \right) \right] \]  

in which \( p \) refers to a directional wave component. \( A_p \) is the complex Fourier amplitude (\( A_{-p} = A_p^* \)), \( \omega_p \) is the angular frequency (\( \omega_{-p} = -\omega_p \)) and \( \psi_p \) is the linear wave phase, linked to the wavenumber by the relation \( \nabla \psi_p = k_p(x, y) \). \( \tilde{P} \) is linked to \( \zeta \) through the continuity equation, so:

\[ \tilde{P}(x, y, t) \approx \sum_{p=-\infty}^{\infty} \tilde{c}_p A_p(x, y) e^{i(\omega_p t - \psi_p(x, y))} \]  

where \( \tilde{c} \) is the wave phase celerity. The Fourier expressions of \( \zeta \) and \( \tilde{P} \) are inserted in the equation (3). We follow for this the guideline presented by Madsen and Sorensen (1993) for 1D situations. First derivatives of \( A_p \), \( k_p \) and \( h \) are assumed to be small, and products of derivatives and higher derivatives of these quantities are neglected. After algebraic manipulations, we get,

- at lowest order, the linear dispersion relation:

\[ \frac{\omega_p^2 h}{g} = \frac{(k_p h)^2 + B(k_p h)^4}{1 + (B + \frac{1}{3}) (k_p h)^2} \]  

- at second order, the coupled differential equations:

\[ \frac{\partial A_p}{\partial t} + \tilde{C}_g \cdot \nabla A_p + \frac{1}{2} \frac{C_g}{k_p} A_p \cdot \nabla k_p + \frac{S_{2,p} - S_{4,p}}{2 S_{1,p}} A_p = \frac{i g}{2 S_{1,p}} N_p \]  

where \( \tilde{C}_g \) is the group velocity:

\[ \tilde{C}_g = \frac{S_{2,p}}{S_{1,p}} \]  

\[ S_{1,p} = \omega_p \left[ 1 + (B + \frac{1}{3}) \frac{h^2 k_p^2}{2} \right] \]
\[ S_{2,p} = \left( gh + 2Bgh^2k_p^2 - \left( B + \frac{1}{3} \right) \omega_p^2 h^2 \right) \]  
(13)

\[ S_{3,p} = 4Bgh^3 \left[ -k_p^2 \left( g + 3Bgh^2k_p^2 - 2(B + 1/3)h^2 \omega_p^2 \right) \vec{k}_p, \vec{\nabla}h \right] \]  
(14)

\[ S_{4,p} = -(\vec{k}_p, \vec{\nabla}h) \left[ g + 5Bgh^3k_p^2 - (2B + 1)\omega_p^2 h \right] \]  
(15)

\[ N_p = \sum_{m=1}^{\infty} 2R_{-m,m+m} A_m A_{m+m} e^{-i(-\omega_m + \omega_{m+m} + \omega_n)} + \sum_{m=1}^{\infty} R_{p-m,m} A_mA_{p-m} e^{-i(-\omega_p + \omega_{p-m} + \omega_n)} \]  
(16)

The left hand side of (10) represents the propagation terms, whereas the right hand side governs the non-linear triads interactions. \( N \) models the exchange of energy towards sub- and super-harmonics through the coupling coefficient, \( R \), which controls the strength of the interactions. Its expression is given by:

\[ R_{p,m} = \left[ \frac{1}{2} \left( k_p^2 + k_m^2 + 2 \vec{k}_p, \vec{k}_m \right) + \right] \]  
\[ \frac{1}{gh} \left[ \frac{\omega_p \omega_m}{(k_p k_m)^2} \left( k_p^2 + k_m^2 \right) \vec{k}_p, \vec{k}_m + \left( k_p k_m \right)^2 \left( \vec{k}_p, \vec{k}_m \right)^2 \right] \]  
(17)

3. STOCHASTIC APPROACHES:

Stochastic Parametrized Zakharov (SPZ) model:

The model proposed by Eldeberky et al. (1996) is based on the so-called Zakharov equation for resonant three-wave interactions (Zakharov, 1968; Zakharov et al., 1992):

\[ \frac{\partial \tilde{a}_{k_3}}{\partial t} = -i \omega_{k_3} \tilde{a}_{k_3} - i \int \left[ R_{312} \tilde{a}_{k_1} \tilde{a}_{k_2} \delta_{3-1-2} + 2R_{132} \tilde{a}_{k_1} a_{k_2}^* \delta_{1-3-2} \right] dk_1 dk_2 \]  
(18)

\( \delta_{3-1-2} \) is shorthand for \( \delta \left( \vec{k}_3 - \vec{k}_1 - \vec{k}_2 \right) \) where \( \delta \) stands for the delta Kronecker symbol. \( R_{312} \) is a coupling coefficient depending on the physics of the interacting waves. For surface gravity waves in intermediate water depth, the expression is given by (Stiassnie and Shemer, 1984; Eldeberky et al., 1996):

\[ R_{312} = \frac{g^{1/2}}{8\pi \sqrt{2}} \left\{ \left[ \vec{k}_3, \vec{k}_1 - (\omega_3 \omega_1 / g^2) \right] (\omega_2 / \omega_1) \right\}^{1/2} \]  
\[ + \left[ \vec{k}_3, \vec{k}_2 - (\omega_3 \omega_2 / g^2) \right] (\omega_1 / \omega_2) \omega_3^{1/2} \]  
\[ + \left[ \vec{k}_1, \vec{k}_2 + (\omega_3 \omega_1 / g^2) \right] (\omega_3 / \omega_1) \omega_2^{1/2} \]  
(19)

A statistical formulation of the three-wave interaction process, expressed in term of the correlation functions of the wave field, can be obtained from (18) (Zakharov et al., 1992). Because of non-linearities, the statistical description consists in a series of interconnected equations where each moment evolves according to the next higher-order moment. The problem is closed by assuming that the fourth-order moments can be expressed as a function of the lower order moments. For resonant wave-wave interactions, Zakharov et
al. (1992) used the quasi-gaussian hypothesis. A broadening of the resonance condition is included in the model by the assumption that the fourth-order cumulant depends on the third-order moment through a coupling coefficient $\Omega$ which represents a frequency uncertainty among the three interacting waves (Holloway, 1980). A small (but finite) value for $\Omega$ is used (Eldeberky et al., 1996). Defining the wave action density $n_k$ by:

$$\langle a_k^* a_k \rangle = 4\pi^2 n_k \delta(k - k')$$  \hspace{1cm} (20)$$

the wave action evolution equation can be expressed as (Zakharov et al., 1992):

$$\frac{dn_k}{dt} = 4 \int \int \tilde{k}_1 \tilde{k}_2 \left[ R_{312}^2 N_{312} \mu_{3-1-2} \delta_{3-1-2} - 2R_{132}^2 N_{132} \mu_{3-1+2} \delta_{3-1+2} \right]$$  \hspace{1cm} (21)$$

where $N_{312}$ depends on the spectral action density functions ($n_j$) of the interacting waves according to:

$$N_{312} = n_1 n_2 - n_3 n_1 - n_3 n_2$$  \hspace{1cm} (22)$$

In Holloway's approach, $\mu_{3-1-2}$ acts as a spectral filter through the frequency mismatch $(\omega_3 - \omega_1 - \omega_2)$ and through the parameter $\Omega$ characterising non-resonant interactions:

$$\mu_{3-1-2} = \frac{\Omega}{(\omega_3 - \omega_1 - \omega_2)^2 + \Omega^2}$$  \hspace{1cm} (23)$$

Eldeberky et al. (1996) showed by numerical simulations that the spectral source term for triad interactions results in an artificial energy decay/gain. This non-conservative feature was explained by the specification of the filter bandwidth $\Omega$. As done by Hasselmann and Hasselmann (1985) for quadruplets interactions, we exploited the basic symmetry of the triplets interactions to study more accurately the problem of energy conservation. The interaction coefficient $R_{312}$, as well as $N_{312}$ and $\mu_{312}$ are invariant with respect to permutations between waves 1 and 2. So, for the collision:

$$\tilde{k}_3 - \tilde{k}_1 - \tilde{k}_2 = 0$$  \hspace{1cm} (25)$$

the changes $\Delta n_j$ in wave action per unit time for the three wavenumbers can be expressed by:

$$\begin{align*}
\Delta n_{k_1} = -1 \\
\Delta n_{k_2} = 4R_{312}^2 N_{312} \mu_{312} \delta(k_3 - k_2 - k_1) d\tilde{k}_1 d\tilde{k}_2 d\tilde{k}_3 \\
\Delta n_{k_3} = +1
\end{align*}$$  \hspace{1cm} (26)$$

leading to:

$$\begin{align*}
\Delta F_{k_1} = -f_1 \\
\Delta F_{k_2} = 8\pi R_{312}^2 N_{312} \mu_{312} \delta(k_3 - k_2 - k_1) d\tilde{k}_1 d\tilde{k}_2 d\tilde{k}_3 \\
\Delta F_{k_3} = +f_3
\end{align*}$$  \hspace{1cm} (27)$$

(26) and (27) show that, for resonant three wave interactions $f_3 = f_1 + f_2$, only the
conservation of energy applies, as expected (Komen et al., 1994). Non-conservation of energy occurs for near-resonant interactions when the linear dispersion relationship is used to link the wavenumber to the frequency since \( f_{\text{lin}}(k_3) < f_{\text{lin}}(k_1) + f_{\text{lin}}(k_2) \). The outcome is a decay of energy during the generation of bound super-harmonics and an increase in energy during the generation of bound sub-harmonics.

For its implementation in a spectral wave model, the SPZ source term is expressed in terms of frequency-directional variance density function \( F(f, \theta) \) (Eldeberky et al., 1996):

\[
S(\omega_1, \theta_1) = 16\pi^2 g \int_0^{2\pi} \int_0^{\pi} \frac{c_2 C_{g2}}{\omega_1 \omega_2} (T_{132} - 2T_{132}) \, d\omega_1 \, d\theta_1 \tag{28}
\]

where

\[
T_{132} = R_{312}^2 \mu_{312} \left[ \frac{\omega_3}{C_{g3}} F_1 F_2 - \frac{\omega_1}{C_{g1}} F_3 F_2 - \frac{\omega_2}{C_{g2}} F_1 F_3 \right] \tag{29}
\]

\( T_{132} \) and \( T_{132} \) represent the sum \( (k_3 = k_1 + k_2) \) and difference \( (k_3 = k_1 - k_2) \) interactions.

The formulation is directionally coupled and allows for both collinear and non-collinear interactions.

**LTA model:**
The parametrized LTA model proposed by Eldeberky and Battjes (1995) and Eldeberky (1996) is based on the evolution equation for complex Fourier amplitudes presented by Madsen and Sorensen (1993). The statistical nature of a wave field allows to transform the equation in term of discrete spectrum of energy. The result is a set of interconnected equations where each moment evolves in terms of the next higher order moment. Assumptions are made on the third-order moment (bispectrum) to close the system. The magnitude of bispectrum (bicoherence) is expressed only in terms of second-order moment (quasi-gaussian hypothesis) whereas a parametrical formulation is given for the phase \( \beta \) (biphase). In order to reduce the computational effort, the triad interactions phenomenon is restricted to self-self interactions. Finally, the net source term is given by (Eldeberky, 1996):

\[
S_{nl}(f_p) = S_{nl}^+(f_p) + S_{nl}^-(f_p)
\]

\[
S_{nl}^+(f_p) = \alpha c_p C_{g_p} R^2_{(p/2,p/2)} \sin|\beta_{p/2,p/2}| \left[ F^2(f_{p/2}) - 2F(f_{p}) F(f_{p/2}) \right] \tag{30}
\]

\[
S_{nl}^-(f_p) = -2 S_{nl}^+(f_{2p})
\]

\( S_{nl}^+ \) represents the positive and negative contributions to the self-interactions; \( c_p \) and \( C_{g_p} \) are the phase and group velocities for the \( p \) harmonic, \( R \) is the sum interaction coefficient derived from the deterministic evolution equation and \( \alpha \) is a tuning parameter.

**Stochastic Parametrized Boussinesq (SPB) model:**

By using the statistical closure hypothesis proposed by Holloway (1980), we built up a stochastic model based on the 2D evolution equation for complex Fourier amplitudes presented in §2. We define the complex wave amplitude \( C_p \) as:

\[
C_p = A_p e^{-i\varphi_p} \tag{31}
\]

So, the evolution equation for \( C_p \) reads, from (10):
\[ \frac{\partial C_p}{\partial t} + \overline{C}_p \cdot \nabla C_p + \frac{1}{2} \frac{C_{g_p}}{k_p} \nabla \cdot \overline{k}_p \cdot C_p + \frac{S_{3,p} - S_{4,p}}{2S_{1,p}} C_p = -i \frac{S_{2,p}}{S_{1,p}} \left( \overline{k}_p, \overline{k}_p \right) C_p \]

(32)

Since:
\[ \frac{\partial \langle C_p C_p^* \rangle}{\partial t} = \left( \langle C_p \frac{\partial C_p^*}{\partial t} \rangle + \langle C_p^* \frac{\partial C_p}{\partial t} \rangle \right) \]

(33)

and,
\[ \nabla \langle C_p C_p^* \rangle = \langle C_p \nabla C_p^* \rangle + \langle C_p^* \nabla C_p \rangle \]

(34)

by defining the discrete variance density \( F_p \) as:
\[ F_p = \langle C_p C_p^* \rangle \]

(35)

the evolution equation for \( F_p \) writes:
\[
\frac{\partial F_p}{\partial t} + \overline{C}_p \cdot \nabla F_p + \frac{C_{g_p}}{k_p} \left( \nabla \cdot \overline{k}_p \right) F_p + \frac{S_{3,p} - S_{4,p}}{S_{1,p}} F_p = -i \frac{g}{S_{1,p}} \sum_{m=-\infty}^{\infty} R_{m,p-m} C_m C_{p-m} \]

(36)

where \( B_{m,p-m} = \langle C_p C_m C_{p-m} \rangle \) is the bispectrum. When \( B = 1/15 \), Madsen et Sorensen (1992) have shown that the shoaling term corresponding to their extended Boussinesq equations fits quite satisfactorily the shoaling term of the first order Stokes theory (percentage errors less than 6% for \( h/\lambda_0 < 0.3 \)). So, we write (36) in the following form:
\[
\frac{\partial F_p}{\partial t} + \nabla \left( \overline{C}_p F_p \right) = -i \frac{g}{S_{1,p}} \sum_{m=-\infty}^{\infty} R_{m,p-m} \text{Im} \left( B_{m,p-m} \right) \]

(37)

where \( \overline{C}_p \) refers here to the group celerity of the first order Stokes theory.

To derive an expression for the bispectrum, we assume stationary conditions. In the limit \( h_x \to 0 \), (32) is reduced to:
\[
\overline{k}_p, \nabla \left( C_p \right) + i \left( \overline{k}_p, \overline{k}_p \right) C_p = \frac{ig}{2S_{2,p}} \sum_{m=-\infty}^{\infty} R_{m,p-m} C_m C_{p-m} \]

(38)

The complex amplitudes, \( C_p \), are expanded in a perturbation series with respect to \( \varepsilon \):
\[ C_p = \varepsilon C_p^{(1)} + \varepsilon^2 C_p^{(2)} + \ldots \]

(39)

and (38) has a simple steady solution:
\[ C_p^{(2)} = \frac{ig}{2S_{2,p}} \sum_{m=-\infty}^{\infty} R_{m,p-m} C_m^{(1)} C_{p-m} \Delta \left( \overline{k}_p, \overline{x} \right) \]

(40)

with \( \Delta \left( \overline{k}_p, \overline{x} \right) \approx \frac{I}{2 \pi i} e^{i \overline{k} \cdot \overline{x}} \)

(41)

and
\[ \overline{k} = \overline{k}_p - \overline{k}_{p-m} - \overline{k}_m \]

(42)
At lowest order, the bispectrum vanishes (gaussian wave field):

$$\langle C_p^{(1)} C_p^{(1)} C_p^{(1)} \rangle = 0$$  \hspace{1cm} (43)

Here, $$\langle C_p^{(1)} C_p^{(1)} C_p^{(1)} \rangle$$ is decomposed as:

$$\langle C_p^{(1)} C_p^{(1)} C_p^{(1)} \rangle = \langle C_p^{(1)} C_p^{(1)} C_p^{(1)} \rangle + \langle C_p^{(1)} C_p^{(1)} C_p^{(1)} \rangle + \langle C_p^{(1)} C_p^{(1)} C_p^{(1)} \rangle$$  \hspace{1cm} (44)

Substitution of the steady contribution of (40) into (44) leads to:

$$\langle C_p^{(1)} C_p^{(1)} C_p^{(1)} \rangle = \frac{i g}{2 S_{2,m} k_m} \sum_{q=-\infty}^{\infty} R_{m-q,q} \frac{\langle C_q^{(1)} C_q^{(1)} C_p^{(1)} \rangle}{i k_m - k_{m-q} - k_q}$$  \hspace{1cm} (45)

where $$\langle C_q^{(1)} C_q^{(1)} C_p^{(1)} \rangle$$ is the fourth order moment, often referred as the trispectrum. We assume that the sum over the quadruple correlations gives a contribution on the triple correlations (Holloway, 1980). So, (45) transforms to:

$$\langle \tilde{k}_p - \tilde{k}_{p-m} - \tilde{k}_m \rangle \langle C_p^{(1)} C_p^{(1)} C_p^{(1)} \rangle = \frac{g R_{m-p,m} \langle C_p^{(1)} C_p^{(1)} C_p^{(1)} \rangle}{S_{2,m} k_m}$$  \hspace{1cm} (46)

where $$K$$ is the tuning parameter of the model (fixed value). Only the imaginary part of the bispectrum is required to close the evolution equation for the variance density, so:

$$\text{Im}\left( B_{m,p-m} \right) = \frac{g K}{K^2 + \Delta k^2} \left[ R_{m-p,m} F_p F_p F_p + \frac{R_{m-p,m}}{S_{2,m} k_{m-p,m}} F_p F_p F_p - \frac{R_{m-p,m}}{S_{2,m} k_{m-p,m}} F_p F_p F_p \right]$$  \hspace{1cm} (47)

with $$\Delta k^2 = |k_p - k_{p-m} - k_m|^2$$.

Substitution of equation (47) into (37) leads to:

$$\frac{\partial F}{\partial t} + \nabla \cdot (\tilde{C}_p F_p) = -\frac{g^2}{S_{1,p} \sum_{m=-\infty}^{\infty} K^2 + \Delta k^2} R_{m,p-m} \left[ R_{m-p,m} F_p F_p F_p + \frac{R_{m-p,m}}{S_{2,m} k_{m-p,m}} F_p F_p F_p - \frac{R_{m-p,m}}{S_{2,m} k_{m-p,m}} F_p F_p F_p \right]$$  \hspace{1cm} (48)
For its implementation in the TOMAWAC spectral wave model, the SPB source term (right hand side of (48)) is expressed in terms of the continuous frequency-directional variance density function $F(f, \theta)$. The source term may be written as:

$$S(f_3, \theta_3) = \int_{0}^{2\pi} \int_{0}^{2\pi} df_1 df_2 d\theta_1 d\theta_2 T_{312}^{SPB} \delta(\theta_1 - \theta_2 - \theta_3) \delta(f_3 - f_1 + f_2)$$

$$-2 \int_{0}^{2\pi} \int_{0}^{2\pi} df_1 df_2 d\theta_1 d\theta_2 T_{132}^{SPB} \delta(\theta_1 + \theta_2 - \theta_3) \delta(f_3 - f_1 + f_2)$$

where $T_{312}^{SPB}$ and $T_{132}^{SPB}$ represent respectively the sum and difference triad interactions.

The formulation is directionally coupled and allows for both collinear and non-collinear interactions.

4. NUMERICAL SIMULATIONS:
The three non-linear source terms presented in §3 have been implemented in the spectral wave model TOMAWAC, developed at the Laboratoire National d’Hydraulique (Benoit et al., 1996). Numerical simulations are compared to the experimental laboratory results presented by Nwogu (1994), for the propagation of crossing seas over a constant slope.

Laboratory Basin description (Nwogu, 1994; Nwogu, 1993)
The three-dimensional wave basin (30 m wide, 20 m long and 3 m deep) is located at the Hydraulics Laboratory, National Research Council of Canada. It is equipped with a segmented directional wave generator. Reflections at the basin sidewalls are reduced by wave energy absorbers made of perforated metal sheets. A bathymetric profile was constructed in the basin. It consists in a constant slope beach (1:25) with an impermeable concrete cover. The free surface elevation was measured along the centreline of the basin with a linear array of 23 water level gauges.

Wave conditions imposed at the wave generator
The incident laboratory wave spectrum at the wave generator ($h = 0.56$ m) is bimodal: it is composed of two sea states characterising local sea and swell components (figure 1). The frequency distributions of the sea states are described by a JONSWAP spectrum characterised by the peak period $T_p$, the significant wave height $H_{m0}$ and the peak enhancement factor $\gamma$. The directional distributions are given by the cosine function:

$$D(\theta) = \cos^2(\theta - \theta_0)$$

Table 1 sums up the wave parameters of the target spectrum.

Table 1. Spectral wave parameters characterising the initial spectrum.
Numerical results

The SPZ source term was activated in the TOMAWAC simulation, with $\Omega = 0.05$. The directional wave spectrum obtained in the shallow water area ($h = 0.18$ m) is presented on figure 2. It shows that the variance density spectrum is affected by refraction, shoaling and non-linear triad interactions. Non-linear wave-wave interactions strongly affect the frequency-directional shape of the spectrum. By collinear wave-wave interactions, energy is transferred from the swell spectral peak towards its two higher harmonics and by non-collinear interactions, energy is transferred from the two primary spectral peaks (swell and local sea) towards the component corresponding to the vector sum of the primary peak wavenumbers. Figure 3 shows a comparison between the non-linear SPZ simulation and measurements for the frequency spectrum. The results obtained with a linear simulation are also presented to point-up the effects of wave-wave interactions on the spectral shape. Figure 3 clearly demonstrates that the non-linear triads interactions cannot be neglected in the shoaling zone. As shown by Eldeberky et al. (1996), the new spectral peaks generated using the SPZ model are shifted towards lower frequencies as compared to measurements. Since the interaction condition between the three interacting waves is imposed through $\delta(k_3 - k_1 - k_2)$, the negative curvature of the linear relationship implies that if $k_3 = k_1 + k_2$, then $f_3 \leq f_1 + f_2$ (Eldeberky et al., 1996).

The simulation using the LTA source term was performed with $\alpha = 0.5$. The numerically simulated shallow water spectrum is presented on figure 4. Since the LTA model is restricted to self-self (collinear) interactions, the simulated shallow water spectrum only shows two new spectral peaks at frequencies $2f_1$ and $2f_2$, where $f_1$ and $f_2$ refer here to
Figure 2: Directional wave spectrum in shallow water ($h=0.18\,m$).
Non-linear simulation using the SPZ source term.

Figure 3: Frequency wave spectrum in shallow water ($h=0.18\,m$).

the peak frequencies of the swell and local sea respectively. Figure 5 shows the frequency wave spectrum in shallow water. The energy at $2f_1$ is strongly overestimated by the LTA model, when $\alpha=0.5$. The transfer of energy towards super-harmonics decreases with $\alpha$. But, since the LTA model is energy flux conservative and is restricted to self-self interaction, the choice of $\alpha$ requires a balance between an overestimation of the primary peaks or an overestimation of the harmonics.
Figure 4: Directional wave spectrum in shallow water ($h=0.18m$).
Non-linear simulation using the LTA source term.

Figure 5: Frequency wave spectrum in shallow water ($h=0.18m$).

The results obtained with the SPB model are presented on figure 6. Collinear and non-collinear wave-wave interactions are both modelled using the SPB source term. Energy is transferred from the swell spectral peak towards its first and second harmonics. The swell also interacts with the local sea and generates components at the vector sum of the local sea and swell components. A comparison of the model to measurements is presented on figure 7. A relatively good fit to measurements is obtained with the SPB source term.
5. CONCLUSIONS:
The spectral deterministic model of Madsen and Sorensen (1993) has been extended to bidimensional situations where combined refraction, shoaling and triads interactions act simultaneously to modify the frequency and directional spreading of the ocean surface energy field. A stochastic source term (SPB) is developed from the deterministic
equations obtained. The model is directionally coupled and implies that the energy transfer among spectral components is governed by collinear and non-collinear near-resonant triad interactions. The consequences are not only distortions of the frequency spectrum, but also alterations of the directional spreading of wave energy. This source term has been compared to two other spectral source terms: the LTA and SPZ models. The LTA model is able to catch the main features of energy transfers from the main spectral peaks towards their higher harmonics. It cannot simulate all the new spectral peaks occurring in crossing seas, but it is characterised by a great computational efficiency. The SPZ model and the SPB are directionally coupled and are able to transfer energy to a third component at the sum vector of the primary waves. The SPB model gives the best results since the frequency of the new components corresponds exactly to the sum frequency of the primary waves, whereas with the SPZ model, a shift towards lower frequency is observed (Eldeberky et al., 1996).

Abstract

The influence of reflection and dissipation on wave-induced mean magnitudes is studied. Starting from linear wave theory the second order quantities are derived in terms of transfer functions considering regular as well as irregular waves. It is shown that any reflective and dissipative natural or artificial structure such as a vegetation field, or an emerged or submerged breakwater, induces spatial variations of the mean quantities such as the mean water level, mass flux, energy flux or radiation stress. The evolution of these magnitudes is analogous to their behavior in the surf zone, showing wave damping and modulation. Compared with the experimental results, the models presented are able to reproduce wave height transformation as well as mean water level variations along the dissipative structures with reasonable accuracy.

Introduction

Wave reflection and dissipation are two important wave transformation processes close to structures or at the shoreline. Through the years, research has been carried out in order to understand the role of reflection and dissipation on coastal engineering problems, especially concentrating on wave height evolution. In this paper attention will be paid to how nonlinear quantities obtained from linear wave theory, such as: mass transport, mean water level, momentum flux, energy flux, radiation stress, etc., are affected by wave reflection and
dissipation. Reflection and dissipation are considered to be induced by natural (vegetation) or artificial emerged or submerged permeable structures. Dissipation by wave breaking is neglected in most of the cases considered since its effects are well known in the surf zone. The detailed examination of these hydrodynamic mean quantities will be a first step to analyze the influence of the presence of the structure on the morphodynamics of its vicinity.

**Theory**

Starting from linear wave theory the second order quantities are derived assuming complex reflection and transmission coefficients including magnitude and phase information. The coefficients and wave amplitudes can be calculated solving the first order problem. The models used are able to consider several structure geometries, porous material characteristics and incident wave climates. Therefore, it can be established how each of the second order magnitudes is affected by these parameters.

For an emerged vertical permeable breakwater on a horizontal bottom, Fig. 1a, the solution based on an eigenfunction expansion presented in Dalrymple *et al.* (1991) is used to evaluate the first order problem. Regular, oblique incident waves are considered to impinge the structure. As a result the potential inside and outside the structure is known and conse-
quently the free surface evolution, velocity, acceleration and pressure field at any point in
the domain considered.
A similar approach is used for a submerged permeable step, Fig. 1a, as shown in Losada
et al. (1996a and b). In these papers the solution also considers irregular incident waves
and the model is extended to analyze submerged permeable structures of arbitrary geometry
on a sloping bottom, Fig. 1b, using a modified mild slope equation. The equation said is
suitable to include wave breaking effects via a Dally et al. (1985) breaking model or others
like the one proposed in Rojakanamthorn et al. (1990).
In order to consider a natural reflective, dissipative medium different than a beach a vegeta-
tion field is studied, Fig. 1c. The wave-induced first order kinematics and dynamics under
regular and irregular waves is evaluated extending the work of Kobayashi et al. (1993) and
Once the first order solution is known for any of the structures considered, mean water
level, mass flux, energy flux and radiation stresses can be calculated. These magnitudes,
time averaged and correct to second order are proportional to the wave height squared.
Regular as well as irregular waves are considered.
The expressions of the mean quantities are formulated in a general form in terms of transfer
functions which vary depending on the structure considered.

Mass transport
To obtain the total mass flux in the x—direction, \( M_x \), the following integration has to be
carried out

\[
M_x = \int_{-h}^0 \rho u dz = \int_{-h}^0 \rho u dz + \int_0^h \rho u dz = \int_{-h}^h \rho u dz
\]  

(1)

Expressing the horizontal velocity in terms of a Taylor series, to second order and using
transfer functions, the mass flux in the x—direction for a monochromatic wave train is

\[
M_x = \frac{1}{2} \alpha^2 \rho \text{Re}[H_\eta H_u^*]
\]  

(2)

where (*) stands for complex conjugate, \( \rho \) is the water density, \( a \) the incident wave ampli-
tude and \( \text{Re}[] \) stands for real part of the magnitude in brackets.
The mass flux can be expressed in terms of the incident directional spectrum of the free
surface \( \eta, S_\eta(f)G(f, \theta) \), by applying the results from the linear theory to individual spectral
components, Battjes (1974), where \( S_\eta(f) \) is a frequency energy spectrum and \( G(f, \theta) \) is a
directional spreading function. This gives

\[
M_x = \rho \int_{-\pi}^{\pi} \int_0^\infty \text{Re}[H_\eta H_u^*]|_{z=0} S_\eta(f)G(f, \theta) df d\theta
\]  

(3)

For an incident unidirectional spectrum, \( S_\eta(f) \), the mass flux is

\[
M_x = \rho \int_0^\infty \text{Re}[H_\eta H_u^*]|_{z=0} S_\eta(f) df
\]  

(4)

Assuming a very narrow incident spectrum (one unique component with amplitude \( a \) we
obtain \( \int_0^\infty S_\tau(f)df = \frac{1}{2} \alpha^2 \) and, therefore, the mass flux can be expressed as eq. (2).

**Mean water level**

The second order mean water surface displacement, \( \bar{\eta} \), can be evaluated averaging the Bernoulli equation over a wave period. Neglecting third order terms and higher, yields:

\[
\bar{\eta} = -\frac{1}{2g} \left( u^2 + v^2 - \bar{w}^2 \right) \bigg|_{z=0} + \frac{C(t)}{g} 
\]

In terms of the transfer functions the mean water level may be expressed as:

\[
\bar{\eta} = -\frac{1}{4g} \alpha^2 \left( |H_u|^2 + |H_v|^2 - |H_w|^2 \right) \bigg|_{z=0} + \frac{C(t)}{g} 
\]  

where the transfer function expression varies depending on the region where the mean water level has to be evaluated.

**Radiation stress**

The radiation stress will be affected by the presence of reflected waves and the dissipation induced by the flow through the porous material or breaking. The four components of the radiation tensor in a fluid region are in terms of the transfer functions

\[
S_{xx} = \frac{1}{2} \alpha^2 \int_{-h}^{0} \rho \left( |H_u|^2 - |H_w|^2 \right) dz + \frac{1}{4} \rho g a^2 |H_\eta|^2 
\]

\[
S_{yy} = \frac{1}{2} \alpha^2 \int_{-h}^{0} \rho \left( |H_v|^2 - |H_w|^2 \right) dz + \frac{1}{4} \rho g a^2 |H_\eta|^2 
\]

\[
S_{xy} = \frac{1}{2} \alpha^2 \int_{-h}^{0} \rho \Re \{H_u H_\eta^*\} dz 
\]

where \( h \) is the water depth.

Above and inside a porous layer the components of the radiation stress due to the wave-induced velocities have to be multiplied by the factor \( \varepsilon \):s

\[
S_{xx} = \frac{1}{2} \alpha^2 \int_{-h+\alpha h}^{-h} \rho \varepsilon \left( |H_u|^2 - |H_w|^2 \right) dz + \frac{1}{4} \rho g a^2 |H_\eta|^2 
\]

\[
S_{yy} = \frac{1}{2} \alpha^2 \int_{-h+\alpha h}^{-h} \rho \varepsilon \left( |H_v|^2 - |H_w|^2 \right) dz + \frac{1}{4} \rho g a^2 |H_\eta|^2 
\]
\[
S_{xy} = \frac{1}{2} a^2 \int_{-h}^{-h+\alpha h} \rho \varepsilon \text{Re}[H_u H_v^*] dz + \frac{1}{2} a^2 \int_{-h+\alpha h}^{0} \rho \text{Re}[H_u H_v^*] dz 
\]

where \( \varepsilon \) is the porosity of the porous material and \( s \) an inertia coefficient, generally taken to be one and \( \alpha h \) is the height of the porous material. Note that \( \alpha = 1 \) corresponds to an emerged vertical permeable structure.

In the Appendix transfer functions, including evanescent modes, in eqs. (2) to (12) for regular incident waves impinging on a submerged permeable step of height \( \alpha h \) are given as an example.

**Results**

In Fig. 2 the wave height, \( H_{rms} \) and the mean water level, \( \bar{\eta} \) evolution is presented, under non-breaking conditions, along two different submerged steps of identical geometry and different material (impermeable and permeable with \( D_{50} = 2.09 \text{ cm} \) and \( \varepsilon = 0.521 \)). The step geometry is given by \( \alpha h = 0.385 \text{ m} \) and \( b = 0.8 \text{ m} \). Different incident wave conditions have been also considered in the experiments described in Losada et al. (1997). The mean water level variation has been obtained using eq. (6) and (14) to (14).

Fig. 3 shows the experimental results in Rivero et al. (1998) versus the numerical results obtained using the mild slope model, Losada et al. (1996a) for a submerged breakwater, with 1:1.5 slopes on both sides, a crown width of 0.61 m and constructed with an impermeable core and an armour layer of quarrystones with mean weight of 25 Kg. The water depth at the toe of the structure was 1.50 m. The mean water level variation is solved using the time-averaged and depth-integrated momentum equation

\[
\frac{\partial S_{xx}}{\partial x} = -\rho g (h + \bar{\eta}) \frac{\partial \bar{\eta}}{\partial x} 
\]

where \( S_{xx} \) is expressed as in eq. (10) and the corresponding transfer functions. Wave breaking takes place along the crest and therefore, it is considered in the modelling using Rojanakamthorn et al. (1990), Méndez et al. (1998).

In general, there is a good agreement between the experimental and numerical wave height transformation for both the rectangular and the trapezoidal breakwaters under breaking and non-breaking conditions. The modulation of wave height induced by the reflection in front and above the breakwater is very well reproduced by the theory. However, behind the breakwater only the trapezoidal breakwater model does reproduce the modulation well since it considers reflection induced by the slope. This is due to the fact that the eigenfunction model used for the rectangular breakwater assumes the region leewards the structure to be semi-infinite.

Results show that the mean water level presents a set-up induced by the reduction in wave height due to dissipation even without breaking. However, results have shown that the portion of the total set-up induced by wave breaking is more important than the part induced by dissipation inside the pores.

In Fig. 4 the theoretical results for wave height variation and nondimensional mean water
Figure 2. Wave height and mean water level evolution along two different submerged steps (impermeable and permeable)
level are compared with the experimental results for artificial seaweed included in Kobayashi et al. (1991). Unfortunately, experimental mean water level data are not available. The experiment was carried out in a 27 m long, 0.5 m wide and 0.7 m high wave flume. The artificial seaweed was made of polypropylene strips with a specific gravity $s = \rho_p = 0.9$. The length, width and thickness of each strip was: $d_v = 0.25 m$, $b_v = 5.2 cm$ and $t_v = 0.03 mm$, respectively. Each of the strips was fixed to a wire net at the bottom of the flume and placed to produce maximum resistance to the incident flow. The vegetation field, located at the center of the flume had a total width of $b = 8 m$, (Kobayashi et al., 1993, fig. 1). The number of uniformly distributed strips per unit horizontal area was $N = 1110$ and $1490$ units/m$^2$.

The wave height evolution is well reproduced by the model including the modulation in front and above the vegetation field induced by reflection. Associated with the wave height decay along the vegetation field there is a clear wave set-up showing similar modulations as the wave height.

Fig. 5 shows the wave height evolution and mean water level variation on an artificial *laminaria hyperborea* field for regular and irregular wave conditions (a: JONSWAP spectrum, $H_{rms,i} = 1.41 m$, $k_p h = 0.65$, $\gamma = 3.3$, $h = 6 m$) and (b: JONSWAP spectrum, $H_{rms,i} = 1.51 m$, $k_p h = 0.51$, $\gamma = 3.3$, $h = 6 m$). $H_{rms,i}$ is the incident root-mean-square wave height. The theoretical results are compared with the experimental data in Dubi (1995). $C_D$ is the drag coefficient used for calibration.

The theoretical and experimental results show the modulation induced by the reflection
Figure 4. Wave height and mean water level evolution in a submerged vegetation field. Comparison between experimental data (Kobayashi et al., 1991) and numerical model results.

at the front and back face of the vegetation field. This modulation is not present in the theoretical models presented in Dubi and Torum (1994, 1996) since they did not consider the regions offshore and leewards the vegetation field in their first order solution. Comparing with Fig. 4, it can be seen that for irregular waves, the modulation of $H_{rms}$ along the vegetation field is less pronounced than for regular waves. Even if the agreement between theoretical and experimental results is good it has to be pointed out that the artificial seaweed used in Dubi (1995) is characterized by, at least, two degrees of freedom and not only one as assumed by the model presented in this paper. In fact, the kelp plant consists of a stipe, which can be regarded as a slender vertical cylinder with uniformly distributed mass and a frond. Therefore, the obtained $C_D$ represents a depth-averaged value.

The $x-$components of the radiation stress and energy flux are presented in Fig. 6 for a submerged vegetation field. The second order magnitudes are nondimensionalized using the average energy and the energy flux, respectively. For irregular waves and considering a TMA spectrum with the given characteristics, results are shown for two different $\mu$ values. The nondimensional friction coefficient $\mu$, is equivalent to the friction coefficient, $f$, for porous media and can be calculated using Lorentz hypothesis of equivalent work, Méndez.
Figure 5. Root-mean-square wave height and mean water level evolution in a submerged vegetation field. Comparison between experimental data (Dubi, 1995) and numerical model results.

(1997). As it can be observed, in front of the vegetation field the energy flux is not very much affected by its presence taking an almost identical value for both $\mu$ values considered. However, as the waves propagate along the vegetation field the energy flux strongly decays especially for the higher friction coefficient. In the leeward region the energy flux magnitude is constant since it has been assumed this region to be semi-infinite.

The radiation stress shows a similar pattern only varying in front of the vegetation field, where, for $\mu = 0.5$, the higher reflection induces a modulation of $S_{zx}$. The strong decay in the radiation stress will result in a set-up along the vegetation field.

For oblique incident regular waves, Fig. 7 presents the evolution of the nondimensional radiation stress component $S_{xy}$ along an emerged permeable vertical structure. Different angles of incidence are considered. From the results it can be concluded that $S_{xy}$ decreases towards the lee face of the vertical structure due to the dissipation induced by the structure. Furthermore, increasing oblique incidence results in higher $S_{xy}$ values until a maximum close to 45° is reached. For higher angle values $S_{xy}$ decreases due to the fact that $S_{xy}$ is proportional to $\sin 2\theta$.

Figure 7. Radiation stress $S_{xy}$ evolution in an emerged permeable breakwater.
Conclusions and further applications

In this paper the influence of reflection and dissipation on wave induced mean quantities is analyzed. The obtained results show that any reflective and dissipative natural, such as vegetation fields, or artificial structure, like emerged or submerged breakwaters induce spatial variations of the mean quantities, water level, mass flux, momentum flux and energy flux, among others, similarly to the surf zone. Computed values are compared to experimental results from different sources. Generally speaking, the agreement between theory and experimentation is very good. From these results the following conclusions may be drawn.

1. The transfer functions are a very convenient and useful tool for computing easy and efficiently the mean quantities in the vicinity of natural or artificial coastal structures.
2. In front of and above the reflective structures considered second order magnitudes are modulated due to the reflection induced by the structure.
3. Over the structure mean momentum flux and mean energy flux are attenuated even if no breaking is present. The dissipation rate is dependent upon wave conditions, breakwater geometry and porous material or vegetation characteristics.
4. The mean water level variations, due to the radiation stress gradients induced by the dissipation associated with both breaking and friction, show a maximum set-down at the beginning of the structure and a progressive increase along the crest reaching its maximum value at the crest or at the leeside of the structure depending on the reflecting conditions. However, it is noticed that the set-up due to breaking is much more important than the one due to dissipation induced by the porous material.
5. The present method can be used to analyze further coastal problems such as: the influence of the mean water level variations on the functionality and stability of breakwaters, the analysis of water table dynamics in shingle beaches, the influence of the presence of dissipative structures on beach profile dynamic models or the evaluation of longshore currents induced by rubble-mound breakwaters, Baquerizo and Losada (1998).

Appendix

In this Appendix the transfer functions, including evanescent modes, in eqs. (2) to (12) for regular incident waves impinging on a submerged permeable step of height $\alpha h$ are given as an example.

\begin{equation}
H_n(x) = \begin{cases} 
\sum_{n=0}^{\infty} \left[ e^{-i q_n x} + R_n e^{i q_n x} \right] & x \leq 0 \\
\sum_{n=0}^{\infty} \left[ A_n e^{-i Q_n x} + B_n e^{i Q_n (x-b)} \right] & 0 \leq x \leq b \\
\sum_{n=0}^{\infty} T_n e^{-i q_n (x-b)} & x \geq b 
\end{cases}
\tag{A.1}
\end{equation}

\begin{equation}
H_u(x, z) = \begin{cases} 
\sum_{n=0}^{\infty} i q_n I_n(z) \left[ e^{-i q_n x} + R_n e^{i q_n x} \right] & x \leq 0 \\
\sum_{n=0}^{\infty} i Q_n M_n(z) \left[ -A_n e^{-i Q_n x} + B_n e^{i Q_n (x-b)} \right] & 0 \leq x \leq b \\
\sum_{n=0}^{\infty} i Q_n P_n(z) \left[ -A_n e^{-i Q_n x} + B_n e^{i Q_n (x-b)} \right] & -h < z \leq 0 \\
\sum_{n=0}^{\infty} -i q_n I_n(z) T_n e^{-i q_n (x-b)} & x \geq b 
\end{cases}
\tag{A.2}
\end{equation}

\begin{equation}
H_w(x, z) = \begin{cases} 
\sum_{n=0}^{\infty} \frac{d I_n(z)}{dz} \left[ e^{-i q_n x} + R_n e^{i q_n x} \right] & x \leq 0 \\
\sum_{n=0}^{\infty} \frac{d M_n(z)}{dz} \left[ A_n e^{-i Q_n x} + B_n e^{i Q_n (x-b)} \right] & 0 \leq x \leq b \\
\sum_{n=0}^{\infty} \frac{d P_n(z)}{dz} \left[ -A_n e^{-i Q_n x} + B_n e^{i Q_n (x-b)} \right] & -h \leq z \leq 0 \\
\sum_{n=0}^{\infty} \frac{d I_n(z)}{dz} T_n e^{-i q_n (x-b)} & x \geq b 
\end{cases}
\tag{A.3}
\end{equation}

where $q_n = \sqrt{k_n^2 - \lambda^2}$, $\lambda = k_o \sin \theta$, $\theta$ is the wave incidence angle and $k_o$ the progressive wavenumber in the offshore region. $I_n(z)$, $M_n(z)$ and $P_n(z)$ are depth functions in the different regions defined associated to the $n$th evanescent mode, Losada et al. (1996a). $R_n$ and $T_n$ are the reflection and transmission coefficients, $R_n$ and $T_n$ are the nondimensional coefficients of the evanescent mode $n$, and $k_n$ is the eigenvalue (wave number) that satisfies the standard dispersion relationship

\begin{equation}
\sigma^2 = g k_n \tanh k_n h
\tag{A.5}
\end{equation}
where $\sigma$ is the wave frequency.

$aA_n$ and $aB_n$ are the complex amplitudes of the waves propagating above the breakwater and $Q_n = \sqrt{K_n^2 - \lambda^2}$. For normal incidence $Q_n = K_n$.

The complex wavenumber $K_n$ can be determined using the complex dispersion equation derived by Losada et al. (1996a) for wave propagation over a porous medium,

$$\sigma^2 - gK_n \tanh K_nh = F_n[\sigma^2 \tanh K_nh - gK_n]$$

where

$$F_n = \left(1 - \frac{\epsilon}{(s - if)} \right) \frac{\tanh K_n \alpha h}{1 - \frac{\epsilon}{(s - if)} \tanh^2 K_n \alpha h}$$

and $f$ is a linearized friction coefficient that can be obtained using the Lorentz equivalent work hypothesis, Sollitt and Cross (1972). This coefficient depends on the intrinsic characteristics of the permeable material $K_p$, intrinsic permeability, $C_f$ turbulent friction coefficient and porosity $\epsilon$. The evaluation of $f$ is flow dependent, therefore the problem has to be solved by iterations, Losada et al. (1996a).

Green-Function Analysis of a Wave Field
over Arbitrary Bathymetry

Hitoshi Nishimura and Moon-Su Kwak

Abstract

A parabolic approximation of the mild slope equation was derived in terms of polar coordinates to describe waves diverging from a point source. Numerical solutions of the equation were used to extend the application of Green-function method to a wave field over arbitrary bathymetry. Validity of the equation obtained and usefulness of the numerical model were demonstrated through trial computations of wave diffraction, refraction and multiple reflection in model basins and in an actual harbor.

Introduction

Green-function method is the most convenient and rational method for analyzing a wave field including diffraction and multiple reflection. It is, however, difficult to apply the method to a basin with non-uniform depth. Barailler and Gaillard's (1967) approach to cope with this problem was not quite successful, and so far computation of this type has been performed only under the condition of uniform depth.

In the method of this type, distribution of wave sources is assumed on every physical or computational boundary, and a horizontally two-dimensional wave field in question is expressed by superposition of waves emitting from all these sources. Application of the method will be readily extended if we could numerically give such unit solutions for arbitrary bathymetry to replace the Hankel function for a horizontal bed. For this purpose, first a parabolic equation is derived after Radder (1979) in the framework of polar coordinates, and then its numerical solutions are superposed to describe wave fields in model and actual harbors.

Parabolic Equation for Unit Solutions

The polar coordinate system will be convenient to describe circular waves emitting from a point source, and it is preferable to provide a rather simple basic equation for them since it has to be numerically solved as many times as the number of wave sources distributed. In this context, a parabolic approximation of the mild slope equation seems to be suitable. Note that a significant part of wave diffraction is automatically taken into account through super-position of unit solutions in the present scheme.

The mild slope equation with respect to the complex wave amplitude is written as

\[ \nabla \left( C_C \nabla \psi \right) + k^2 C_C \psi = 0 \]  

(1)

where \( k \) is the wave number, \( C \) is the phase velocity, and \( C_s \) is the group velocity of waves, all depending on the local water depth.

As is widely known, a conversion of the dependent variable \( \psi \) reduces the above equation to the form of Helmholtz equation

\[ \nabla^2 \phi + k^2 \phi = 0 \]  

(3)

or, in terms of the polar coordinates \((r, \theta)\),

\[ \frac{\partial^2 \phi}{\partial r^2} + \frac{1}{r} \frac{\partial \phi}{\partial r} + \frac{1}{r^2} \frac{\partial^2 \phi}{\partial \theta^2} + k^2 \phi = 0 \]  

(4)

Now, \( \phi \) is decomposed into two parts \( \phi^+ \) and \( \phi^- \), each corresponding to waves diverging from and converging to the origin:

\[ \phi = \phi^+ + \phi^- \]  

(5)

and its gradient is also decomposed in the form of

\[ \frac{\partial \phi}{\partial r} = A^+ \phi^+ + A^- \phi^- \]  

(6)

Eliminating \( \phi^- \) from these two expressions, we obtain

\[ \phi^+ = - \frac{A^-}{A^+ - A^-} \phi + \frac{1}{A^+ - A^-} \frac{\partial \phi}{\partial r} \]  

(7)

Introduction of asymptotic expressions of Hankel function
\[
\phi^+ \approx \sqrt{\frac{2}{\pi kr}} \cdot \exp \left[ \pm i \left( kr - \frac{\pi}{4} \right) \right] \tag{8}
\]
leads to
\[
\frac{\partial \phi^\pm}{\partial r} = \left( -\frac{1}{2r} \pm i k \right) \phi^\pm \tag{9}
\]
or, through comparison with Eq. (6),
\[
A^\pm = -\frac{1}{2r} \pm ik \tag{10}
\]
It is noted that the derivatives of the wave number \( k \) were ignored; the validity of such approximation was discussed by Corones (1975).

Equation (7) is then rewritten as
\[
\phi^+ = \alpha \phi + \beta \frac{\partial \phi}{\partial r} \tag{11}
\]
where
\[
\alpha = \frac{1}{2} - \frac{i}{4kr} , \quad \beta = -\frac{i}{2k} \tag{12}
\]
and, therefore,
\[
\frac{\partial \phi^+}{\partial r} = \frac{\partial \alpha}{\partial r} + \left( \alpha + \frac{\partial \beta}{\partial r} \right) \frac{\partial \phi}{\partial r} + \beta \frac{\partial^2 \phi}{\partial r^2} \tag{13}
\]
Using Eq. (4), the second derivative term can be eliminated as
\[
\frac{\partial \phi^+}{\partial r} = \left( \frac{\partial \alpha}{\partial r} - \beta kr - \frac{\beta}{r^2} \frac{\partial^2}{\partial \theta^2} \right) \phi + \left( \alpha + \frac{\partial \beta}{\partial r} - \frac{\beta}{r} \right) \frac{\partial \phi}{\partial r} \tag{14}
\]
Considering Eqs. (5) and (6) and excluding the converging waves, we finally obtain a parabolic equation for diverging waves as follows:
\[
\frac{\partial \phi}{\partial r} = \left( -\frac{1}{2r} + ik + \frac{i}{8kr} \right) \phi + \frac{i}{2kr^2} \frac{\partial^2 \phi}{\partial \theta^2} \tag{15}
\]
Computation of Unit Solution

To solve Eq. (15) for a wave source, the area of interest is covered by a local \( r - \theta \) grid with its origin at the source point (Fig. 1). The equation as well as variables is discretized, where the Crank-Nicolson scheme is adopted as in normal Cartesian coordinate analyses. In this case, the origin is a singular point that rejects numerical treatment. A Hankel function solution, therefore, has to be assumed in a very small circular region around the origin, that is, a small area of uniform depth is supposed in the
immediate vicinity of the source point. Starting from the outer edge of the central region, outward marching scheme computation is repeated until reaching the computational boundary.

Validity of the basic equation (15) was examined through trial computation under the simplest condition of uniform depth. Figure 2 shows the numerically calculated amplitude and phase of diverging waves in comparison with the Hankel function. It is seen that the numerical solution is sufficiently accurate except for the close vicinity of the origin. Introduction of asymptotic expression in the derivation of the equation inevitably causes abrupt reduction of accuracy near the origin. Our tentative conclusion is that the equation describes diverging waves with sufficient accuracy for the range of \( kr > 0.8 \).

Figure 2 illustrates calculated crestlines of diverging waves over varying depth. In this example, straight and parallel depth contours were assumed with linearly varying wave celerity in the on-offshore \((x)\) direction, so that wave refraction can be analytically solved as also shown in the figure. A good agreement is observed between numerical and analytical solutions except for extremely shallow water area, where the relatively coarse computational grid (large grid spacing-wavelength ratio) resulted in reduction of accuracy.

Figure 1. Computational \( r - \theta \) grid.
Figure 2. Comparison of numerical solution with the Hankel function.
Application of Generalized Green-Function Method

A water region of interest is first divided into several convex polygonal subregions surrounded by physical and imaginary (artificial) boundaries. Physical boundaries are more or less reflective, and imaginary boundaries are either absorbing or transmissive (merely separating subregions). Continuation conditions of both surface elevation and gradient are imposed along a common boundary connecting two subregions. Wave sources are distributed on every boundary, each producing a field of diverging waves.

One can avoid this procedure of region dividing. If the entire water area is regarded as one region, then all the wave sources have global influence even beyond the physical boundaries. Definition of subregions and local wave sources for it makes the physical implication of each source much more explicit, some representing wave reflection and the other wave transmission. This is important for simple and rational treatment of partial reflection and transmission of waves. In addition to this, computational labor is largely saved by handling multiple subregions of smaller size when unit wave fields are numerically calculated.

An overall wave field in a subregion is given by summation of unit waves from all the sources on its boundaries, automatically satisfying the linear basic equation. Intensities of the wave sources are to be determined.
so as to satisfy all the boundary conditions imposed. Rational treatment of boundary conditions of various types was discussed by Nishimura et al. (1994, 1997). Note that the source intensities cannot be correctly determined on the basis of local energy conservation (See also Lee, 1971).

(1) Model harbor with sloping bottom

Figure 3 illustrates a model harbor whose bottom is uniformly sloped. The plan shape of the model was specified by Coastal Engineering Committee, JSCE, for comparison of computational methods. The entire region was divided into four subregions R₁ to R₄ as shown in the figure, and the above described Green-function method was applied to this problem. All the boundaries were divided into small segment of 1/20 wavelength, and the effect of each segment was represented by a wave source located at its middle point. Refraction of unit waves were taken into account by applying the parabolic equation (15) for surface elevation and gradient of unit waves. Reflection coefficient was assumed to be unity for vertical walls and 0.4 for wave absorbing boundaries.

The relative wave height distribution thus obtained is described in Fig. 4 in comparison with the result of hydraulic experiments conducted under similar conditions. It is seen that the computation well reproduces a complicated field of standing waves after multiple diffraction due to breakwaters and multiple reflection due to harbor walls. Diffracted waves

![Figure 4. Model basin with sloping bottom.](image-url)
Figure 5. Distribution of relative wave height (period = 0.70s).

Figure 6. Distribution of relative wave height (period = 0.72s).
are often underestimated in numerical models of direct integration type, but no such tendency is observed here. Sound estimation of wave diffraction is a notable merit of this method.

Under the condition of multiple reflection, a slight difference in the wave period causes significant change in the wave height distribution as demonstrated in Fig. 5. Computation well follows this sensitive response of the basin.

(2) Actual basin with arbitrary bathymetry

For further examination of the present method, it was applied to a wave field in Soma Harbor, Fukushima Pref., Japan. Figure 6 shows location of the harbor as well as depth contours in and around it. The incident wave height and period were assumed at 3.5m and 8.0s. A comparison of calculation and experiment is given in Fig. 7, where the agreement is again reasonable. Slight reduction in accuracy as compared with the previous example may be ascribed to the uncertain evaluation of reflection coefficients (assumed at 0.9 for vertical walls and 0.3 for absorbing walls) and lower resolution (boundary segments of 1/10 wavelength).

![Figure 7. Soma Harbor.](image-url)
Figure 8. Distribution of relative wave height in Soma Harbor.
Concluding Remarks

A parabolic equation for waves diverging from a point source was derived using asymptotic expression of the Hankel function. It proved that numerical solutions of the equation well works as unit waves in applying the Green-function method to a basin with arbitrary bathymetry. This numerical model quite accurately simulates refraction, diffraction and multiple reflection of waves, providing a useful tool for linear analysis of a horizontally two-dimensional wave field.

Acknowledgment

The authors' gratitude is due to Tetra Co., Ltd., for kindly providing experimental data both for the standard model basin and for Soma Harbor.

Abstract

Wave induced pore pressure and instantaneous liquefaction are known to occur and cause loss of bearing capacity of sand. Wave bottom pressure \( p \) forms the boundary condition for the wave induced pore pressure. It is believed that not only variation of the pressure itself, but also the variations of its first and second order spatial derivative play an important role in the formation of liquefaction. An experimental and a preliminary numerical study on unidirectional water wave propagation over a bar are presented. Emphasis is placed upon investigation on the wave induced pressure gradient at the seabed. Single sinusoidal, two-component sinusoidal and five-component sinusoidal waves are investigated in a wave flume of constant water density \( \rho \). Only the results for single sinusoidal waves are reported herein. The variation of the dimensionless pressure gradient \( C_p = (\partial p / \partial x) / (\rho g) \) was within \( \pm 0.4 \) for all experiments with a tendency of larger values for downslope gradients (negative values) than for upslope. \( g \) is the acceleration gravity. The numerical results, based on the two-dimensional Green-Naghdi theory for fluid sheets - level II, compare well for sea bed pressures and gradients, but the sea surface does not fit the observations so well.

The Numerical Model

Introduction

A new generation water wave model concept has developed during the last two decades. Its fundamental principle is known as the Green-Naghdi theory of fluid sheets,
hereafter referred to simply as GN theory (Green, Laws and Naghdi, 1974). The foundation for its application in water waves is discussed in the original work of Green and Naghdi (1986, 1987).

Webster and Kim (1990) use this theory to investigate the dispersion of large amplitude gravity waves in deep water. A level III GN-theory (a nonlinear 2D fluid sheet model) is used to simulate a train of steep regular waves and a random wave record corresponding to steep seas measured during hurricane Camille. An analysis of the simulated random wave record shows that linear dispersion, Airy theory with Wheeler stretching, often assumed for referring a random wave train from one point in space to another, does not result in conservative estimates of two important quantities used in design: the crest elevation and particle velocity under the crest. In regular waves the model reproduce (and confirmed by laboratory experiments) the tendency that the leading edge of a packet of relatively steep waves always appears to break before very many waves are created.

Demirbilek and Webster (1992a, 1992b) derived a version of the GN-theory applicable for shallow water to moderate water depths and where the water depth may vary rapidly. The model named GNWAVE3 is as a nonlinear 2D numerical wave flume that simulates the wave transformation in shallow water in a finite difference scheme. Areas of applications may be wave transformation over submerged obstacles, reflections of waves, time history of bottom-mounted pressure gage measurements for estimation of surface wave conditions in coastal design projects. The theory is particularly suited for the collision of waves with natural and man-made structures, and their impact on preventive and hydraulic structures. The model is intended to be implemented in the Coastal Modeling System (CMS) provided by the Waterways Experiment Station, U.S. Army Corps of Engineers, Vicksburg, USA.

The purpose of using GNWAVE3 in this project is to study the feasibility of its application on the computation of wave motion over a bar. Later, it would be of interest to compare the performance of this model to results obtained with numerical wave flumes based on more conventional wave models (e.g. the Boussinesq formulation) and with more data from field and/or laboratory experiments.

Overview of theory

This overview follows the description of the model development given in Demirbilek and Webster (1992a). The GN approach to water wave theory is fundamentally different from the perturbation methods used in classical wave theory. In contrast to the Stokes and Boussinesq theories, the equations of motion in the GN theory are derived by enforcing exact kinematic and dynamic boundary conditions on the free surface and on the bottom, and by enforcing conservation of mass, but approximating the conservation of momentum. In short, the treatment of the field equation and nonlinear boundary conditions by perturbation methods and GN theory are the antithesis of one another. The essential clue
of GN wave theory is that the vertical dependence of the kinematics of the fluid flow is restricted and prescribed a-priori. That is, a set of shape-functions (like the $e^{ikz}$ in deep water Airy theory) that serve as a basis for the vertical dependence is introduced. In this way the method achieves a simplification by reducing the computational domain from three dimensions to two (or from two dimensions to one in the case of 2D flows). The theory also yields governing equations for the flow, which are solved numerically in a more efficient manner than those from a conventional finite-difference, finite-element or similar schemes.

In the following, the theoretical development behind GNWAVE3 is outlined. Although GNWAVE3 is a model for 2D inviscid flow, the development of GN theory in general is not at all limited to such fluids. The governing equations are the GN level II shallow water equations originally constructed by Shields (1986) and reported by Shields and Webster (1988). The coordinate system $Oxyz$, with the $Oz$ axis oriented vertically up and the $Oxy$ plane horizontal and corresponding to the undisturbed free surface. We assume that the fluid velocity $v(x,y,z;t) = (u, 0, w)$ can be approximated as

$$v(x, z; t) = \sum_{n=0}^{2} W_n(x; t) \psi_n(z)$$  \hspace{1cm} (1)

where

$$W_n = (u_n, 0, w_n) ; \hspace{0.5cm} n = 0, 1, 2$$  \hspace{1cm} (2)

are vector coefficients associated with the shape-functions $\psi_n(z)$. The vector coefficients are unknown spacial- and time-dependent functions to be determined as a part of the solution. In the general GN-theory the number of shape-functions is not fixed to three. The theory put restrictions on the choice of shape-functions to those that possess the following property:

$$\int dz \nu^n \psi^m = \sum_{r=0}^{n} a^n_r \psi_r , \hspace{0.5cm} (n \leq m)$$  \hspace{1cm} (3)

$a^n_r$ are some constants. There are many function sets that satisfy (3). For instance, Webster and Kim (1990) use $\psi_n(z) = z^n \ e^{\alpha z}$, $n = 0, 1, 2$ as their set of shape-functions for deep-water waves. In GNWAVE3 polynomial functions $\psi_n(z) = z^n$ form the shape-function set. The linear function $\psi_1 = z$ was selected since it coincides with the $z$ dependence found in linear shallow water wave theory.

The kinematic assumption (1) is inserted into the equations for conservation of mass, conservation of momentum (Euler equations), and the kinematic boundary conditions on the free surface $z = \beta(x; t)$ and at the bottom $z = \alpha(x, t)$. These equations are all satisfied identically by this method. When (1) is substituted into the momentum equation and the resulting equation is required to be satisfied everywhere in the fluid domain, many more equations than the required number would be obtained. To overcome this difficulty, the shape-functions $\psi_m$ are used as weighting functions to develop the required number of equations to be solved. Euler's equations are multiplied by each $\psi_n(z)$ and integrated from
the sea bottom to the free surface. The weighted momentum equations express the conservation of momentum in some integral sense and consequently the conservation of momentum is satisfied only approximately. The determination of the evolution equations in terms of derivatives of the primary variables requires a prodigious amount of algebraic manipulation. For theory of level I or of level II it is not too difficult to obtain this by hand, however, for higher level of the theory mathematical symbolic processors should be used.

In GNWAVE3 the velocity profile is modeled as

\[ u(x, z; t) = u_0(x; t) + u_1(x; t)z + u_2(x; t)z^2 \]  
\[ w(x, z; t) = w_0(x; t) + w_1(x; t)z + w_2(x; t)z^2 \]

Fulfillment of the continuity equation implies that \( u_2(x; t) = 0 \), and consequently the horizontal velocity profile is restricted to linear variation with depth.

It is now possible to eliminate the vertical vector coefficients as well as the integrated pressure coefficients. The final sets of governing equations involving the three unknown functions \( \beta(x; t), u_0(x; t), u_1(x; t) \) (free surface elevation and the two remaining coefficients of the horizontal velocity respectively) are rather difficult to derive without the help of mathematical symbolic software.

Although the equations may seem large and complicated they may be integrated with little difficulty. Together they form a system of three coupled, partial differential equations that are of first order in time and of third order in space and the highest order of mixed derivatives are of first order in time and second order in space. Thus the system of equations can be summarized as

\[ \mathbf{A} \mathbf{\dot{\xi}} + \mathbf{B} \frac{\partial \xi}{\partial x} + \mathbf{C} \frac{\partial^2 \xi}{\partial x^2} = \mathbf{g} ; \quad \xi = (\beta, u_0, u_1)^T. \]  

The matrices \( \mathbf{A}, \mathbf{B}, \mathbf{C} \) and the vector \( \mathbf{g} \) are functions of \( x \) and \( \beta, u_0, u_1 \) and their derivatives. With prescribed boundary conditions at both ends of the domain the equations can be solved through a numerical technique. The domain of \( x \) over which a solution to the equations is desired is assumed to be a finite difference scheme of uniformly spaced grids in the \( x \)-direction spaced a distance \( \Delta x \) apart. Time is assumed to be discretised with intervals \( \Delta t \). The spatial distribution of \( \xi \) is first found by a central difference technique combined with a forward backward substitution. The updated values for \( \xi \) is obtained through a two step forward explicit scheme.
The Pressure Relation

Taking the vector dot product between the vectored equations of motion and the vertical unity vector \( e_3 \) and integrating from the sea bed to the free surface, we obtain an explicit expression for the bottom pressure (\( e_i \) is the \( x \)-direction unity vector).

\[
\int_a^b \left( \frac{\partial (\rho v)}{\partial t} + u \frac{\partial \rho v}{\partial x} + w \frac{\partial \rho v}{\partial z} \right) e_3 \, dz = \int_a^b \left( - \frac{\partial p}{\partial x} e_1 - \frac{\partial p}{\partial z} e_3 + \rho g e_3 \right) \cdot e_3 \, dz
\]

\[
\int_a^b \left( \frac{\partial (\rho v)}{\partial t} + u \frac{\partial \rho v}{\partial x} + w \frac{\partial \rho v}{\partial z} \right) \, dz = \int_a^b \left( - \frac{\partial p}{\partial z} - \rho g \right) \, dz = - (p_b - p_a) + \rho g (\alpha - \beta)
\]

Assuming the surface pressure \( p_s \) equal to zero and denoting the bottom pressure \( p_a = \bar{p} \) this results in:

\[
\bar{p} = - \rho g (\alpha - \beta) + \int_a^b \left( \frac{\partial (\rho v)}{\partial t} + u \frac{\partial \rho v}{\partial x} + w \frac{\partial \rho v}{\partial z} \right) \, dz
\]

Within the limits of level II theory and uneven bottom this expression can be rewritten in terms of the variables \( u_0 \) and \( u_1 \) and their derivatives with respect to time and horizontal variation and \( \beta \) in addition to the known bottom variation \( \alpha(x) \). The resulting equation is:

\[
\bar{p} = \bar{p}_r + \bar{p}_{u_1} \frac{\partial u_0}{\partial t} + \bar{p}_{u_1} \frac{\partial^2 u_0}{\partial x \partial t} + \bar{p}_{u_1} \frac{\partial u_1}{\partial t} + \bar{p}_{u_{11}} \frac{\partial u_1}{\partial x} \frac{\partial u_1}{\partial x} \frac{\partial u_1}{\partial x}
\]

where

\[
\bar{p}_r = - \left( \rho g (\alpha - \beta) - \rho (\alpha - \beta)^2 \left( \frac{\partial u_0}{\partial x} \right)^2 \right) / 2 + \rho \left( \frac{\partial \alpha}{\partial x} \right)^2 (\alpha - \beta) u_1 (2u_0 + (\alpha + \beta)u_1) / 2
\]

\[
+ \rho \frac{\partial^2 \alpha}{\partial x^2} \left( \frac{\partial u_0}{\partial x} \right)^2 (2u_0 + (\alpha + \beta)u_1) / 2 - \rho \frac{\partial \alpha}{\partial x} (\alpha + \beta) \frac{\partial u_0}{\partial x} (u_0 + \beta u_1)
\]

\[
+ \rho (\alpha - \beta)^2 \frac{\partial^2 u_0}{\partial x^2} (3u_0 + (\alpha + 2\beta)u_1) / 6 - \rho (\alpha - \beta)^2 (\alpha + \beta) \frac{\partial u_0}{\partial x} \frac{\partial u_1}{\partial x} / 12
\]

\[
+ \rho \frac{\partial \alpha}{\partial x} (\alpha - \beta) (3\alpha - \beta) u_0 + \alpha (\alpha + \beta) u_1 \frac{\partial u_1}{\partial x} / 12 - \rho (\alpha - \beta)^2 (\alpha + \beta)^2 \left( \frac{\partial u_1}{\partial x} \right)^2 / 8
\]

\[
+ \rho (\alpha - \beta)^2 \left( 4(\alpha + \beta) u_0 + 3(\alpha + \beta)^2 u_1 \right) \frac{\partial^2 u_1}{\partial x^2} / 24
\]

\[
\bar{p}_{u_1} = - \frac{\partial \alpha}{\partial x} (\alpha - \beta) \rho, \quad \bar{p}_{u_{11}} = (\alpha - \beta)^2 \rho / 2, \quad \bar{p}_{u_1} = - \alpha \frac{\partial \alpha}{\partial x} (\alpha - \beta) \rho \quad \text{and}
\]

\[
\bar{p}_{u_{11}} = (\alpha - \beta)^2 (2\alpha + \beta) \rho / 6.
\]
Initial Conditions

For this shallow water study it is assumed that the time history of the waves is known at \( x = 0 \). The waves are input not only as local wave height history \( \beta(0,t) \), but also as a history of the corresponding values of the other variables in this Level II theory \( (u_0(0,t) \text{ and } u_1(0,t)) \). These variables are obtained from the solution of steady waves on a flow (linearized for small wave amplitude and flow speed = - celerity of the waves). These linear solutions for waves propagating with a celerity \( c \) are:

\[
\beta(0,t) = \beta_0 \cos(kx - \omega t) = \beta_0 \cos(k(x - ct))
\]

\[
u_0(0,t) = \beta_0 \frac{12g(20 + 7(kd_s)^2)}{c(240 + 104(kd_s)^2 + 3(kd_s)^4)} \cos(\omega t)
\]

\[
u_1(0,t) = \beta_0 \frac{120g(kd_s)^2}{cd_s(240 + 104(kd_s)^2 + 3(kd_s)^4)} \cos(\omega t)
\]

\[
c = \sqrt{\frac{24gd_s((kd_s)^2 + 10)}{240 + 104(kd_s)^2 + 3(kd_s)^4}}
\]

where \( d_s \) is the still water depth at the wave generator and \( g \) is the acceleration of gravity. Thus, \( u(0,z,t) = u_0(0,t) + u_1(0,t)z \) is the horizontal particle velocity at the wave paddle. Here \( z \) is measured positive upwards from the seabed. Figure 1 compares the distribution to that obtained from Airy wave theory, in the case of a \( T = 2.3 \) s wave period and a \( H = 0.2 \) m high wave in water depth of 0.6 m and of a 9.65 s wave of 3.0 m height in 35 m water depth.

![GNWAVE3 vs Airy](image1.png)

**Figure 1.** Wavemaker boundary conditions (horizontal particle velocity) in GNWAVE3 compared to Airy linear wave theory.

The boundary condition at the other end of the wave flume is modeled either as fully reflective or fully open.
GNWAVE3 Performance Example

A simple test run of GNWAVE3 shows its capability of time-simulation of waves. This test run is performed with wave-data from one of the experimental runs, but with constant water depth equal to 0.70 m. Other inputs to the model is the same as for the reference experiment bp136150 described later. A time-series recording at x=5 meters is shown in Figure 2 and a snapshot of the surface elevation after 39.95 seconds is shown in Figure 3. The time function in Figure 2 has been analyzed with respect to zero-upcrossings and also a peak-to-peak analysis to establish two sequences of wave periods. Similarly the function in Figure 3 has been analyzed with respect to zero-upcrossings, and the sequence of identified wave-lengths was found. The results are seen in Figure 4 together with the average values. In Table 1 the derived wave parameters are compared to values obtained by Airy wave theory and by an analytical nonlinear model known as the Fourier-series model, both available in (ACES, 1992). The Fourier-series model requires knowledge of the vertically integrated flow in the flume. It was set equal to zero in this example.

GNWAVE3, which is a numerical model based on the first principles of conservation of momentum and continuity of mass demonstrates stability and accuracy that of sufficient quality for this example test. E.g. the deviations between GNWAVE3 results and Airy theory are less 0.5 % both in wavelength and celerity.

Laboratory Experiments

Setup

The experimental setup is shown in Figure 5. The experiments were carried out in a wave flume with a trapezoidal bar. The flume is 40 m long, 5 m wide. Around the bar the water depth was 0.70 m, on the bar plateau the depth was 0.25 m. Free surface waves were measured by parallel-wire resistance gauges at three stations. Two pressure sensors of type Kistler 4043 were installed in the sea bed near the top break of the slope at a location were waves were expected to break. The numerical model was gauged at the same five locations, see Table 2 and Figure 5. Gauge 1 measures surface elevation at the beginning of the slope, Gauge 2 measures the surface elevation near the top break of the slope, Gauge 3 measures the surface elevation on the bar plateau. Gauge 4 and Gauge 5 measures bottom pressures at Gauge 2, from which the bottom pressure gradient can be estimated by computing the differences. All the gauges were leveled to zero before each run, thus only the dynamical part of the processes were recorded. The accuracy of the gauges is indicated in Table 2. However some zero-drift was detected during the analysis of data, thus the mean levels of the processes have been somewhat adjusted before the final presentation.
Results

The experiments included one-component, two-component and five-component sinusoidal waves. The results shown below are for one-component waves only. Preliminary inspection of the other runs reveals similar pressure gradients. Results for both breaking and nonbreaking waves are included. Table 3 summarizes the results in which:

- $H_1$ is an estimate for the wave height at Gauge 1; $H_1 = (\eta_{1,\max} - \eta_{1,\min})$.
- $T$ is an estimate for the wave period = average time between peaks over about a 20 s interval.
- $H_2$ is an estimate for the wave height at Gauge 2; $H_2 = (\eta_{2,\max} - \eta_{2,\min})$.
- $H_0$ is the deep water wave height given by the Airy theory shoaling coefficient (computed from $H_1$, $T$ and $d_1$; $d_1$ - the still water depth at Gauge 1).
- $\lambda_0$ is the deep water wave length; $\lambda_0 = gT^2 / 2\pi$.
- $\lambda_S$ is the wave length in the constant depth part of the flume in front of the slope determined by the Airy wave theory: $\lambda_S = 2\pi/k_S$ where $k_S$ is given by: $\omega^2 = gk_S \tanh k_sd_S$ and $\omega = 2\pi / T$; $d_S$ - the water depth at start of the slope).
- $C_p$ is the dimensionless dynamic pressure gradient defined as:

$$C_p = \frac{1}{\rho g} \frac{\partial p}{\partial x} \approx \frac{1}{\rho g} \frac{p_4 - p_5}{x_4 - x_5}.$$  \hspace{1cm} (14)

Column of positive index refers to positive values, column of negative index refers to negative values.

- $H_2/d_2$ is a breaking wave index (rule of thumb: waves break for approx. 0.78).

($d_2$ = depth at Gauge 2).
• $\xi$ is a local Irribarren number defined as $\xi = \tan \theta / \sqrt{H_2 / \lambda_0}$.
• $Ir$ is the Irribarren number based on deep water wave height, i.e. $Ir = \tan \theta / \sqrt{H_0 / \lambda_0}$.

The three latter parameters are used as dimensionless variables for graphical presentation. They appear to be powerful parameters to determine for which wave conditions large pressure gradients are favorable. Figure 6 shows the variability of $C_p$ with respect to these dimensionless numbers. It is seen that the values of $C_p$ are all within $\pm 0.4$ and that the largest values occur for the steepest waves just about breaking. The Irribarren number is often used for breaker type classification (Battjes, 1974), as listed below in Table 3. According to this table all runs should have resulted in spilling breakers. That was not the case. In Table 4 is listed the observed type of breakers. When these observations are held together with the results in Table 3, we see that the plunging breakers are associated with the largest values of $C_p$. $|C_p| < 0.4$ is believed not sufficient to cause liquefaction in a saturated seabed. If the seabed contains a fraction of gases these levels may be sufficient. (Moshagen, 1997).

Figure 6 Variation of the dynamic pressure gradient, $C_p$. 
Comparisons - GNWAVE3 and Experimental Results

Raw time-series plots of $\eta_1, \eta_2, \eta_3, p_4, p_5$ and $C_p$ are available for all runs in a separate report (Arntsen, 1996). In this paper only one run will be presented. The output of the model was sampled at flume positions close to those in the physical model. However, since the model operates at discrete time and spacial steps a slight difference in locations are present. The output of the model are "snapshots" at prescribed times, and/or timeseries at prescribed positions. In this run, 5 sets of timeseries were recorded at the gauges 1-5 plus a snapshot at time 30 seconds after switching the model on. The model was set to run for 40 seconds, but collapsed due to "wave breaking" after 30.1 seconds. The spatial discretization was $dx = 0.0462$ m and the time discretization was $dt = 0.0227$ s. A snapshot of the surface elevation is shown in Figure 7, while a timeseries of the surface elevation at Gauge 2 is shown in Figure 8. Figure 9 is an intercomparison between observations and results from the numerical model for the run with reference $bp136150$. Although the fit of surface elevations are not so well in shape and phase, the model seem to predict the bed pressure fluctuations excellently. Also the amplitude of the waves before breaking is in good agreement. Breaking is identified by the "noisy" results close to the downslope break-point in Figure 7. It is believed that the model would perform better if that slope has been modeled less steep. Some of the deviations in amplitude are definitively caused by that the model has not run sufficiently long time to establish a stable solution. Cf. the initial disturbances in Figure 8. All considered, the GNWAVE3 seems to be a fairly good tool for the modeling of bed-pressure fluctuations in non-breaking shallow water waves.
Conclusions

GNWAVE3 seems to be a good tool for modeling bottom-pressure fluctuations in non-breaking shallow water waves. The observed levels of pressure gradients are believed not sufficient to cause liquefaction in a saturated seabed. However, if the seabed contains fraction of gases, these levels may be sufficient.

A MULTI-LEVEL MODEL FOR NONLINEAR DISPERSIVE WATER WAVES

Susumu Kanayama¹, Hitoshi Tanaka² and Nobuo Shuto³

Abstract

To improve the accuracy of depth-integrated models for water waves, it is important to express the vertical characteristic of wave motion properly. In the present study, a multi-level model for nonlinear dispersive water waves is derived, in which vertical profile of horizontal velocity is assumed to be a chain of quadratic portions. The properties of the model in dispersion relation and second order nonlinear interactions turned out to converge to that of the Stokes wave theory, with the increasing number of layers.

Introduction

In many coastal projects, depth-integrated horizontal wave models play very important roll in estimating wave deformation. To improve the accuracy of depth-integrated model, it is important to express the vertical characteristic of wave motion properly. In the long wave model such as widely used Boussinesq equations and modified Boussinesq equations by Nwogu(1993), the vertical distribution of horizontal velocities are assumed to be quadratic. The higher order Boussinesq type equations by Kioka·Kashiwara(1995), Madsen et.al(1996), Gobbi·Kirby(1996) and so on, have high accuracy in dispersion and nonlinearity. In these equations, vertical distribution of horizontal velocities are assumed to be bi-quadratic. Different approaches were used by Nadaoka et.al(1994), Nochino(1994) and Isobe(1994), who expressed the vertical characteristic of wave motion as a combination of some components with properly chosen vertical distribution functions. The components are combined by applying the Galerkin method or variational principle to the Euler equation of motion to yield the coupled vibration equation for water waves, which have high accuracy in dispersion and nonlinearity. As vertical distribution functions, Nadaoka et.al(1994) employed hyperbolic cosine type function, whereas Nochino(1994) used the Legendre's polynomials, and Isobe(1994) chose even-order polynomial functions.

In the present work, with the objective of expressing the vertical characteristics of wave motion properly, a multi-level model for nonlinear dispersive water waves is derived and analyzed, in which vertical profile of horizontal velocity is assumed to be a chain of quadratic portions.

**Model Equations**

The conceptual diagram of the present multi-level model for nonlinear dispersive water waves is shown in Fig. 1. Static water depth is divided into several layers, whose number is \( N \) and numbered downward. The upper edge of first layer corresponds to still water level, and lower edge of \( N \)-th layer to the bottom. \( d_n \) is the thickness of \( n \)-th layer and \( h_n \), the depth of lower edge, \( u_n \) are level-averaged horizontal velocities, and \( u_b \) the horizontal velocity at the bottom.

Velocities are assumed to be expressed by (1) and (2). Horizontal velocities vary quadratically over a level, and vertical velocities linearly. For individual layer, this is the same as the standard Boussinesq equations.

\[
\begin{align*}
\mathbf{u}(z) &= \mathbf{u}_n + \frac{1}{6}(d_n^2 - 3(h_n + z)^2) \nabla (\nabla \cdot \mathbf{u}_n) \\
&\quad + \frac{1}{2}(d_n - 2(h_n + z))\{ \sum_{i=n+1}^{N} \nabla (d_i \nabla \cdot u) + \nabla h_n \nabla \cdot \mathbf{u}_n + (\mathbf{u}_b \cdot \nabla h) \} \quad (1) \\
\mathbf{w}(z) &= -\sum_{i=n+1}^{N} d_i \nabla \cdot \mathbf{u}_i - (h_n + z) \nabla \cdot \mathbf{u}_n - \mathbf{u}_b \cdot \nabla h \quad (2)
\end{align*}
\]

By substituting (1) into depth-integrated continuity equation (3), the continuity equation of multi-level model is obtained as (4).

\[
\frac{\partial \eta}{\partial t} + \nabla \int_{-h}^{\eta} \mathbf{u} \, dz = 0 \quad (3)
\]

\[
\frac{\partial \eta}{\partial t} + \sum_{i=1}^{N} \nabla (d_i u_i) + \nabla (\eta u_1) - \nabla \left[ \frac{1}{2} \eta (d_1 + \eta) \{ \sum_{i=1}^{N} \nabla (d_i \nabla \cdot u_i) + (\mathbf{u}_b \cdot \nabla h) \} \right] \quad (4)
\]

![Fig. 1. The conceptual diagram of the multi-level model for nonlinear dispersive water waves](image-url)
Momentum equations are expressed by (6), which are obtained by substituting (1) and (2) to (5), and averaging over individual layer. Equation (5) is the Euler equation of motion modified by using the irrotational condition.

\[
\frac{\partial \mathbf{u} }{\partial t} + \frac{1}{2} \nabla ( \mathbf{u} \cdot \mathbf{u} + w_s^2 ) + g \nabla \eta = - \nabla \int_z \tau \frac{\partial \mathbf{w}}{\partial t} d z'
\]

\[
\frac{\partial \mathbf{u}_n}{\partial t} + \frac{1}{2} \nabla ( \mathbf{u} \cdot \mathbf{u} + w_s^2 ) + g \nabla \eta \\
= \nabla [ \eta \sum_{i=1}^{N} d_i \nabla \cdot \frac{\partial \mathbf{u}_i}{\partial t} + \frac{1}{2} (\eta^2 \nabla \cdot \frac{\partial \mathbf{u}_i}{\partial t}) + \eta \frac{\partial \mathbf{u}_b}{\partial t} \cdot \nabla h ] \\
+ \sum_{i=1}^{N} \sum_{i+j+1}^{N} \nabla (d_i d_j \nabla \cdot \frac{\partial \mathbf{u}_i}{\partial t}) + \sum_{i=1}^{N} \frac{1}{2} \nabla (d_i^2 \nabla \cdot \frac{\partial \mathbf{u}_i}{\partial t}) \\
+ \sum_{i=n+1}^{N} d_n \nabla \frac{\partial \mathbf{u}_n}{\partial t} - \sum_{i=n+1}^{N} (\nabla h_{n-1}) d_i \nabla \cdot \frac{\partial \mathbf{u}_i}{\partial t} \\
+ \frac{1}{2} \nabla (d_n^2 \nabla \cdot \frac{\partial \mathbf{u}_n}{\partial t}) - \frac{1}{6} d_n \nabla (\nabla \cdot \frac{\partial \mathbf{u}_n}{\partial t}) \\
- \frac{1}{2} d_n (\nabla h_n) \nabla \cdot \frac{\partial \mathbf{u}_n}{\partial t} + \sum_{i=1}^{n-1} \nabla (d_i \frac{\partial \mathbf{u}_b}{\partial t} \cdot \nabla h) \\
+ \frac{1}{2} d_n \nabla (\frac{\partial \mathbf{u}_b}{\partial t} \cdot \nabla h) - (\nabla h_{n-1}) (\frac{\partial \mathbf{u}_b}{\partial t} \cdot \nabla h) 
\]

In the momentum equations (6), \( \mathbf{u}_s \) and \( w_s \) are the velocities at the free surface, which are expressed by (7) and (8).

\[
\mathbf{u}_s = \mathbf{u}_1 + \frac{1}{6} d_n^2 \nabla (\nabla \cdot \mathbf{u}_1) - \frac{1}{2} \eta^2 \nabla (\nabla \cdot \mathbf{u}_1) \\
- (\frac{1}{2} d_i + \eta)[ \sum_{i=n+1}^{N} \nabla (d_i \nabla \cdot \mathbf{u}_i) + \nabla (\mathbf{u}_b \cdot \nabla h) ] 
\]

\[
w_s = - \sum_{i=1}^{N} d_i \nabla \cdot \mathbf{u}_i - \eta \nabla \cdot \mathbf{u}_n - \mathbf{u}_b \cdot \nabla h 
\]

\( \mathbf{u}_b \) the horizontal velocities at the bottom is determined by the relation (9), combined with \( \mathbf{u}_N \) the \( N \)-th layer-averaged velocity.

\[
\mathbf{u}_b = \mathbf{u}_N + \frac{1}{6} d_n^2 \nabla (\nabla \cdot \mathbf{u}_N) + \frac{1}{2} d_n [ \nabla (\mathbf{u}_b \cdot \nabla h) + (\nabla h) \nabla \cdot \mathbf{u}_N ] 
\]

Thus, fundamental system of multi-level model is obtained, which is composed of one continuity equation, layers number of momentum equations and bottom condition. For the momentum equations (6), the convenient form is given by (10), in which the contributions of \( \mathbf{u}_i \) to \( \mathbf{u}_n \) in linear dispersion terms are shown explicitly.
\[
\frac{\partial \mathbf{u}_n}{\partial t} + \frac{1}{2} \nabla (\mathbf{u}_s \cdot \mathbf{u}_s + w_s^2) + g \nabla \eta \\
\quad = \nabla [\eta \sum_{i=1}^{N} d_i \nabla \cdot \frac{\partial \mathbf{u}_i}{\partial t} + \frac{1}{2} (\eta^2 \nabla \cdot \frac{\partial \mathbf{u}_i}{\partial t}) + \eta \frac{\partial \mathbf{u}_b}{\partial t} \cdot \nabla h] \\
\quad + \sum_{i=1}^{N} \alpha_{nj} \nabla (\nabla \cdot \frac{\partial \mathbf{u}_i}{\partial t}) + \sum_{i=1}^{N} \beta_{nj} \nabla \frac{\partial \mathbf{u}_i}{\partial t} + \gamma_n \nabla \cdot \frac{\partial \mathbf{u}_b}{\partial t} + \delta_n \frac{\partial \mathbf{u}_b}{\partial t}
\]

where coefficients in linear dispersion terms are given as follows.

\[\alpha_{nj} = \alpha_{1n} + \alpha_{2n} + \alpha_{3n} + \alpha_{4n}\]  

\[\alpha_{1n} = \begin{cases} 
0 & (n \leq 1) \\
\sum_{m=1}^{n-1} d_m d_i & (n > 1, i > n - 1) \\
\sum_{m=1}^{i-1} d_m d_i & (n > 1, i \leq n - 1) 
\end{cases}\]  

\[\alpha_{2n} = \begin{cases} 
0 & (n \leq 1) \\
\frac{1}{2} d_i^2 & (n > 1, i > n - 1) 
\end{cases}\]  

\[\alpha_{3n} = \begin{cases} 
\frac{1}{2} d_n d_i & (n < i) 
\end{cases}\]  

\[\alpha_{4n} = \begin{cases} 
0 & (n \neq i) \\
\frac{1}{3} d_i^2 & (n = i) 
\end{cases}\]  

\[\beta_{nj} = \beta_{1n} + \beta_{2n} + \beta_{3n} + \beta_{4n}\]  

\[\beta_{1n} = \begin{cases} 
0 & (n \leq 1) \\
\sum_{m=1}^{n-1} \nabla (d_m d_i) & (n > 1, i > n - 1) \\
\sum_{m=1}^{i-1} \nabla (d_m d_i) & (n > 1, i \leq n - 1) 
\end{cases}\]  

\[\beta_{2n} = \begin{cases} 
0 & (n \leq 1) \\
d_i \nabla d_i & (n > 1, i > n - 1) 
\end{cases}\]  

\[\beta_{3n} = \begin{cases} 
\frac{1}{2} d_n \nabla d_i - d_i \nabla h_{x-1} & (n < i) 
\end{cases}\]
\[ \beta_{n_i} = \begin{cases} 0 & (n \neq i) \\ d_i \nabla d_i - \frac{1}{2} d_i \nabla h_i & (n = i) \end{cases} \]  

(20)

\[ \gamma_n = \sum_{m=1}^{n-1} d_m \nabla h + \frac{1}{2} d_n \nabla h \] 

(21)

\[ \delta_n = \sum_{m=1}^{n-1} \nabla (d_m \nabla h) + \frac{1}{2} d_n \nabla (\nabla h) - \nabla h_{n-1} \nabla h \] 

(22)

A remarkable feature of multi-level model is applicability to quasi-3 dimensional problem with vertical and horizontal closed boundaries. Vertical closed boundaries can be simply treated by setting the corresponding horizontal velocities to be zero. Horizontal closed boundaries can be treated by following manner (Fig. 2). Vertical velocities at the horizontal closed boundaries are set to be zero by condition (23), where \( h_B \) is the depth of horizontal closed boundaries which corresponds to the lower edge of \( n_B \)-th layer. In this case, the number of equations exceed the number of unknowns. To make the system closed, a new unknown \( p_B \) the pressure under the closed boundary should be introduced.

\[ w (-h_B) = - \sum_{i=n_B}^{N} d_i \nabla \cdot u_i - u_b \cdot \nabla h = 0 \]  

(23)

By expressing the modified Euler equation (5) using \( p_B \), (24) is obtained for the region under the horizontal closed boundary.

\[ \frac{\partial u}{\partial t} + \frac{1}{2} \nabla (u_B \cdot u_B) + \nabla (\frac{p_B}{\rho}) = -\nabla \int_{z}^{-h_B} \frac{\partial w}{\partial t} dz \]  

(24)

Equation (24) is expressed with dependent variables of multi-level model as (25). At the side edge of horizontal closed boundary, variable \( p_B \) is connected to that of ordinary region.

\[ \frac{\partial u_n}{\partial t} + \frac{1}{2} \nabla (u_B \cdot u_B) + \nabla (\frac{p_B}{\rho}) \]

\[ = \sum_{i=n_B+1}^{N} \sum_{j=1}^{N} \nabla (d_i d_j) \nabla \cdot \frac{\partial u_j}{\partial t} + \sum_{i=n_B+1}^{N+1} \frac{1}{2} \nabla (d_i^2 \nabla \cdot \frac{\partial u_j}{\partial t}) \]

\[ + \sum_{i=n_B+1}^{N} \frac{1}{2} d_n \nabla (d_i \nabla \cdot \frac{\partial u_j}{\partial t}) - \sum_{i=n_B+1}^{N} (\nabla h_{n-1}) d_i \nabla \cdot \frac{\partial u_j}{\partial t} \]

\[ + \frac{1}{2} \nabla (d_n^2 \nabla \cdot \frac{\partial u_n}{\partial t}) - \frac{1}{6} d_n \nabla (\nabla \cdot \frac{\partial u_n}{\partial t}) - \frac{1}{2} d_n (\nabla h_n) \nabla \cdot \frac{\partial u_n}{\partial t} \]

\[ + \sum_{i=1}^{n_B} \nabla (d_i \nabla \cdot \nabla h) + \frac{1}{2} d_n \nabla (\nabla \cdot \nabla h) - (\nabla h_{n-1}) (\nabla \cdot \nabla h) \]  

(25)
In this manner, the multi-level model proposed in this study can be applied to quasi-3 dimensional problem.

**Properties of Model Equations**

In this section we will analyze the linear and nonlinear characteristics of the present model. The procedure employed here is fundamentally the same as previous works, for example Madsen et al. (1996).

For simplicity, we treat the one dimensional version of the equations with constant depth, which are expressed by (26), the continuity equation and (27), the momentum equations with the velocities at the free surface expressed by (28) and (29).

\[
\frac{\partial \eta}{\partial t} + \sum_{i=1}^{N} \frac{\partial}{\partial x} \left( d_i \frac{\partial u_i}{\partial x} \right) + \frac{\partial}{\partial x} \left( \eta \frac{\partial u_i}{\partial x} \right) - \frac{1}{2} \frac{\partial}{\partial x} \left[ \eta \sum_{i=1}^{N} d_i \frac{\partial^2 u_i}{\partial x^2} \right] + \frac{1}{6} \frac{\partial}{\partial x} \left[ \eta \left( d_i^2 - \eta^2 \right) \frac{\partial^2 u_i}{\partial x^2} \right] = 0
\]  

(26)

\[
\frac{\partial u_i}{\partial t} + u_i \frac{\partial u_i}{\partial x} + w_i \frac{\partial u_i}{\partial x} + g \frac{\partial \eta}{\partial x} = \frac{\partial}{\partial x} \left[ \eta \sum_{i=1}^{N} d_i \frac{\partial^2 u_i}{\partial t \partial x} + \frac{1}{2} \eta \frac{\partial^2 u_i}{\partial t \partial x} \right] + \sum_{j=i+1}^{n} d_i d_j \frac{\partial^3 u_j}{\partial t \partial x^2} + \frac{1}{2} \frac{\partial}{\partial x} \left( \eta \sum_{i=1}^{N} d_i \frac{\partial^2 u_i}{\partial x^2} \right) + \frac{1}{3} \frac{\partial}{\partial x} \left( \eta \sum_{i=1}^{N} d_i \frac{\partial^2 u_i}{\partial x^2} \right)
\]

(27)

\[
u_i = u_i + \left( \frac{1}{6} d_i - \frac{1}{2} \eta^2 \right) \frac{\partial^2 u_i}{\partial x^2} - \left( \frac{1}{2} d_i + \eta \right) \sum_{i=1}^{N} d_i \frac{\partial^2 u_i}{\partial x^2}
\]

(28)

\[w_i = - \sum_{i=1}^{N} d_i \frac{\partial \eta}{\partial x} - \eta \frac{\partial u_n}{\partial x} - u_b \frac{\partial h}{\partial x}
\]

(29)

We look for solutions of the form expressed by (30) and (31), where $\varepsilon$ is a small parameter.

\[
\eta = \varepsilon \eta^{(1)} \cos(kx - \omega t) + \varepsilon^2 \eta^{(2)} \cos(2kx - 2\omega t)
\]

(30)

\[u_n = \varepsilon u_n^{(1)} \cos(kx - \omega t) + \varepsilon^2 u_n^{(2)} \cos(2kx - 2\omega t)
\]

(31)

Substituting them to (26) and (27), the equations for first order of $\varepsilon$ are given by (32) and (33).

\[\omega \eta^{(1)} + k \sum_{i=1}^{N} d_i u_i^{(1)} = 0
\]

(32)

\[\omega u_n^{(1)} - gk \eta^{(1)} + k \omega \left[ \sum_{i=1}^{N} d_i \sum_{j=i+1}^{N} d_j \frac{\partial}{\partial x} + \frac{1}{2} \sum_{i=1}^{N} d_i^2 \right] u_i^{(1)} + \frac{1}{3} d_n^2 u_n^{(1)} = 0
\]

(33)
These are homogenous equations and non-trivial solutions require the determinant of the system to vanish to provide the dispersion relation.

In Fig. 2, the dispersion relation of the present model is compared with that of the linear theory. In this case, thickness of $n$-th layers are set to be $n$-times of first layer so that deeper layer has larger thickness. With the increasing number of layers, linear dispersion relation of the multi-level model converges to that of linear theory. Four layers are enough for sufficiently accurate dispersion for $kh$ up to 10.

Distribution of $\{u_n^{(1)}\}$ for various values of $kh$ can also be obtained from (32) and (33), which provide the vertical distribution of linear components of velocities according to (1) and (2). In Fig. 3, vertical distribution of horizontal velocity $u(z)$ of the present model is compared with that of the linear theory. Fig. 4 shows plots similar to Fig. 3 for vertical velocity $w(z)$. Although larger number of layers is required to reproduce the exact solution as $kh$ increase, plots for $N=6$ and $N=8$ show very accurate reproduction so that they are hard to distinguish, for the range of $kh$ smaller than 20.

Similarly, the equations for second order of $\epsilon$ are given by (34) and (35). From these equations, the second order surface elevation and velocities are obtained, which should be compared with that of Stokes second order wave theory.

$$\omega \eta^{(2)} + k \sum_{i=1}^{N} d_i u_i^{(2)} = \frac{1}{2} k [(1 - \frac{1}{6} d_i^2 k^2) u_i^{(1)} + \frac{1}{2} d_i k^2 \sum_{i=1}^{N} d_i u_n^{(1)}] \eta^{(1)} = 0$$

(34)

$$\left(\omega + \frac{1}{3} k d_i^2 \right) u_i^{(2)} + k \omega \left( \sum_{i=1}^{N} \sum_{j=i+1}^{N} d_i d_j + \frac{1}{2} \sum_{i=1}^{N} d_i^2 \right) u_i^{(2)} - g k \eta^{(2)}$$

$$= \frac{1}{4} k [(1 - \frac{1}{6} d_i^2 k^2) u_i^{(1)} + \frac{1}{2} d_i k^2 \sum_{i=1}^{N} d_i u_n^{(1)}]^2$$

$$- \frac{1}{4} k^3 \left( \sum_{i=1}^{N} d_i u_i^{(1)} \right)^2 - \frac{1}{2} k^2 \omega \eta^{(1)} \sum_{i=1}^{N} d_i u_i^{(1)}$$

(35)

The water-surface elevation including second order of $\epsilon$ is expressed by equation(36), where $H$ is wave height. On the other hand, according to Stokes second order theory, it also can be expressed by equation(37).

$$\eta = \frac{H}{2} \cos(kx - \omega t) + \frac{H^2 \eta^{(2)}}{4(\eta^{(1)})^2} \cos(2(kx - \omega t)}$$

(36)

$$\eta = \frac{H}{2} \cos(kx - \omega t) + \frac{H^2}{16} k \cosh kh (\cosh 2kh + 2) \cos(2(kx - \omega t)}$$

(37)

The amplitude of second term of equation (36) and (37) are compared in Fig.5, both are plotted being divided by wave number. In this case, wave height is 20% of still water depth. It is seen that the results of the present model converge to that of Stokes wave theory, with the increasing number of layers. Thus, it is confirmed that nonlinear interaction characteristic of the present model is accurate up to the second-order.

Fig. 4 Vertical distribution of linear components of vertical velocity \( w(z) \)

Fig. 5 Second-order nonlinear interaction
Numerical Approach

The differential equations are discretized by using a time-centered implicit scheme with variables defined on a space-staggered rectangular grid. The resulting system of difference equations is reduced to a block tridiagonal system, which is solved by generalized Thomas algorithm.

An example of 2-HD simulation with three layers is for oblique wave incidence to sloping beach of 1:20. Regular, unidirectional waves with the period of 10 sec and the wave height of 3 m are generated at the depth of 24 m with the incident angle of 25 deg. In this example, a little simplified version of momentum equation is employed, which are expressed by (38).

\[
\frac{\partial u_n}{\partial t} + (u_n \cdot \nabla)u_n + \frac{1}{d_n} \int_{-h_n}^{-h_{n-1}} w \frac{\partial u}{\partial z} dz + g \nabla \eta = \sum_{i=1}^{n-1} \sum_{j=1}^{N} d_i d_j \nabla (\nabla \cdot \frac{\partial u_j}{\partial t}) + \sum_{i=1}^{n-1} \frac{1}{2} d_i^2 \nabla (\nabla \cdot \frac{\partial u_i}{\partial t}) + \frac{1}{3} d_n^2 \nabla (\nabla \cdot \frac{\partial u_n}{\partial t}) + \varepsilon_T (\nabla \cdot \nabla) u_n
\] (38)

The third term in left hand side of (38) is expressed by (39) with dependent variables of multi-level model.

\[
\frac{1}{d_n} \int_{-h_n}^{-h_{n-1}} w \frac{\partial u}{\partial z} = \frac{1}{3} d_n^2 \nabla u_n \nabla (\nabla \cdot u_n) + \frac{1}{2} \nabla (d_n \nabla u_n \sum_{i=n+1}^{N} d_i \nabla u_i) + (\sum_{i=n+1}^{N} d_i \nabla u_i)(\sum_{i=n+1}^{N} d_i \nabla (\nabla \cdot u_i))
\] (39)

In this expression, bottom sloping, vertical acceleration over still water surface, and nonlinearity of vertical momentum equation are neglected. In equation (23), \( \varepsilon_T \) is the eddy viscosity according to breaking wave propagation model by Katayama and Sato (1993).

Fig. 6 depicts a perspective views of calculated wave fields. A vector plot of the layer-averaged velocity of first and third layer is shown in Fig. 7. Co-existence of longshore current and undertow is well described by the present model.

Next example is wave diffraction simulation by submerged horizontal plate. In this case, linear and 1-dimensional version of multi-level model with five layers is employed. Fig. 8 shows the spatial profile of the propagating wave for different relative submerged depth of horizontal plate. The transmission coefficients \( K_T \) agree with the result of simulation by boundary element method, which is shown in brackets. Thus, the applicability of present model to quasi-3 dimensional problem is confirmed.
Fig. 6 Perspective view of the wave field for oblique wave incidence

Fig. 7 Time-averaged velocity field for oblique wave incidence
Fig. 8 Computation for linear wave diffraction by submerged horizontal plate.

\( \frac{D}{h} = 0.07 \quad K_T = 0.92 \) (0.96)

\( \frac{D}{h} = 0.4 \quad K_T = 0.77 \) (0.79)

\( \frac{D}{h} = 0.66 \quad K_T = 0.98 \) (0.98)
**Conclusions**

(1) A multi-level model is proposed for computing nonlinear dispersive waves. The accuracy of the model is first examined in terms of the convergence of linear dispersion relation along with quadratic transfer function. It is found that the model gives satisfactory results if the number of layers is properly chosen.

(2) The model is secondly applied to 2-HD wave propagation on sloping beach, and coexisting property of longshore current and undertow can be predicted.

(3) The applicability of the present model to quasi-3 dimensional problem is confirmed by reproducing the diffraction wave field with submerged horizontal plate.

Recent Extensions to Local Polynomial Approximation Models

Andrew B. Kennedy

Abstract

Local polynomial approximation models for water wave simulation are examined with the aim of improving accuracy and efficiency. Several potential improvements are considered. The first is based on a linearisation of the solution for Laplace's equation and is shown to have good theoretical characteristics. However, it is found to have a fatal instability to high wavenumber bottom disturbances. The second method uses empirical collocation adjustment to provide better agreement with exact solutions for steady waves. This method provides significant improvements in accuracy for a given level of approximation and is recommended for future use.

Introduction

For the computation of water wave evolution over varying topography, there have been two main areas of effort in recent years. One has focused on improvements to Boussinesq-type models, continually increasing the range of validity to encompass deeper and higher waves (Nwogu, 1993., Schäffer and Madsen, 1995, Wei et al., 1995, Gobbi et al., 1998). Despite increasing complexity, solution times remain reasonable enough to consider wave motion in two horizontal dimensions. This remains a very active area of research. At the other extreme from Boussinesq equations are numerical solutions of Laplace's equation using boundary element methods (BEM, e.g. Dold and Peregrine, 1980, Grilli et al., 1994). These offer unparalleled accuracy in any depth and can even compute overturning waves. However, despite significant advances (Wang et al, 1995), they are extremely computationally intensive; enough that large domains for one horizontal dimension can become problematic, and two dimensional computations are extremely limited in scope. Although research continues in this area, boundary element models are considered to be a relatively mature field.

Local polynomial approximation methods (LPA, Kennedy and Fenton, 1996, Kennedy and Fenton, 1997, Kennedy, 1997) were introduced as a way of bridging

---

1Center for Applied Coastal Research, University of Delaware, Newark, DE. 19716 USA.
this gap between highly accurate, computationally intensive models (BEM), and Boussinesq models of moderate accuracy and expense. The basis of these models is a polynomial representation of arbitrary degree in the vertical coordinate combined with a weighted residual solution of the continuity equation for potential flow. For lower levels of approximation, accuracy is comparable to high end Boussinesq equations, while higher levels of approximation can provide accuracy comparable to some implementations of boundary element models. Computational expense lies in between BEM and Boussinesq schemes. A comparison of an advanced Boussinesq and LPA models is given in this volume (Gobbi et al., 1998).

This paper reports recent efforts to improve the accuracy and efficiency of LPA models. Two basic strategies are considered: one which makes further approximations which slightly degrade nonlinear properties, but potentially offers great computational savings, and a second method which improves linear and nonlinear accuracy for a given level of approximation with no increase in computational expense.

Local Polynomial Approximation Model

Local polynomial approximation models all assume potential flow, and are essentially weighted residual solutions of Laplace’s equation combined with potential flow evolution equations. The velocity potential is assumed to vary in the vertical coordinate, $z$, like a polynomial of some specified degree. This may be represented as

$$\phi(x, y, z) = \sum_{j=0}^{n-1} A_j(x, y)z^j$$

where $A_j(x, y)$ is an initially unspecified function of the horizontal coordinates. The level of approximation, $n$, controls the degree of polynomial and, hence, the accuracy of the computation. To specify these functions, boundary conditions must be given at the free surface $z = \eta(x, y)$ and bed $z = -h(x, y)$, and continuity must be imposed over the entire flow field. The bottom boundary condition is

$$\phi_x + \phi_yh_x + \phi_yh_y = 0 \quad \text{on} \quad z = -h(x, y)$$

The condition at the free surface specifies the velocity potential

$$\phi(x, y, z = \eta(x, y)) = \phi^{(s)}(x, y)$$

where $\phi^{(s)}(x, y)$ is the known free surface velocity potential. For all methods considered here, these two equations will remain unchanged. In a more general sense, this is not entirely necessary, and Kennedy (1997) presents a method similar to Dommermuth and Yue (1987), which expands (3) about the still water level, with some loss of accuracy. However, in this paper attention instead will be paid to Laplace’s equation, which imposes continuity throughout the flow.
field. In its most general form, the LPA approximation to the field equation becomes

$$\int_{-h}^{h} W_j(x, y) (\phi_{xx} + \phi_{yy} + \phi_{z2}) dz = 0, \quad j = 1, \ldots, n - 2$$  \hfill (4)

where $W_j(x, y)$ are weighting functions, which can take almost any form. Kennedy and Fenton (1996) used polynomial weighting functions, but here, as in Kennedy and Fenton (1997), weighting functions will be taken to be Dirac delta functions. This turns (4) into a set of collocation equations

$$\phi_{xx} + \phi_{yy} + \phi_{z2} = 0 \text{ on } z = z_j(x, y), \quad j = 1, \ldots, n - 2$$  \hfill (5)

The set of collocation points in Kennedy and Fenton (1997) were given as

$$z_j = -h + (\eta + h) \alpha_j$$  \hfill (6)

where $\alpha_j$'s were chosen so that $z_j$'s were the Gauss-Legendre points for $N = n-2$, using the free surface and the bed as limits. This set was chosen because of continuity considerations, and will be considered as the standard against which the revised methods will be judged.

With the addition of conditions on the lateral boundaries, equations (2-4) form a set of linear equations which may be solved to find the flow field. Once interior velocities are known, the system may be advanced in time using the evolution equations

$$\eta_t = -\left(\int_{-h}^{h} \phi_x dz\right)_x + \left(\int_{-h}^{h} \phi_y dz\right)_y$$  \hfill (7)

and

$$\phi_t^{(s)} = -g\eta - \frac{1}{2} \left(\phi_x^2 + \phi_y^2 + \phi_z^2\right) + \phi_z \eta_t$$  \hfill (8)

In Kennedy and Fenton (1997), an equation different from (7) was used to update the free surface elevation. This in general did not analytically guarantee conservation of mass for approximate solutions, but because the Gauss-Legendre collocation points were used, overall conservation was guaranteed for levels of approximation $n \geq 4$. However, in this paper different collocation points will be used, and to guarantee overall continuity, (7) is employed.

This system of equations defined by (1-8) may be solved in a variety of ways, for both one and two horizontal dimensions. However, for simplicity, and because of computational constraints, we will limit tests to one horizontal dimension. Here, a good method involves complex polynomials and is detailed in Kennedy and Fenton (1997). This will be the base method used here.

In the previously referenced papers, these models have been shown to provide good accuracy with a reasonable computational cost for a variety of conditions.
However, two possible areas of improvement seem obvious. The first concerns the number of computational variables. According to (1), \( n \) variables define the flow field at each computational point. Each of these makes its way into the system of unknowns which must be solved at each time step. If the number of computational unknowns were reduced, computational speed would almost certainly increase. This will form one avenue of exploration. The second concerns the accuracy of any given level of approximation. The weighting functions in (4) were not specified using a strict theoretical basis and indeed none will be used now. Instead, sets of points will be found for different levels of approximation that provide some sort of best fit to a theoretical special case, such as wave celerity over a level bed. For both avenues of improvement, results will then be tested using the experiments of Ohyama et al. (1995), which measured wave transformation over a submerged breakwater.

**Improved Speed: Linearised B-Splines**

The first effort at improvement will be directed towards increasing computational speed. In the previous section, it was stated that one way to do this would be to reduce the number of computational unknowns that form the system of equations that must be solved at each time step. Unfortunately, despite significant effort, no such technique has been found for the general case of fully nonlinear wave motion in two horizontal dimensions. However, if one small additional approximation is made, a method exists which promises great improvements in computational efficiency. The change that must be made is to the field equation, (6), which becomes

\[
ZJ = A(-l + \alpha_j)
\]

where \( \alpha_j \)'s are identical to those previously used. Linearly, computations will be identical but, because collocations are chosen with respect to the still water level and not the instantaneous free surface, nonlinear properties should be slightly worse. However, because collocation points are invariant with time, it is possible to use what we will call the linearised B-spline approximation to speed computations. This may only be used for one horizontal dimension, as it makes use of the complex polynomial solution method. A detailed discussion of the method (only used there for expansion techniques) is given in Kennedy (1997), but a brief description will be given here. Essentially, because equations (2,5) are homogeneous, it is possible to rewrite the basis functions used in the complex polynomial solution method so that (2,5) are satisfied and the number of equations to be solved is equal to the number of computational points (plus additional boundary conditions). As an additional bonus, the bandwidth of the resulting matrix equation is reduced, further increasing speed. The new basis functions are analogous to B-splines, which may also be thought of as methods to eliminate homogeneous equations. It would be possible to rewrite these basis functions even when (6) is used, but because the collocation points change with the free surface, they would need to be rederived at each time step, actually
slowing computations. However, with (9), collocation points remain constant with time and the revised basis functions would only need to be computed once, at the beginning of computations.

Before testing the new technique, it is helpful to consider the change to the nonlinear properties caused by the approximation (9). Figure 1 shows the amplitude of the second harmonic of LPA Stokes-type steady waves compared to exact results. Two levels of approximation are shown: \( n = 5 \), which contains \( z^4 \) terms in the velocity potential, and \( n = 7 \), which contains \( z^6 \) terms. The original formulation for the level of approximation \( n = 5 \) has a second harmonic which remains quite accurate into water of depth \( kh = 2\pi \), while the linearised basis functions show greater error at high wavenumbers. Still, error remains small up to a dimensionless wavenumber of \( kh = 5 \), which is quite good. Using the level of approximation \( n = 7 \), second harmonics for both the original and linearised versions are extremely accurate to wavenumbers of \( kh = 3\pi \).

![Figure 1: Second harmonics for a second order steady wave compared to Stokes' solution](image)

A special case of subharmonics, second order setdowns under a steady wave were also calculated and provided a major surprise: setdowns using both the fully nonlinear and linearised basis functions were identical. Figure 2 shows setdown magnitudes relative to Stokes’ solution plotted on a semi-logarithmic scale. For the level of approximation \( n = 5 \), results are very good until a dimensionless wavenumber of \( kh = 2.5 \), when error increases very quickly. For the higher level of approximation \( n = 7 \), error remains small until around \( kh = 4 \). For
high wavenumbers, both levels of approximation can show order of magnitude errors in setdown. However, since setdown decays exponentially with increasing wavenumber, for the most part the error is merely a "different flavour of zero", and should make little difference to computations. For very high wavenumbers around \( kh = 6 \), the lower level of approximation does begin to show errors which may not be negligible in terms of absolute, rather than relative, error.

Figure 2: Second order setdown for a second order steady wave compared to Stokes' solution. Symbols identical to previous figure.

These results show a small, but noticeable difference in nonlinear accuracy between the original and linearised basis functions. Computations using the level of approximation \( n = 7 \) and the linearised basis functions were then tested against the experimental results of Ohyama et al (1995). Figure 3 shows a schematic drawing of the experimental setup, where monochromatic waves propagated over a steep-sided submerged bar. All waves had an initial height \( H/h = 0.1 \), and cases 2, 4, and 6 had periods \( T \sqrt{g/h} = 5.94, 8.91, 11.88 \) respectively.

It was here that the problems with the linearised B-spline approximation became apparent. For all cases tested, and with all spatial and temporal resolutions used, computations became unstable as waves passed from the crest of the shelf onto the back slope. The reason for this was not readily obvious, but became apparent after some additional analysis. The culprit was a nonlinear instability to short wavelength bottom disturbances. Consider a small amplitude
sinusoidal bottom disturbance in otherwise quiescent water. The water level is assumed to be at elevation $\eta = 0.5h$, similar to that under the crest of a very large wave. Although this is somewhat different from what happens when the wave crest passes over the sharp corner of the submerged bar, it provides an illuminating demonstration of model response to short wavelength disturbances in topography.

Figure 4 plots the structure of the resulting vertical velocity field, showing the exact solution using hyperbolic functions, the fully nonlinear LPA solution, and the LPA solution using linearised basis functions, both with the level of approximation $n = 7$. The wavenumbers shown straddle the Nyquist wavenumber used in computations. The fully nonlinear LPA solution closely resembles the exact decaying relation for both short wavenumbers tested, but results using the linearised functions show wild oscillations and large amplitudes above the still water level. This is because the linearised functions have collocation points which extend only from the bed to the still water level. Above this, the linearised basis functions essentially extrapolate the interpolated solution.
of Laplace's equation. In contrast, the fully nonlinear solution has collocation points which move with the instantaneous water surface (Eq. (6)). This ensures that solutions of the field equation are interpolations rather than extrapolations, as with the linearised solution. Possible solutions to this dilemma would be to increase the range of collocation points using the linearised functions to above the still water level, but this has its own problems. Both linear and nonlinear performance would deteriorate for any given level of approximation, perhaps enough to cancel out any increase in efficiency. No completely satisfactory solution has yet been found.

This instability to bottom disturbances is also of concern for higher order Boussinesq-type approximations, which extrapolate solutions of Laplace's equation using Taylor series. In fact, the higher order Boussinesq model of Gobbi et al. (1998) has also exhibited instabilities in computational tests with sharp corners (M. Gobbi, pers. commun.). Clearly, the extrapolation of a decaying function with a polynomial remains an area of difficulty.

Improved Accuracy: Revised Collocation

Although the efforts to improve efficiency in the previous section ultimately proved unworkable, results here were much more successful. The question was quite simple: for a given level of approximation, \( n \), find the set of collocation points which best optimises certain analytic properties, and see if this translates to better performance for real computations.

To begin with, the analytic property chosen for comparison was small amplitude phase celerity, as it greatly influences accuracy in comparison with experiments such as Ohyama et al. (1995). The exact celerity was expanded in a Taylor series about the long wavelength limit \( kh = 0 \), and LPA celerities were made to match as many terms as possible. First of all, we will start with the low level of approximation, \( n = 3 \), although this level is of little practical use. One free collocation point is available for manipulation, and for any choice of collocation points, the LPA dispersion relationship is accurate to \( O(kh^2) \). However, for the choice \( \alpha_1 = 1/\sqrt{5} \), dispersion is accurate to \( O(kh^4) \). In fact, the resulting dispersion relationship is the [2,2] Padé approximant found in Nwogu (1993) and Wei et al. (1995). For the level of approximation \( n = 5 \), three collocation points were available, while the base level of accuracy was \( O(kh^4) \). With the choice of \( \alpha_1 = 0.1255280883 \), \( \alpha_2 = 0.5008959415 \), \( \alpha_3 = 0.8419853513 \), accuracy is increased to \( O(kh^{10}) \). For the level of approximation \( n = 7 \), however, no optimised approximation was found. This was due to the lack of a general solution for dispersion; i.e. dispersion relationships could be found for any particular set of \( \alpha_j \)'s, but not for the general set. Solutions using the Gauss-Legendre points were close to optimal, but the possibility for improvements remains.

Figure 5 shows the original and improved dispersion relationships compared to the exact small amplitude solution. For the level \( n = 3 \), the resulting relationship is usable up to the nominal deep water limit of \( kh = \pi \), which is a
significant improvement. However, in contrast to the Gauss-Legendre relationship, phase speeds are greatly overpredicted for high wave numbers. For the level \( n = 5 \) errors in improved phase speed remain less than 1 percent until a dimensionless depth of approximately \( kh = 9 \). However, this level is still somewhat less accurate than the level of approximation \( n = 7 \), which has excellent accuracy. Clearly, dispersion relationships can be much improved.

![Graph showing LPA celerities using Gauss-Legendre (GLE) and new collocation points. Squares, GLE \( n = 3 \); stars, new collocation \( n = 3 \); +, GLE \( n = 5 \); triangles new collocation \( n = 5 \); x GLE \( n = 7 \).](image)

Figure 5: LPA celerities using Gauss-Legendre (GLE) and new collocation points. Squares, GLE \( n = 3 \); stars, new collocation \( n = 3 \); +, GLE \( n = 5 \); triangles new collocation \( n = 5 \); x GLE \( n = 7 \).

Nonlinear performance is improved as well. Figure 6 shows amplitudes of second harmonics for a steady wave relative to Stokes’ solution. For all levels of approximation, results are much asymptotically much improved, although at higher wave numbers, the revised collocation points tend to show greater error. Subharmonics show a similar trend. Figure 7 shows a significant improvement in the accuracy of the steady wave setdown for the levels of approximation \( n = 3 \) and \( n = 5 \). Notably, for the level of approximation \( n = 5 \) using the new collocation points, absolute errors remains small over the entire range considered. Accuracy for the level of approximation \( n = 7 \), however, remains significantly better.

We will now consider computational results over the topography of Ohyama et al. (1995) which, as mentioned previously, is shown in Figure 3. Fortunately, computations with the revised collocation points showed none of the instabilities
of the previous section. Full experimental results are available for comparison at both Stations 3 and 5. However, almost any nonlinear model will give good results at Station 3, while good agreement at Station 5 is much more difficult. Therefore, instead of showing results at Station 3, we will merely say that all comparisons were uniformly excellent, no matter what levels of approximation were used. Figure 8 shows results at Station 5 for the level of approximation $n = 5$, for both the original and revised collocation points. For case 2, the shortest wave, computations using the original collocation show some error, while this error is greatly reduced with the revised collocation. For case 4, computations show a similar trend, although the reduction in error is not as large. For case 6, agreement using the improved collocation is quite good, while results using the original formulation show higher harmonics which are visibly too large.

Figure 9 shows results for the level of approximation $n = 7$. For all cases considered, results are excellent, with experimental and computational results nearly identical. Once again, the higher level of approximation gives results somewhat better than the improved lower level.

Discussion and Conclusions

Analytic results and computational tests using the revised collocation points show significant improvements in accuracy for all levels of approximation. Since
a change in collocation points provides no increase in computational expense, there seems to be no reason why this new feature should not be adopted as a matter of routine.

It should be possible to increase nonlinear accuracy further by changing the collocation technique itself. If the definition for collocation points (6) is changed to

\[ z_j = h(\alpha_j - 1) + \beta_j \eta \]  

where \( \alpha_j \)'s are unchanged, linear dispersion will be the same, but an additional parameter will be available to tune second or third order nonlinear characteristics. Although no comprehensive effort has yet been made to optimise \( \beta_k \) parameters, ad hoc tests show that significant improvement in nonlinear parameters is indeed possible. Figure 10 shows second harmonics computed using (10) using the set \( \beta_1 = 0.0319, \ \beta_2 = 1.4018, \ \beta_3 = 1.4297 \). Although this set is not fully optimised, significant improvement can be seen. However, manipulation of this sort introduces a dependency on the definition of the still water level which was not present in the previous fully nonlinear LPA solutions. Slight changes in the still water level from what was assumed could lead to significant changes in the model properties if (10) were used, negating any advantage that might be gained. Still, this idea may deserve further consideration.

Another possible area of investigation lies in what quantities should be op-
timised for best results. Previously, linear dispersion was the only analytic quantity used, but the experience with the linearised B-splines suggests that it might be wise to include response to bottom disturbances in the optimisation criteria. Yet another candidate is linear shoaling, although this would involve a significantly more complicated analysis.

Practical performance of the linearised B-spline approximation was quite disappointing, and the solution does not appear to be simple. The basic problem of extrapolating a decaying function is fundamental, and requires careful thought. Several possible solutions were proposed in an earlier section, but all will require testing.

So in conclusion, it can be stated that revised collocation offers significant improvements in accuracy for all levels of approximation considered and should be used on a regular basis. However, the linearised B-spline approximation exhibits a strong nonlinear instability to short wavenumber bottom disturbances, and presently remains unworkable.

Depth inversion for nonlinear waves shoaling over a barred-beach

Stéphan T. Grilli¹, M. ASCE, and Jesper Skourup²

ABSTRACT: Characteristics of periodic wave shoaling over a barred-beach are calculated in a fully nonlinear numerical wave tank. Variations of wave elevation, slopes, height, asymmetry, and celerity are discussed. Over and beyond the bar, classical highly nonlinear decomposition phenomena occur in a modulation region (MR); in shallower water, shoaling reoccurs. Depth inversion algorithms developed and calibrated for mild slopes are applied to the barred-beach. Expectedly, errors on depth prediction occur in the MR; suggestions for improvements are made.

INTRODUCTION

Depth inversion algorithms

Depth inversion refers to a class of numerical/experimental methods by which the ocean bottom bathymetry in coastal areas is predicted using properties of waves measured on the ocean surface. Such properties are typically obtained by remote sensing or video based technique [see Grilli, 1998, for a brief summary of these] and often consist, in their raw form, in spatial and temporal variations of wave phases. Multiple phase diagrams separated in time can provide estimates of wave celerity and wavelength [hence, wave period] which, in turn, using a dispersion relationship, can provide estimates of the depth variation. Both the quality of the initial data and the accuracy of the dispersion relationship in representing real wave behavior will affect the accuracy of the depth prediction.

Most state-of-the-art methods still use the linear dispersion relationship to carry out depth inversion, according to the methodology outlined above [Dugan,
Grilli (1998), however, studied the depth inversion problem for mildly and monotonously sloping beaches and showed, for shallow enough water, nonlinear effects and their influence on wave celerity \( c \) cannot be neglected. Such so-called *amplitude dispersion effects* make higher waves travel faster and lead to overestimation of the water depth \( h \), when depth inversion is simply the result of "inverting" the linear dispersion relation. To account for amplitude dispersion effects, wave height data \( H \) or, at least, deep water steepness \( k_0 H_o \) must also be known \([k_o \text{ and } H_o \text{ are the deep water wavenumber and wave height, respectively}].\) For periodic waves, normalized wave steepness \( kH/k_0 H_o \) was shown by Grilli and Horrillo (1996,1998b) to provide an almost one-to-one relationship with relative depth \( kh \) in the shoaling region and, also [surprisingly], to be well predicted by linear wave theory (LWT). Hence, assuming simultaneous observations of surface elevations are available, they suggested that this parameter could be used to model the wave height variation, and thus predict \( k_0 H_o, \) in the *depth-inversion problem*.

Following this approach, assuming both wave phases and wave height data are available, Grilli (1998) developed a new *Depth Inversion Algorithm* [referred to as DIA1] and validated it for simulated wave data. This algorithm uses a dispersion relation \( c(k_o h, k_0 H_o) \) which is empirically based on results of computations in a fully nonlinear wave tank [NWT; see next Section]. In all cases, rms-errors on depth inversion with DIA1 were less than a few percent whereas the linear dispersion led to rms-errors 5 to 10 times larger, particularly in the shallower water region. Accurate spatial measurements of wave elevations, for instance using remote sensing techniques such as Synthetic Aperture Radar (SAR), are still quite problematic under the current state of the technology. Hence, to eliminate the need for wave height data, an alternate parameter related to wave skewness, also function of \( k_0 H_o, \) was identified and shown to be quite sensitive to depth variations (Grilli and Horrillo, 1996,1998b). This parameter is the ratio of forward to backward wave slopes, noted, \( s_2/s_1 \approx L_1/L_2 \) [Fig. 1b, assuming \( H_1 \approx H_2; \) i.e., a measure of wave left to right spatial asymmetry]. Unlike \( H, \) this parameter can also be retrieved from spatial wave phase information. Thus, Grilli (1998) developed a second algorithm [referred to as DIA2], using an empirical relationship \( s_2/s_1(k_o h, k_0 H_o), \) also fitted to results of computations in the NWT, to predict \( k_0 H_o \) before the nonlinear dispersion relation is "inverted" to predict depth. Although DIA2 provided slightly larger errors on depth prediction than DIA1, these were still much smaller than when using LWT.

In actual field situations, DIA1 and DIA2 would thus predict the depth variation \( h(x) \) in the direction of wave propagation, for waves almost normally incident to the shore [i.e., about cross-shore], based on sets of values of \( c(x) \) and \( L(x) \) [obtainable from wave phases], and either \( H(x) \) (DIA1) or \( s_2/s_1(x) \) (DIA2), simultaneously measured at a number of locations \( x, \) using remote sensing techniques (Fig. 1). In both algorithms, wave period \( T \) is first predicted as the mean of observed \( L/c \) values [where \( L = (L_c(x) + L_d(x))/2; \) Fig. 1b], and \( k_0 H_o \) is then predicted [with, \( k_o = \frac{(2\pi)^2}{g T^2})], \) either based on wave height data, using the LWT steepness
Figure 1: (a) Sketch of periodic wave shoaling computations in the numerical wave tank. (—) typical bottom topography and (—- - - -) least square fit to the topography : \( h/h_o = 0.0758 (74.20 - x/h_o)^{0.64} \) (Dean’s profile). (b) Blow-up of part (a) and definition of some of the wave geometric characteristics used in DIA1 and DIA2.

relationship (DIA1), or on wave asymmetry data, using the empirical relationship for \( S_2/S_1(k_a h, k_o H_0) \) (DIA2). The celerity relationship \( c(k_o h, k_o H_0) \) is finally inverted to predict depth \( h \) [see details in Grilli, 1998].

Computation of wave shoaling in a numerical wave tank

Nonlinear properties of periodic waves of height \( H_0 \) and period \( T \) in deep water, shoaling over "cylindrical beaches" with monotonously decreasing and mildly sloping depth variation \( h(x) \) (Fig. 1), were used by Grilli (1998) to calibrate depth inversion algorithms DIA1 and DIA2.

These properties were obtained by Grilli and Horrillo (1996, 1998b), using a two-dimensional (2D) numerical wave tank (NWT), which combined [Grilli et al., 1989; Grilli and Subramanya, 1996; Grilli and Horrillo, 1997; Fig. 2a]: (i) a higher-order Boundary Element (BEM) solution of Fully Nonlinear Potential Flow (FNPF) equations in domain \( \Omega \); (ii) an exact generation of finite amplitude periodic waves [Streamfunction Waves] at the deeper water extremity (\( \Gamma_r \)); and (iii) an Absorbing Beach (AB) at the far end of the tank [featuring both free surface absorption on \( \Gamma_f \)].
and lateral active absorption (AP) on $\Gamma_2$; Clément, 1997]. A feedback procedure was developed to adaptively calibrate the beach absorption coefficient so as to absorb the period-averaged energy of waves entering the AB at $x = x_t$. After absorption of initial transient waves, computations in the NWT reached a quasi-steady state for which reflection from the AB was very small. Nonlinear properties of waves were then calculated and validation tests were performed to assess their sensitivity to the AB location and to the resolution of the spatial discretization. Numerical results were compared to laboratory experiments for periodic wave shoaling over a mild slope, and propagation over a bar [Beji and Battjes, 1994]. All the tests were found satisfactory. Details of model equations, numerical methods and validation applications can be found in the above-referenced papers.

Grilli and Horrillo (1996,1998b) calculated shoaling of waves of various heights and periods up to very close to the breaking point, over 1:35, 1:50, and 1:70 slopes, both plane and natural [i.e., with a bathymetry following Dean’s (1991) equilibrium beach profile; see, e.g., Fig. 1a]. Local [i.e., variations of shoaling coefficient $K_s = H/H_0$, celerity $c$, relative wave height $H/h$, steepness $kH$, and asymmetry $s_2/s_1$], and integral properties of shoaling waves were calculated. Due to the low reflection from the slope and the AB, wave properties were found to be very repeatable for successive waves.

For mild slopes, nonlinear properties of waves of different height and period but same deep water steepness $k_0H_0$ were found to be almost identical for the same relative depth $kh$. This allowed Grilli (1998) to use results for a plane 1:50 slope to calibrate DIAs which were later successfully applied to other slopes. In the shallower water region, linear, weakly nonlinear, and higher-order steady wave theories did not, in general, accurately predict shoaling wave properties, especially for $H/h > 0.15$. Linear wave theory, in particular, was in error by up to 85% for the wave celerity. The weak nonlinearity and/or the lack of wave skewness in these theories were identified as the main sources of errors.

### WAVE SHOALING OVER BARRED-BEACHES

#### General features

Grilli and Horrillo (1998a) used the same NWT as above to calculate periodic wave shoaling over a barred-beach, modeled as a Dean’s equilibrium profile with average slope 1:50 (Fig. 2), and a bar located towards the top of the slope, with a 1:20 seaward, a 1:10 shoreward slope, and a crest with nondimensional depth 0.2. [The geometry of this bar is similar to that of Beji and Battjes’ (1994) experiments which were used to validate shoaling computations in the NWT.]

Since waves of moderate incident steepness initially behave as predicted by LWT, the computations are initiated in intermediate water depth $h^*_o = 0.6h_o$, in the de-shoaling zone. Corresponding wave characteristics in deep water (depth $h_o$) are back-calculated using LWT. Three incident waves of nondimensional height $H^*_o = \ldots$

\( H_o^*/h_o = 0.06 \) and periods \( T = T' \sqrt{g/h_o} = 5.5, 6.5, \) and \( 7.5 \) are successively generated at \( \Gamma_1 \), as exact finite amplitude zero-mass-flux streamfunction waves (Grilli and Horrillo, 1997). General data for these three waves are summarized in Table 1. An AB is specified in the NWT for \( x' > x_1' = 30 \), with a tapered bottom variation aimed at improving energy absorption (Grilli and Horrillo, 1997); the depth at the AB entrance is \( h_1' = 0.1 \), and \( h_1' = 0.5 \) at its extremity. Numerical data in the NWT [i.e., spatial and temporal discretizations] are selected for each case in order to ensure high accuracy of the computations.

A typical result for the calculated free surface shape is shown in Fig. 2, for case 1 (Table 1) at \( t' = 86.64 = 15.75T' \) from the (cold) start of the computations. At this stage, the initial transient front has been absorbed in the AB and computations have reached a quasi-steady state. This is confirmed in Fig. 2c which shows two free surface profiles obtained at a one-period time interval: the two profiles are nearly identical, except for small high-frequency oscillations close to the AB entrance (\( x' > 28 \)). Seaward of the bar (\( x' < 21 \)), wave shoaling appears qualitatively similar to that obtained for monotonous mild slopes (e.g., Fig. 1): as waves propagate up the beach, their length reduces, their height increases, and their profile becomes increasingly front/back asymmetric (i.e., skewed), with higher and narrower crests, and longer and shallower troughs. Shoreward of the bar (\( x' > 21 \)), however, the free surface profile appears very different from typical shoaling profiles, and decomposes into higher-frequency oscillations. Such decomposition phenomena of waves propagating over obstacles are well known and have been observed, e.g., by Byrne (1969) and Young (1989), and modeled, e.g., by Massel (1983), Rey (1992), Rey et al (1992), Driscoll et al (1992), and Ohyama and Nadaoka (1994). Just before entering the AB, close to the breaking point (\( x' \geq 28 \)), waves somewhat recover the sawtooth/soliton-like shape typical of pre-breaking shoaling waves.

Unlike in Driscoll et al's (1992) and Ohyama and Nadaoka's (1994) work, the present study features a varying beach topography. Hence, when waves reach the bar, due to the initial shoaling over the mildly sloping base-profile of the beach, they are
already significantly nonlinear with a height of about 45% of the local depth, and significant energy transferred to bound second and higher-order harmonics. Upon reaching the deeper water region behind the bar, wave nonlinearity drops and, as over a flat bottom, the higher harmonics are released as free waves. These free waves induce significant spatial modulations of the wave profile, quite apparent in Fig. 2, over some distance but, further onshore, as waves again propagate up the base-profile of the beach and depth decreases, shoaling reoccurs and, for sufficiently shallow depth, the free higher harmonics, again, become bound to the main wave and the wave profile reassumes a typical shoaling shape. Therefore, unlike with underwater obstacles over constant depth, the modulation region shoreward of the bar is limited in extension by the reducing depth, clearly, as a function of incident wavelength, bar berm geometry, and beach slope. In the case of Fig. 2, the modulation region covers a horizontal distance of about 5-6h0.

**Detailed features**

Detailed variations of local wave parameters over the barred-beach are now presented and, more specifically, in the modulation region beyond the bar, where wave behavior is irregular. Fig. 3, parts a to d, shows normalized wave harmonics ai [i = 1, 2, 3], height H, slopes s1 and s2, and celerity c, respectively, calculated for case 2. [Since results for the three cases are qualitatively similar, only detailed results for case 2 are presented here.] Both the FNPF results for a 1:50 natural slope [i.e., the base-profile of the beach without the bar] and those predicted by LWT for the barred-beach, have been plotted. Fig. 4, parts a and c shows comparisons of normalized wave height and celerity, calculated for cases 1, 2, and 3, as a function of k0h; and part b shows wave front/back asymmetry s2/s1 as a function of x/h0.

In Fig. 3a, as mentioned before, standard wave shoaling occurs in front of the bar (x' < 21; Fig. 2), where wave energy is continuously transferred from the fundamental to bound higher-order harmonics [the initial slight increase in a1 is due to reflection by the slope]. As a result, wave shape becomes increasingly skewed and sawtooth-like. Upon passing over the bar berm (x' > 21), waves reach the deeper water region beyond the bar and the harmonics are released as free waves. This results in marked oscillations in harmonic amplitudes and in strong spatial modulations of the wave profile. The modulation length for a2 is approximately 5.6h0, i.e., about twice the wavelength in the middle part of the modulation region. Waves reassume their sawtooth-like shoaling shape before entering the AB (x' ≥ 30), and the harmonic amplitudes seem to come back to a prolongation of what they were before reaching the bar.

In Fig. 3b, similarly, the FNPF wave height variation for the barred-beach departs from that corresponding to the base-profile, upon reaching the bar berm. Towards the end of the modulation region beyond the bar, however, the barred-beach results seem to agree better with the latter. As expected from earlier studies, LWT
Figure 3: Normalized NWT results for case 2 (Table 1), over barred-beach of Fig. 2, compared with (---) LWT results for the same case; (- - -) NWT computations for the natural 1:50 base-profile (without a bar): (a) First three wave harmonic amplitudes $a_i$. (b) Wave height (---). (c) Front (---) ($s_2 = H_2/L_2$) and back (- - -) ($s_1 = H_1/L_1$) wave slopes ($\gamma_0 = H_0/L_0$). (d) Wave celerity (---); (- - -) application of based-profile results to the barred-beach.
Figure 4: Normalized NWT results as a function of $k_0h$ for cases: (——; a) 1; (---; b) 2; and (-----; c) 3 in Table 1; and (----) indicates LWT results. (a) Wave height. (b) front/back asymmetry. (d) Wave celerity.
significantly underpredicts wave height. In Fig. 4a, due to wave modulations, the FNPF height variations for the barred-beach are multiple-valued functions of relative depth $k_0h$ [whereas LWT gives superimposed single-valued results; this would also be the case for results of the base-profile]. The patterns of wave height variations beyond the bar in the three cases show clear similarities.

In Fig. 3c, prior to reaching the bar, both front and back wave slopes, $s_2 = H_2/L_2$ and $s_1 = H_1/L_1$, continuously increase due to shoaling, with a larger relative increase for the front slope than for the back slope, due to increasing wave skewness. As a result, the front/back asymmetry $s_2/s_1$ in Fig. 4b, also continuously increases before the bar, from a value of 1 in deep water. For the beach base-profile, Grilli and Horrillo (1996,1998b) showed that this pattern is maintained up to reaching the AB. On the barred-beach, however, the modulations in wave shape beyond the bar induce significant changes in wave slopes. In each case, the wave front slope first reaches a maximum at around $x' = 19$, then drops over the bar berm and stabilizes beyond the bar, to finally increase again. The back slope keeps increasing over and beyond the berm and reaches a maximum at about 4.3 $h_0$ after the front slope reaches its maximum; the back slope then drops until $x' = 25$ [where water depth is about equal to the bar berm depth] and then stabilizes. In Fig. 4b, except for a backward shift in space of 1.5$h_0$ or so, equal to the berm width, wave front/back asymmetry seems to correlate well in all cases, with the variations of $H/H_0$, such as in Fig. 3b for case 2, in the spatial region over and beyond the bar.

In Fig. 3d, the FNPF wave celerity variation for the barred-beach departs from that corresponding to the base-profile upon reaching the bar seaward slope. When corrected for depth, however, the latter results stay accurate until reaching the bar berm at $x' = 20$. This is because the 1:20 seaward slope is mild enough for the FNPF results, calculated for the same depth on the 1:50 natural slope, to apply in the present case. As expected, LWT underpredicts celerity before reaching the bar berm [and increasingly so, the longer the wave]. Celerity increases over and beyond the bar, as a result of the increasing depth, and then strongly oscillates in the modulation region, due to changes in wave height inducing amplitude dispersion effects for the celerity. Finally, just before reaching the AB, wave celerity seems to stabilize and agree better with the FNPF results calculated for the base-profile without the bar. As expected, FNPF results calculated for the base-profile and corrected for depth do not capture the celerity oscillations in the modulation region. They also overpredict celerity over the bar berm. This is also the case for LWT. In Fig. 4c, due to wave modulations, the FNPF celerity variations calculated for the barred-beach, for each case, are multiple-valued functions of relative depth $k_0h$ [whereas LWT gives superimposed single-valued results; this would also be the case for results of the base-profile corrected for depth]. Similarly to wave height, the patterns of wave celerity variations beyond the bar show clear similarities in the three cases.

The results for wave shape and celerity variations over and beyond the bar show that highly nonlinear phenomena of wave decomposition, harmonic generation,
and nonlinear exchanges of energy between harmonics occur and strongly affect the variation of wave parameters, as compared to the case without a bar. A further confirmation of the strong nonlinearity is given by calculating the typical nonlinearity parameters, \( \delta = H/h \) and \( \varepsilon = kH/2 \), as a function of \( x \). Due to shoaling, in all cases, the wave height to depth ratio \( \delta \) already reaches a large 45 to 50% value over the bar, then drops beyond the bar, due to the increasing depth. For \( x' > 25 \), as shoaling re-occurs, \( \delta \) starts increasing again, to eventually reach \( O(1) \) values or more, before waves enter the AB. Similarly, wave steepness, \( \varepsilon \), keeps increasing due to shoaling up to reaching a large 0.10 to 0.12 value at the bar; it then oscillates beyond the bar to finally increase again up to 0.12 to 0.17 [for comparison, the deep water steepness of the limiting Stokes wave is \( \varepsilon_{ol} = 0.44 \)].

**DEPTH INVERSION OVER BARRED-BEACHES**

Results presented in the previous Section for periodic wave shoaling over a barred-beach show how local properties of waves such as \( H/H_0 \), \( s_2/s_1 \), and \( c/c_0 \), differ from the results obtained by Grilli and Horrillo (1996,1998b) for monotonously decreasing mild slopes. Differences mostly occur in the region over and at the lee side of the bar, the so-called *wave modulation region*. As variations of local wave properties with \( k_0h \) and \( k_0H_0 \) are the bases for the depth inversion algorithms DIA1 and DIA2 proposed by Grilli (1998), it is expected that these algorithms will perform poorly to retrieve depth over and directly beyond the bar.

To confirm this prediction, DIA1 was applied to the results of cases 1, 2, and 3 in Table 1. To be fair, the wave height data used to estimate \( k_0H_0 \) in the algorithm, and the wavelength data used to estimate \( T \), were limited to the monotonously varying region before the bar-berm, over the 1:50 natural base-profile and the 1:20 seaward slope of the berm [for \( x' < 20 \)]. In a real field case, this monotonous part of the data could easily be identified. The corresponding direct prediction of both \( H \) [and thus \( k_0H_0 \)] and \( T \) gave \( R^2 \) values of better than 99.3%. Depth was then retrieved using the celerity computed over the whole barred-beach, by inverting the FNPF celerity predicted on a mild slope for the same incident wave steepness and relative depth [i.e., such as the one plotted in Fig. 3d as curve (- - - -)]. Fig. 5, parts a to c, shows the results of this depth inversion for cases 1 to 3 in Table 1, compared to the actual depth variation and to the prediction of LWT. As expected, before the bar, for \( x' < 20 \), DIA1 gives quite a good prediction of depth whereas LWT overpredicts depth. Beyond the bar, however, both DIA1 and LWT fail to model the oscillatory behavior of wave celerity (Fig. 3d) and, hence, instead, wrongly predict an oscillatory bottom topography within the wave modulation region. In fact, as wave nonlinearity initially decreases in this region, thus reducing amplitude dispersion effects on the celerity, LWT does a somewhat better job in locating both the berm depth and the shape of the shoreward side of the berm. Beyond the modulation region [\( x' \geq 28 \)], as shoaling more or less re-occurs as would be expected over the base-profile, the depth prediction in DIA1 improves while LWT again overpredicts depth.
Figure 5: Depth inversion for the barred-beach and cases [Table 1]: (a) 1; (b) 2; and (c) 3. (------) Actual depth variation; (---) prediction by inversion of LWT dispersion relation; (- - -) prediction by application of DIA1. (d) mean of results of the three cases in parts a-c.
In Fig. 5d, the depth predictions for the three cases have been averaged which, due to both different modulation regions and amplitudes of oscillations, somewhat limits the effects of wave decomposition on depth prediction. We thus see that DIA1 provides a good depth prediction for $x' < 20$ and $x' > 28$. In between, in the modulation region, depth is underpredicted by DIA1 and, as explained above, LWT does a somewhat better job in predicting depth.

CONCLUSIONS

Shoaling of three periodic waves was calculated over a barred-beach in a two-dimensional fully nonlinear NWT. Results showed that: (i) prior to reaching the bar berm, wave shoaling occurs as over mild slopes; (ii) for waves with large nonlinearity over the bar [such as here with $H/h = 0.45 - 0.50$], the increasing depth beyond the bar induces highly-nonlinear wave decomposition phenomena, with energy transfer between harmonics and the release of bound higher-harmonics into free waves; (iii) a modulation region appears beyond the bar, with a spatial extension function of the incident wave period/length, in which wave parameters such as celerity $c$, height $H$, and asymmetry $s_2/s_1$, become strongly oscillatory; (iv) repetitive patterns of variations of wave front and back slope occur in the modulation region; these could be used to locate the berm and predict the extension of the modulation region in DIAs; (v) as shoaling re-occurs beyond the modulation region, waves eventually reassume a shape and behavior similar to that observed over mildly sloping beaches; and (vi) since variations of local wave properties over mild slopes are the bases for the earlier depth inversion studies (Grilli, 1998), DIA1, expectedly, performs poorly within the modulation region; its performance is good otherwise.

For DIA1 to perform better in the modulation region, wave parameters would have to be analyzed and parameterized in the algorithm, based on the present and other similar computations of wave characteristics over barred-beaches. This is the object of future extensions to this work.

NUMERICAL MODEL OF FULLY-NONLINEAR WAVE REFRACTION AND DIFFRACTION

Masahiko Isobe* and Samir Abohadima†

Abstract

Nonlinear mild-slope equations are a set of equations which were derived to analyze fully-nonlinear and fully-dispersive wave transformation. In the present study, it is shown that refraction-diffraction equations including the mild-slope equation, nonlinear shallow water equations and Boussinesq equations are derived as special cases of the nonlinear mild-slope equations. Then, a numerical model is developed for fully-nonlinear wave refraction and diffraction on the basis of the nonlinear mild-slope equations. The model is verified through comparison of numerical results with theoretical and experimental results. Finally, effect of nonlinearity on wave diffraction through a breakwater gap is discussed.

1 Introduction

Mild-slope equation derived by Berkhoff (1972) is used to predict transformation of linear waves due to refraction and diffraction. Boussinesq equations were derived for analyzing transformation of weakly-nonlinear and weakly-dispersive waves, and modified versions have been proposed to apply them in deeper water. However, waves are strongly nonlinear especially in very shallow water.

Nonlinear mild-slope equations are among the equations which were derived recently to analyze fully-nonlinear and fully-dispersive wave transformation. In deriving the equations, the velocity potential is expanded into a series in terms of a given set of vertical distribution functions and then substituted into the Lagrangian defined by Luke (1967). The equations are obtained by applying the variational principle to the Lagrangian. No assumptions are made in the derivation so that they are

†Graduate student, ibid. (Email: abohadim@coastal.t.u-tokyo.ac.jp)
applicable even to strongly nonlinear and strongly dispersive waves and more general than any other wave equations derived so far. In the present study, the mild-slope equation, nonlinear shallow water equations, and Boussinesq equations are derived as special cases of the nonlinear mild-slope equations.

Then, a fully nonlinear and fully dispersive numerical model is developed based on the nonlinear mild-slope equations to predict wave refraction and diffraction. Linear dispersion characteristic of the model is first examined by comparing with the small amplitude wave theory. Next, the model is applied to wave transformation due to a circular shoal and diffraction through a breakwater gap. These results show the validity of the present model. Further discussion is made on the effect of nonlinearity on the wave diffraction.

2 Relation Between Nonlinear Mild-Slope Equations and Various Wave Equations

2.1 Nonlinear mild-slope equations

The nonlinear mild-slope equations are derived from the Lagrangian, $L$, obtained by Luke (1967):

$$ L[\phi, \eta] = \int_{t_1}^{t_2} \int_{A} \int_{-h}^{\eta} \left\{ \frac{\partial \phi}{\partial t} + \frac{1}{2} (\nabla \phi)^2 + \frac{1}{2} \left( \frac{\partial \phi}{\partial z} \right)^2 + gz \right\} \, dz \, dA \, dt \quad (1) $$

where $\phi$ is the velocity potential, $\eta$ the water surface elevation, $t_1$ and $t_2$ arbitrary times, $A$ arbitrary area on the horizontal plane, $h$ the water depth, $g$ the gravitational acceleration, $z$ the vertical coordinate and $t$ the time. To terminate the above Lagrangian with respect to $\phi$ and $\eta$ is equivalent to satisfy the Laplace equation, kinematic bottom boundary condition, and kinematic and dynamic surface boundary conditions.

The vertical distribution of the velocity potential, $\phi$, is expressed as a series in terms of a set of vertical distribution functions, $Z_a$:

$$ \phi(x, z, t) = \sum_{a=1}^{N} f_a(x, t) Z_a(z; h(x)) \equiv f_a Z_a \quad (2) $$

where $f_a$ are the coefficients to $Z_a$ and therefore independent of $z$, and $x = (x, y)$ denotes the position vector on the horizontal plane. As is normally the case, the expression of $Z_a$ can include the local water depth $h(x)$ as a parameter. Substitution of the above expression into the definition of the Lagrangian (1) and analytical
integration in the vertical direction yields the following expression:

\[ L[f_\alpha, \eta] = \int_{t_1}^{t_2} \int_A \chi(f_\alpha, \eta) \, dA \, dt \]  

(3)

where

\[ \chi(f_\alpha, \frac{\partial f_\alpha}{\partial t}, \eta, \frac{\partial \eta}{\partial t}) = \frac{g}{2}(\eta^2 - h^2) + \tilde{Z}_\beta \frac{\partial f_\beta}{\partial t} + \frac{1}{2} A_{\gamma \beta}(\nabla f_\gamma)(\nabla f_\beta) + \frac{1}{2} B_{\gamma \beta} f_\gamma f_\beta \]

\[ + C_{\gamma \beta} f_\gamma (\nabla f_\beta)(\nabla h) + \frac{1}{2} D_{\gamma \beta} f_\gamma f_\beta (\nabla h)^2 \]

(4)

and

\[ A_{\alpha \beta} = \int_{-h}^{h} Z_\alpha Z_\beta \, dz, \quad B_{\alpha \beta} = \int_{-h}^{h} \frac{\partial Z_\alpha}{\partial z} \frac{\partial Z_\beta}{\partial z} \, dz, \quad C_{\alpha \beta} = \int_{-h}^{h} \frac{\partial Z_\alpha}{\partial h} Z_\beta \, dz, \]

\[ D_{\alpha \beta} = \int_{-h}^{h} \frac{\partial Z_\alpha}{\partial h} \frac{\partial Z_\beta}{\partial h} \, dz, \quad \tilde{Z}_\alpha = \int_{-h}^{h} Z_\alpha \, dz \]

(5)

To terminate the Lagrangian with respect to \( f_\alpha \) and \( \eta \), the following Euler equations should be satisfied:

\[ \frac{\partial \chi}{\partial f_\alpha} = \frac{\partial}{\partial t} \left[ \frac{\partial \chi}{\partial \left( \frac{\partial f_\alpha}{\partial t} \right)} \right] + \nabla \left[ \frac{\partial \chi}{\partial \left( \nabla f_\alpha \right)} \right] \]

(6)

\[ \frac{\partial \chi}{\partial \eta} = \frac{\partial}{\partial t} \left[ \frac{\partial \chi}{\partial \left( \frac{\partial \eta}{\partial t} \right)} \right] + \nabla \left[ \frac{\partial \chi}{\partial \left( \nabla \eta \right)} \right] \]

(7)

Substituting the definition of \( \chi \), Eq. (4), into the above equations and neglecting the second and higher order terms in the bottom slope, we obtain the following equations:

\[ Z_\alpha \frac{\partial \eta}{\partial t} + \nabla (A_{\alpha \beta} \nabla f_\beta) - B_{\alpha \beta} f_\beta + (C_{\beta \alpha} - C_{\alpha \beta}) (\nabla f_\beta)(\nabla h) + \frac{\partial Z^m_\alpha}{\partial h} Z^m_\beta f_\beta (\nabla h)(\nabla h) = 0 \]

(8)

\[ g \eta + Z^m_\beta \frac{\partial f_\beta}{\partial t} + \frac{1}{2} Z^m_\gamma Z^m_\beta (\nabla f_\gamma)(\nabla f_\beta) + \frac{1}{2} \frac{\partial Z^m_\alpha}{\partial z} \frac{\partial Z^m_\alpha}{\partial z} f_\gamma f_\beta + \frac{\partial Z^m_\alpha}{\partial h} Z^m_\beta f_\gamma (\nabla f_\beta)(\nabla h) = 0 \]

(9)

where

\[ Z^m_\alpha = Z_\alpha|_{z=\eta}, \quad \frac{\partial Z^m_\alpha}{\partial z} = \frac{\partial Z_\alpha}{\partial z}|_{z=\eta} \]

(10)

Equation (8) is a vector equation with \( N \) components and Eq. (9) is a scalar equation, whereas the unknowns are \( \eta \) and \( f_\alpha \) (\( \alpha = 1 \) to \( N \)). Thus the above set of partial differential equations evolutional in the horizontal two dimensions are closed if an appropriate set of initial and boundary conditions are given. We call the set as nonlinear mild-slope equations (Isobe, 1994). No assumptions other than the series expression of the velocity potential are made to derive the nonlinear mild-slope equations; therefore the equations include full nonlinearity and full dispersivity as long as sufficient number of terms are used in the series.
Various wave equations such as mild-slope equation, nonlinear shallow water equations and Boussinesq equations are derived theoretically upon ordering nondimensional parameters. Each ordering results in a specific vertical distribution of wave motion. In a sense, ordering and vertical distribution are equivalent, and the validity of a wave equation depends on the accuracy of the vertical distribution instead of the magnitudes of nondimensional parameters used in the assumption. In the following, it is shown that various wave equations are derived from the nonlinear mild-slope equations by giving a proper set of vertical distribution functions.

2.2 Relation with mild-slope equation

The mild-slope equation (Berkhoff, 1972) is a linear refraction-diffraction equation in which vertical distribution is expressed by the hyperbolic cosine function. Hence we first linearize the nonlinear mild-slope equations (8) and (9):

\[ Z^\circ \frac{\partial \eta}{\partial t} + \nabla (A_{\alpha\beta} \nabla f_{\beta}) - B_{\alpha\beta} f_{\beta} + (C_{\alpha\beta} - C_{\alpha\beta}^0) (\nabla f_{\beta}) (\nabla h) = 0 \]  

\[ g\eta + Z^\circ \beta \frac{\partial f_{\beta}}{\partial t} = 0 \]  

where the superscript \( ^\circ \) denotes the quantity evaluated at the mean water level instead of the water surface. Next we express the velocity potential by only one vertical distribution function of hyperbolic cosine type:

\[ \phi(x, z, t) = f(x, t) Z(z) \]  

\[ Z(z) = \frac{\cosh k(h + z)}{\cosh kh} \]  

where \( k \) satisfies the linear dispersion relation. Then, Eqs. (11) and (12) become

\[ \frac{\partial \eta}{\partial t} + \nabla \left( \frac{CC_g}{g} \nabla f \right) + \frac{1}{g} \left( k^2 CC_g - \sigma^2 \right) f = 0 \]  

\[ g\eta + \frac{\partial f}{\partial t} = 0 \]  

Eliminating \( \eta \) from the above two equations, we obtain the following time-dependent form of the mild-slope equation:

\[ \nabla \left( CC_g \nabla f \right) + \left( k^2 CC_g - \sigma^2 \right) f - \frac{\partial^2 f}{\partial t^2} = 0 \]  

If we assume a sinusoidal oscillation as:

\[ f = f e^{-i\omega t} \]
we finally obtain the mild-slope equation:

$$\nabla \left( C \nabla \hat{f} \right) + k^2 C \nabla \hat{f} = 0$$

(19)

Equations for refraction and diffraction of linear random waves are obtained by taking multiple components in Eqs. (11) and (12). The vertical distribution functions are defined as

$$Z_\alpha = \frac{\cosh k_\alpha (h + z)}{\cosh k_\alpha h}$$

(20)

$$\sigma_\alpha^2 = g k_\alpha \tanh k_\alpha h$$

(21)

Then, Eqs. (11) and (12) become

$$\frac{\partial \eta}{\partial t} + A_{\alpha\beta}^{\circ} \nabla^2 f_\beta - B_{\alpha\beta}^{\circ} f_\beta = 0$$

(22)

$$g \eta + \sum_{\beta=1}^{N} \frac{\partial f_\beta}{\partial t} = 0$$

(23)

where

$$A_{\alpha\beta}^{\circ} = \begin{cases} 
\frac{1}{g} \frac{\sigma_\alpha^2 - \sigma_\beta^2}{k_\alpha^2 - k_\beta^2} & (\alpha \neq \beta) \\
\frac{1}{g} c_\alpha^2 n_\alpha & (\alpha = \beta)
\end{cases}$$

$$B_{\alpha\beta}^{\circ} = \begin{cases} 
\frac{1}{g} \frac{k_\alpha^2 \sigma_\beta^2 - k_\beta^2 \sigma_\alpha^2}{k_\alpha^2 - k_\beta^2} & (\alpha \neq \beta) \\
\frac{1}{g} \sigma_\alpha^2 (1 - n_\alpha) & (\alpha = \beta)
\end{cases}$$

(24)

From Eqs. (22) and (23), $\eta$ can be eliminated to yield

$$- \frac{1}{g} \sum_{\beta=1}^{N} \frac{\partial^2 f_\beta}{\partial t^2} + A_{\alpha\beta}^{\circ} \nabla^2 f_\beta - B_{\alpha\beta}^{\circ} f_\beta = 0$$

(25)

By assuming progressive waves with the angular frequency $\hat{\sigma}$ and wave number $\hat{k}$:

$$f_\alpha = a_\alpha e^{i(k x - \hat{\sigma} t)}$$

(26)

Equation (25) becomes

$$\sum_{\beta=1}^{N} \left( \frac{\hat{\sigma}^2}{g} - B_{\alpha\beta}^{\circ} \right) a_\beta = \hat{k}^2 \sum_{\beta=1}^{N} A_{\alpha\beta}^{\circ} a_\beta$$

(27)

To have a nontrivial solution, $\hat{k}^2$ is determined as an eigenvalue for a given $\hat{\sigma}$. It can easily be proved that $\hat{k} = k_\alpha$ for $\hat{\sigma} = \sigma_\alpha$, and therefore the dispersion relation is exactly satisfied at the frequencies $\sigma_\alpha$ ($\alpha = 1$ to $N$). This suggests that the dispersion relation is accurately satisfied even if the frequency is not equal to either of the selected frequencies. Therefore, transformation of random waves with a wide spectrum can accurately be calculated by Eqs. (22) and (23).
2.3 Relation with nonlinear shallow water equations

In the nonlinear shallow water equations (Stoker, 1957), vertical distribution of the pressure is hydrostatic and that of the horizontal water particle velocity is uniform. Therefore we take one component of the vertical distribution function which is uniform:

\[ Z = 1 \]  
(28)

Then, the matrices \( A_{a\beta}, B_{a\beta} \) and \( C_{a\beta} \) defined by Eq. (5) have one component, respectively, as

\[ A = h + \eta, \quad B = 0, \quad C = 0 \]  
(29)

and the nonlinear mild-slope equations (8) and (9) become

\[ \frac{\partial \eta}{\partial t} + \nabla [(h + \eta) \nabla f] = 0 \]  
(30)

\[ g\eta + \frac{\partial f}{\partial t} + \frac{1}{2} (\nabla f)^2 = 0 \]  
(31)

By rewriting the above equations in terms of \( u \):

\[ u = \nabla \phi = \nabla f \]  
(32)

the nonlinear shallow-water equations are obtained:

\[ \frac{\partial \eta}{\partial t} + \nabla [(h + \eta)u] = 0 \]  
(33)

\[ \frac{\partial u}{\partial t} + (u \nabla)u + g \nabla \eta = 0 \]  
(34)

2.4 Relation with Boussinesq equations

Since the vertical distribution of the horizontal water particle velocity in the Boussinesq equations is expressed by the linear combination of uniform and parabolic components, the following two vertical distribution functions are employed:

\[ Z_1 = 1, \quad Z_2 = \frac{(h + z)^2}{h^2} \]  
(35)

Then, the nonlinear mild-slope equations (8) and (9) become

\[ \frac{\partial \eta}{\partial t} + \nabla \left[ (h + \eta) \nabla f_1 + \frac{(h + \eta)^3}{3h^2} \nabla f_2 \right] + \frac{(h + \eta)^2(h - 2\eta)}{3h^3} (\nabla f_2)(\nabla h) \]

\[ - \frac{2(h + \eta)}{h^3} f_2(\nabla \eta)(\nabla h) = 0 \]  
(36)
\begin{align*}
\frac{(h + \eta)^2}{h^2} \frac{\partial \eta}{\partial t} + \nabla \left[ \frac{(h + \eta)^3}{3h^2} \nabla f_1 + \frac{(h + \eta)^5}{5h^4} \nabla f_2 \right] - \frac{4(h + \eta)^3}{3h^4} f_2 \\
- \frac{(h + \eta)^2(h - 2\eta)}{3h^3} (\nabla f_1)(\nabla h) - \frac{2(h + \eta)^2\eta}{h^5} f_2(\nabla \eta)(\nabla h) = 0 \tag{37}
\end{align*}

\begin{align*}
\frac{g\eta}{h^2} + \frac{\partial f_1}{\partial t} + \frac{(h + \eta)^2 \partial f_2}{h^2} + \frac{1}{2} \left\{ \nabla f_1 + \frac{(h + \eta)^2}{h^2} \nabla f_2 \right\}^2 + \frac{1}{2} \left\{ \frac{2(h + \eta)}{h^2} f_2 \right\}^2 \\
- \frac{2(h + \eta)\eta}{h^3} f_2 \left\{ \nabla f_1 + \frac{(h + \eta)^2}{h^2} \nabla f_2 \right\} (\nabla h) = 0 \tag{38}
\end{align*}

The assumption of $O[H/h] \sim O[(h/L)^2]$ ($H$: wave height, $h$: water depth, $L$: wavelength) leads to the following ordering:

\[ \nabla h \sim O\left[ \sqrt{\varepsilon} \right], \quad \eta \sim f_1 \sim O[\varepsilon], \quad f_2 \sim O[\varepsilon^2] \tag{39} \]

By considering the above ordering, Eqs. (36) to (38) are simplified as

\begin{align*}
\frac{\partial \eta}{\partial t} + \nabla \left[ \frac{(h + \eta)}{3} \nabla f_1 + \frac{h}{3} \nabla f_2 \right] + \frac{1}{3} (\nabla f_2)(\nabla h) = 0 \tag{40}
\end{align*}

\begin{align*}
\frac{\partial \eta}{\partial t} + \nabla \left[ \frac{h}{3} \nabla f_1 \right] - \frac{4}{3h} f_2 - \frac{1}{3} (\nabla f_1)(\nabla h) = 0 \tag{41}
\end{align*}

\begin{align*}
g\eta + \frac{\partial f_1}{\partial t} + \frac{\partial f_2}{\partial t} + \frac{1}{2} (\nabla f_1)^2 = 0 \tag{42}
\end{align*}

Then, because

\begin{align*}
u = \nabla \phi = \nabla f_1 + \frac{(h + z)^2}{h^2} \nabla f_2 - \frac{2z(h + z)}{h^3} f_2 \nabla h \tag{43}
\end{align*}

\begin{align*}
\tilde{u} \approx \nabla f_1 + \frac{1}{3} \nabla f_2 + \frac{1}{3h} f_2 \nabla h \tag{44}
\end{align*}

Equations (40) to (42) are combined to yield the Boussinesq equations (Peregrine, 1967):

\begin{align*}
\frac{\partial \eta}{\partial t} + \nabla [(h + \eta)\tilde{u}] = 0 \tag{45}
\end{align*}

\begin{align*}
\frac{\partial \tilde{u}}{\partial t} + (\tilde{u} \nabla) \tilde{u} + g \nabla \eta = -\frac{h^2}{6} \frac{\partial}{\partial t} \nabla (\tilde{u}) + \frac{h}{2} \frac{\partial}{\partial t} \nabla (h \tilde{u}) \tag{46}
\end{align*}

### 3 Verification of Numerical Model

#### 3.1 Outline of numerical model

A finite difference numerical model is developed based on the nonlinear mild-slope equations, in which the nonlinear equations are solved by simple successive substitution or Newton-Raphson scheme.
Non-reflective boundary conditions are installed along the boundaries by introducing sponge layers in which an energy dissipation term, \( D \), is added to the left side of Eq. (9) (Cruz et al., 1994):

\[
D = \varepsilon(x) \sum_{\alpha=1}^{N} f_{\alpha}
\]

where

\[
\varepsilon(x) = \frac{r \varepsilon_m}{2(\sinh r - r)} \left[ \cosh \left( \frac{r x}{F} \right) - 1 \right]
\]

\[
\varepsilon_m = \theta \sqrt{g/h}
\]

and \( F \) is the width of the sponge layer, \( \theta = 1.0 \) to 2.0 and \( r = 3 \). Incident waves are given as a discontinuity at the interface between the actual calculation domain and sponge layer (Ishii et al., 1996). Still water is the initial condition for all calculations.

### 3.2 Effect of vertical distribution functions

A typical example of sets of vertical distribution functions is a set of polynomial functions:

\[
Z_{\alpha} = \left( 1 + \frac{z}{h} \right)^{2(\alpha-1)}
\]

The coefficients are easily calculated as

\[
Z_{\alpha}^n = \zeta^{2(\alpha-1)}
\]

\[
A_{\alpha\beta} = \frac{h \zeta^{2(\alpha+\beta)-3}}{2(\alpha + \beta) - 3}
\]

\[
B_{\alpha\beta} = \frac{4(\alpha - 1)(\beta - 1) \zeta^{2(\alpha+\beta)-5} h}{2(\alpha + \beta) - 5}
\]

\[
C_{\alpha\beta} = 2(\alpha - 1) \zeta^{2(\alpha+\beta)-4} \left[ \frac{\zeta}{2(\alpha + \beta) - 3} + \frac{1}{2(\alpha + \beta) - 4} \right]
\]

\[
D_{\alpha\beta} = \frac{4(\alpha - 1)(\beta - 1) \zeta^{2(\alpha+\beta)-5} h}{2(\alpha + \beta) - 5} \left[ \frac{\zeta^2}{2(\alpha + \beta) - 3} - \frac{\zeta}{\alpha + \beta - 2} + \frac{1}{2(\alpha + \beta) - 5} \right]
\]

where

\[
\zeta = \frac{h + \eta}{h}
\]

The above set of polynomial functions gives an accurate linear dispersion relation even in deep waters (Isobe, 1994); however hyperbolic cosine functions are expected to be more effective in deep water. In the present study, two sets are examined for propagation of permanent waves with various water depths and wave heights. In the
first set (CASE A), the following two functions are taken as the vertical distribution functions:

\[ Z_1(z) = 1, \quad Z_2(z) = \left(1 + \frac{z}{h}\right)^2 \]  \hspace{1cm} (57)

The second set (CASE B) is

\[ Z_1(z) = \left(1 + \frac{z}{h}\right)^2, \quad Z_2(z) = \frac{\cosh k(h + z)}{\cosh kh} \]  \hspace{1cm} (58)

in which \( Z_1 \) and \( Z_2 \) are expected to become effective in shallow and deep waters, respectively.

Figures 1 to 3 show sample results of 1-D propagation of permanent waves. Permanent waves are incident at \( x/L = 1 \) and a sponge layer is installed from \( x/L = 3 \) to 9, and thus the actual region is from \( x/L = 1 \) to 3. The distributions of \( \eta/H_1 \) and \( H/H_1 \) (\( H \): wave height and \( H_1 \): incident wave height), are shown in the

![Fig. 1](image)

**Fig. 1** Comparison between exact and numerical solutions of water surface profile of permanent waves (\( h/L_0 = 0.1, \frac{H_1}{h} = 0.3, \frac{H_1}{L_0} = 0.03, U_r = 16 \)).
figure. Since Fig. 1 is for weakly nonlinear waves on an intermediate water depth in which $h/L_0 = 0.1$ (h: water depth and $L_0$: deep water wavelength of linear waves), the agreement with theory is good for the two sets of vertical distribution functions. Figure 2 is for highly nonlinear waves on a shallow water. Nonlinear effect is well reproduced by the two sets. However, for deep water as shown in Fig. 3, difference in wavelength is significant in CASE A, indicating that the dispersion effect is not enough. In general, the vertical distribution functions of CASE B are appropriate in deep water, whereas those of CASE A give numerical solution even for near-breaking waves in shallow water.

The numerical model of CASE B is applied to wave diffraction due to a circular shoal for which an experiment is conducted by Ito and Tanimoto (1972). Figure 4 shows the bottom configuration in the prototype scale and wave height distributions along cross-shore and alongshore directions. The water depth in the uniform region

![Fig. 2](image)

Fig. 2  Comparison between exact and numerical solutions of water surface profile of permanent waves ($h/L_0 = 0.005$, $H_1/h = 0.3$, $H_1/L_0 = 0.0015$, $U_r = 450$).
is 15 m, the wave period 5.1 s and the incident wave height 1 m, resulting in fairly strong nonlinearity. Comparison of wave height distribution between calculation and measurement indicates the validity of the present model.

3.3 Effect of nonlinearity on wave diffraction

Diffraction of waves through a breakwater gap is calculated to elucidate the effect of nonlinearity on diffraction. Figure 5 shows an example in which $h/L_0 = 0.05$, $B/L = 2$ ($B$: gap width and $L$: wavelength of linear waves), and $H_1/L_0 =$ 0.0002, 0.024, and 0.032. As can be seen from comparison among the three figures, nonlinearity accelerates diffraction, causing smaller wave height in direct wave incidence region along $y = 0$ and larger wave height in the shadow region. This implies that the function of breakwater to make a calm region behind it is less effective in
Fig. 4  Comparison of calculated wave height distribution around a circular shoal with measurement by Ito and Tanimoto (1972).
Fig. 5 Effect of wave nonlinearity on diffraction behind a breakwater gap \((B/L = 2, h/L_0 = 0.05)\).
4 Conclusion

Nonlinear mild-slope equations are derived only by expanding the velocity potential into a series in terms of a given set of vertical distribution functions and hence include full nonlinearity and full dispersivity. In the former part of the present paper, it was shown that the mild-slope equation, nonlinear shallow water equations and Boussinesq equations can be derived as special cases of the nonlinear mild-slope equations. It was also shown that the dispersion relation is accurately expressed by linearized forms of the nonlinear mild-slope equations.

A numerical model is developed based on the nonlinear mild-slope equations. The validity of the model is verified through calculations of waves of permanent type and wave transformation around a circular shoal. The result for diffraction of waves through a breakwater gap showed the larger diffraction effect for the more nonlinear waves. This suggests the importance to consider nonlinear effect in the diffraction diagrams since they are used to predict tranquility in the shadow region for rough incident waves. Systematic calculations will be made in the future.

A Comparison of Higher Order Boussinesq and Local Polynomial Approximation Models

Mauricio F. Gobbi¹, Andrew B. Kennedy² and James T. Kirby²

Abstract

Two recent approaches for computing wave evolution over varying topography are presented: the high order Boussinesq model of Gobbi and Kirby (1998) and the local polynomial approximation (LPA) method of Kennedy and Fen- ton (1997). Both analytical results and numerical solutions of Gobbi and Kirby (1998) model and two variants of the LPA method are presented and compared with exact solutions and laboratory measurements of waves propagating over submerged features.

Introduction

The increasing availability of high-speed computers has encouraged several researchers to work towards implementing deterministic nonlinear models and their numerical solutions for more accurate predictions of wave transformation in coastal areas. A great deal of effort has been made to extend the validity of \( O(\mu^2) \) (\( \mu \sim \) depth to length ratio) Boussinesq-type models to both deeper water (e.g., Nwogu, 1993; Schäffer et al., 1995) and highly nonlinear conditions (Wei et al., 1995). Recently, noticing that existing Boussinesq models, which assume a second degree polynomial approximation for the velocity potential's vertical (\( z \)) dependency, have poor kinematics prediction in deep water, Gobbi et al. (1998) have derived a new Boussinesq-type model for a flat bed, which assumes that the velocity potential has a fourth degree polynomial dependency in \( z \). The model's dependent variables are defined to give a (4,4) Padé linear dispersion relationship, and is fully nonlinear. Comparisons of several linear and nonlinear properties with exact solutions show great improvement of Gobbi et al. (1998) over Wei et al. (1995). A variable depth version of the model has been derived by Gobbi and Kirby (1998), and comparisons with laboratory experimental data show, again, very significant improvement over the model by Wei et al. (1995). We shall refer to these fourth order models as GKW98.

²Center for Applied Coastal Research, University of Delaware, Newark, DE. 19716 USA.
Recently, several local polynomial approximation methods have been developed (Kennedy and Fenton, 1997) which seek to provide local solutions to Laplace’s equation in a weighted residual sense by assuming a local polynomial for the velocity potential at each local subdomain, where a subdomain is bounded by the bottom, the free surface, and vertical interfaces. The solution is subject to bottom and free surface constraints and continuity of the velocity and velocity potential at the subdomains’ interfaces. With the problem completely specified for a given time, the coefficients of the polynomial are calculated. The kinematic and dynamic free surface boundary conditions are then used to advance the solution in time, and provide new free surface constraints for the next time step. Of the several variants of LPA methods, in this paper we shall look at two cases: both with only one horizontal dimension and fully nonlinear, one with fourth degree (somewhat comparable to GKW98) and one with sixth degree polynomial vertical representation of the velocity potential.

We briefly present both the GKW98 and LPA models, and then look at analytical properties of the linearized models and Stokes second harmonic amplitudes. Finally, the models are compared with experimental data.

Fully Nonlinear, $O(\mu^4)$ Boussinesq Model

This model, which was derived by Gobbi and Kirby (1998), consists of a set of coupled evolution equations which approximate the mass flux and momentum conservation in an arbitrary depth located at elevation $z = -h(x,y)$, where $(x,y)$ are the horizontal spatial coordinates. The dependent variables are the free surface displacement $\eta$ and the weighted average of the eulerian velocity between two arbitrary elevations, $z_a$ and $z_b$ in the water column, $\mathbf{u}$, with weight parameter $\beta$. The choice of of these elevations and the weight parameter are related to the accuracy of the linear dispersion properties of the model. The nondimensionalized mass conservation equation is given by

$$\eta_t + \nabla \cdot \mathbf{M} = 0; \quad \mathbf{M} = \int_{-h}^{\delta \eta} \nabla \phi dz,$$

with

$$\mathbf{M} = H \left\{ \tilde{\mathbf{u}} + \mu^2 \left[ \left( Ah - \frac{H}{2} \right) (2\nabla h F_{22} + \nabla F_{21}) + \left( Bh^2 - \frac{H^2}{3} \right) \nabla F_{22} \right] \right. + \mu^4 \left[ \left( Ah - \frac{H}{2} \right) (2\nabla h F_{42} + \nabla F_{41} + 2\nabla h F_{44} + \nabla F_{43}) \right. \right.$$

$$\left. + \left( Bh^2 - \frac{H^2}{3} \right) (\nabla F_{42} + 3\nabla h F_{45} + \nabla F_{44}) \right.$$

$$\left. + \left( Ch^3 - \frac{H^3}{4} \right) (4\nabla h F_{46} + \nabla F_{45}) + \left( Dh^4 - \frac{H^4}{5} \right) \nabla F_{46} \right\},$$

and $H = h + \delta \eta$. The pair of momentum conservation equations is given by

$$\mathbf{U}_t = -\nabla \eta - \frac{\delta}{2} \nabla \left( |\mathbf{u}|^2 \right) + \Gamma_1 (\eta, \tilde{\mathbf{u}}) + \Gamma_2 (\eta, \mathbf{u}),$$
where

\[
U \equiv \hat{u} + \mu^2 \left[ (A - 1) h (2\nabla h F_{21} + \nabla F_{21}) + (B - 1) h^2 \nabla F_{22} \right] + \mu^4 \left[ (A - 1) h (2\nabla h F_{42} + \nabla F_{41} + 2\nabla h F_{44} + \nabla F_{43}) + (B - 1) h^2 \nabla F_{44} + 3\nabla h F_{45} + \nabla F_{44} \right] + (C - 1) h^3 (4\nabla h F_{45} + \nabla F_{45}) + (D - 1) h^4 \nabla F_{46} \right] (4)
\]

\[
\Gamma_1 \equiv \mu^2 \nabla \left[ \delta \eta F_{21t} + \left( 2h \delta \eta + \delta^2 \eta^2 \right) F_{22t} \right] + \mu^4 \nabla \left[ (A - 1) h (2\nabla h F_{41} + \nabla F_{41}) + \left( 2h \delta \eta + \delta^2 \eta^2 \right) (F_{41t} + F_{44}) + \left( 3h^2 \delta \eta + 3h \delta^2 \eta^2 + \delta^3 \eta^3 \right) F_{45t} + \left( 4h^3 \delta \eta + 6h^2 \delta^2 \eta^2 + 4h \delta^3 \eta^3 + \delta^4 \eta^4 \right) F_{46t} \right] (5)
\]

\[
\Gamma_2 \equiv - \mu^2 \delta \nabla \left\{ \hat{u} \cdot \left[ (Ah - H) (\nabla F_{21} + 2\nabla h F_{22}) + (Bh^2 - H^2) \nabla F_{22} \right] + \frac{1}{2} \left[ (F_{21} + 2HF_{22})^2 \right] \right\} - \mu^4 \delta \nabla \left\{ \hat{u} \cdot \left[ (Ah - H) (\nabla F_{41} + 2\nabla h F_{42} + \nabla F_{43} + 2\nabla h F_{44}) + (Bh^2 - H^2) \nabla F_{42} \right] \right\} (6)
\]

\[
F_{21}(\hat{u}) \equiv G \nabla h \cdot \hat{u} (7)
\]

\[
F_{22}(\hat{u}) \equiv \frac{1}{2} G \nabla \cdot \hat{u} (8)
\]

\[
F_{41}(\hat{u}) \equiv - |\nabla h|^2 \left[ (A - 1) \nabla h \cdot \hat{u} + (B - A) h \nabla \cdot \hat{u} \right] (9)
\]

\[
F_{42}(\hat{u}) \equiv - \frac{1}{2} \nabla^2 h \left[ (A - 1) \nabla h \cdot \hat{u} + (B - A) h \nabla \cdot \hat{u} \right] (10)
\]

\[
F_{43}(\hat{u}) \equiv \nabla h \cdot \nabla (Ah \nabla h \cdot \hat{u}) + \frac{1}{2} \nabla h \cdot \nabla \left( Bh^2 \nabla \cdot \hat{u} \right) (11)
\]

\[
F_{44}(\hat{u}) \equiv \frac{1}{2} \nabla^2 (Ah \nabla h \cdot \hat{u}) + \frac{1}{2} \nabla^2 \left( Bh^2 \nabla \cdot \hat{u} \right) - \frac{1}{2} \nabla^2 \nabla h \cdot \hat{u} - \nabla h \cdot \nabla (\nabla h \cdot \hat{u}) (12)
\]

\[
F_{45}(\hat{u}) \equiv - \frac{1}{6} \nabla^2 h \nabla \cdot \hat{u} - \frac{1}{3} \nabla h \cdot \nabla (\nabla \cdot \hat{u}) - \frac{1}{6} \nabla^2 (\nabla h \cdot \hat{u}) (13)
\]

\[
F_{46}(\hat{u}) \equiv - \frac{1}{24} \nabla^2 (\nabla \cdot \hat{u}) (14)
\]

where \( G \equiv (1 + \mu^2 |\nabla h|^2)^{-1} \). The nondimensional parameters appearing are \( \delta \) and \( \mu \), characterizing the importance of nonlinearity and dispersion, respectively.
Local Polynomial Approximation Method

The local polynomial approximation method is a finite depth, potential flow technique for computing wave evolution over varying topography. It was designed to provide high accuracy with a reasonable computational cost, and remains general enough that the order of approximation may be easily changed.

The local polynomial approximation method used here is identical to that presented in Kennedy and Fenton (1997). In contrast to the presentation there, where the numerical solution method was highlighted, it is presented here in as a dimensionless set of differential equations for the approximate solution of Laplace’s equation coupled with potential flow evolution equations. The velocity potential $\phi$ is assumed to be represented in the vertical coordinate $z$, by a polynomial of arbitrary degree

$$\phi(x, z) = \sum_{j=0}^{n-1} A_j(x) z^j$$  \hspace{1cm} (15)

where the $A_j$’s are functions only of the horizontal coordinate. The level of approximation $n$ controls the degree of polynomial used and hence the accuracy. Here, the levels of approximation $n = 5$ and $n = 7$ will be used which have, respectively, fourth and sixth degree polynomial approximations in the vertical direction $z$. The initially unknown functions $A_j$ must be chosen to satisfy the bottom boundary condition at the bed location $z = -h(x)$

$$\phi_z + \phi_x h_x = 0 \text{ on } z = -h$$  \hspace{1cm} (16)

and also the free surface boundary condition

$$\phi(x, z = \eta(x)) = \phi(s)(x)$$  \hspace{1cm} (17)

This leaves $n - 2$ constraints needed to completely specify the distribution of the $A_j$ functions. These are found by imposing an approximation to the full field equation at collocation points in the vertical plane

$$\nabla^2 \phi = 0 \text{ on } z_j = -h + (\eta + h)\alpha_j, \ j = 1, 2, \ldots, n - 2$$  \hspace{1cm} (18)

For all results presented here, collocation points, $z_j$, are taken to be the Gauss-Legendre points for $N = n - 2$, using the free surface and the bed as limits.

With the addition of global boundary conditions on the lateral boundaries, a set of block-banded linear equations results which completely specifies the problem. Once the system of equations has been solved, the flow field may be
determined and the free surface elevation and velocity potential may be advanced to the next time step using the free surface evolution equations

\[ \eta_t = -\left( \int_{-h}^{\eta} \phi_x dz \right)_x \]  

(19)

\[ \phi_t^{(s)} = -\eta - \frac{1}{2} (\phi_x^2 + \phi_z^2) + \phi_x \phi_t \]  

(20)

It is very simple to extend the system of equations to three dimensions, but because of computational considerations, this is not advisable. For one horizontal dimension, a good solution technique uses complex polynomials to represent the flow field as detailed in Kennedy and Fenton (1997), but this particular technique cannot be extended into an extra dimension.

Analytical Properties

For very small amplitude waves propagating over a level bottom, a progressive sinusoidal wave solution can be substituted into the linearized constant depth versions of both GKW98 and LPA to give an approximation to the exact linear dispersion relationship. Details can be found in Gobbi et al. (1998) for GKW98 dispersion, which results in a (4,4) Padé approximant to the exact relationship, and in Kennedy (1997) for the LPA formulations. Figure 1 shows the ratio to the exact solution of the linear phase speed calculated for GKW98, LPA \( n = 5 \), and LPA \( n = 7 \). It is clear that the GKW98 phase speed sits in between the two LPA results in terms of accuracy. Figures 2 and 3 show the vertical profile of the horizontal and vertical velocity amplitudes, respectively, normalized by their value at the free surface, for GKW98 and both LPA results. Notice the effect of the more powerful representation of the vertical dependence in LPA \( n = 7 \) over both GKW98 and LPA \( n = 5 \), which are quite comparable.

Turning to a second order nonlinear property, figure 4 shows the ratio to the full theory solution of the amplitude of the second harmonic of a Stokes expansion of GKW98 and both LPA’s. For this case, both LPA solutions give better result than the GKW98 model. This is probably because the GKW98 model was derived for optimized performance in a linear sense, whereas the LPA method uses the full water column in the specification of the problem.

Comparisons with Laboratory Measurements

In this section we compare the computations from GKW98 and both LPA implementations presented earlier with experimental data of waves propagating over submerged sills. First we use data from Beji and Battjes (1993) and Luth et al. (1994) consisting of regular waves propagating over a structure resembling a sand bar. Then we use the data from Ohyama et al. (1994) where the submerged structure has much steeper slopes, resembling a submerged breakwater. These two experiments have become quite popular for tests of wave propagation models, and the reader is referred to the original papers for additional information.
Figure 1: Ratio to exact solution of phase speed.

Figure 2: Horizontal velocity profile. Exact (solid), GKW98 (dot), LPA n=5 (dash-dot), LPA n=7 (dash).
Figure 3: Vertical velocity profile. Exact (solid), GKW98 (dot), LPA n=5 (dash-dot), LPA n=7 (dash).

Figure 4: Ratio to full problem solution of Stokes second harmonic amplitude.
The experiments performed by Beji and Battjes (1993) and Luth et al. (1994) have the same geometric characteristics, except for the length scale in Luth et al. (1994), which is twice as large as in Beji and Battjes (1993). In Luth et al. (1994) all gauge locations used in Beji and Battjes (1993) were repeated, and another run of measurements was performed with the gauges at different locations. Here, we re-scale all measurements to the scales used in Beji and Battjes (1993). The layout of the experimental set-up with the locations of the measurement stations and the geometry of the flume are illustrated in Figure 5.

Three sets of data were collected using different incident wave conditions. We refer to these data sets as cases (a), (b), and (c). In case (b), wave breaking occurred and this case was disregarded. The incident wave amplitude and period were 0.01m, 2.02s, and 0.0205m, 1.01s, for cases (a) and (c) respectively.

In all cases, the data from gauges at 2.0m or 4.0m were used to synchronize the data with the models. Figures 6, 7, and 8 show, respectively, comparisons of GKW98, LPA $n = 7$, and LPA $n = 5$, with the case (a) of the Delft experimental data at several gauge locations. For this case, all three models’ performance are quite satisfactory, with GKW98 and LPA $n = 7$ showing excellent agreement, while LPA $n = 5$ shows larger discrepancies, due to its less accurate linear phase speed. Similarly, figures 9, 10, and 11 show comparisons with case (c). Notice that because the incident waves in this case are shorter, it is a more demanding case than case (a), especially behind the bar, where nonlinear superharmonics are released as free waves, and are much shorter than the incident wave. For this case, LPA $n = 7$ performs best, followed by the also very good agreement of GKW98, but LPA $n = 5$ has poor agreement behind the structure. This result is in agreement with the linear phase speed results shown in figure 1.

We now compare the numerical results to the Ohyama experimental data. Summarizing the experimental setup, the wave flume is 65m long and 1.0m wide. The total depth of the flume is 1.6m. The location of the center of the bar was 28.3m from the wavemaker. Figure 12 shows a sketch of the flume. Three tests with incident wave periods 1.34s, 2.01s, and 2.68s, (cases 2, 4, 6, respectively) and fixed amplitude equal to 0.025m will be used in the comparisons. No wave breaking occurred in any of the tests. The time series were synchronized with the computations at station 3. Figures 12, 13, and 14 show the comparisons

Figure 7: Comparisons of free surface displacement with case (a) of Delft experimental data at several gauge locations. LPA n=7 (dash-dot), data (solid).
Figure 8: Comparisons of free surface displacement with case (a) of Delft experimental data at several gauge locations. LPA n=5 (dash-dot), data (solid).

Figure 9: Comparisons of free surface displacement with case (c) of Delft experimental data at several gauge locations. GKW98 (dash-dot), data (solid).
Figure 10: Comparisons of free surface displacement with case (c) of Delft experimental data at several gauge locations. LPA \( n=7 \) (dash-dot), data (solid).

Figure 11: Comparisons of free surface displacement with case (c) of Delft experimental data at several gauge locations. LPA \( n=5 \) (dash-dot), data (solid).
Figure 12: Sketch of wave flume of the Ohyama experiment.

Figure 13: Comparisons of free surface displacement with case 2 of Ohyama experimental data. Computations (dash-dot), data (solid).

for the three cases, and it is possible to see that GKW98 and LPA \( n = 5 \) are comparable for cases 2 and 4, while LPA \( n = 7 \) outperforms them for these cases. In case 6, GKW98 and LPA \( n = 7 \) are comparable, while LPA \( n = 5 \) shows poorer performance. It might seem surprising that GKW98 does not perform in Ohyama cases 2 and 4 as well as in the Delft cases (a) and (c), since the incident wave conditions are not that different. This is due to the steep bottom slopes in Ohyama's cases which violates the intrinsic mild-slope assumption of GKW98 \((w \ll u)\), which the fourth order polynomial for the potential's vertical dependence is not powerful enough to handle, for large enough \( \mu \).

Conclusions

Fully nonlinear local polynomial approximations and a \( O(\mu^4) \) Boussinesq model were compared both in terms of analytical properties and of agreement
Figure 14: Comparisons of free surface displacement with case 4 of Ohyama experimental data. Computations (dash-dot), data (solid).

with experimental data. In general, because of its more accurate dispersion, the Boussinesq model performed better than the LPA with the same level of polynomial accuracy \((n = 5)\), while the sixth degree polynomial LPA \((n = 7)\) proved to be more accurate than both. The Boussinesq model has the advantage of being potentially faster in terms of computational time, and its 3-D implementation is more natural than the LPA methods shown here, which uses complex formulation to solve Laplace's equation and therefore cannot be extended to 3-D in an efficient manner. However, it is much simpler to extend the LPA model to any level of accuracy desired. The authors are now working on improvements in nonlinear behavior of Boussinesq models, improvements on dispersion properties of LPA methods, and 3-D implementation of the models.

Experiments on nonlinear wave groups shoaling in a tank

L. Shemer¹, Haiying Jiao² & E. Kit³

Abstract

Evolution of periodically generated wave groups of different shapes that propagate over a sloping beach is studied experimentally and theoretically, by solving numerically the cubic Schrödinger equation. The agreements and disagreements between the experimental and the numerical results are discussed.

Introduction

Real sea waves can be described quite faithfully by JONSWAP spectrum (Hasselmann et al., 1973). One of the important features of this spectrum is its quite narrow frequency band, which results in notable wave groupiness even in the open seas. It has been observed in many field experiments that the distribution of waves in a group approaching the shore becomes more uniform, so that the maximum wave height in the group decreases. Such a transformation of wave groups has important practical consequences, since it affects directly the value of the maximum wave height in the group. The importance of the significant wave height as a design parameter is generally recognized in coastal engineering. This demodulation effect may result from the dissipation in the bottom boundary layer, as well as from the nonlinear and dispersive effects, as shown in numerical simulations based on the Korteweg-de Vries equation by Kit et al. (1995). The reduction in the maximum wave height with decrease of the water depth was also obtained numerically by Barnes and Peregrine (1995). In the present study, the transformation of a deterministic wave group over a sloping beach is investigated experimentally, in a laboratory wave tank, and theoretically, by a numerical solution of

model equations. The simplest nonlinear theoretical model which is capable of describing
the evolution of propagating wave packet with a narrow spectrum in the range of water
depths from deep to intermediate is the so-called cubic Schrödinger equation (CSE) (see,
e.g., Mei 1989). This equation was derived first by Zakharov (1968) and Hasimoto & Ono
(1972) and has been extensively applied for description of wave group evolution in deep
water.

Experimental Facility and Procedure

Experiments are performed in a wave tank that is 18 m long, 1.2 m wide and filled to
a mean water depth of 0.6 m. A computer-operated wavemaker is located at one end of
the tank. A false bottom made of thick marine plywood is installed in the tank. The
effective water depth is 0.3 m in the vicinity of the wavemaker. The bottom slope is 1:30
for the length of 7.5 m along the tank. The last 5 m of the false bottom represent a
horizontal flat surface with the effective depth of 0.05 m. At the far end of the false bottom
is located a wave energy-absorbing beach. Two sets of four wave gauges, each on its own
bar, are used in this study. The first set of the gauges is of resistance type, while the
second one is of the capacitance type. The distance between the two consecutive probes is
0.4 m for the resistance wave gauges and about 0.3 m for the capacitance probes. Each
probe-supporting bar is mounted on a separate carriage that can be moved along the tank.
More sensitive capacitance probes are used for measurements in the shallow water area,
while resistance probes are used in the rest of the tank. Detailed measurements of
instantaneous surface elevation are carried out at eight fixed measuring stations, thus
covering 32 locations along the tank.

Wave groups with three different shapes are selected in this study. The equations
describing the driving signal applied to the wavemaker are as following:

\[
s(t) = A_0 \sin(\Omega t) \sin(\omega t), \quad \Omega = \omega / 20 \tag{1}
\]

\[
s(t) = A_0 \sin(\Omega t) \sin(\omega t), \quad \Omega = \omega / 20 \tag{2}
\]

\[
s(t) = A_0 \exp \left( - \left( t / 5T \right)^2 \right) \sin(\omega t), \quad -16T < t < 16T \tag{3}
\]

where the carrier wave period \( T = 2\pi / \omega \). These signals are repeated periodically. The first
two driving signals produce identical wave groups envelopes, but their spectra differ
essentially. The forcing signal (1) has a simple bimodal spectrum. The spectrum of (2)
consists of a set of discrete frequencies, where 3 dominant modes can be identified. The
third signal produces wave groups that are widely separated and have a discrete spectrum,
which requires a considerable number of modes for its accurate description. Experiments
are carried out for \( T = 0.7 \) s and for three values of the driving amplitude \( A_0 \), corresponding
to a nearly linear, nonlinear, and strongly nonlinear wave steepnesses. In the vicinity of the
wavemaker, the maximum values of the wave steepness \( \alpha_k k_0 \) in the group are
approximately 0.07, 0.14 and 0.21. Variation of the wave group velocity along the tank
and modification of the wave power spectra are measured.
Theoretical Model

The cubic Schrödinger equation (CSE) for a mild slope is selected as the theoretical model. The CSE is written in a form given by Mei (1989):

$$-i\mu A - iA_x + \alpha A_{tt} + \beta |A|^2 A = 0$$  \hspace{1cm} (4)

where $A(X, \tau)$ is the complex wave group envelope, and the slow variables are related to the coordinate along the tank $x$ and the time $t$ as

$$X = \varepsilon^2 x; \quad \tau = \frac{1}{\varepsilon} \int_0^x \frac{dX}{c_g(X)} - \epsilon t$$  \hspace{1cm} (5)

In (5), $c_g = \partial \omega / \partial k$ is the group velocity, $k$ being the local wave number, and $A(X=0, \tau = 0) = \alpha / \epsilon$. The local values of the $X$-dependent coefficients in the CSE are defined in the dimensionless form by

$$\frac{\mu}{k_o} = \frac{d\omega}{dX} \frac{(1 - \tanh^2 q)(1 - q \tanh q)}{k_o [ \tanh q + q(\tanh^2 q)]},$$ \hspace{1cm} (6)

$$\frac{\alpha \omega^2}{k_o} = \frac{\omega^2}{k_o c_g^3} \frac{\partial^2 \omega}{\partial k^2},$$ \hspace{1cm} (7)

$$\frac{\beta}{k_o^3} = \frac{1}{n} \left[ \frac{4 q + 8 - 2 \tanh^2 q}{16 \sinh^4 q} - \frac{1}{2 \sinh^2 2q} \frac{(2 \cosh^2 q + n)^2}{\tanh q} \right],$$ \hspace{1cm} (8)

where $q = kh$, $k_o = k(X=0)$ and the parameter $n = c_g k / \omega$ represents the local value of the ratio of group and phase velocities and is given by

$$n = \frac{1}{2} \left( 1 + \frac{2q}{\sinh 2q} \right)$$ \hspace{1cm} (9)

It is well known that the coefficient $\beta$ of the nonlinear term given by (8) and (9) changes its sign at $q=1.36$. For $q>1.36$, $\beta>0$, corresponding to the focusing condition, while for $q<1.36$, $\beta<0$ and wave energy defocusing occurs. The radian frequency of the carrier wave $\omega$ is related to its wave number $k$ by the dispersion relation

$$\omega^2 = kg \tanh q,$$ \hspace{1cm} (10)
where \( g \) is the acceleration due to gravity. Equation (4) is solved numerically using an implicit finite difference scheme with periodic in \( \tau \) boundary conditions. Initial conditions at \( \tau = 0 \) are in accordance with the shapes defined by (1) to (3). The variation of the surface elevation \( \eta \) is obtained using the complex amplitude \( A(X, \tau) \) from the solution of (4) and the relations (5) between the scaled \( (X, \tau) \) and the physical \( (x, t) \) variables as

\[
\eta(x, t) = e^{A(X, x)} e^{i(kx - \omega \tau)} + c.c.,
\]  

where \( c.c. \) denotes complex conjugate.

**Results and Discussion**

The results for the wave groups excited by the driving signal given by the equations (1) – (3) are presented in Figures 1 – 3, respectively, for the two extreme values of the forcing amplitude, \( \alpha_0 k_0 = 0.07 \) and \( \alpha_0 k_0 = 0.21 \).

![Figure 1](image)

Figure 1. The measured surface elevation \((a and b)\) and the computed group envelopes \((c and d)\) for the driving signal (1).

In each Figure, the results are given at two locations along the tank, \( x = 0.25 \text{ m}, h = 0.3 \text{ m} \) (Figures \( a \) and \( c \)), and \( x = 7.0 \text{ m}, h = 0.075 \text{ m} \) (Figures \( b \) and \( d \)). The measured variation in time of the instantaneous surface elevation is given in Figures \( a \) and \( b \), where the curves representing the low and the high amplitudes are shifted in the vertical
direction. The corresponding variation in time of group envelopes obtained numerically is given in Figures c and d.

The most striking effect observed in this study is the difference in the evolution of wave groups excited by the driving signals (1) and (2). In the vicinity of the wavemaker, both types of wave groups look practically identical, see Figures 1a and 2a. At a larger distance, the wave groups generated by (1), Figure 1b, tend to retain their identity, although nonlinear effects are clearly visible, while the wave groups excited by (2), Figure 2b, are spread significantly. This spreading can be interpreted as the demodulation effect. Certain spreading can also be observed in the detached wave groups excited using (3), Figure 3b. For all shapes of the forcing signals, the initially symmetric wave groups at higher amplitude lose their symmetry. The trough-crest asymmetry is clearly visible at high amplitude of forcing at both locations. This asymmetry is a clear indication of the appearance of the higher harmonics in the surface elevation spectrum. In addition to the trough-crest asymmetry, left-right asymmetry is observed at the remote measuring station at high amplitude of forcing. This effect is most prominent for the driving signal (3), Figure 3b, although it also can be observed in Figure 1b. Note that similar group shapes were observed in experiments and obtained numerically in deep water by solving the modified nonlinear Schrödinger equation (Lo & Mei 1985).
The demodulation effect observed in the experiments away from the wavemaker is clearly seen in the numerical simulation as well, Figure 2d. Contrary to that, wave group shapes for the forcing signals (1) and (3) do not change notably, although certain focusing effects can be observed at high amplitude of forcing in Figures 1d and 3d. It should be mentioned here that the left-right asymmetry observed in the experiments could not be obtained in the framework of the adopted theoretical model, since the CSE conserves the symmetry of the initial conditions. In Figures c and d, the envelope corresponding to the temporal variation of wave groups at the carrier frequency only is presented, and the contribution of the bound waves at higher harmonics, which leads to the trough – crest asymmetry observed in the experiments, is not accounted for.

![Figure 3](image)

Figure 3. The measured surface elevation (a and b) and the computed group envelopes (c and d) for the driving signal (3).

Both the experimental and the numerical results indicate that for the driving signals (1) and (3) no considerable variation in the maximum wave amplitude can be observed for the conditions employed in this study. For the driving signal given by (2), both the experiments and the computations give considerable spreading of the wave energy in the group. The results presented in Figures 1 – 3 thus suggest that the adopted theoretical model is capable of providing a reasonable pattern of wave group evolution over a sloping beach. The CSE can therefore be used to investigate the wave group evolution over larger distances, which could not be verified experimentally due to the limitations of the experimental facility.
Figure 4. The computed variation of the wave group envelopes with the distance from the wavemaker for the bottom slope 1:30; initial depth $h=0.6m$. a) driving signal (1), b) driving signal (2), c) driving signal (3).
Computations were therefore performed wave groups of high wave steepness ($a_0k_0 = 0.21$) for the driving signals given by (1) to (3) for the same slope of 1:30 as in the experiments, but with the initial depth of $h=0.6$ m. The results at three locations along the tank for the duration corresponding to two wave groups are presented in Figure 4. The locations selected for the presentation correspond to the initial wave group at the wavemaker, $x=0$ m, $h=0.6$ m, intermediate depth at $x=9.0$ m, $h=0.3$ m, and shallow water at $x=16.0$ m, $h=0.067$ m.

Figure 5. The measured surface elevation (a and b) and the computed group envelopes (c and d) for the constant water depth $h=0.6$m and the driving signal (3).

The qualitative difference in the evolution pattern of wave groups excited by signal (1), Figure 4a, and (2), Figure 4b, is quite evident. The wave groups excited by the driving signal (1) initially exhibit strong focusing, and the maximum amplitude is nearly doubled at $x=9.0$ m. As the waves propagate over more shallow water, strong defocusing occurs, and the wave energy is spread nearly uniformly in the group. It should be stressed here that due to the symmetry properties of the driving signal (1) and the CSE (4), the node points in the envelope distribution in time are conserved in the course of the evolution process. This particular feature does not apply to the driving signals (2) and (3). The qualitative difference between the driving signals (1) and (2) is responsible for the different evolution patterns on Figures 4a and 4b. Contrary to Figure 4a, no strong
focusing is observed at the initial stages of evolution for the driving signal (2), and at both locations in Figure 4b, $x=9.0$ m, $h=0.3$ m, and $x=16.0$ m, $h=0.067$ m, the waves are distributed essentially uniformly along the group.

Evolution pattern for the detached groups in Figure 4c is similar qualitatively to that observed in Figure 4a. Here too, the wave energy is initially focused at $x=9.0$ m, $h=0.3$ m. At larger distances from the wavemaker and in more shallow water demodulation is obtained. Although the driving signal (3) does not require conservation of the node points as it is the case for the signal (1), the groups are initially sufficiently separated, so that no substantial interference between the neighboring groups can occur for the time and length scales employed in the present computations.

Figure 6. The measured surface elevation ($a$ and $b$) and the computed group envelopes ($c$ and $d$) for the constant water depth $h=0.6$ m, $T=0.9$ s and the driving signal (3).

These computational results suggest that it may be instructive to study wave group evolution in water of constant depth. The representative experimental and numerical results for the two extreme forcing amplitudes ($a_0k_0 = 0.07$ and $a_0k_0 = 0.21$) for the deep ($h=0.6$ m) and shallow ($h=0.012$ m) water cases are given in Figures 5 and 6, respectively. The driving signal (3) is used in the results of Figure 5, while the signal (1) is employed in Figure 6.

For the conditions of Figure 5, focusing (increase in the maximum wave amplitude within the group) is obtained for the high forcing amplitude both in the experiments
(Figure 5b) and in computations (Figure 5d). For the low amplitude of forcing, no significant variation of the maximum wave amplitude along the tank is obtained in Figures 5a and 5c.

In shallow water the spreading of the wave energy is obtained experimentally for the high amplitude of forcing in Figure 6b. The corresponding demodulation effect is observed in the numerical simulations presented in Figure 6d. At low amplitude of forcing, no significant effects are observed neither in experiments (Figure 6a), nor in computations (Figure 6c).

A more detailed analysis of the evolution of nonlinear wave groups in water of a constant intermediate depth is presented in Shemer et al. (1998). The experimental results are compared in this study with the numerical solutions of the CSE. In an additional study, Kit et al. (1998), nonlinear wave group evolution in shallow water is investigated. The measurements of the temporal and spatial variation of the instantaneous surface elevation are supported by the numerical solutions of the Korteweg-de Vries equation.

Concluding remarks

The present study indeed confirms that wave groups propagating over a sloping beach undergo modulation and subsequent demodulation and their wave energy tends eventually to spread more uniformly over the group. In the case of the constant water depth, defocusing is obtained in shallow water, while in deeper water, the trend is opposite and wave energy focusing leading to increase of the maximum wave height above its initial value is observed.

The current investigation reveals that shoaling wave groups having identical initial envelope shapes but different spectral contents may undergo completely different evolution processes. Specifically, groups having a bimodal spectrum, driving signal (1), retain their clear identity in the process of propagation, and their envelope periodically attains zero. For wave groups with the same shape and more complicated spectra, driving signal (2), the wave energy tends to become more uniformly distributed along the group, so that the clear distinction between the groups vanishes.

The simplest possible nonlinear model, the cubic Schrödinger equation, which contains an additional term accounting for mild water depth variation and is thus capable of describing wave group shoaling, is selected here. The coefficient of the nonlinear term in this equation changes its sign in the course of wave group propagation toward the beach.

The total body of experimental and numerical results accumulated in this study indicates that the cubic Schrödinger equation (4) constitutes a reasonable model for studies of shoaling of nonlinear gravity wave groups over a sloping beach. CSE appears to be able to capture successfully the global features of nonlinear wave group transformation for the whole range of the water depth variation employed here. It also reflects correctly
in general the effect of the initial maximum wave steepness $k_0 \alpha_0$ on the group evolution pattern. The CSE thus can be considered as a robust, albeit crude model for description of the nonlinear wave group evolution and transformation in water of slowly varying depth.

MODULATION OF BICHROMATIC WAVE TRAIN IN A WAVE TANK

Motohiko Umeyama

Abstract

The instability of bichromatic wave train in water of intermediate depth is investigated by means of a perturbation method. The analytical solution, treated as the result of an initial value problem, yields the modulation and disintegration of the wave train, caused by the interaction of two incident waves of finite amplitude. A laboratory study was also conducted to measure the surface elevations of bichromatic waves generated by several types of compound sinusoidal signals. The calculation using the third-order finite-amplitude wave equation is carried out, and its prediction is compared with the measured data obtained under several experimental conditions.

Introduction

For surface waves in water of arbitrary depth, small disturbances cause the instability as the waves propagate after a certain distance. Eventually the instability leads to loss of coherence, while the wave energy distributes over a broad spectrum. Benjamin and Feir(1967), using a perturbation approach, studied the instability of nonlinear deep-water waves, and showed that weakly nonlinear free-surface waves are inherently unstable to modulated periodic disturbances. In the following paper, Benjamin(1967) qualitatively explained the experimental evidence, known as side-band instability, using a second-order perturbation solution, and predicted that the side-band frequency components grow exponentially in time. Their results, however, are limited to the initial instability. Since then, much theoretical effort has been expended to search for an uniformly valid equation describing the behavior of the Stokes' wave train; for example, Lighthill(1967) examined the early stage of the nonlinear modulation of a wave packet using Whitham's theory(1965) based on an averaged Lagrangian, and Chu and Mei(1970) extended the Whitham's theory to derive the modulation equation for slowly varying Stokes' waves. On the
other hand, Zakharov (1968) derived the cubic Schrödinger equation which predicts the spatial evolution of the wave packet, and later, Zakharov and Shabat (1972) obtained an exact solution of the nonlinear Schrödinger equation. Their solutions predict the disintegration of initially uniform wave train into a definite number of wave groups. Yuen and Lake (1975) proved that Whitham’s theory yields the same nonlinear Schrödinger equation when applied consistently to the order considered. All these solutions can be only applied to the case of the monochromatic wave train. The instability of the bichromatic wave train, having a set of discrete frequencies, has been regarded as the similar phenomenon which can be described by the evolution equation of the monochromatic wave. The instability by the bichromatic wave motion develops slowly as waves propagate from the wavemaker, and the growth rate of the instability becomes greater as the wave steepness increases. An example is found in a recent literature by Stansberg (1994), who observed a strong variation of wave pattern downstream the wave tank.

Despite the interest in the subject, few theoretically justifiable equation is available, to date, for predicting modulated surface displacements responsible for bichromatic waves. The purpose of this study is to investigate the modulation and disintegration of the bichromatic wave train in water of intermediate depth. A perturbation method is applied to the velocity potential and the vertical displacement of the water surface. The present equation predicts the surface displacements during the period of transition from a stationary state to a steady state in a finite distance from the wavemaker. The solution explains the instability of the periodic wave train mathematically as a result of the interaction of two incident waves propagating in the same direction.

Theory

Now we consider a two-dimensional irrotational wave motion bounded above by a free surface and below by a rigid horizontal bed, and assume the fluid to be inviscid and incompressible. The Eulerian velocity components of the water particles can be expressed in terms of a velocity potential \( \Phi (x, y, t) \) such as

\[
\begin{align*}
  u(x, y, t) & = \frac{\partial \Phi}{\partial x} \\
  v(x, y, t) & = \frac{\partial \Phi}{\partial y}
\end{align*}
\]

where \( u(x, y, t) = \) horizontal velocity; \( v(x, y, t) = \) vertical velocity; \( x = \) horizontal coordinate; and \( y = \) vertical coordinate measured from the still water level, respectively. For incompressible flow, the velocity potential must satisfy Laplace equation such as

\[
\frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} = 0.
\]

The kinematical and dynamical boundary conditions at the free surface are

\[
\begin{align*}
  g\eta + \frac{\partial \Phi}{\partial t} + \frac{1}{2} \left( \frac{\partial \Phi}{\partial x} \right)^2 + \left( \frac{\partial \Phi}{\partial y} \right)^2 & = 0 \quad \text{on } y = \eta, \\
  \frac{\partial \eta}{\partial t} + \frac{\partial \Phi}{\partial x} \frac{\partial \eta}{\partial x} - \frac{\partial \Phi}{\partial y} & = 0 \quad \text{on } y = \eta,
\end{align*}
\]
where \( \eta(x,t) \) = vertical displacement of the water surface measured from \( y = 0 \); 
\( g \) = acceleration due to gravity; and \( t \) = time. No fluid can pass perpendicular to the plane horizontal bottom, and therefore the bottom boundary condition is 
\[
\frac{\partial \Phi}{\partial y} = 0 \quad \text{on} \ y = -h, \tag{6}
\]
where \( h \) = water depth from the still water level.

In the finite-amplitude wave theory, the perturbation method is used to solve eqs.(3), (4), (5) and (6). The dependent variables are defined in terms of a power series, with successively smaller terms defined by a small perturbation parameter raised to a higher power in each succeeding term. Therefore, the velocity potential, vertical displacement and angular frequency for a third-order wave of finite amplitude can be expressed as

\[
\Phi = \epsilon \Phi^{(1)} + \epsilon^2 \Phi^{(2)} + \frac{1}{2} \epsilon^3 \Phi^{(3)} + O(\epsilon^4), \tag{7}
\]
\[
\eta = \epsilon \eta^{(1)} + \epsilon^2 \eta^{(2)} + \frac{1}{2} \epsilon^3 \eta^{(3)} + O(\epsilon^4), \tag{8}
\]
\[
\sigma = \sigma^{(0)} + \epsilon \sigma^{(1)} + \frac{1}{2} \epsilon^2 \sigma^{(2)} + O(\epsilon^3), \tag{9}
\]
where \( \epsilon \) = perturbation parameter; \( \sigma \) = angular frequency; and \( O() \) = order symbol. The superscripts \( (1), (2), \) and \( (3) \) denote quantities corresponding to the first-order, second-order and third-order perturbation solutions.

Goda and Abe(1968) developed a progressive wave theory for finite amplitude waves using a power series expansion. The results for a third-order progressive wave are as follows.

The perturbation functions of velocity potential are

\[
\Phi^{(1)} = \frac{\sigma^{(0)} \coth k(y + h)}{k^2 \sinh kh} \sin(kx - \sigma t), \tag{10}
\]
\[
\Phi^{(2)} = \frac{1}{k^2} \sigma^{(0)} \alpha_2^{(2)} \cosh 2k(y + h) \sin 2(kx - \sigma t), \tag{11}
\]
\[
\Phi^{(3)} = \frac{1}{k^2} \sigma^{(0)} \alpha_1^{(3)} \cosh 3k(y + h) \sin 3(kx - \sigma t), \tag{12}
\]
in which

\[
\alpha_2^{(2)} = \frac{3 (\epsilon^4 - 1)}{8 \cosh 2kh},
\]
\[
\alpha_1^{(3)} = \frac{(\epsilon^2 + 3)(9\epsilon^5 - 22\epsilon^3 + 13\epsilon)}{32 \cosh 3kh}.
\]

The perturbation functions of vertical displacement are

\[
\eta^{(1)} = \frac{1}{k} \cos(kx - \sigma t), \tag{13}
\]
\[
\eta^{(2)} = \frac{1}{k} \beta_1^{(2)} \cos 2(kx - \sigma t), \tag{14}
\]
\[
\eta^{(3)} = \frac{1}{k} \left\{ \beta_1^{(3)} \cos(kx - \sigma t) + \beta_2^{(5)} \cos 3(kx - \sigma t) \right\}. \tag{15}
\]
in which

\[ \beta_1^{(3)} = \frac{3c^3 - c}{4}, \]
\[ \beta_1^{(3)} = \frac{3c^4 + 8c^2 - 9}{8}, \]
\[ \beta_2^{(3)} = \frac{3(9c^6 - 3c^4 + 3c^2 - 1)}{32}. \]

The perturbation functions of angular frequency are

\[ \sigma^{(0)} = \sqrt{gk \tanh kh}, \quad \sigma^{(1)} = 0, \quad \sigma^{(2)} = \frac{k^2 \sigma^{(0)} 9c^4 - 10c^2 + 9}{8}, \]

in which \( k = \) wave number; and \( c = \coth kh. \)

When two incident waves of finite amplitude interact, the free surface conditions in eqs.(4) and (5) cannot be satisfied by a simple superposition of two waves. The two original waves propagating in the same direction deform as a result of the interaction, and the difference due to the deformation results in the formation of nonlinear bichromatic waves. The combination of two (the first and second) incident wave trains with different wave amplitudes, \( a_I \) and \( a_{II} \), and a pair of discrete wave periods, \( T_I \) and \( T_{II} \) is considered here. The solution of bichromatic waves, therefore, must be composed of the first third-order incident wave, second third-order incident wave, and resonance effect. The velocity potential and the surface displacement of bichromatic waves are expressed as

\[ \Phi = \epsilon \Phi_I^{(1)} + \epsilon^2 \Phi_I^{(2)} + \frac{1}{2} \epsilon^3 \Phi_I^{(3)} + \lambda e \Phi_{II}^{(1)} + (\lambda e)^2 \Phi_{II}^{(2)} + \frac{1}{2} (\lambda e)^3 \Phi_{II}^{(3)} \]
\[ + \epsilon^2 \Phi_F^{(2)} + \frac{1}{2} \epsilon^3 \Phi_F^{(3)}, \]

\[ \eta = \epsilon \eta_I^{(1)} + \epsilon^2 \eta_I^{(2)} + \frac{1}{2} \epsilon^3 \eta_I^{(3)} + \lambda e \eta_{II}^{(1)} + (\lambda e)^2 \eta_{II}^{(2)} + \frac{1}{2} (\lambda e)^3 \eta_{II}^{(3)} \]
\[ + \epsilon^2 \eta_F^{(2)} + \frac{1}{2} \epsilon^3 \eta_F^{(3)}, \]

in which

\[ \epsilon = a_I k_I, \quad \lambda = \frac{a_{II} k_{II}}{a_I k_I}. \]

In these equations, the subscripts \( I, II, \) and \( F \) denote the first incident wave, second incident wave, and resonance effect, respectively.

The angular frequency of the third-order incident wave increases with increasing wave amplitude if the wave number is given. For bichromatic waves, therefore, the angular frequency of each incident wave is disturbed in order to obtain the correction terms. Taking into account the secondary effect, the perturbations of angular frequencies are expressed as

\[ \sigma_I = \sigma_I^{(0)} + \frac{1}{2} \epsilon^2 (\sigma_I^{(2)} + \sigma_{IF}), \]
\[ \sigma_{II} = \sigma_{II}^{(0)} + \frac{1}{2} \epsilon^2 (\lambda \sigma_{II}^{(2)} + \sigma_{II F}), \]
where $\sigma_{IF}$ and $\sigma_{HF}$ denote the third-order angular frequencies induced by the interaction of the first and second incident waves, respectively. In the above equations, the first and third order perturbation frequencies are already given in eqs.(16) and (18).

Now, a generalized theory for a bichromatic wave system is formulated to the third order. The dynamical and kinematical free-surface boundary conditions are used to obtain linear partial differential equations for each order of the approximation. In formulating the expressions, it is convenient to replace the nonlinear free-surface boundary conditions in eqs.(4) and (5) by conditions to be satisfied about $y = 0$ instead of $y = \eta$. Expanding eqs.(4) and (5) into a Taylor series in $y$, and substituting eqs.(19), (20), (21) and (22) into these equations, the boundary conditions for the second and third powers are as follows.

The second-order equations are:

\[
\frac{\partial \Phi^{(2)}_{F}}{\partial t} + \frac{\partial \Phi^{(2)}_{E}}{\partial \eta} = -\lambda\left(\frac{\sigma^{(0)}_{IF}}{\sigma_{I}} \frac{\partial^{2} \Phi^{(1)}_{I}}{\partial \eta^{2}} + \frac{\sigma^{(0)}_{IF}}{\sigma_{H}} \frac{\partial^{2} \Phi^{(1)}_{H}}{\partial \eta^{2}} + \frac{\partial \Phi^{(1)}_{I}}{\partial \xi} \frac{\partial \Phi^{(1)}_{H}}{\partial \eta} + \frac{\partial \Phi^{(1)}_{I}}{\partial \eta} \frac{\partial \Phi^{(1)}_{H}}{\partial \xi}\right), \tag{23}
\]

\[
\frac{\partial \Phi^{(2)}_{E}}{\partial \eta} - \frac{\partial \Phi^{(2)}_{F}}{\partial t} = \lambda\left(\frac{\partial \Phi^{(1)}_{I}}{\partial \xi} \frac{\partial \Phi^{(1)}_{H}}{\partial \eta} - \frac{\partial \Phi^{(1)}_{I}}{\partial \eta} \frac{\partial \Phi^{(1)}_{H}}{\partial \xi} - \eta^{(1)}_{I} \frac{\partial^{2} \Phi^{(1)}_{I}}{\partial \eta^{2}} - \eta^{(1)}_{H} \frac{\partial^{2} \Phi^{(1)}_{H}}{\partial \eta^{2}}\right). \tag{24}
\]

The third-order equations for $[\lambda]$ are:

\[
\frac{1}{2}(g\eta^{(3)}_{F}) + \frac{\partial \Phi^{(3)}_{E}}{\partial \eta} + \frac{\partial \Phi^{(3)}_{F}}{\partial \xi} + \frac{\lambda}{\sigma_{IF}} \frac{\partial \Phi^{(1)}_{H}}{\partial t} = -\lambda\left(\frac{\sigma^{(0)}_{IF}}{\sigma_{I}} \frac{\partial^{2} \Phi^{(1)}_{I}}{\partial \eta^{2}} + \frac{\sigma^{(0)}_{IF}}{\sigma_{H}} \frac{\partial^{2} \Phi^{(1)}_{H}}{\partial \eta^{2}} + \frac{\partial \Phi^{(1)}_{I}}{\partial \xi} \frac{\partial \Phi^{(1)}_{H}}{\partial \eta} + \frac{\partial \Phi^{(1)}_{I}}{\partial \eta} \frac{\partial \Phi^{(1)}_{H}}{\partial \xi}\right),
\]

\[
\frac{\partial \Phi^{(3)}_{E}}{\partial \eta} - \frac{\partial \Phi^{(3)}_{F}}{\partial \xi} = -\lambda\left(\frac{\partial \Phi^{(1)}_{I}}{\partial \xi} \frac{\partial \Phi^{(1)}_{H}}{\partial \eta} - \frac{\partial \Phi^{(1)}_{I}}{\partial \eta} \frac{\partial \Phi^{(1)}_{H}}{\partial \xi} - \eta^{(1)}_{I} \frac{\partial^{2} \Phi^{(1)}_{I}}{\partial \eta^{2}} - \eta^{(1)}_{H} \frac{\partial^{2} \Phi^{(1)}_{H}}{\partial \eta^{2}}\right). \tag{25}
\]
The third-order equations for $|\lambda^2|$ are:

\[
\frac{1}{2\lambda}(\eta^{(3)}_F + \frac{\partial \Phi^{(3)}_F}{\partial t} + \frac{\sigma_{IF}}{\sigma} \frac{\partial \Phi^{(1)}_I}{\partial t}) = ..., \tag{27}
\]

\[
\frac{1}{2\lambda}(\frac{\partial \Phi^{(3)}_E}{\partial t} - \frac{\partial \eta^{(3)}_E}{\partial t} - \frac{\sigma_{IF}}{\sigma} \frac{\partial \eta^{(1)}_I}{\partial t}) = ..., \tag{28}
\]

The right hand sides of eqs. (27) and (28) are same as those of eqs. (25) and (26) except for the subscripts $I$ and $II$ which are switched.

By differentiating eq.(23) with respect to $t$, eliminating $\eta_{F1}$ from eqs.(23) and (24), and substituting the expressions for $\Phi_I^{(1)}$, $\Phi_{II}^{(1)}$, $\eta_I^{(1)}$, and $\eta_{II}^{(1)}$ into the combined equation, the free-surface boundary condition on $y = 0$ is given by

\[
g \frac{\partial \Phi^{(3)}_E}{\partial y} + \frac{\partial^2 \Phi^{(3)}_E}{\partial t^2} = \frac{\lambda}{2kIk_{II}}\left\{ (\gamma_1 + \gamma_2) \sin(\chi_I - \chi_{II}) + (\gamma_2 - \gamma_1) \sin(\chi_I + \chi_{II}) \right\}, \tag{29}
\]

in which

\[
\gamma_1 = (\sigma_I - \sigma_{II})\{(\eta^{(0)}_I)^2 - \eta^{(0)}_{II} (1 + \sigma_{II})\},
\]

\[
\gamma_2 = \frac{k_{II}}{k_I} \eta^{(0)}_I \eta^{(0)}_II - \frac{k_I}{k_{II}} \eta^{(0)}_{II} \eta^{(0)}_I - (\eta^{(0)}_I \eta^{(0)}_II),
\]

\[
\gamma_2 = (\sigma_I + \sigma_{II})\{(\eta^{(0)}_I)^2 + \eta^{(0)}_{II} (1 + \sigma_{II})\},
\]

\[
\gamma_2 = \frac{k_{II}}{k_I} \eta^{(0)}_I \eta^{(0)}_II + \frac{k_I}{k_{II}} \eta^{(0)}_{II} \eta^{(0)}_I + (\eta^{(0)}_I \eta^{(0)}_II),
\]

where $\chi_I = k_I x - \sigma_I t$; and $\chi_{II} = k_{II} x - \sigma_{II} t$. Eqs.(3), (6) and (29) are satisfied by

\[
\Phi^{(3)}_E = \frac{\lambda}{k_I k_{II}} \left\{ \alpha^{(2)}_{F1} \sin(\chi_I - \chi_{II}) + \alpha^{(2)}_{F2} \sin(\chi_I + \chi_{II}) \right\}, \tag{30}
\]

in which

\[
\alpha^{(2)}_{F1} = \frac{\gamma_1 + \gamma_2}{2 \cosh(k_I - k_{II}) h} \frac{\cosh(k_I - k_{II}) (y + h)}{\omega'_{II - I} - (\sigma_I - \sigma_{II})^2},
\]

\[
\alpha^{(2)}_{F2} = \frac{\gamma_2}{2 \cosh(k_I - k_{II}) h} \frac{\cosh(k_I + k_{II}) (y + h)}{\omega'_{I + II} - (\sigma_I + \sigma_{II})^2}.
\]

The corresponding surface displacement is obtained by substituting eq.(30) into eq.(23). Finally the second-order surface displacement by the resonance effect are obtained as

\[
\eta^{(2)}_E = \frac{\lambda}{2gk_I k_{II}} \left\{ \beta^{(2)}_{E1} \cos(\chi_I - \chi_{II}) + \beta^{(2)}_{E2} \cos(\chi_I + \chi_{II}) \right\}, \tag{31}
\]

in which

\[
\beta^{(2)}_{E1} = \frac{\omega'_{II - I} \gamma_1 - (\sigma_I - \sigma_{II})^2 \gamma_2}{(\sigma_I - \sigma_{II}) [\omega'_{II - I} - (\sigma_I - \sigma_{II})^2]},
\]

\[
\beta^{(2)}_{E2} = \frac{\omega'_{I + II} \gamma_2 + (\sigma_I + \sigma_{II})^2 \gamma_2}{(\sigma_I + \sigma_{II}) [\omega'_{I + II} - (\sigma_I + \sigma_{II})^2]},
\]

\[
\omega'_{II - I} = g(k_I - k_{II}) \tanh(k_I - k_{II}) h,
\]

\[
\omega'_{I + II} = g(k_I + k_{II}) \tanh(k_I + k_{II}) h.
\]
The second-order surface displacement by the resonance effect have two components with wave numbers and frequencies consisting of the sums and differences of those of the first and second incident waves. These amplitudes are bounded in time and their magnitude is dependent on the water depth.

To find the third-order velocity potential $\Phi_F^{(3)}$ and surface displacement $\eta_F^{(3)}$, the same procedure is followed in the second-order approximation. Eliminating $\eta_F^{(3)}$ from eqs.(25) and (26), the combined free-surface boundary condition on $y = 0$ is obtained for $[\lambda]$ as

$$
\frac{\partial \Phi_F^{(3)}}{\partial y} + \frac{\partial \Phi_{FF}^{(3)}}{\partial t^2} - \frac{2\lambda \sigma_{HH} \sigma_{\eta \eta}^{(3)} c_H}{k_H} + \frac{g}{2} \sin \chi_H
$$

$$
= \frac{2\lambda}{k_I k_H} \left( \{ (2\sigma_I - \sigma_H) b_1 + g b_4 \} \sin(2\chi_I - \chi_H) \right)
+ \left\{ (2\sigma_I + \sigma_H) b_2 + g b_5 \right\} \sin(2\chi_I + \chi_H) + (\sigma_H b_3 + g b_6) \sin \chi_H,
$$

in which

$$
b_1 = \frac{\sigma_H^{(0)} \sigma_{12}^{(3)}}{2} + 2\sigma_I^{(0)} \alpha_{12}^{(2)} \sinh 2k_I h - \sigma_I^{(0)} \sigma_{12}^{(2)} (c_H \cosh 2k_I h + \sinh 2k_I h)
$$

$$
+ \frac{\sigma_H^{(0)} \sigma_{I}^{(0)} k_{II} c_H}{8k_I} - \frac{\sigma_I^{(0)} \sigma_{II}^{(0)} k_{II} (c_I + c_{II})}{4k_I} - \frac{\sigma_I^{(0)} \sigma_{II}^{(0)} c_{II}}{2} + \frac{\sigma_I^{(0)} c_I}{4}
$$

$$
+ \frac{\sigma_I^{(0)} \{ \omega_{I-II}^{(2)} \gamma_{11} + (\sigma_I - \sigma_{II})^2 \gamma_{21} \}}{4gk_I (\sigma_I - \sigma_{II}) \omega_{I-II}^{(2)}} + \frac{(\gamma_{11} + \gamma_{21}) (\sigma_I - \sigma_{II}) \omega_{I-II}^{(2)}}{4gk_I \omega_{I-II}^{(2)}}
$$

$$
- \frac{\sigma_I^{(0)} c_I (\gamma_{11} + \gamma_{21}) (k_I - k_{II})}{4 \omega_{I-II}^{(2)} (\sigma_I - \sigma_{II})} + \frac{\sigma_I^{(0)} (\gamma_{21} - \gamma_{22}) \omega_{I+H}^{(2)}}{4gk_I \omega_{I+H}^{(2)} (\sigma_I + \sigma_{II})}
$$

$$
b_2 = \frac{\sigma_H^{(0)} \sigma_{12}^{(3)}}{2} + 2\sigma_I^{(0)} \alpha_{12}^{(2)} \sinh 2k_I h - \sigma_I^{(0)} \sigma_{12}^{(2)} (c_H \cosh 2k_I h - \sinh 2k_I h)
$$

$$
+ \frac{\sigma_H^{(0)} \sigma_{I}^{(0)} k_{II} c_H}{8k_I} - \frac{\sigma_I^{(0)} \sigma_{II}^{(0)} k_{II} (c_I - c_{II})}{4k_I} + \frac{\sigma_I^{(0)} c_I}{4}
$$

$$
+ \frac{\sigma_I^{(0)} \{ \omega_{I+H}^{(2)} \gamma_{21} + (\sigma_I + \sigma_{II})^2 \gamma_{22} \}}{4gk_I (\sigma_I + \sigma_{II}) \omega_{I+H}^{(2)}} + \frac{(\gamma_{21} - \gamma_{22}) (\sigma_I + \sigma_{II}) \omega_{I+H}^{(2)}}{4gk_I \omega_{I+H}^{(2)} (\sigma_I + \sigma_{II})}
$$

$$
- \frac{\sigma_I^{(0)} c_I (\gamma_{21} - \gamma_{22}) (k_I + k_{II})}{4 \omega_{I+H}^{(2)} (\sigma_I + \sigma_{II})} + \frac{\sigma_I^{(0)} (\gamma_{11} + \gamma_{12}) \omega_{I-II}^{(2)}}{4gk_I \omega_{I-II}^{(2)} (\sigma_I - \sigma_{II})}
$$

$$
b_3 = \frac{\sigma_H^{(0)} \sigma_{12}^{(3)}}{2k_I} - \frac{\sigma_I^{(0)} \sigma_{II}^{(0)} c_{II}}{2k_I} - \frac{\sigma_I^{(0)} c_{II}}{2}
$$

$$
+ \frac{\sigma_I^{(0)} \{ \omega_{I-II}^{(2)} \gamma_{11} + (\sigma_I - \sigma_{II})^2 \gamma_{12} \}}{4gk_I (\sigma_I - \sigma_{II}) \omega_{I-II}^{(2)}} + \frac{(\gamma_{11} + \gamma_{12}) (\sigma_I - \sigma_{II}) \omega_{I-II}^{(2)}}{4gk_I \omega_{I-II}^{(2)} (\sigma_I - \sigma_{II})}
$$

$$
- \frac{\sigma_I^{(0)} c_I (\gamma_{11} + \gamma_{12}) (k_I - k_{II})}{4 \omega_{I-II}^{(2)} (\sigma_I - \sigma_{II})} + \frac{\sigma_I^{(0)} (\gamma_{11} + \gamma_{12}) \omega_{I-II}^{(2)}}{4gk_I \omega_{I-II}^{(2)} (\sigma_I - \sigma_{II})}$$
\[
\sum_{i}^{(0)} \frac{\sigma_{i+H} \gamma_{21} - (\sigma_{I} + \sigma_{II})^2 \gamma_{22}}{4gk_{I}(\sigma_{I} + \sigma_{II})\left\{\omega_{I+H} - (\sigma_{I} + \sigma_{II})^2\right\}} + \frac{(\gamma_{21} - \gamma_{22})(\sigma_{I} + \sigma_{II})\omega_{I+H}}{4gk_{I}(\omega_{I+H} - (\sigma_{I} + \sigma_{II})^2)} \\
- \frac{\sigma_{I}^{(0)} c_{I}(\gamma_{21} - \gamma_{22})(k_{I} + k_{II})}{4(\omega_{I+H} - (\sigma_{I} + \sigma_{II})^2)}
\]

\[
b_{4} = - \frac{\beta_{11}^{(0)} \sigma_{I+H} c_{II}}{2} - \alpha_{12}^{(0)} k_{II} \cosh 2k_{I}h - 2\alpha_{12}^{(0)} \sigma_{I}^{(0)} k_{I} \cosh 2k_{I}h - \beta_{11}^{(0)} \sigma_{I}^{(0)} k_{I} c_{I}
\]

\[
b_{5} = \frac{\beta_{11}^{(0)} \sigma_{I+H} c_{II}}{2} + \alpha_{12}^{(0)} k_{II} \cosh 2k_{I}h - 2\alpha_{12}^{(0)} \sigma_{I}^{(0)} k_{I} \cosh 2k_{I}h - \beta_{11}^{(0)} \sigma_{I}^{(0)} k_{I} c_{I}
\]

\[
b_{6} = - \frac{\sigma_{II}^{(0)} k_{II}^{2}}{2} - \frac{\sigma_{II}^{(0)} k_{II}}{2}
\]

The final results of \(\Phi_{F}^{(3)}, \eta_{F}^{(3)}, \sigma_{IF}, \) and \(\sigma_{II}F\) become

\[
\Phi_{F}^{(3)} = \lambda \left[ \begin{array}{ll}
\psi_{I} & 2 \sin \frac{2\sigma_{I} - \sigma_{II} + \sigma_{F1}}{2} t \sin \frac{2\sigma_{I} - \sigma_{II} - \sigma_{F1}}{2} t \sin(2k_{I} - k_{II})x \\
\sin(2\sigma_{I} - \sigma_{II}) t \cos(2k_{I} - k_{II})x \end{array} \right] \cosh(2k_{I} - k_{II})(y + h)
\]
\[
\eta_{r}^{(3)} = \frac{\lambda}{gk_{1}k_{II}} \left[ \psi_{1}\{(2\sigma_{I} - \sigma_{II} + \sigma_{F_{1}}) \cos \frac{2\sigma_{I} - \sigma_{II} + \sigma_{F_{1}}}{2} \cos \frac{2\sigma_{I} - \sigma_{II} - \sigma_{F_{1}}}{2} t \sin \frac{2\sigma_{I} - \sigma_{II} - \sigma_{F_{1}}}{2} \sin(2k_{I} + k_{II})x \right.
\]
\[
+ \sin(2\sigma_{I} + \sigma_{II})t \cos(2k_{I} + k_{II})x \} \cosh(2k_{I} + k_{II})(y + h) \right] \]
\[
+ \lambda[\text{same as the above except for the subscripts I and II being switched}],
\]

\[
\eta_{r}^{(3)} = \lambda \frac{gk_{1}k_{II}}{2\sigma_{I} - \sigma_{II} + \sigma_{F_{1}}} \cos \frac{2\sigma_{I} - \sigma_{II} + \sigma_{F_{1}}}{2} \cos \frac{2\sigma_{I} - \sigma_{II} - \sigma_{F_{1}}}{2} t \sin \frac{2\sigma_{I} - \sigma_{II} - \sigma_{F_{1}}}{2} \sin(2k_{I} + k_{II})x \]
\[
+ \sin(2\sigma_{I} + \sigma_{II})t \cos(2k_{I} + k_{II})x \} \cosh(2k_{I} + k_{II})(y + h) \right] \]
\[
+ \lambda[\text{same as the above except for the subscripts I and II being switched}],
\]

\[
\sigma_{IF} = \frac{-2\lambda^{2}k_{I}(\sigma_{I}b_{3} + gb_{5})}{k_{II}(2\sigma_{I}c_{I} + gk_{I})},
\]
\[
\sigma_{II} = \frac{-2k_{II}(\sigma_{I}b_{3} + gb_{5})}{k_{II}(2\sigma_{II}c_{II} + gk_{I})},
\]
in which

\[
\psi_{1} = \frac{2\{(2\sigma_{I} - \sigma_{II})b_{4}g_{3}\}}{(2\sigma_{I} - \sigma_{II})^{2} - \sigma_{F_{1}}^{2}},
\]
\[
\psi_{2} = \frac{2\{(2\sigma_{I} + \sigma_{II})b_{4}g_{3}\}}{(2\sigma_{I} + \sigma_{II})^{2} - \sigma_{F_{2}}^{2}},
\]
\[
\sigma_{F_{1}}^{2} = g(2k_{I} - k_{II})\tanh(2k_{I} - k_{II})h,
\]
\[
\sigma_{F_{2}}^{2} = g(2k_{I} + k_{II})\tanh(2k_{I} + k_{II})h.
\]

Since \(2\sigma_{I} - \sigma_{II}\) is nearly equal to \(\sigma_{F_{1}}\) in eq.(34), the trigonometric functions \(\sin \frac{2\sigma_{I} - \sigma_{II} - \sigma_{F_{1}}}{2} t\) and \(\cos \frac{2\sigma_{I} - \sigma_{II} - \sigma_{F_{1}}}{2} t\) are slowly varying in comparison with the functions \(\sin \frac{2\sigma_{I} + \sigma_{II} - \sigma_{F_{1}}}{2} t\) and \(\cos \frac{2\sigma_{I} + \sigma_{II} - \sigma_{F_{1}}}{2} t\). The low-frequency factor on \(\frac{2\sigma_{I} - \sigma_{II} - \sigma_{F_{1}}}{2} t\) induces an amplitude modulation on the high-frequency factor on \(\frac{2\sigma_{I} + \sigma_{II} - \sigma_{F_{1}}}{2} t\). The resulting modulated oscillation causes the phenomenon of beats, which are limited to the initial stage.
Experiments

For the purpose of verifying the present wave theory, experiments were conducted in the 26-m-long, 0.5-m-wide, and 0.8-m-deep wave tank at Tokyo Metropolitan University. A piston-type wave generator is placed at one end of the tank, and a wave-absorber is installed at the opposite end to reduce the wave reflection. A series of electronic signals were produced by an arbitrary wave-form synthesizer, which controlled the motion of wave paddle. The surface elevations were measured using resistance wave gauges at four horizontal locations, 10.0, 12.5, 15.0, and 17.5m from the wave paddle. The water depth was varied from 20 to 40cm. In each water depth, several strokes of paddle motion were prescribed. The bichromatic waves composed of a pair of cosine waves have two incident wave amplitudes \( a_I \) and \( a_H \), and two incident wave periods \( T_I \) and \( T_H \). The wave conditions used in the present experiment were \( T_I = 0.5 \text{sec} \) and \( T_H = 0.55 \text{sec} \), or \( T_I = 0.5 \text{sec} \) and \( T_H = 0.6 \text{sec} \) for a pair of bichromatic wave periods and \( a_I : a_H = 1 : 1, 1 : 2, \) or \( 2 : 1 \) for the corresponding ratio of two incident wave amplitudes. In each experimental condition, wave data were collected from four wave gauges continuously at a frequency of 47Hz for about three minutes in order to provide data samples sufficiently long for FFT analyses.

Results

A series of wave records observed at four fixed points and these amplitude spectra are shown in Fig. 1. The abscissa and ordinate in figure(a) show the time in seconds, and the surface displacement above the still water level in cm, respectively, while those in figure(b) show the frequency in Hz, and the amplitude in cm, respectively. The periods of the first and second incident waves are \( T_I = 0.5 \text{sec} \) and \( T_H = 0.55 \text{sec} \), and the ratio of the first incident wave amplitude to the second incident wave amplitude is \( a_I : a_H = 1 : 1 \). In this case, the water depth is \( h = 40 \text{cm} \). The measured wave profiles are different from the input bichromatic wave signal, by which the wave paddle motion is prescribed. The wave train at each location exhibits an appreciable modulation, even though the wave form itself is nearly uniform at each point. The modulation becomes smaller as the waves propagate from the wave paddle to the opposite end of the wave tank. Each spectrum contains four major frequency components within relatively narrow range of frequencies. The third-order frequency components by the wave interaction at \( x=10 \text{m} \) are the largest; they decrease their amplitudes rapidly toward the end of the wave tank. Fig. 2 shows similar plots of the bichromatic waves for \( T_I = 0.5 \text{sec}, T_H = 0.6 \text{sec}, a_I : a_H = 1 : 1, \) and \( h = 40 \text{cm} \). The modulation is not so large in this case. The basic profile of wave train remains the same throughout the entire process. The carrier-frequency and second-harmonic components of incident waves are quite evident but the third-order frequency components by the wave interaction are not seen clearly in the spectrum. The energy transfer within the spectrum is not appreciable, while the dissipation of the total energy is small.

Several free-surface elevations obtained from four different experiments are compared to theoretical results computed by the third-order perturbation equation[(20)]. To describe the natural profile of bichromatic wave train, each calculated
Fig. 1 Surface displacements of bichromatic wave train and FFT analyses for $T_I = 0.5\text{sec}, T_{II} = 0.55\text{sec}, a_I : a_{II} = 1 : 1$, and $h = 40\text{cm}$.

Fig. 2 Surface displacements of bichromatic wave train and FFT analyses for $T_I = 0.5\text{sec}, T_{II} = 0.6\text{sec}, a_I : a_{II} = 1 : 1$, and $h = 40\text{cm}$.

value is plotted for thirty seconds at intervals of 0.02 sec. Comparisons of the measured free-surface displacements with the theoretical ones are presented in Figs.3-6. In these figures, (a) shows the experimental data plot, and (b) shows the theoretical profile. A set of time series for $T_I = 0.5\text{sec}, T_{II} = 0.55\text{sec}, a_I : a_{II} = 1 : 1$, and $h = 40\text{cm}$ are presented in Fig.3(a). The modulation caused by the interaction of two incident waves occurs in all locations, and the resonant nonlinear interaction leads to the disintegration of the wave envelope. The original periods of incident waves, however, remain constant throughout the process of the modulation. Fig.3(b) shows an example of calculated wave profiles for a pair of initial amplitudes, $a_I = a_{II} = 0.37\text{cm}$. These initial amplitudes were determined from actual free-surface measurements by the wave gauge at $x = 10\text{m}$. Fig.4 shows a comparison of the measured data for $T_I = 0.5\text{sec}, T_{II} = 0.55\text{sec}, a_I : a_{II} = 1 : 1$ and $h = 20\text{cm}$, and the theoretical calculation for $a_I = a_{II} = 0.34\text{cm}$. Although the pe-

\( (T_1 = 0.5\text{sec}, T_\text{II} = 0.55\text{sec}, a_1 : a_\text{II} = 1 : 1, \text{and } h = 40\text{cm}). \)

Fig. 4 Measured and calculated surface displacements
\( (T_1 = 0.5\text{sec}, T_\text{II} = 0.55\text{sec}, a_1 : a_\text{II} = 1 : 1, \text{and } h = 20\text{cm}). \)

periods of the first and second incident waves and the ratio of amplitudes of them are the same as those in the previous case, the water depth is shallower. In this case, the modulation is also found at all locations. A basic difference to the previous experiment for \( h = 40\text{cm} \) is observed under the nodes of the envelope. Fig. 5 presents a set of time series for \( T_1 = 0.5\text{sec}, T_\text{II} = 0.55\text{sec} \) and \( a_1 : a_\text{II} = 1 : 2, \) in the water depth of \( h = 20\text{cm}, \) and the calculated surface displacements for \( a_1 = 0.22\text{cm} \) and \( a_\text{II} = 0.44\text{cm}. \) The agreement between the measured data and the theoretical result is reasonable on the tendency of a change of wave train. Fig. 6 shows a set of temporal records of surface displacements for \( T_1 = 0.5\text{sec}, T_\text{II} = 0.6\text{sec}, a_1 : a_\text{II} = 1 : 2 \) and \( h = 20\text{cm}. \) The theoretical results were calculated by the present third-order bichromatic wave equation for \( a_1 = 0.38\text{cm} \) and \( a_\text{II} = 0.76\text{cm}. \) The measured data are well described by the theoretical curves in spite of such difference in the two wave periods and amplitudes.
Conclusions

The equation based on a finite-amplitude approximation was derived to calculate the surface displacements of bichromatic waves in water of intermediate depth. Experiments were also performed to investigate the modulation of bichromatic wave train in our wave tank. From the results of this study, the following conclusions are drawn.

When a wave train is generated by a pure bichromatic-wave paddle motion, the wave train usually modulates in the wave tank. This tendency is more prominent when the difference of the first and second incident wave periods become small; accordingly, measurable modulation did not develop in our tank length, when the bichromatic waves with the periods $T_I = 0.5 \text{sec}$ and $T_{II} = 0.6 \text{sec}$ were generated. The water depth affects to the disintegration of wave train; indeed, the modulation...
tends to disintegrate into smaller wave envelopes when the water depth increases. The third-order amplitudes by the wave interaction are larger than the first-order amplitudes when the difference between the first and second incident wave periods is smaller. The results obtained in this study are physically valid over the range of our interest.

SIMULATION OF NONLINEAR WAVE DEFORMATION BY A SHOAL IN 3D

Paul de Haas 1 and Maarten Dingemans 1

Abstract

Three-dimensional propagating nonlinear waves can be simulated with a time-domain numerical model based on a boundary integral equation method. For the simulation of nonlinear wave deformation by a shoal, a domain decomposition method is used to increase the efficiency of the model. Features and efficiency of the domain decomposition method are described and its application to the shoal problem is discussed.

1 Introduction

In the modelling of refraction and shoaling of waves, it is important to describe the nonlinear free-surface boundary conditions properly. It is known, for example, that non-linearity opposes convergence and divergence of wave ray paths. In order to assure the correctness of modelling non-linearity, physical experiments are often used.

We present a three-dimensional time-domain numerical model, based on a boundary integral equation method, which computes the propagation of waves with the exact nonlinear boundary conditions over an arbitrary bottom geometry. This method is therefore able to provide additional material suitable for verification. The results of a computation of the model are compared with the shoal experiment (Berkhoff et al. (1982)) in order to determine the accuracy of the model. Because the study of such problems requires large computational effort, the use of efficient numerical techniques is imperative. Here we present a domain decomposition method which reduces the computational costs of the boundary integral equation method considerably.

This paper is organized as follows. First the numerical model is described in Section 2. In Section 3 the domain decomposition method is described and its

1Delft Hydraulics, P.O. Box 177, 2600 MH Delft, The Netherlands
efficiency is discussed. In Section 4 the application of the domain decomposition
technique to the shoal problem is discussed. Finally some conclusions will be
stated in Section 5.

2 Numerical model

2.1 Description

In the mathematical model for nonlinear water waves considered here, the motion
of the water is described by the usual potential-flow equations for inviscid irrotati-
onal fluid motion with a free surface on water of varying depth. It is described
by the field equation for the velocity potential $\phi$ (Laplace's equation)

$$\Delta \phi = 0,$$

and the boundary conditions on the free surface $\partial \Omega_{FS}$

$$\begin{align*}
\frac{D\phi}{Dt} &= \frac{1}{2}(\nabla \phi)^2 - gz - \frac{P}{\rho} \\
\frac{D}{Dt} \cdot n &= \frac{\partial \phi}{\partial n} \\
x &\in \partial \Omega_{FS}
\end{align*}$$

and on the bottom $\partial \Omega_B$

$$\frac{\partial \phi}{\partial n} = 0, \ x \in \partial \Omega_B. \tag{3}$$

Appropriate in- and outflow boundary conditions are formulated on the lateral
boundaries.

The numerical model consists of a time marching scheme for the evolution
of the free surface and its boundary conditions. At every time-step, Laplace's
equation for the velocity potential is solved by using a boundary integral equa-
tion method (BIEM). In the BIEM, only the boundary of the fluid domain is
discretized into quadrangular panels represented by a collocation point in the
centre of the panel. For each collocation point a Fredholm integral equation of
the second kind equivalent with Laplace's equation is formulated (see e.g. Broeze
(1993)). These integral equations are discretized and by using the boundary
conditions a system of linear equations is built and subsequently solved. Insertion
into equations (2) of the solution obtained in this way, provides the time
derivatives which are needed for the time marching scheme.

For the time integration of the collocation points, a Lagrangian description
is used in combination with (small) tangential correction velocities to control
the grid motion. In the present implementation the Lagrangian description is
required to obtain stability near the inflow boundaries, see Broeze (1993). The
lateral boundaries move along with the free-surface grid with uniform velocities
over each vertical. Due to the Lagrangian motion the grid distorts during the
time-domain simulation. For this reason a mixed Eulerian-Lagrangian description
is preferred which controls the grid in the inside of the domain and retains the
stability. This is however not implemented in the model yet but seems to be of importance to be used in combination with domain decomposition, as will be pointed out in Section 4. See furthermore Broeze (1993) for a more detailed description of the method employed here.

Boundary integral equation methods are very suitable for solving Laplace’s equation on such domains because they only require a discretization of the boundary of the domain. Compared with field discretization methods, the advantages of a BIEM are a much smaller amount of grid points and a natural description of the evolution of the free surface. On the other hand, the computational requirements for some specific parts of the solution algorithm depend superlinearly on the number of collocation points and often form the bottleneck for the computation of large-scale wave problems. These parts are the discretization of the boundary integral equations and the solution of the resulting system of linear equations. The domain decomposition technique is used to tackle these problems.

2.2 Applications

There are a number of applications for which the model can be used. For verification the model can be used to check higher-order wavemaker theory for both translating and rotating wavemakers in two dimensions. In this application the boundary condition related to the moving wavemaker is imposed on the exact position of the wavemaker in time. Because the full nonlinear free surface boundary conditions are solved, the accuracy of the wavemaker theory can be investigated with respect to its order.

The model can also be used for verification of the modelling of the nonlinear free-surface conditions in other wave models, like Boussinesq models. This is especially useful when experimental verification material is hard to get, for example in large scale problems. This also applies to the modelling of wave interaction with bottom topography.

As a simulation model, the numerical model can be useful when interaction with objects is involved, for example with ships. Wave forces and run-up can be determined in order to simulate its motion. A development which has progressed considerably recently, is the simulation of ship and water motion through a simultaneous solution of the equations of motion of the ship and the governing potential flow equations. These are coupled through the boundary conditions on the hull of the ship, which are taken on the exact wet part of the (moving) ship. Development on these kind of computations is still ongoing, see Berkvens (1998).

For most interesting applications however, limited computer capacity often still prohibits the use of the model, especially in three dimensions. Therefore the development of numerical techniques, such as domain decomposition, is needed.
3 Domain decomposition

3.1 Description

The domain decomposition method described here consists of a division of the computational domain into subdomains (see Figure 1) and an iterative procedure which generates a sequence of solutions in the subdomains that converges towards the solution in the original domain.

![Figure 1: Domain subdivided into 8 subdomains (Panels on the front lateral boundaries are not shown)](image)

Every step of the iterative procedure consists of first solving Laplace’s equation for the potential $\phi$ on the separate subdomains simultaneously and secondly formulating new boundary conditions on the subdomain interfaces. In the latter part the subdomain problems are coupled.

There are many possibilities in the way information can be exchanged between the subdomains. We have chosen here to use the so-called DD/NN-scheme. Every odd step of the iterative procedure Dirichlet conditions are imposed on all interfaces. Neumann conditions are imposed at all even steps. These steps are illustrated in Figure 2 for the first two steps of a two-subdomain problem.

This scheme is also known as a Neumann-Neumann preconditioner in the context of domain decomposition methods for field discretization techniques, see e.g. Le Tallec (1994). In the field of time-domain BIEM’s for nonlinear water waves a similar technique was used by Wang et al. (1994) in 2D. In their work interfaces are used to formulate a block-structured matrix which is then solved iteratively. In the present approach the subdivision and the coupling is formulated on the continuous level. It is implemented numerically through separate discretizations for all subdomains leading to matrices to be solved per subdomain and a separate coupling algorithm. The present method has been presented in De Haas et al. (1996) where it was applied to the simulation of propagating nonlinear wave groups in 2D. For a general impression of work being done in the field of domain decomposition the reader can consult for instance Quarteroni (1994).
3.2 Implementation and application

In the application of the domain decomposition technique to the time-domain numerical model described here, the domain is divided in one direction only. It is possible to change the subdivision of the domain during the computation which may for example be useful when initially having large subdomains in parts where hardly no waves are present and required CPU time per node is small, and small subdomains in parts where a lot of wave action takes place. We have chosen to use a fixed initial subdivision of the computational domain with subdomains of equal size so that no reorganization of data over the subdomains is necessary and the number of nodes in all subdomains is (approximately) the same.

In the present implementation, each subdomain is treated numerically as a one-domain problem with respect to both the solution of Laplace's equation and the time integration. This implies that for each subdomain the interfaces move as if they were in- and outflow boundaries of this subdomain, moving along with the free-surface grid in a Lagrangian fashion. The subdomain problems are coupled to ensure a unique description of the interface position (the motion of each interface is determined from solutions of the neighbouring subdomains) and they are coupled through the averaging of the interface boundary conditions as required in the iterative process.

3.3 Convergence characteristics

The performance of the domain decomposition method is determined by the convergence of the iterative process. It can be monitored on each interface by considering the jump across the interface between the solutions on both sides. The convergence on the interfaces depends on the geometrical form of the subdomains and on the coupling scheme used. Convergence characteristics for 2D-problems have been outlined in De Haas e.a. (1996) and are repeated here with inclusion
of typical three-dimensional aspects.

- The convergence of the iterative procedure deteriorates if there is more asymmetry near the interfaces due to a disturbed free surface or an uneven bottom. In numerical experiments it was shown that it is mainly determined by the slope in the direction perpendicular to the interface, see De Haas and Zandbergen (1996).

- If either the length-to-height ratios or the length-to-width ratios are not too small (typically larger than 1) then convergence on each interface is not influenced by iterative processes on other interfaces.

Implications of these features with respect to the division of a computational domain in more than two subdomains can be considered in two ways.

- For a fixed length-to-height ratio $L/h$ of the computational domain, the convergence of the iterative procedure deteriorates as the number of subdomains $N$ increases. For problems with an even bottom a specific number $\tilde{N}$ (and corresponding length $\tilde{l} = L/\tilde{N}$) exists for which the iterative process on one interface is influenced by the iterative processes on neighbouring interfaces.

- For a fixed length-to-height ratio $l/h$ of the subdomains, the convergence rate does not change as the number of subdomains increases, in the case of rectangular subdomains of equal size $l > \tilde{l}$. In applications with a disturbed free surface over an even bottom it is seen that convergence is determined by the interface with the worst convergence. The number of iterations has an upper bound which is independent of $N$.

Examples of the first type of computation are shown in Section 3.4. The shoal problem treated in Section 4 represents a problem with an uneven bottom.

3.4 Efficiency

The efficiency of the domain decomposition technique is of course related to the convergence of the iterative method. It is considered for the case of a computational domain with a fixed length-to-height ratio and illustrated with an example.

- If for a computational domain with a fixed length the number of subdomains is increased, on the one hand the number of required iterations will increase. On the other hand, the CPU-time to solve Laplace's equation per subdomain decreases, since the subdomains become smaller. In general a certain optimal number of subdomains exists with respect to required computer capacity to solve a given water-wave problem.

- If the computational domain is built from subdomains with a fixed length-to-height ratio and the number of subdomains is increased, the number of iterations increases but remains below a upper bound independent of
the number of subdomains used. Therefore the computational costs per subdomain have an upper bound independent of the number of subdomains and the maximum total computational cost per time step can be given by a function linearly dependent on the size of the computational domain.

Results are shown for the fully nonlinear water wave problem illustrated in Figure 1. This problem involves a Fourier series solution which propagates undisturbed in water of constant depth. It is computed using the method by Rienecker and Fenton for waterdepth \( h = 10.0 \text{ m} \) and wavelength \( \lambda = 60.0 \text{ m} \). The computations are started from an initial state prescribed by the solution with the wave direction under an angle of 30° with the positive \( x \)-direction, see Figure 1.

In the first example a computational domain of length \( L = 153.8 \text{ m} \) is considered with subdivisions into 2, 4 and 8 subdomains. Time domain computations are done over the time interval \([0, 10]\) s. Required CPU times are measured for computations using Gaussian elimination and for computations using a conjugate gradient type of solver for the system of linear equations. To reduce CPU times these computations are performed for a wave height \( H = 2.5 \text{ m} \) instead of the wave height \( H = 5.0 \text{ m} \) shown in Figure 1. For the investigation of the number of iterations the waveheight \( H = 5.0 \text{ m} \) is only used for the 8-subdomain problem. The number of required iterations is shown in Figure 3. The number of required iterations for the 2- and 4-subdomain problem is approximately equal. For the 8-subdomain problem the number of required iterations is significantly larger. The variation during the considered time interval is clearly visible for the 8-subdomain problem with \( H = 5.0 \text{ m} \). This variation is related to the varying distortion of the free-surface grid and the connected interfaces. After approximately one wave period the number of required iterations is on the initial level again because all

![Figure 3: Number of iterations \( k \) required per timestep during the computation over the time interval \([0, 10]\) using 2, 4 and 8 subdomains indicated by the thick, medium thick and thin line respectively, for \( H = 2.5 \text{ m} \). The dashed line corresponds to the 8-subdomain computation with \( H = 5.0 \text{ m} \).](image)
the free surface collocation points have made the same excursion through space. The initial domain is recovered apart from a Lagrangian drift in the wave propagation direction. See Figure 4 in which the domain at \( t = 10.0 \, \text{s} \approx 1.53T \) is shown.

Figure 4: Domain at time level \( t = 10 \, \text{s} \) using 8 subdomains. Again the networks of the front lateral boundary are not shown.

With respect to the computational requirements results are shown in Figure 5. The following observations are made:

- The CPU-time for the one-domain problem is much smaller using CGS compared with using Gaussian elimination. This is due to the small efficiency of the latter method for large numbers of panels.
For the computations using Gaussian elimination, the CPU-times for the subdivisions are smaller than the CPU-time for the original one-domain problem. If the results are corrected for the performance of the system still less CPU-time is required except for the two-subdomain problem.

For the computations using CGS, reductions in CPU-time are obtained in all cases up to a factor 3 when using 8 subdomains. The performance is hardly affected so that it can be concluded that the number of floating point operations is decreased.

The memory required for these computations is largely decreased when using domain decomposition.

4 Shoal problem

For the intercomparison of some wave propagation models a laboratory experiment was set up at Delft Hydraulics in which a coastal area was schematized, see Berkhoff et al. (1982). The bottom geometry consists of a sloping bottom with slope 1/50 and a shoal. A number of tests were done with different wave conditions. Wave heights were measured along a number of sections. See also Dingemans (1997), sections 4.6 and 5.6.6. Figure 6 shows the geometry of the shoal experiment.

Figure 6: The geometry of the shoal experiment.

The experiment has been used by Broeze (1993) to test the accuracy of the present numerical model. Due to the relatively large domain and the limited number of panels given the available memory at the time, computations were restricted to only a part of the domain and using coarse resolutions. Nevertheless
the results agreed fairly well with the measured data. Figure 7 shows computed and measured wave heights along four sections.

![Wave height plots](image)

Figure 7: Wave heights relative to height of incoming wave. Computed (solid line) and measured (dashed line) wave heights along sections 2 and 3 (upper two plots) and 6 and 7 (lower two plots).

The domain decomposition technique has the potential to decrease the restrictions mentioned above with respect to the limited available memory. Using domain decomposition more panels can be used taking up the same amount of memory. The computational domain can be increased or a finer resolution can be used.

In application to the shoal problem, however, we found that stability problems occurred due to the Lagrangian motion of the grid and a subsequent deterioration of the convergence of the iterative process. These problems were not solved in the limited time available. A representative computation for these problems is shown in Figure 8.

At the time level shown in this figure, the iterative process diverges on the interfaces located near \( y = 13.1 \) m and \( y = 16.5 \) m. Most probably it is related to the distortion of the grid on the interfaces, especially on the interface near \( y = 13.1 \) m. Due to the large variation of wave height in the region behind the shoal, the variation in horizontal velocities of the free-surface grid is large which causes the grid to distort. As a consequence the interface located behind the shoal distorts as well.

Also subdivisions in the direction perpendicular to the incoming wave direction were applied and showed to be much more stable. But still simulation over the time interval \([0, 18]\) s (required to obtain periodic wave height measurements) did not succeed. As pointed out in Section 2, the use of a mixed
Figure 8: Domain of the shoal-problem at $t = 9.26$ s in the computation using 4 subdomains. The networks in the front lateral boundary are not shown. Waves enter the domain from the right.

Eulerian-Lagrangian method seems to be required to successfully apply the domain decomposition technique.

5 Conclusion

Domain decomposition is a suitable technique to improve the efficiency of boundary integral equation methods, especially in domains originating from water wave problems. In the application to time domain simulations of propagating nonlinear water waves over even bottoms, it leads to large reductions of required computer capacity. In the application to simulations of waves propagating over uneven bottoms, the method still fails. This is probably related to the Lagrangian motion of the free-surface grid and the consequent deterioration of the convergence process.

Variations in Nonlinearly Evolved Nearshore Spectra and Their Significance in the Estimation of Wave Forces

Serdar Beji and Kazuo Nadaoka

Abstract

Variability of spectral estimates is examined with respect to the nonlinearity of the wave field considered. Both measured field data and numerical simulations are used for checking the extent of variations, which are quantified as histograms that closely follow the chi-square distribution. An absolute assessment of the variations over the entire frequency band of a spectrum is also made and found to approach to a mean of 70% regardless of the frequency concerned. Finally, it is observed that a nonlinearly evolving wave field of initially constant spectral shape gradually assumes a spectral variability, which is characterized by the chi-square distribution. The last finding provides a clue for a possible cause of the variations observed in the estimates of spectra.

Introduction

Despite the important implications concerning uncertainties in the estimation of wave loads, deviations of individual spectral samples from the final spectral estimate, as computed through ensemble averaging and frequency smoothing, appear to have received little attention. Borgman (1972) questioned the validity of the use of the chi-square confidence interval for high sea conditions and tested the accuracy of the method using wave data from a hurricane. His comparison with the theory yielded some discrepancies but the overall conclusion was that the chi-square approximation was acceptable even for hurricane waves. Donelan and Pierson (1983) presented an extensive examination of wind-generated laboratory and field wave data with special emphasis on the sampling variability of the spectral peak. They showed that while the scaling according to the spectral peak would bias the spectral estimates, the sampling variability of the spectra was in good accord with the chi-square distribution. The latter finding is in line with Borgman's (1972) conclusion.

It is well known that nonlinear evolutions of surface gravity waves are highly dependent on the phase values of the interacting wave components. Thus, unlike linear waves, depending solely on the initial phase values, a nonlinear random wave field of a certain spectral shape may evolve quite differently from a wave field of the same spectral shape but different initial phases. Variations in such nonlinearly evolved spectra are not negligible and therefore a closer examination may lead to interesting results. In particular, some hints as to the source of the variability observed in spectral estimates may be gained.

This work first examines the sampling variability of the spectra of field measurements in the nearshore zone (Nakamura and Katoh, 1992) and confirms that the chi-square distribution is a good approximation to these variations. The agreement with the theory is remarkable because for these highly nonlinear waves the surface displacements do not exactly satisfy the Gaussian distribution. Absolute deviations of the individual spectra from the ensembled mean are also computed for the entire frequency band and found to resemble a white-noise with a mean level of approximately 70%. The effect of nonlinearity on the spectral variability is investigated by performing a numerical test, which simulates the nonlinear evolution of an initially constant spectral shape over a gently decreasing depth. The numerical results show that the initially constant spectral shape gradually assumes a variability, which is in accord with the chi-square distribution. This finding indicates that nonlinearity may be a responsible mechanism for the observed spectral variability.

For practical applications, the crucial aspect of the spectral variability lies in the uncertainties it implies in the estimation of wave loads, which is essential for a safe design. Possible further investigations on the subject are mentioned in closing.

Analysis of Field Measurements

The spectral variations are first examined by using field data. Two particular data sets from the field measurements of Nakamura and Katoh (1992) were selected; namely, the data of 25 February 1989 and 28 February 1989. The measurements were performed at the Hazaki Oceanographical Research Facility (HORF) near Kashima, Japan. The site of the field observations was a natural sandy beach facing the Pacific Ocean. Ten ultrasonic wave gauges were used; of which seven were installed on the 427 m-long observatory pier while the remaining three were deployed at water depths of 9 m (Station 8), 14 m (Station 9), and 24 m (Station 10), located respectively at the distances 1.3, 2.1, and 3.2 km from the shoreline.

The data of 25 February 1989 was recorded prior to a storm and displayed a typical sea state with significant wave height $H_s=1.5$ m and period $T_s=4.8$ s at the offshore station (Station 10) where the waves were essentially linear. On the other hand, the data of 28 February 1989 was recorded in the aftermath of the storm and the spectrum at Station 10 represented a swell with $H_s=2.2$ m and $T_s=12.4$ s; the waves were nonlinear. While the water depths at Stations 10 to 8 were too deep to cause depth-induced breaking, most of the waves at the remaining stations were either breaking or broken.
For computations the data at each station was first segmented into $M=12$ groups of $N=1024$ data points and Fourier transformed. Out of the 512 unique Fourier pairs the first 256 components, which covered the frequency range of 0.0-0.5 Hz, were considered sufficient to capture almost all the wave energy present and therefore the subsequent computations were performed by using the first 256 transformed pairs.

For each separate set, comprising the Fourier components $a_{nm}$ and $b_{nm}$ for $n = 1,...,256$ and $m = 1,...,12$ the Fourier amplitudes $C^2_{nm} = a^2_{nm} + b^2_{nm}$ were frequency smoothed by a five-point running average

$$\overline{C^2_{nm}} = \frac{1}{5} \sum_{i=n-2}^{n+2} C^2_{in}.$$  

(1)

Using the above frequency smoothed values, a segment averaging was performed

$$\hat{C}^2_n = \frac{1}{12} \sum_{m=1}^{12} \overline{C^2_{nm}},$$

(2)

which in turn could be used to obtain the spectral estimates $\hat{S}_n = \hat{C}^2_n / \Delta f$ with $2 \times 5 \times 12 = 120$ degrees of freedom. Here, $\Delta f = 1 / N\Delta t = 1.953 \times 10^{-3}$ Hz, and $\Delta t = 0.5$ s is the sampling interval.

Since it has implicitly been assumed that the process is approximately Gaussian, the 90% confidence level for the estimated spectral variance with 120 degrees of freedom may be computed as (see Bendat and Piersol, 1971, p.114)

$$P\left( \frac{120\hat{S}_n}{\chi^2_{120,0.05}} < S_n < \frac{120\hat{S}_n}{\chi^2_{120,0.95}} \right) = 0.90,$$

(3)

where $S_n$ is the true but unknown spectral variance corresponding to the frequency $n\Delta f$. Substituting $\chi^2_{120,0.05} = 146.57$ and $\chi^2_{120,0.95} = 95.70$ gives

$$P(0.82\hat{S}_n < S_n < 1.25\hat{S}_n) = 0.90,$$

(4)

which indicates that the true spectrum is known to within ±25% or a range of 43% at the 90% confidence level. Figure 1 shows the estimated spectrum with 120 DOF and a single realization with 2 DOF for the data of 28 February 1989 at Station 10.
Hypothetically, the random variable \( r = C_n^2 / S_n \Delta f \) is distributed according to \( \exp(-r) \) for \( r \) greater than zero. Since \( S_n \) is not known, the estimate \( \hat{S}_n \) can be used for testing the hypothesis that the computed \( r \) values will follow the exponential law.

The computations were done for the data of both 25 and 28 February 1989 using all 12 segments with 256 components covering the frequency range 0.0-0.5 Hz. Consequently, 3072 values of \( r \) were obtained. Strictly speaking, vanishingly small values of \( \hat{S}_n \) should have been avoided to prevent possible errors, however no problems were encountered and therefore the entire range of \( \hat{S}_n \) values was used.

In Figure 2 the histograms for the 3072 values of \( r \) for a class interval 0.05 wide is shown over the range \( 0 < r < 5 \) for three selected stations. Each histogram has been normalized by its value in the first interval (0.00-0.05).

![Figure 2. Normalized histograms of the ratio, \( r \), of raw spectral estimates to the smoothed average spectral estimates for Stations 10, 6, and 2. Left column: 25 February 1989, right column: 28 February 1989. The solid line is the theoretical curve \( \exp(-r) \).](image-url)
In order to obtain quantitative estimates of the spectral variations, the field data is analyzed in a different manner. Instead of treating the spectral variations regardless of frequency, the mean absolute percentage of deviations from the estimate for each frequency component are computed according to the formula

$$\epsilon_n = \frac{1}{12} \sum_{m=1}^{12} \left| \frac{\tilde{S}_n - C_{nm}^2 / \Delta f}{\tilde{S}_n} \right|,$$

and then plotted over frequency. Figure 3 shows the results corresponding to the stations shown in Figure 2.

As it is seen from the above graphs, the mean absolute percentages of individual deviations from the estimated spectral values exhibit a random distribution over frequency with a mean of approximately 75%. Further computations have shown that the number of frequency averaging determines the exact value of the mean percentage with the trend that the higher the number of frequency merging the higher the resulting mean percentage. This is to be expected because the frequency averaging essentially pulls down the estimated spectral shape, resulting in smaller and smaller spectral values. Therefore, if a meaningful mean deviation percentage were to be obtained, it would be best not to introduce any frequency smoothing at all.
As an alternative, instead of $C_{nm}^2$, one could use $\overline{C}_{nm}^2$ in equation (5) to eliminate the quantitative effect of frequency smoothing. Computations without any frequency smoothing but with different number of FFT points and of ensemble averaging have yielded that the mean absolute deviations center around 70% with no sensitivity to the number of FFT points and to the number of ensemble averaging. Likewise, use of $\overline{C}_{nm}^2$ in equation (5) has yielded nearly the same numerical value for different frequency averaging operations. Thus, it has been concluded that the mean absolute deviations center around 70% with a random-noise type appearance over frequency regardless of the characteristics of the wave field considered.

A possible cause for the noise-like distribution of spectral variations over entire frequency band may be attributed to a nonlinear mechanism allowing continuous energy flow among spectral components. For testing the validity of such a notion, a numerical experiment was carried out with supportive results. The computations and results are described in detail in the following section.

A Numerical Experiment

Using a nonlinear wave model, nonlinear evolution of an initially constant spectral shape over decreasing water depth is now investigated. The wave model may be considered as a generalized KdV equation (Korteweg and de Vries, 1895), which is valid for arbitrary ratios of depth to wavelength (Nadaoka et al., 1994; Beji and Nadaoka, 1997a)

$$
\begin{align*}
C_p \eta_t + \frac{1}{2} C_p \left( C_p + C_g \right) \eta_x - \frac{(C_p - C_g)}{k^2} \eta_{xx} - \frac{C_p (C_p - C_g)}{2k^2} \eta_{xxx} \\
+ \frac{1}{4} \left[ C_p \left( C_g \right)_x + \left( C_p - C_g \right) \left( C_p \right)_x \right] \eta + \frac{1}{4} g \left( 3 - \frac{C_g}{C_p} - \frac{k^2 C_p^4}{g^2} \right) \eta^2 \eta_x = 0,
\end{align*}
$$

(6)

where $C_p$, $C_g$, and $k$ are respectively the phase and group velocities and the wave-number computed according to the linear theory dispersion relation for a dominant wave frequency $\omega$ and a given local depth $h$, the subscripts $x$ and $t$ indicate partial differentiation with respect to space and time, respectively.

Based on the above unidirectional wave equation a spectral model was developed (Beji and Nadaoka, 1997b; 1998) resulting in a set of evolution equations describing the spatial changes of the component wave amplitudes of a prescribed incident wave field. No detail is given here; the complete derivation can be found in Beji and Nadaoka (1998). It must be indicated that the wave model itself is not crucial so long as it contains a nonlinear mechanism to generate harmonics thus allowing continuous redistribution of energy.

For numerical investigations a uniformly decreasing depth of 1:50 slope followed by a horizontal section is selected. Waves first steepen due to decreasing depth and then the energy exchange takes place as they travel over the shallow constant depth region. The water depth at the incident boundary is 25 m, which reduces to 5 m after a distance of 1000 m. For the next 1000 m, the water depth remains constant at 5 m.
The wave field at the incident boundary is assumed linear with a Bretshneider type spectral shape and a typical mean period $T_m = 12$ s. For ensuring the linearity of the incident wave field as well as preventing any possible breaking in the shallow region, the incident mean wave height is taken $H_m = 1.0$ m, a moderate value. Twelve realizations with constant spectral shape but different initial phase assignments are performed. As in the field measurements, the computations were done using 256 Fourier pairs with $\Delta f = 1.953 \times 10^{-3}$ Hz, and a five-point running average was applied for frequency smoothing. Thus, all the statistical values given in the previous section apply to the numerical simulations as well.

In Figure 4, the left column shows the histograms for three selected stations while the right column gives the mean absolute percentage of spectral variations for the same stations.

Figure 4. Histograms of spectral variability (left) and mean absolute percentage of variations (right) for an initially constant spectral form at three different locations. Station 1 (not shown) is the incident boundary at $x=0$ m and $h=25$ m; Station 2, $x=250$ m and $h=20$ m; Station 3, $x=750$ m and $h=10$ m; Station 4, $x=2000$ m and $h=5$ m. Histograms for Station 2 and 3 are normalized by their largest values whereas histogram for Station 4 is normalized by its value in the first interval, as in Figure 2.
From the graphs for Station 2 it is seen that the histogram is quite unlike the theoretical chi-square distribution (due to the initially imposed unvarying spectral heights for all realizations) but increasing nonlinearity begins manifesting itself in the lower frequency portion of the wave spectrum by introducing an appreciable variability in that particular region. At Station 3, the histogram is broader but still not quite like its theoretical shape. The effect of nonlinearity has now spread to the higher frequency part of the spectrum; however, the main frequency band (0.05-0.12 Hz), which contains the primary energy of the spectrum remains almost unaffected as can be observed by remarkably low percentages of mean absolute variations. The main frequency band is the last to be modified because the sub- and super-harmonics must reach to appreciable levels before they could interact with it. After travelling the shallow constant depth region of 1000 m, the wave field at Station 4 is completely modified by the wide-spread nonlinear interactions and it has attained a spectral variability which is in excellent agreement with the chi-square distribution. Also, the mean absolute percentages of deviations show a white-noise type random distribution over frequency with a mean of 75%, as for the field measurements given in Figure 3. The results of overall computations imply the existence of a nonlinear mechanism behind the observed spectral variability. This nonlinear mechanism needs not be in the form of a second-order nonlinearity as in here, it may be a cubic nonlinearity, e.g. the nonlinear Schrödinger equation, or a higher order nonlinearity that would permit energy exchange among spectral components.

While the chi-square distribution is linked to the properties of stationary Gaussian processes, the examination of the field data used here shows that this may not be strictly the case. For instance, computing the histograms for the surface elevation distributions at Stations 10 and 6 of 28 February 1989 data results in the graphs shown in Figure 5. While the distribution of Station 10 may be accepted as Gaussian, the distribution of Station 6 clearly diverges from the theoretical curve. However, the histograms of spectral variations for both Station 10 and Station 6 satisfy the theoretical chi-square distribution very closely, as is seen in Figure 2. This particular point was Borgman’s (1972) principal motivation for investigating the validity of the chi-square confidence intervals for high sea conditions.

![Figure 5. Histograms for distributions of surface displacements for the data of 28 February 1989 at Station 10 and Station 6.](image-url)
The point that the wave field needs not be truly Gaussian in order that the corresponding spectral variations be chi-square distributed is especially mentioned here because except for a few stations of the data of 25 February 1989, almost all the other data (measured or computed) were actually representing nonlinear waves.

Concluding Remarks

Analysis of the field data comprising linear and highly nonlinear wave fields has confirmed the validity of the standard assumption that the spectral variabilities follow the chi-square distribution. It is also observed that the wave field does not necessarily need to be truly Gaussian for its spectral variability to follow the chi-square distribution. The numerical simulation of a nonlinearly evolving spectrum has shown that an initially constant spectral shape gradually assumes a variability, which is in perfect agreement with the chi-square distribution. Therefore, nonlinear interactions may be at least partially responsible for the variability observed in spectral computations. Once the spectral variability is attained, it remains preserved even if the wave field becomes linear as, for instance, by breaking or moving into deeper regions.

The quantitative assessments of the variability show that on the average 70% deviation of a spectral component from the smoothed and segment averaged value is possible. In estimating the extreme wave loads this percentage may be interpreted as an indicator of the additional transient loads. For making reliable assessments, it is necessary to investigate the actual wave load variations by performing computations with wave fields having such variable spectra.

Wave Refraction across a Current with Strong Horizontal Shearing

Richard R. Simons and Ruairi D. Maciver

Abstract

Experiments have been performed with regular deep-water waves propagating obliquely across a relatively narrow jet-type current. Measurements have been made of wave refraction using an 8-element wave array and 3d acoustic Doppler flowmeters. Results show that wave height and celerity follow the trends predicted by gradually-varied flow theory, but with wave height modulated by weak reflections as the waves pass across the jet. Direction of wave propagation is found to be sensitive to the presence of internal reflections from the shear layers.

Introduction

It is now widely accepted that non-linear wave-current interaction plays an important role in the evolution of coastal flow. Currents are generated by wind stresses, tides and river estuary discharges, and when waves move across such spatially varying mean flows, they experience significant changes in amplitude, celerity, direction, kinematics, and bed friction, all of which affect both their local characteristics and their potential impact on the wider coastal environment.

Many theoretical models of coastal flows are based on the assumption that waves are moving through a gradually varying medium, for instance, where there is a gently sloping seabed or a current contains only weak horizontal shearing. Conventionally, when regular long-crested waves cross a horizontally sheared current, the angle of refraction and Doppler-shifted celerity are determined by application of Snell's Law to the wave orthogonals, while the change in wave height

is determined from the conservation of wave action through wave ray tubes (Jonsson, 1990). This form of analysis is appropriate when the width of the shear layer is many times the length of the incident wave, such as where waves propagate across the Gulf Stream. In that particular case, the width of the jet current is approximately 300 times the incident wave length.

However, it is often the case that waves propagate through waters where bathymetry and currents vary rapidly, for instance, where rivers or tidal inlets discharge into the ocean. Under such circumstances the width of the jet may be less than 5 times the incident wave length. An important consequence of such rapidly varying conditions is that significant wave reflection may take place at both shear layers, a phenomenon not normally included in wave refraction models.

There have been a number of attempts to model wave refraction across a rapidly varying current, extending the slowly-varying WKB solution to allow reflections (McKee, 1977; McKee, 1996), or including a vortex sheet to simulate the reflecting shear layer (Smith, 1983; Kirby, 1986). The availability of data against which these theories can be validated has been restricted by the practical difficulties involved in performing equivalent experiments. At a laboratory scale the flow conditions typically achievable can produce refraction of only a few degrees, and the accurate measurement of such small changes presents a significant difficulty. However, motivated by a parallel project at University College Cork to develop a new model, the present paper describes tests carried out under controlled conditions in the UK Coastal Research Facility (UKCRF) at Wallingford aimed at providing both a better understanding of the processes controlling current refraction and data for model validation.

The experiments were designed to investigate the behaviour of waves in water of constant depth as they pass obliquely across a narrow jet-like current with strong horizontal shear. The refraction has been established at several locations across the shore-parallel current from oscillatory velocity vectors and from a directional wave array. The project addresses one of the areas highlighted in a recent review (Thomas and Klopman, 1997) as requiring attention, and offers a unique data set against which models can be tested.

**Experiments**

The UKCRF has been designed to provide a controlled environment in which various coastal processes can be simulated and investigated at relatively large scale. While the main aim is to provide data for validation of models describing a range of coastal phenomena, it also offers the opportunity to improve fundamental understanding of the physics. The design and capabilities of the basin are described in an earlier paper (Simons et al., 1995).
For the present tests, water depth was fixed at 0.5m above a bed roughened with 10mm diameter granite chippings. A jet-like current was generated in the offshore flat-bed region of the basin. This jet had a Gaussian horizontal distribution of velocity across its nominal width of 7 metres and a streamwise centreline near-surface velocity of 0.25m/s. Long-crested waves, generated in still water offshore from the jet current, were propagated through the jet current before being spent on a 1-in-20 plane beach. Preliminary tests used regular wave periods of both 0.8s and 0.9s, wave heights of 40mm, and angles of incidence between wave orthogonal and shore-normal of 0° and ±30°. Parameters for the main test programme described here are set out in Table 1 below.

Vertical profiles of mean and wave-induced velocities were measured at regular positions across and at three sections along the horizontally varying current using three 3d Nortek acoustic Doppler velocimeters (ADVs) mounted one above the other. Surface elevation was measured using the "Octoprobe", an array of eight wave probes mounted in a fixed geometry, 0.85m long by 0.6m wide, as described by
Teisson and Benoit (1994). The array was traversed across the jet current with one wave probe located exactly above the three ADV velocimeters, and provided wave heights, reflection coefficients and wave propagation direction. Four additional wave probes were also deployed on tripods, at fixed locations in the basin to provide a common reference for phase analysis of all data channels.

The objectives of the test programme were: with no waves present, to establish a stable jet current parallel to the wave generators, and to measure the velocity field across the jet and through the depth at three cross-sections; then, with no jet current flowing, to measure the velocity field for regular long-crested waves propagating obliquely or normal to the shoreline; and finally, with those waves propagating across the jet current, to measure the wave refraction and wave height at regular positions across the jet current, and to determine the Doppler-shifted wave celerity at the same locations.

**Figure 1:** Horizontal velocity vectors for 30° waves: no current flowing [straight lines indicate mean direction of wave propagation].

**Methods of analysis**

To determine the local direction of wave propagation as the waves refract across the jet current, five different methods of analysis were considered.

The first of these ("Method 1") used only data from the ADV velocity probes to generate the ensemble average horizontal velocity vector at phases through the wave cycle. A least-squares method was then adopted to identify the mean direction
of the velocity vector. An alternative method, calculating the direction using only the
1st harmonic of the horizontal velocity vector, yielded almost identical results. It
should be noted that the vectors were never the ideal straight lines that a clean, long-
crested wave should produce, but were always mildly contorted closed curves, as
shown in fig.1 for a case with no current. This suggests that waves of different
frequency or direction of propagation were present in the basin.

"Method 2" used data from the 8 wave probes deployed in the Octoprobe, and
related the 1st harmonic phase difference between pairs of probes a known distance
apart to the two unknowns, namely, local direction of wave propagation and absolute
wave celerity. If the flow field was homogeneous, it would then be possible to
produce 7 independent estimates of phase difference and, adopting an appropriate
numerical technique, solve for celerity and direction. However, the present tests
specifically included rapidly varying currents, and estimates predicted a possible 15%
variation in celerity along the length of the Octoprobe. In order to improve the spatial

Figure 2: Variation in wave phase on an orthogonal section across the jet current.
resolution, it was decided to analyse the data as two separate cross-shaped groups with 5 probes in each group. Adopting a least-squares optimisation, it was then possible to deduce two independent sets of results for each deployment position. While this method was restricted to identifying the dominant propagation direction at a single incident wave frequency, it was found to be robust, made no assumptions concerning the local wave celerity, and produced reliable results for all test conditions investigated.

"Method 3" looked at the variation in phase of the 1st harmonic along a shore-normal transept as measured by the four co-linear wave probes on the spine of the Octoprobe as it was traversed across the jet current (fig.2). At any particular location the rate of change of phase is related directly to the component of celerity in the shore-normal direction. Then, making the (initially unsupported) assumption that the local absolute celerity can be calculated from the incident wave celerity and the local mean velocity (as measured by the ADV probes) using simple Doppler shift, it is possible to calculate the angle of incidence between the jet current and the local direction of wave propagation, in other words, the wave refraction. While this method worked well for the case with waves following the current, it failed to yield solutions for the opposing current case and has not been applied further.

The next ("Method 4") used data from the Octoprobe to produce full directional spectra, providing both the directional distribution of wave energy at the incident wave frequency and the distribution between different frequencies at positions across the jet current. At each deployment location, analysis was performed on two groups of wave probes (with 4 probes in each) to improve spatial resolution. Spectra were calculated using the Iterative Maximum Likelihood Method (Pawka, 1983), adapted to include a dispersion relation varying with direction and local jet current strength. Implicit in this modification is the assumption, used in "Method 3", that the local wave celerity can be calculated from a simple Doppler-shift of celerity from linear wave theory using the local mean current velocity.

Finally, from the data recorded, it would be possible to calculate the wave parameters using collocated measurements of water surface elevation and wave-induced velocities. However, time has so far precluded such analysis.

Results

Preliminary observations with no waves present confirmed that the jet current took on the desired Gaussian horizontal profile, but a gradual increase in width of the jet was noted as it propagated along the basin. However, this change was sufficiently weak to be deemed negligible along the 10m length of basin in which detailed velocity measurements were made. Some meandering of the jet was also detected in the time-series of u and v velocity components, and spectral analysis confirmed
oscillations between 40s and 100s, suggesting streamwise length scales of between 10m and 25m.

With the current turned off, waves of 0.8s period were then propagated shore-normal and at +/- 30° to shore-normal to assess both the quality of the waves and the reliability of the measuring and analysis techniques. Time-series of water surface elevations showed that the waves remained regular, with wave heights constant to 5% and no modulation. Spatial variation of wave height suggested reflection coefficients from the beach of less than 5%. The angle of wave propagation was found to be determined to within +/- 1.5° of the direction requested at the wave maker using data from the Octoprobe, with slightly poorer estimates from the velocity vector method.

When the waves were propagated across the jet current, the first notable observation was that the jet current had itself been moved laterally - inshore and away from the wave generators by 0.3m when the waves followed the current, offshore and towards the wave generators by 1.4m when the waves opposed the current. This change can be seen in the reference current plotted at the bottom of most subsequent diagrams, and changes in wave properties should be viewed relative to that location.

Fig.3 shows the local wave celerity and angle of propagation measured by the Octoprobe using "Method 2" when waves at 30° incidence propagate across the following jet current. The 20% increase in celerity observed at the centre of the jet agrees well with simple 1st order Doppler-shifted theory as used for gradually varied flows (Jonsson, 1990). However, the direction of propagation varies sinusoidally across the jet (oscillating about the predicted refraction pattern), with almost no refraction measurable at the centre and with 6° shifts in the two shear layers on either side. IMLM analysis ("Method 4") produced very similar results. In contrast, the propagation angle deduced from the velocity vectors (fig.4) shows rather higher angles of refraction - again varying sinusoidally across the jet but phased differently from the results reported above - with a 15° shift in the offshore shear layer. Despite the spatial variation in refractive angle, the scale is close to the 6° predicted from Snell's Law for slowly varying flow.

Figs.5 & 6 show the corresponding refraction patterns when the waves propagate into the opposing jet current. In this case the 20% decrease in celerity predicted by theory is again well matched to data from the Octoprobe, as is the refracted angle of propagation at the centre of the jet. However, inshore of the jet, the angle of refraction is erratic. The shift in propagation direction towards shore-normal calculated at the centre of the jet from the velocity vectors (particularly using ADV2) is significantly greater than found using the other methods or predicted by gradually-varied theory.

With the waves propagating orthogonally across the jet current, no significant
changes in celerity or angle of propagation were observed, although the scatter in all data sets was greater than observed in the absence of the current.

Figs. 4 & 6 also show the variation in wave height measured across the jet current for the following and opposing current cases respectively. It can be seen that, within the bounds of experimental scatter, the significant wave height indicates a
partial standing wave pattern (<10%) superimposed on the weak variation in $H_s$ predicted by theory as the waves propagate across the jet. In contrast, the graph of 1st harmonic wave height $H_1$ confirms the reflection pattern but suggests that $H_1$ decays rapidly across the jet. This apparent anomaly is caused by different methods
Figure 5: Variation of wave celerity and direction (from Octoprobe) across the jet current: opposing current case.

of analysis: $H_s$ has been calculated from the standard deviation of the wave surface time-series, whereas $H_i$ comes from Fourier analysis of the ensemble-averaged surface profile (phase-locked to one of the offshore fixed wave probes). The problem arises because wave time-series records on the inshore side of the jet current exhibit
modulation patterns; these cause the ensemble-averaging process to move in and out of phase, thus reducing the amplitude of the resulting ensemble average and of the wave harmonics calculated from it. Clearly, in this situation, the significant wave height $H_s$ is giving the true picture as far as wave height change across the jet is

**Figure 6:** Variation of wave height and direction (from velocity vectors) across the jet current: opposing current case.
The modulation in wave amplitude referred to above is an interesting phenomenon which needs to be considered when interpreting the results from this study. Time-series of wave surface elevation recorded at various locations across the jet current (fig.7) show that while there is some modulation at the offshore edge, the effect is worse inshore, where the waves have already propagated across the jet for some distance. These features generally exhibit time-scales of approximately 30s, which is rather lower than those noted above in relation to the meandering of the jet current.

While it has not yet been possible to model the observations in detail, it is
clear from the descriptions above that the angles of propagation (figs.3-6) observed on the jet can be explained as the effect of reflections (<10%) from the jet-current shear layers superimposed on the refraction angle predicted by gradually-varied flow theory. The phase of these reflected waves will vary depending on the exact location of the jet current at the point of reflection; similarly, the phase of the incident waves will depend on the location of the jet at the point where they first enter the shear layer. Hence the wave modulation will be related to the meandering of the jet but will not necessarily correlate with the time variation at any one point along the basin. The resultant wave pattern on the jet will thus be a function of incident wave characteristics, reflection coefficient from the shoreward shear layer, possible secondary internal reflection from the offshore shear layer, the mean horizontal jet current profile, and the temporal and spatial scales of the current meandering.

Conclusions

A significant data set has been acquired, providing information on the transformation of regular waves propagating across a narrow jet-like current with strong horizontal shear. Four methods have been used to measure the refraction of waves on the spatially varying current. One of these methods has been able to provide an independent measure of the local wave celerity on the jet current, and this confirms the predictions from a simple Doppler shift of linear wave theory.

The apparent angle of propagation of the incident waves does not follow a simple variation across the jet, but has been shown to be sensitive to the effect of small waves reflected from the shear layers.

In the absence of the jet current, wave amplitude is constant with time. When the current is added, the wave amplitude becomes modulated by the interaction of the incident waves with reflections from the gradually-meandering shear layer.

When waves are propagated across the jet-like current in a large wave basin such as the UKCRF, the jet is moved laterally. For following waves it translates towards the shoreline; for opposing waves it translates away from the shore.

Random Waves on a Vertically-sheared Current

C. Swan and R. L. James

Abstract

This paper considers the interaction between two-dimensional random waves and a co-linear, depth-varying, current. Two rotational wave-current models, capable of incorporating the effects of a depth dependent vorticity distribution, are combined with a conservation equation describing the total energy flux. This provides new solutions capable of predicting the change in a wave spectrum due to the interaction with a current. Comparisons between these solutions and a new data set confirms that a successful wave-current model must incorporate both the Doppler shift associated with the surface current and the near-surface vorticity distribution. Typical design calculations, based on a uniform current approximation, commonly satisfy neither of these constraints. Accordingly, they are shown to provide a poor description of the laboratory data. Furthermore, the nature of the wave-current interaction, which is shown to be significantly larger than the nonlinear wave-wave interactions, involves both a current-induced change in the wave motion and a wave-induced change in the current. While the former is reasonably well understood, the latter remains difficult to predict. Indeed, both parts of this overall interaction are shown to be strongly vorticity dependent.

1. Introduction

The nonlinear interaction between waves and a co-existing current is an important feature of many coastal and offshore environments. Accordingly, several authors have considered the case of regular waves on a variety of current profiles (see, for example, the recent review article by Thomas and Klopman, 1997). In its simplest form the current profile, $U(z)$, is assumed to be uniform with depth. In this case no vorticity is present and it has been conclusively shown that both the dispersion equation and the associated water particle kinematics are well described by a Doppler shifted solution (Fenton, 1985). Likewise, the change in the wave height, $\Delta H$, which arises when the waves first propagate onto the current, can be modelled via the conservation of wave action.

1 Reader and 2 Research Assistant, Department of Civil and Environmental Engineering, Imperial College, London SW7 2BU.
(Thomas, 1990). Alternatively, if it is assumed that the current profile is represented by a linear shear, then a uniform vorticity distribution \( \sigma = dU/dz \) is introduced. In this case the wave motion again remains irrotational, but additional vorticity dependent terms arise within the dispersion equation so that the Doppler shifted solution is no longer applicable. In this case the water particle kinematics have been considered by Tsao (1959) and Kishida and Sobey (1988); while a linear formulation of a conservation equation for wave action has been provided by Jonsson \textit{et al.} (1988).

More recently, solutions have been presented which address the case of waves on a current profile that varies arbitrarily with depth. In particular, considerable attention has been paid to cases in which the current profile is strongly sheared close to the water surface. Such cases are practically important since they are representative of a wind-driven current, and may also correspond to a typical estuarine outfall in the near-shore coastal region. In these cases the vorticity distribution is strongly non-uniform and, consequently, the wave motion becomes rotational. In terms of kinematic predictions an analytical model describing this type of interaction has been proposed by Swan (1992) and recently modified by Swan and James (1998); while numerical formulations are provided by Dalrymple (1974), Chaplin (1990), Thomas (1990) and Cummins and Swan (1993). In contrast, the initial wave height change, \( \Delta H \), caused by the interaction with a strongly sheared current is more difficult. In the absence of an appropriate (nonlinear) conservation of wave action equation, the conservation of total energy flux, \( R_x \), must be applied.

Although the advances noted above have greatly enhanced our understanding of nonlinear wave-current interactions, they are restricted in the sense that they have principally considered the case of regular waves on currents. In practice the waves observed in most offshore and coastal locations are random, or irregular, with a significant frequency spread. In these cases the design engineer may be primarily concerned with the changes in a wave spectrum due to the interaction with a sheared current. It is this task which the present paper will address. Section 2 commences with a description of the experimental facility in which two-dimensional random waves were super-imposed on a depth-varying current. The essential characteristics of both an analytical wave-current model (Swan and James, 1998) and a multi-layered numerical model (Cummins and Swan, 1993) are briefly outlined in section 3. Using these results, a conservation of total energy flux equation is outlined, and verified with comparisons to a fifth-order conservation of wave action equation (Thomas, 1990) for the simplified case of regular waves on a uniform current. Comparisons between the laboratory data and both the analytical and numerical models are presented in section 4; while section 5 provides some concluding remarks concerning the extent of the wave-current interaction, the importance of the vorticity distribution, and those areas which require further consideration.

2. Experimental Apparatus and Measuring Procedure

The experimental work undertaken within this study was conducted in a purpose built wave-current flume. This facility is located in the Hydraulics Laboratory within the
Department of Civil and Environmental Engineering at Imperial College, London. The flume has an overall length of 25m, a width of 0.3m, and a working depth of 0.7m. The waves are generated by a bottom-hinged, numerically controlled, wave paddle located at one end of the wave flume. At the opposite end the wave energy is absorbed by a large block of poly-ether foam, the front face of which is cut to form a vertical wedge with an included angle of 30°. With this passive absorber in place, the reflection coefficient across a broad range of regular wave conditions was less than 2%. Further details of the wave flume are provided by Baldock et al. (1996).

Within the present tests the current was introduced via three loops of pipework. These allow a re-circulating and reversible current with a maximum volume discharge of 0.05m³/s. A sketch indicating the layout of the experimental facility is given on figure 1. Measurements undertaken within the wave-current flume include both time-histories of the water surface elevation, $h(t)$, recorded at a number of fixed spatial locations, and point measurements of the water particle kinematics to define both the shape of the current profile (acting in the absence of the waves) and the extent of the wave-current interaction. The surface elevation data was recorded via an array of surface-piercing resistance gauges. Individually, these consist of two vertical wires, each with an external diameter of 1mm, placed 10mm apart. Previous experience has shown that these gauges cause almost no disturbance of the flow field, and allow the water surface elevation to be recorded with an accuracy of ±1mm. The velocity data was recorded using a three beam Laser Doppler anemometer based on a 30mW helium-neon laser. This system was established in a forward scatter mode for optimal signal to noise ratio, and allows two components of the water particle velocity to be recorded simultaneously with an accuracy of ±2%. In each of the cases presented the measuring section was located 2.8m downstream of the wave paddle.

To create a vertically-sheared current at the measuring section, the mean flow was introduced in the form of an upwelling immediately downstream of the wave paddle (figure 1). With careful modifications of the inlet conditions a steady, two-dimensional,
current was achieved in which the surface velocities were of the order of $U_e = 0.6 \text{m/s}$ and the surface vorticity was as large as $(dU/dz)_z = 2.0 \text{m/s/m}$. Figure 2a describes the time-variation of the current profile over a period of 3 hours; while figure 2b describes the cross-tank variation. These results clearly suggest that the current profile is both steady and two-dimensional. In contrast, figure 2c describes the downstream variation in the current profile. Although there clearly remains some downstream variation, i.e. $dU/dx \neq 0$, this is at least one order of magnitude smaller than the gradient in the $z$ direction. Hence, we are able to conclude that the nature of the wave-current interaction is dominated by the vertical shear in the current profile.

3. Modelling Work

In this section we will briefly mention two methods which have previously been applied to the modelling of regular waves on depth-varying currents. The first is the multi-layered numerical model outlined by Cummins and Swan (1993); while the second corresponds to the weakly nonlinear analytical solution described by Swan and James (1998). Although the results of these models are shown to be in good mutual agreement, the latter model is much easier to apply in the context of random waves. Indeed, the agreement between these models is an important finding in itself since it implies that the analytical formulation, which is only accurate to a second-order of wave steepness, has a wider range of applicability than one might expect.

3.1 Numerical Modelling

The scheme proposed by Cummins and Swan (1993) is essentially a five-layered equivalent of the two-layered or bi-linear shear model originally proposed by Dalrymple

Figures 2a-2c. Characteristics of the current profile.
(a) Variation with time: $t = 0$, 1hr, 2hrs and 3hrs; (b) Cross-tank variation: $y = 0.25b$, 0.5b and 0.75b; (c) Downstream variation: $x = 0$, 1.4m, 2.1m and 2.8m.
(1974). If the computational domain is defined according to figure 3a, the stream function, \( \psi \), in the \( i^{th} \) fluid layer, where \( i=1, ..., 5 \), is given by:

\[
\psi = (c - U_{i-1}) z - \left( \frac{U_i - U_{i-1}}{d_{i-1} - d_i} \right) \left( \frac{z^2}{2} + d_{i-1} z \right) + \sum_{n=1}^{N} \left[ X_i(n) \sinh \left( \frac{2\pi n z}{\lambda} \right) + Y_i(n) \cosh \left( \frac{2\pi n z}{\lambda} \right) \right] \cos (nkx)
\]

where the Cartesian co-ordinates \((x,z)\) have their origin at the mean water surface, \( z \) is measured vertically upwards and \( x \) in the direction of wave propagation, \( c \) is the phase velocity, \( d_i \) is the depth of the \( i^{th} \) fluid layer, \( U_i \) defines the current profile, and \( \lambda \) is the wave length. Within (1) the first term on the right hand side ensures that the solution is steady; the second term defines the current profile, approximated by a series of linear shear currents; while the third term defines the oscillating flow field and includes the unknown coefficients \((X_i, Y_i)\). A solution of this type is appropriate to the description of the equilibrium conditions arising in a combined wave-current flow.

Assuming that the wave height, \( H \), the wave period, \( T \), the water depth, \( d \), and the current profile, \( U(z) \) (occurring in the presence of the waves) are defined, the usual boundary conditions coupled with a number of compatibility constraints applied at the interfacial sections \((z=\xi_i, \text{where } i=1, ..., 5)\) allow the flow field to be solved. Solutions for the wave length, \( \lambda \), the surface profile, \( \eta \), the oscillatory velocity components \((u,v)\) and the pressure, \( p \), are thus achieved. Using this approach the order of the approximation was typically set at \( N=8 \) for nonlinear waves on a strongly sheared current, and the calculations undertaken on a standard 200MHz personal computer. Detailed comparisons between this model and a data set concerning regular waves on a variety of strongly sheared currents are provided by Swan et al. (1998).
3.2 Analytical Modelling

In contrast to the numerical scheme noted above, the analytical model is restricted to a second-order of wave steepness and is based on the orthogonal transformation indicated on figure 3b.

![Cartesian (x,z) and Curvi-linear (ξ,η)](image)

Figure 3b. Co-ordinate arrangement and solution domain

Within the (ξ,η) frame, η=0 defines the free-surface, η=-d, the bottom boundary, and the current profile (again specified in the presence of the waves) is defined by a third-order polynomial such that in a stationary frame of reference:

\[ U(\eta) = (P + 2Q\eta + 3R\eta^2 + 4S\eta^3) \delta_\eta(\eta + md) \]  

(2)

where P, Q, R and S are constants, η=-md defines the vertical extent of the current, i.e. 0≤m≤1, and \( \delta_\eta \) is a step function such that \( \delta_\eta(y) \) is 0 if y<0 or 1 if y≥0. After solving the two-dimensional vorticity equation in general orthogonal co-ordinates for an inviscid fluid, subject to the usual boundary conditions, the stream function, \( \psi \), is given by:

\[ \psi = -c\eta + \left( Q\eta^3 + R\eta^3 + S\eta^4 \right) \delta_\eta(\eta + md) - P\eta\delta_\eta(-\eta - md) \]

\[ + a \left( 2Q\eta + 3R\eta^2 + 4S\eta^3 + \frac{6S\eta}{k^2} + f_\sigma \right) \frac{\sinh k(d + \eta)}{\sinh kd} \cos(k\xi) \delta_\eta(\eta + md) \]

\[ + a \left( -\frac{3R\eta}{k} - \frac{6S\eta^2}{k} + f_\sigma \right) \frac{\cosh k(d + \eta)}{\sinh kd} \cos(k\xi) \delta_\eta(-\eta - md) \]

(3)

where the constant coefficients \( f_\sigma, f_\theta \) and \( f_c \) are dependent on the wave characteristics and the current profile. Applying this solution, the velocity components in the (ξ,η) directions are given by:

\[ u_\zeta = J^{1/2} \frac{\partial \psi}{\partial \eta} \quad \text{and} \quad u_\eta = -J^{1/2} \frac{\partial \psi}{\partial \zeta} \]

(4)

where the Jacobian, J, is defined by \( J = \partial(\xi,\eta)/\partial(x,z) \). Within this solution the first term on
the right side of (3) reflects the translation of the co-ordinate axis; the second and third terms define the current profile; while the remaining terms provide a first approximation to the nonlinear wave-current interaction. Comparisons between this solution, the numerical model discussed in section 3.1, and a number of regular wave cases on strongly sheared currents, are provided in Swan and James (1998). This paper also gives explicit solutions for the Jacobian and the dispersion equation.

3.3 Energy Flux

We have already noted that in the case of nonlinear waves interacting with a strongly sheared current (with non-uniform vorticity) a conservation equation for wave action has not, as yet, been derived. Accordingly, a simpler approach, originally proposed by Longuet-Higgins and Stewart (1960) in their derivation of the radiation stress tensor, is adopted. This ensures that the total energy flux associated with both the wave and the current is conserved. In effect, the total energy flux comprises three distinct contributions. The first arises due to the rate at which work is done by the pressure, $p$. If we consider the combined wave-current flow, this contribution is defined by:

$$R_1 = \iint p u_x \, dz \, dx$$

(5)

where $u_x$ is the total horizontal velocity including both the wave and the current components, i.e. $u_x = u + U$. The second contribution arises from the additional transport of kinetic energy and is given by:

$$R_2 = \iint \left( \frac{1}{2} \rho u^2 \right) u_x \, dz \, dx$$

(6)

where $\rho$ is the density of the fluid and $u = u_x + u_z$. Similarly, the third contribution represents an additional transport of potential energy and is given by:

$$R_3 = \iint \left( \rho g z \right) u_x \, dz \, dx$$

(7)

where $g$ is the gravitational acceleration and $d$ the total water depth. Combining these results gives a total energy flux of $R_x = R_1 + R_2 + R_3$. Assuming that this total flux is constant, one can add the energy flux associated with the current (acting alone) with the energy flux associated with the waves (again acting alone), and equate this to the total energy flux in the combined wave-current environment:

$$R_{f\text{(current)}} + R_{f\text{(waves)}} = R_{f\text{(waves+current)}}$$

(8)

If this equation is combined with the results of either the numerical model (section 3.1) or the analytical solution (section 3.2) the wave height change, $\Delta H$, which arises when the wave and the current first interact, can be determined.

To verify this energy flux formulation we first considered a simple waves only situation (no current) and compared the sum of (5), (6) and (7) with the energy flux
calculated according to $E c_g$, where $E$ is the energy in one wave length and $c_g$ is the group velocity. Figure 4a presents the results of this comparison for regular waves ($T=10s$, $d=50m$) in which $E c_g$ was calculated using a high-order stream function solution. The observed agreement is clearly very good, with minor deviations only arising in the very steepest waves. In a second test, we considered the case of regular waves ($H=7.5m$, $T=10s$, and $d=50m$) propagating on a uniform current. In this case the wave height change predicted using the present formulation, i.e. (8), coupled with a high-order stream function solution was compared to the linear solution proposed by Bretherton and Garrett (1968) and the fifth-order solution proposed by Thomas (1990). The latter solutions being based upon the conservation of wave action. Figure 4b contrasts these results and shows good agreement between the present energy flux approach and the nonlinear conservation of wave action. Indeed, this figure also highlights the importance of the nonlinear terms when seeking to define the change in wave height.

4. Discussion of Results: Random Waves

The solutions outlined in sections 3.1 and 3.2 were formulated to solve the interaction of regular waves with depth-varying currents. Nonetheless, they can be applied in a 'linear' sense to the individual components of a random or irregular sea in an attempt to determine a first approximation to the changes in the wave spectra. If this approach is adopted, the nonlinear interaction between the individual wave components and the co-existing current are correctly modelled, but the nonlinear wave-wave interactions (together with any subsequent interactions that these components have with the current) are neglected. However, it will be shown that for a typical Pierson-Moskowitz (P-M) spectrum interacting with a strongly sheared current, the nonlinear wave-wave interactions are negligible in comparison to the wave-current interactions. As a result, the present approach should provide a good first approximation to any changes in the wave spectrum.

The first P-M spectrum investigated in the laboratory study had an average zero up-crossing period of $T_u=0.94s$ and a significant wave height (measured in the absence of a current) of $H_s=0.062m$. This case therefore corresponds to a relatively linear sea state. The characteristics of this spectrum measured on quiescent water (or in the absence of a current) are indicated by the uppermost curve on figure 5a. This spectrum was generated by the summation of 99 individual wave components with random phasing; it was calculated from two time-histories of the water surface elevation, each recorded at 25Hz for a duration of 600s. Preliminary tests confirmed that this spectrum was highly repeatable, being both stationary and ergodic. In subsequent tests the current profile indicated on figure 2a was generated within the wave flume. Having allowed sufficient time for the profile to become stable, an identical signal to that described above was sent to the wave paddle. The resulting water surface elevations, involving the waves on the current, were again recorded and the corresponding spectra calculated in an identical manner. The results of this process are indicated by the second solid line on figure 5a. The effect of the wave-current interaction, in terms of spectral changes, is clearly apparent.
Figure 4a. Energy flux for waves only case

Figure 4b. Wave height change on a uniform current

Figure 5a-5b. Changes in a linear spectrum
The remaining curves indicated on figure 5a correspond to the predicted wave spectrum assuming that: (a) the current is uniform with depth and has a value equal to the surface current; (b) the current is uniform with depth and has a value such that the total (depth-integrated) mass flux is conserved; and (c) the current varies linearly with depth. These comparisons suggest that while solution (a) correctly models the Doppler shift, it entirely neglects the vorticity and therefore over-predicts the change in the wave spectrum. Alternatively solution (b), which is commonly applied in a design context, fails to model either the Doppler shift or the vorticity profile, and consequently provides the worst prediction of the wave-spectra on the current. In contrast, the solution which uses a linearly-sheared current correctly describes the Doppler shift, and makes some attempt to model the effects of the vorticity. As a result, this latter model provides an improved description of the measured spectra. Nevertheless, even in this case, there remain significant differences between the measured and predicted data.

In contrast figure 5b compares the wave spectra measured on the current with the results of both the numerical model and the analytical solution described in sections 3.1 and 3.2. In each of these solutions iterative calculations were undertaken to determine the individual wave heights which satisfy the total energy flux constraint (8). In applying this approach it is assumed that there is no transfer of energy between components within the spectrum. This point is further discussed below. Furthermore, it is important to note that although the iterative calculations are relatively straightforward, those based on the numerical model can be somewhat time-consuming. Whereas those based on the analytical model are rapid and easy to apply. In essence, this latter solution is no more difficult to apply than a second-order Stokes' model.

The comparisons provided on figure 5b confirm that both these solutions provide a much improved description of the wave spectra measured in the presence of the current. Indeed, this is to be expected since these models (and only these models) allow the affects of both the Doppler shift and the vorticity distribution to be correctly incorporated. Furthermore, comparisons between figures 5a and 5b suggest that the vorticity can be of equal importance to the Doppler shift when attempting to predict the changes in the wave spectra due to the interaction with a sheared current.

Figures 6a and 6b present a similar sequence of results in which the P-M spectrum measured in quiescent water has an average zero up-crossing period of $T_z=0.98s$ and a significant wave height of $H_s=0.090m$. In this case the sea-state is more nonlinear, with some evidence of occasional wave breaking. However, the frequency of the breaking events was such that they had no significant influence on the characteristics of the wave spectrum. In figure 6a the measured and predicted spectra show similar trends to those identified on figure 5a, although the differences are inevitably somewhat larger. This is particularly true of the linearly-sheared current (Jonsson et al., 1978) since this neglects the nonlinear terms in the wave-current interaction. Figure 6a also includes an additional curve, which indicates the magnitude of the second-order nonlinear wave-wave interactions (the scale appropriate to this curve is given on the right hand axis). Comparisons between this curve and the change in the wave spectrum due to the interaction with the current confirm that the wave-current interaction is indeed dominant.
In Figure 6b the results are (unfortunately) somewhat different from those given on figure 5b. In this case, the comparisons suggest that neither of the present methods provide a good description of the spectral changes, although they do represent a significant improvement over the solutions indicated on figure 6a. However, it is interesting to note that the apparent shortcomings are equally applicable to both the numerical calculations and the second-order analytical model. This suggests that the 'errors' do not arise as a result of higher-order nonlinear terms within the wave-current interaction. Indeed, the present results confirm that the weakly nonlinear analytical model is more widely applicable than one might expect.
The most probable explanation for the 'errors' in figure 6b lie in our treatment of the current profile. In previous studies, concerning regular waves on a vertically-sheared current, considerable effort was made to determine the current profile in the presence of the waves. Indeed, good agreement between the measured and predicted oscillatory velocities was only achieved when this profile was applied within either the analytical solution or the numerical model. In the present case this approach has not been adopted. Indeed, the results presented in figures 5 and 6 were calculated using the current profile measured in the absence of waves. The reason for this difference is clear. In a regular wave case the magnitude of the current was calculated along an empirically determined streamline. This approach allows the characteristics of the current, in particular its gradient, to be determined close to the water surface. In random waves it is simply not possible to undertake such an approach.

Nevertheless, if we return to our previous regular wave data, it is clear that the extent of the current change is dependent upon the wave height, or more probably the wave steepness. For example, figure 7 considers four regular wave cases and describes the change in the magnitude of the surface current as a function of the wave steepness. Taking into account this change, it is clear that as the steepness of a random sea-state increases, the present methods will provide less reliable results. Furthermore, it is clear that if the change in a wave spectrum due to the interaction with a current is to be adequately predicted, the change in the current due to the presence of the waves must be defined. Recent work by Groeneweg and Klopman (1998) provide a possible method for investigating this effect. However, if the results of recent regular wave studies are to be believed, it would appear that in random waves the current profile will be continuously changing as it attempts to adjust to the local (or instantaneous) wave conditions. In such circumstances it may be very difficult to separate those parts of the fluid motion that relate individually to the wave and the current.

In an attempt to account for the extent of the current change, $\Delta u$, particularly that arising close to the water surface, the present study has reconsidered the current change arising in several regular wave cases, and has applied a similar change to the present
study. Having identified a 'modified' current profile, the iterative calculations were repeated and a new wave spectrum determined. The results of this procedure are presented on figure 8. This is identical to the case considered in figures 6a and 6b, and contrasts the spectrum measured in the presence of the waves with two predictions based on the analytical formulation. The first assumes the current remains unchanged; while the second is based upon our best estimate of the changed current profile. The improvement in the solution is clearly significant, and highlights the importance of the wave-induced current change. However, it should be noted that although the peak of the spectrum is in good agreement, its overall shape is no longer self-similar. This clearly raises the possibility of significant energy transfers within the spectrum due to subtle changes in the current profile.

![Figure 8. Spectral predictions based on a changed current](image)

5. Concluding Remarks

The present paper has considered the modification of a random wave spectrum due to the interaction with a depth-varying current. New experimental data has been presented, and the results shown to be in reasonable agreement with a new calculation procedure based upon the conservation of total energy flux. Although this solution represents a significant improvement over existing design methods (traditionally based upon a uniform current approximation), difficulties remain concerning the description of a current profile in the presence of waves. Indeed, the present study has clearly demonstrated that in the case of a depth-varying current, the nature of the wave-current interaction involves both a current-induced change in the wave motion, and a wave-induced change in the current. Finally, the present study has also shown that a relatively simple, weakly nonlinear, analytical solution can be surprisingly effective, and provides clear guidance as to the importance of the vorticity distribution.

Wave Setup and Other Tidal Anomalies in Coastal Rivers

Eko Santoso¹, David Hanslow², Peter Nielsen¹ & Kevin Hibbert²

Abstract

The tailwater level is together with rainfall the most important input to flood modeling in coastal rivers. Thus, the need for an ocean-river interface which can provide tailwater levels for numerical models is obvious. The state of the art is however not very advanced. Detailed waterlevel profiles through the Brunswick River entrance from 500m inside the breakwaters to 150m outside during a wide range of weather conditions revealed that the wave setup through the zone of wave breaking is much smaller than what is being used by practicing modelers in Australia. Barometric effects of the order 1cm per hPa is only a minor part of the tidal anomalies, which range up to 0.8m 500m inside the breakwaters, and wind effects, although not modeled in detail, are estimated to be small on the fairly narrow continental shelf of South East Australia. Tidal anomalies of the order 0.5 to 0.7 metres have been observed in the absence of rainfall and strong local winds during Cyclone Roger in 1993. An offshore record indicated that a substantial fraction of this tidal anomaly (of the order 0.25m) also occurred in 25m of water offshore from the Tweed River on the border between New South Wales and Queensland. This indicates the presence of weather related oceanic forcing of a nature which is not understood in detail.

1. Introduction

The state of the art of flood modeling in coastal rivers at present is not very advanced in general. In particular, the tailwater level, which is an important input to the flood model, is not accurately predicted.

¹Department of Civil Engineering, The University of Queensland, St. Lucia, Australia 4072. Fax:+61 7 3365 4599
²New South Wales Department of Land and Water Conservation, Coastal Branch, 10 Valentine Avenue, Parramatta, NSW 2150.
Precise prediction of tailwater levels is important during both normal and emergency situations. People may benefit from the coastal environment and should be protected from natural disasters. Several past records show that extreme water levels cost millions of dollars to the people and the government. The February 1993 low water level event cost the New South Wales Oyster Industry millions of dollars when the oyster cages became exposed to the air. At the same time, flooding along the coastal rivers costs the NSW Government tens of millions of dollars per annum (Hanslow and Nielsen, 1992). The storm surge event on 17 February 1996 caused heavy inundation in Gold Coast canal jetties and roads (Nielsen, Voisey and Santoso, 1997). Hence, Australia needs better flood models in general and better models of river entrance water levels in particular.

Several weather-related forcing mechanisms have been identified, however, there is still lack of precise quantification for better prediction. A quantitative model of Coriolis effects on longshore currents, as one of the most probable driving forces during cyclone events, is developed.

2. Historical Data

The difference between the measured water levels and the astronomically predicted levels are called tidal anomalies. Extreme water levels, which include large anomalies, have been studied for decades, but still the forcing mechanisms are not quite clear.

2.1. The inverse barometer effect

Extreme water levels usually show significant, negative correlation with the local barometric pressure. Investigations at several tidal stations on the East Coast of Australia found the sea level depressed about half the theoretical amount of 1 cm per hectopascal. Conversely, greater than theoretical values were typical for some locations on the West Coast. On Lord Howe Island the inverse barometer law gives accurate predictions. This is an indication that the continental shelf is influential (Hamon, 1962, 1963, 1966, Robinson 1964). In the Bay of plenty, New Zealand, the inverse barometer law applies accurately over a limited range of periods (Goring and Bell, 1993). Investigation of the Manly Hydraulics Laboratory database shows that the low barometric pressures alone is not appropriate to predict the tidal anomalies. For instance, theoretical barometric set-up during Cyclone Justin (March 1997) accounts for only 25% of the observed tidal anomaly (see Figure 1).

2.2. Wave set-up

Wave set-up, which has been long believed to be an important contributor to extreme water levels, has negligible influence to the overheight water level in most river entrances. Thus, historical data from the Brunswick River (1987 to 1996) show that offshore wave heights are not correlated with the tidal anomalies. In fact, some very high waves coincided with negative tidal anomalies (see Figure 2).
Figure 1. Tidal anomaly and barometric set-up at Rosslyn Bay during Cyclone Justin, March 1997. The theoretical barometric set-up (1 cm/hPa) contributes a minor fraction to the observed tidal anomaly. Data courtesy of National Tidal Facility, Adelaide.

Figure 2. Tidal anomaly versus offshore root mean square wave heights at Brunswick Heads. Even for the very shallow (just navigable by fishing vessels) Brunswick River there is very little correlation between offshore wave height and tidal anomaly just inside the wave breaking in the river. Data courtesy of the MHL, Sydney.
The New South Wales Government has sponsored field investigations at the Brunswick River entrance (Brunswick Heads) over the last decade, headed by Dr. Peter Nielsen. The primary achievement of this work has been detailed water level profiles through the river entrance from 300m inside the breakwaters to 150m outside during a wide range of weather conditions. It was found that different water levels between inner and outer river entrance were caused by hydraulic gradient in the entrance during flood and ebb tides (see page 250, Hanslow and Nielsen, 1992).

2.3. Rainfall

Previous investigations found that rainfall contributes significantly to the tidal anomaly for gauges in rivers with small cross section of river entrance compared with the large river catchment area.

Data from the Brunswick River show the correlation between rainfall intensity in the river catchment and tidal anomalies in the river entrance (Figure 3). The plots show vertical clusters, which consist of 6 one-hourly tidal anomalies versus cumulative rainfall for the six hours period. The lower part of each cluster indicates the fresh water flow has not reached the tide gauge yet. The appropriate cumulative time applied in the plot is site specific, dependent on the characteristics of river catchment.

![Figure 3. Hourly tidal anomalies versus 6 hourly cumulative rainfall at the Brunswick River. Data courtesy of the MHL, Sydney.](image-url)
Tide gauges installed in rivers with small entrance to the large catchment ratios such as the Brunswick and the Tweed Rivers are quite sensitive to rainfall. Hence, rainfall over these two catchment areas in the period of 15 to 17 February 1995 contributes significantly to the high tidal anomalies (see Figure 4).

![Tidal Anomaly Chart](image)

Figure 4. Tidal anomalies generated by heavy rainfall on 16 February 1995 event. Tidal anomalies at the Brunswick and Tweed Rivers are high compared with that of Tweed Offshore, which was not influenced by fresh water flow. Data courtesy of the MHL, Sydney.

2.4. Negative anomalies

Negative anomalies, which cannot be generated by rainfall or wave setup are of interest for evaluating the variation of other driving mechanisms along the coast. Thus, the negative tidal anomalies at the Gold Coast Seaway and at Ballina (at the Richmond River entrance), which are only 80 km apart show quite different trends for the more significant events (see Figure 5). These data imply that along the coast of NSW and Queensland the strength of the oceanic driving mechanisms vary significantly.

3. Long Periodic Waves

Travelling cyclones are some times able to generate long periodic waves. Low barometric pressure at the center of cyclone causes the sea water level to rise in a mound shape. As the cyclone moves into the shallow water, the combination of high wind stresses on the surface and friction on the ocean bed generate long wave (Stark, 1977; Lighthill, 1998).
The motion of long waves parallel to a coastline can generate a number of edge wave modes, and only the fundamental mode is stimulated by the large-scale pressure disturbances (Greenspan, 1956). However, Reid (1958) stated that if wind stress is considered, cyclones could generate higher order of edge waves.

The amplitude of the long waves is dependent on the local topography. Shoaling, diffraction and reflection are of primary importance for the extreme water levels along the coast.

The presence of long periodic waves was observed at tidal stations along the East Coast of Australia (Figure 6). The event ten days before Cyclone Violet showed the movement of a long wave. The phase shift of the tidal anomaly peaks of Ballina, Brunswick River and Tweed Offshore around 21 February 1995 were less than a day. This is because the distance between Ballina to Brunswick and Brunswick to Tweed Head are about 30 km and 65 km respectively. The tidal anomaly peaks at Rosslyn Bay and Cape Ferguson, where separated about 700 km and 1250 km from Brunswick, occurred 3 and 4 days later. Another travelling long wave can be seen in Figure 7, during Cyclone Justin.
4. Cyclone Justin

As discussed above, travelling cyclones can generate continental shelf waves. Stationary cyclones however, do not have this ability. They generate different types of tidal anomalies. Our best example is Cyclone Justin (March 1997), which was stationary in the Coral Sea, in the North East of Townsville, for about two weeks. Tidal anomalies in the order of 0.5 to 0.8 m were generated along the North Coast of Queensland, but no significant were found south of Mooloolaba (see Figure 7).
Figure 7: Tidal anomalies generated by Cyclone Justin. The peaks of tidal anomaly move northward from Rosslyn Bay to Cooktown as shown by the dotted line. Data courtesy of MHL, NTF and Queensland Transport.

4.1. Wind set-up

The cyclonic wind component perpendicular to the shoreline may generate set-up in the shallow waters, particularly where the shelf is wide and shallow. The strength and duration of the winds, and the width of continental shelf are important components generating the wind set-up. However, the estimated wind set-up at Rosslyn Bay, about 700 km southward the center of cyclone, was very small even though it is located on the widest continental shelf in East Australia.
Onshore wind speeds at Rosslyn Bay during the cyclone were quite weak. Taking into account the depth of shelf edge $h_o=200\, m$, the width of the continental shelf is $W_{shelf}$, with the constant shelf gradient $dh/dx=200/W_{shelf}$, wind set-up generated by wind blowing perpendicular to the coast can be estimated as follows (see Nielsen and Hanslow, 1995).

$$\bar{\eta}(h)=\frac{\rho_{air}}{\rho_{sw}gh_o}C_f U_{10}^2 W_{shelf} \ln \left( \frac{h_o}{h} \right)$$

(1)

where $\rho_{air}$ and $\rho_{sw}$ are the density of air and sea water respectively, $U_{10}$ is wind speed at $10\, m$ above sea level, $C_f$ is the sea-air friction coefficient, $h$ is the water depth. By taking $\rho_{air} = 1.3\, kg/m^3$, $\rho_{sw} = 1025\, kg/m^3$, $W_{shelf} = 260\, km$, $U_{10} =2.5\, m/s$ (see Figure 8), $C_f =0.002$ (Toba et al, 1990), wind set-up at Rosslyn Bay; where the tide gauge is located at $1.8\, m$ water depth, is estimated to be at most $0.01\, m$.

4.2. Coriolis Effects on Longshore Currents

Cyclone Justin was stationary in the Coral Sea for more than 2 weeks (see Figure 9). Therefore, it is reasonable that clockwise cyclical currents may be generated during the event. Due to the Earth’s rotation, north going longshore current will be pushed against the land and that causes a coastal sea level to rise.
The Coriolis effect on longshore current component can quantitatively be modeled as follows (see Figure 10). The Coriolis acceleration is:

$$f = 2\Omega \sin \phi$$

where, $\Omega$ is the angular speed of earth's rotation on its axis, $\phi$ is the latitude of point on earth. The Coriolis acceleration on longshore current $U$ is then $Uf$. Combine acceleration of gravity and Coriolis forms tilting water level with gradient of:

$$i = \frac{Uf}{g}$$

Taking Cape Fergusson as an example, which is situated at latitude $19^\circ S$ and average longshore current at Myrmidon Reef ($18^\circ 16' S, 147^\circ 22' E$) of 0.6 m/s. The Coriolis acceleration is $f = 2 \times 7.2 \times 10^{-5} \times \sin 19^\circ = 4.7 \times 10^{-5} \text{ s}^{-1}$. The gradient of tilting water level will be $i = Uf/g = 0.6 \times 4.7 \times 10^{-5}/9.8 = 2.9 \times 10^{-6}$.

This magnitude indicates that water level to rise $2.9 \times 10^{-3} \text{ m}$ per kilometer. Assuming uniform flow across the continental shelf near Cape Fergusson, which is approximately $100 \text{ km}$ wide, the extra water level height near the shoreline would be $100 \times 2.9 \times 10^{-3} = 0.29 \text{ m}$.
5. Conclusion

Detailed water level profiles through the Brunswick River entrance show that offshore wave height has no correlation to the tidal anomaly. Barometric effects of the order 1cm per hPa and wind set-up are minor parts of the tidal anomalies.

The exceedance plot of negative tidal anomalies is of interest for evaluating the variation of other forcing mechanisms than wind waves and rainfall.

Effects of the Coriolis force on longshore currents are another driving mechanism of tidal anomalies along the East Coast of Australia. During Cyclone Justin, tidal anomalies of the order 0.4 to 0.8 meters were generated along the northern Queensland coast. Up to 50% of these can be accounted for by the Coriolis effect on wind driven longshore currents.
6. References

Abstract

Measurements of mean velocity profiles in a wave-current flume have shown some features for which the mechanism is far from trivial. A 2DV model based on the so-called Generalized Lagrangian Mean formulation is developed to study the influence of waves on the mean motion, the mean horizontal velocity in particular. This influence can be split in two parts, viz. a direct effect of the waves via wave-induced driving forces and an indirect effect of waves via secondary circulations. To include both effects an existing 1DV model is extended by introducing lateral variations including side-wall boundary layers. Resulting formulations have been implemented in an existing 2DV non-hydrostatic numerical flow model. Computations for regular waves following and opposing a turbulent current have been carried out and compared with both experimental results and results from an existing numerical model.

Introduction

Understanding the mechanism of wave-current interaction is of great importance for a good prediction of vertical profiles of horizontal velocities. The study of these profiles is relevant from both a hydrodynamic point of view (bed friction), and a morphodynamic point of view. Observations in laboratory experiments by e.g. Kemp & Simons (1982; 1983) and Klopman (1994) of the effect non-breaking waves on a steady turbulent current over a rigid rough bed show significant and unexpected changes in the profiles of the mean horizontal velocity (see figure 1).

To the authors' knowledge only Nielsen & You (1996) and Dingemans et al. (1996) presented theoretical models to explain the wave-induced changes in the Eulerian-mean horizontal velocity profiles. The model of Nielsen & You (1996) is based on a local force balance. In a steady two-dimensional flow the
vertical variation of the total shearing force per unit area of a cross-section was balanced by the horizontal variation of the total normal stress. Assuming linear wave theory, expressions were derived for the mean wave contribution $(\langle \tilde{u} \tilde{w} \rangle)$ and for the local radiation stress. Although their model gives a qualitative explanation of the physical mechanisms involved, quantitative agreement with Klopman's results was obtained only after a significant ad hoc enhancement of $(\tilde{u} \tilde{w})$ by a linearly depth-dependent empirical factor. The empirical adjustment is based on the fact that the interaction with a current induces extra vorticity of the wave motion.

Dingemans et al. (1996) developed a 2DV model, the results of which were compared with the wave flume experiments of Klopman (1994). A detailed description of this model is given in the report of Van Kester et al. (1996). The effect of waves has been incorporated by adding the so-called Craik-Leibovich (CL) vortex force, consisting of $\tilde{u}^S \times \tilde{\omega}$ with $\tilde{u}^S$ the Stokes drift and $\tilde{\omega} = \nabla \times \tilde{u}$ the mean vorticity. Among others Leibovich (1983) showed that under certain assumptions the vortex force is the main term in the ensemble-averaged momentum equations in a so-called GLM formulation. Dingemans et al. (1996) observed in their simulations that secondary lateral circulations induced by the CL vortex force caused changes in the vertical structure of the mean horizontal flow. However, due to poor estimates of the Stokes drift and the CL vortex force in the boundary layers, quantitative agreement with Klopman's experimental results was not obtained for situations of waves following or opposing
a current.

Groeneweg & Klopman (1998) developed a 1DV model, based on the Generalized Lagrangian Mean (GLM) formulation. This approach, in which the Lagrangian motion is described in a fixed Eulerian framework, has been introduced by Andrews & McIntyre (1978) in order to obtain a clear separation of the mean and fluctuating motion. In the model lateral variations have been neglected. Comparison with Klopman’s results shows both qualitative and quantitative agreement.

An intriguing point is that two models of Nielsen & You (1996) and Groeneweg & Klopman (1998) confirm the theory that changes of the mean horizontal velocity profile are purely caused by phenomena in longitudinal direction, whereas Dingemans et al. (1996) suppose the secondary lateral circulations to be the reason for changes in the mean horizontal velocity profile in streamwise direction. Their prediction of the existence of lateral circulations is supported by laboratory measurements of Klopman (1997).

The purpose of this work is to develop a 2DV model, which describes the mean flow under the influence of the wave motion, in a Generalized Lagrangian Mean (GLM) formulation in order to provide more insight in the effect of the secondary circulations on the mean horizontal velocity profile. The work is presently in a preliminary state and the results of the developed 2DV model are not yet completely satisfactory. Therefore, the presentation of the model will not be given in detail and frequent reference is made to Groeneweg & Klopman (1998) (to be denoted as GK hereafter). General formulations of the flow equations in a GLM setting as well as a 1DV application of a combined wave-current problem have been given in detail in that paper.

GLM approach

As already mentioned in the introduction a hybrid Eulerian-Lagrangian approach, the so-called GLM approach, will be adopted to simulate the combined motion of waves and currents in a flume. For the definition of the GLM theory we refer to Andrews & McIntyre (1978), or for an introductory outline to McIntyre (1980) and Dingemans (1997, note 2.10.6). The notation in this paper is exactly the same as applied by GK. Here, only the essential idea of the GLM theory is outlined. A Cartesian coordinate system \((x, y, z)\) is used, where \(z\) is the vertical direction, \(x\) and \(y\) the horizontal coordinates in longitudinal and lateral direction respectively. Central in the GLM description is the mapping \(x \rightarrow x + \xi(x, t)\), where \(\xi(x, t)\) is a field denoting the displacement about the position \(x\). By introducing \(\varphi^\xi(x, t) = \varphi(x + \xi(x, t), t)\) for an arbitrary particle-related function \(\varphi\), Andrews & McIntyre (1978) define a Lagrangian
mean operator \( \overline{()} \) by

\[
\overline{\varphi(x,t)} = \frac{1}{T} \int_{t-T/2}^{t+T/2} \varphi(x,t) \, dt,
\]

where in our case \( \langle () \rangle \) will be a time-average operator. This implies that the average assigned to the fixed point \( x \) is taken over disturbed positions \( x + \xi(x,t) \). In order that \( \xi \) is a true disturbance, it is required that \( \xi(x,t) = 0 \).

The fluctuation \( \varphi^f \) is defined in a natural way as \( \varphi^f = \varphi^L - \varphi^E \), and thus \( \varphi^L = 0 \).

Finally, the difference between the GLM velocity and Eulerian mean velocity is given by the so-called Stokes drift, \( \mathbf{u}^S = \mathbf{u}^L - \mathbf{u} \). A Stokes correction \( \varphi^S \) can be expressed in terms of fluctuating quantities.

In GK the three-dimensional GLM flow equations have been derived in a general way. Therefore, the lateral 2DV model, providing a local solution in a cross-sectional plane, can be obtained just by neglecting variations in longitudinal direction of GLM quantities, except for the hydrostatic part of the GLM pressure which is related to the GLM surface elevation \( \zeta^L \). The total pressure \( p^L \) is decomposed in a hydrostatic and non-hydrostatic part, \( p^L = \rho g \left( \zeta^L - z \right) + q^L \). The horizontal gradient of the hydrostatic pressure, \( \partial \zeta^L / \partial x \), is assumed constant over the entire cross-section and chosen such that the discharge of the combined flow equals the discharge \( Q \) of the flow without waves. A cross-section at a distance \( x \) from the wave maker is defined as \( \Omega(x) = \{ (y,z) : -L \leq y \leq L, -h \leq z \leq \zeta^L(x,y,t) \} \). Here we restrict ourselves to vertical side walls and a horizontal bottom profile.

The flow equations in GLM coordinates are of the same form as those in Eulerian formulation. Only the wave-induced driving forces in the momentum equations are different, and a wave-related correction in the continuity equation causes the mean velocity to be no longer divergence free.

The wave-induced driving forces are expressed in terms of fluctuating quantities in GK. The 1DV model presented in that paper provides the vertical profiles of the fluctuating quantities as well. In order to take side wall effects into account we adopt a procedure that was also used by Mei et al. (1972), who analyzed mass transport caused by progressive waves for a situation of constant viscosity and no initial current. A cross-section \( \Omega(x) \) of the flume is subdivided into five regions, viz. the inviscid core region and the boundary layers at the bottom, the free surface and the two side walls. This is sketched in figure 2.

Analogous to the analysis of Mei et al. (1972) viscous effects are neglected outside the side wall boundary layers. Consequently, the lateral variations of the amplitude functions of the fluctuating quantities can be neglected. The flow equations for the fluctuating motion are then reduced to those derived for the 1DV problem in GK. The solution of the latter problem will be denoted by \( \varphi = \varphi_1 \). Following e.g. Mei et al. (1972) one can easily show that the first order first harmonic velocity including the no-slip condition at the side walls.
satisfies Stokes’ shear wave solution given by
\begin{align}
\tilde{u} &= [1 - \exp(\beta Y)] \tilde{u}_1, \\
\tilde{v} &= \tilde{v}_1 = 0, \\
\tilde{w} &= [1 - \exp(\beta Y)] \tilde{w}_1.
\end{align}

with the factor \( \beta = (-i \omega_0/\nu)^{1/2} \) and \( Y \) the distance to the nearest side wall. The influence of the mean current and variations of the eddy viscosity \( \nu \) have been neglected in the side-wall boundary layers. To sum up: the 1DV model is used to determine the vertical distribution of the fluctuating quantities. The 2DV profiles are obtained by multiplying the 1DV profile (subscript 1) by a \( y \)-dependent factor, which only affects the fluctuating motion in the side-wall boundary layers.

The distribution of the wave-induced driving forces in the entire cross-section can now easily be found by substituting the laterally varying oscillating quantities in the general expressions for the driving forces.

**Implementation of GLM equations in existing numerical model**

Although the flow equations are given in a GLM formulation, their form is similar to their Eulerian counterpart. For this reason an Eulerian flow solver can be used to integrate the GLM flow equations. We have chosen for the 2DV non-hydrostatic flow solver developed by Van Kester et al. (1996). For the numerics in this model one is referred to *loc. cit.* After the wave-induced driving forces \( \mathbf{S}^L \) and the GLM-correction term in the continuity equation have been evaluated, implementation of these terms is straightforward.
The implementation of the boundary conditions at the bottom and side-walls needs special care. In Van Kester et al. (1996) partial-slip conditions are imposed at those boundaries, using a logarithmic law-of-the-wall formulation. This type of boundary condition differs from the no-slip condition used in the 1DV model. Therefore, correct expressions had to be determined for these boundary conditions in a GLM setting. For the time being the simplest possible approach has been adopted. The formulation applied by Van Kester et al. (1996) is based on a formulation of Grant & Madsen (1979) and takes the presence of the wave motion into account. Given a shear velocity at a certain distance from the wall, the friction velocity and related shear stress are determined. This formulation is given in an Eulerian framework. In order to obtain the GLM shear stress at a closed boundary, the following algorithm has been applied:

1. The GLM velocity at a certain height or distance from the side wall is transformed to its Eulerian equivalent at the same height.

2. The formulation of Grant & Madsen (1979) which has been applied by Van Kester et al. (1996), is used to determine the Eulerian shear stress at the boundary.

3. The Eulerian shear stresses are transformed to GLM shear stresses by adding the Stokes correction of the shear stress under consideration.

Finally, for simulating turbulent flow a turbulence model has to be implemented. In a first approach a classical turbulence model has been used. Any of the turbulence models implemented by Van Kester et al. (1996) can be used. For this study a $k – \varepsilon$ model was chosen. In order to take the wave influence into account, boundary conditions for the turbulent kinetic energy and dissipation are related to the shear velocity near the boundary. As mentioned above the shear velocities are determined using a logarithmic law of the wall. For closure of the turbulence model the production term is computed with Eulerian velocities, which are determined by transforming the GLM velocities.

Model results

Mean velocities have been computed for situations of following and opposing waves. In order to compare the model results with experimental data, the initial conditions of one of Klopman's (1994; 1997) measurements have been applied. In the present model a turbulent current with a constant discharge of $Q = 0.08 \text{ m}^3\text{s}^{-1}$ was generated in a 1.0 m wide flume ($L = 0.50 \text{ m}$) with a still-water depth $h = 0.50 \text{ m}$. A monochromatic wave field following or opposing the current with a wave period $T = 1.44 \text{ s}$ (relative to the flume) and wave
amplitude $a = 0.060 \, \text{m}$ is superposed on the current. All presented results refer to the situation at $t = 1600 \, \text{s}$ and have been obtained on an equidistant grid with horizontal and vertical resolution $\Delta x = 0.01 \, \text{m}$, resp. $\Delta y = 0.0125 \, \text{m}$ and a time step $\Delta t = 0.02 \, \text{s}$.

In the present 2DV model the wave-induced driving forces depend via the orbital quantities on the factor $\beta = (-i \omega / \nu)^{1/2}$. In our analysis the quantity $\nu$ was assumed independent of the lateral direction. We have taken $\nu = 10^{-4} \, \text{m}^2 \, \text{s}^{-1}$ in all experiments, representing a turbulent oscillatory motion. This choice for $\nu$ leads to a factor $\beta$ for which $\text{Re}(\beta) = -(\omega / 2 \nu)^{1/2} \approx -148 \, \text{m}^{-1}$.

Since velocity measurements have been carried out at fixed locations and are thus Eulerian, the GLM velocities $\mathbf{u}^L$ have to be transformed to Eulerian velocities. In this section these are denoted as $U$. As already mentioned $U = \mathbf{u}^L - \mathbf{u}^S$.

In figure 3 and 4 the results for the mean velocity distribution in a cross-section at $x = 22.5 \, \text{m}$ from the wave maker and the mean horizontal velocity profile in streamwise direction in the center of the flume are shown for the situation of waves propagating in the current direction. The agreement with measurements of Klopman (1997) is only qualitative. The direction of the computed secondary circulation is correct, but the velocity magnitude is a factor 2, and at the side walls even a factor 3 larger than measured. Near the side wall the maximum velocity magnitude is $2.0 \, \text{cm} \, \text{s}^{-1}$ and in the center $1.6 \, \text{cm} \, \text{s}^{-1}$. The computed secondary circulations are comparable to those obtained by Dingemans et al. (1996). The mean horizontal velocity in the center of the flume is fairly well predicted by the 2DV model. Compared with the measurements of Klopman (1994) and the 1DV results of GK there is a slight overprediction in the lower region of the flume and an underprediction in the higher region.

In figure 5 and 6 the results have been plotted for the situation that waves are propagating in the opposite direction. Once again, the maximum velocity magnitude near the side wall is $2.5 \, \text{cm} \, \text{s}^{-1}$ and in the center of the flume $1.8 \, \text{cm} \, \text{s}^{-1}$, which is even an overprediction of Klopman's (1997) experimental data with a factor 4 to 5. The prediction of the mean horizontal velocity profile in streamwise direction is even worse. Whereas for the situation of waves following the current at least the trend was predicted correctly, this is not true in the opposite case. In the upper 40% of the flume the velocity gradient seems to vanish whereas the experiments of Klopman (1994) and the 1DV computations of GK show an increasing velocity gradient.

The side walls should have less effect on the mean velocity profile in the center of the flume when a wider flume is considered. The secondary lateral circulations should then decrease in magnitude. Moreover, the 2DV solution should converge to the 1DV solution as $L \rightarrow \infty$. However, we remark that
Figure 3: Mean velocity distribution in cross-section for waves following the current. Note difference between horizontal and vertical scale.

Figure 4: Mean streamwise horizontal velocity profile in center of the flume for waves following the current.
Figure 5: Mean velocity distribution in cross-section for waves opposing the current.

Figure 6: Mean streamwise horizontal velocity profile in center of the flume for waves opposing the current.
some principal differences in the formulation of both models, such as the turbulence model and boundary layer treatment, will induce some differences in the results.

To study the effect mentioned above, the same situation with a following current is considered as before, but now in a 5 m wide flume. The discharge is increased proportionally, $Q = 0.40 \text{ m}^3\text{s}^{-1}$. In figure 7 the velocity distribution is shown only in the region 50 cm from the left side wall. The velocity magnitude is obviously smaller, at most 0.8 mm s$^{-1}$. A circulation cell can still be observed. Our main interest concerns the mean horizontal velocity profile in the center of the flume as given in figure 8. Comparing this with the distribution obtained in a 1 m wide flume only shows a slight difference.

![Figure 7: Mean velocity distribution in a part of the cross-section for waves following the current in a 5 m wide flume.](image_url)

**Discussion**

Two important philosophies explaining the wave-induced changes in the mean horizontal velocity profiles are known so far. One is based on a 1DV local force balance neglecting lateral variations, and in the other secondary circulations in the cross-section are essential. In order to find out which phenomenon is dominant a 2DV numerical flow model based on the GLM formulation has
been developed. It is still in a preliminary state and the numerical results obtained so far are not always satisfactory.

Numerical experiments with the 2DV model for a 1 m and a 5 m wide flume give almost similar predictions of the mean horizontal velocity in streamwise direction in the center of the flume and a significant difference for the order of magnitude of the circulations. One might therefore conclude that phenomena in streamwise direction are dominant over those in lateral direction. However, the 2DV model overpredicts the velocity components in vertical and lateral direction measured by Klopman (1997). Two possible reasons are given here. Firstly, the computations have been carried out on a regular grid with a grid size of 1 cm, which was too coarse to represent the side-wall boundary layers well. These are only a few millimeters thick (order $\beta^{-1}$). An irregular grid which is finer towards the boundaries has already been implemented. Results of these numerical experiments will be reported in the future.

Secondly, in the formulation of wave effects in the partial slip conditions and the $k-\varepsilon$ turbulence model, the simplest approaches have been applied. GLM quantities are computed by Eulerian based models. Transformations from GLM to Eulerian and vice versa have been carried out only at the beginning and at the end of those processes. Improvement of this approach might lead to better results for the circulations.

Furthermore, extra attention has to be paid to the mean horizontal velocity profile for the situation of opposing waves. Towards the free surface a completely deviant behavior was observed compared to the measurements and
predictions with the 1DV model. The cause of this is unknown for now and will be considered carefully in the near future.

Vorticity and surf zone currents

D. H. Peregrine\(^1\) and O. Bokhove\(^2\)

Abstract

Water wave breaking is of considerable importance in the transfer of momentum from the waves to currents. Near shore lines most of the water motions are dominated by breaking waves. Recent work on the generation of vorticity by breaking waves and bores in the surf zone on beaches within the shallow water approximation has shown that non-uniformity in the strength of bores is an important source of potential vorticity. This is illustrated by discussing the generation of longshore currents and illustrated with a numerical example of vorticity generation due to a non-uniform bed. These demonstrate that the horizontal excursion of vorticity transported by the incident waves may be a significant factor in interpreting velocity measurements at a fixed site.

Introduction

The role of horizontal eddies in surf zone currents, and the generation of their vorticity are discussed in Peregrine (1995, 1998). The latter paper gives a quantitative measure of vorticity generation by bores, which is briefly recounted below. The aim of this paper is to look at some of the implications of this vorticity generation.

Note: the vorticity that is being discussed here is not the vorticity caused directly by the breaking of the wave and the subsequent organised and turbulent motions on the scale of

745
the wave crest. Rather, we are concerned with vorticity on a larger scale, at the scale of
the crest length or wave length of the wave, such as is important in describing mean
currents generated by breakers.

The usual way to model the transfer of momentum from waves to currents is to average
over the wave motion, assuming the waves to be sufficiently regular for this to be
appropriate. The resulting equations have a momentum transfer term, that is known as
radiation stress following its development by Longuet-Higgins & Stewart (1964). These
averaged equations include mean currents and mean pressures: a standard way of
studying fluid motion. However, an alternative way of analysing any flow is to consider
its vorticity. Peregrine (1995) points out that surf zone flows on beaches of gentle slope
are almost two-dimensional flows in the horizontal, and that little attention had been
given to the properties of such flows such as are used in the geophysical fluid dynamics
for atmospheres and oceans. This has been followed up by numerical modellers
including vorticity plots in their results which have clearly shown discrete eddies even
when radiation stress is used to drive the currents (Allen, Newberger & Holman, 1996;

After summarising the main result on vorticity generation from Peregrine (1998) and
noting the importance of potential vorticity in these flows, we present a comparison
between the usual radiation stress description of the generation of longshore currents and
the view that is obtained by considering potential vorticity generation. Then data from a
numerical computation of a normally incident wave meeting a non-uniform bar is shown
to generate eddies. The accuracy of this inviscid computation is verified by the
maintenance of their potential vorticity as they are convected by the wave motion.

**Vorticity generation by bores in shallow water**

The simplest dynamic model for waves breaking on a beach of gentle slope is for
shallow water. The equations for finite amplitude shallow water waves, e.g. see Stoker
(1957), permit waves to steepen until the necessary approximation of gentle surface
slopes is no longer valid. In practice, if the variation of surface elevation is large enough
compared with the depth, waves break shortly after they steepen significantly. Thus, if
details of the breaking and the associated turbulent motions are on shorter length and
time scales than are of immediate interest, the breaking event can be modelled as the
development of a surface and current discontinuity in the shallow water equations. Such
discontinuities are bores and are dynamically consistent if mass and momentum are
conserved.

For the development of wave generated currents it is these longer scales that are most
relevant. Modelling of waves on a beach with the shallow water equations plus bores has
developed from early numerical models (Keller, Levine & Whitham, 1960; Hibberd &
Peregrine; 1979) to more effective examples (e.g. Kobayashi & Wurjanto, 1992; Watson,
Peregrine & Toro, 1992). These examples are of one-dimensional models, and only now
are models with two horizontal dimensions which include bores being used in this area. However, comparisons with one-dimensional experiments described in Barnes, Peregrine & Watson (1994) show that although fine details of wave breaking are poorly modelled the overall generation of currents is well described.

Kelvin’s circulation theorem can be derived for the shallow water equations, as can the conservation of potential vorticity following material particles. Potential vorticity is defined by \( \frac{\text{vorticity}}{\text{total waterdepth}} \). Note that conservation of potential vorticity implies a change in vorticity for any water that changes its depth. This is a dynamically important feature and generates or absorbs vorticity, but the major point for discussion here is the generation of potential vorticity.

Derivation of Kelvin’s circulation theorem and of the material conservation of potential vorticity from the shallow water equations requires that the flows be represented by continuous and differentiable functions. The development of bores introduces a complicating feature: the discontinuity of velocity and depth that represents a bore gives a rate of change of circulation in any material circuit that cuts through the bore unless it has another section through the bore in the opposite direction at a point where the bore has the same properties. It is clear that velocity, and hence circulation along a material line, is changing most rapidly at bores. By considering the effect of a bore on a material circuit over a small time interval Peregrine (1998) derives the rate of change of circulation due to one intersection with the bore. It turns out to have a magnitude equal to the rate of energy dissipation in the bore at that point, divided by the water density. This neat result has the nice feature that to a large extent the rate of dissipation is related to the visible strength of a bore in terms of the intensity of splashing and air entrainment.

However, we need to discuss the large-scale generation of potential vorticity. Peregrine (1998) derives a formula for the generation of vorticity by considering the change in vertical vorticity, \( \Omega \), that occurs in an infinitesimal material circuit as it passes through a bore. The result, at a bore that has an increase in water depth from \( h_1 \) to \( h_2 \), is \( \Delta \Omega_A + \Delta \Omega_D \). Here \( \Delta \Omega_A \) is the change in vorticity due to the vertical stretching of fluid elements:

\[
\Delta \Omega_A = \left( \frac{h_2}{h_1} - 1 \right) \Omega,
\]

where \( \Omega \) is the original vorticity of the fluid element. This part represents no change in the pre-existing potential vorticity. On the other hand, the motion of the bore over running water in front of it gives the change of vorticity

\[
\Delta \Omega_D = \left[ \frac{2h_2}{gh_2(h_1 + h_2)} \right] \frac{1}{2} \frac{dE_D}{dy}, \quad \text{where} \quad E_D = \frac{g(h_2 - h_1)^3}{4h_1h_2}
\]

is the dissipation rate at the bore divided by fluid density. This does represent generation of potential vorticity:
Pratt (1983) also derived this result from manipulation of the shallow water equations and bore relations.

As may be seen, a bore with uniform properties, such that $E_D$ is constant, conserves potential vorticity. On the other hand if the bore varies due to non-uniformities in $E_D$, then new potential vorticity is generated. Non-uniformities in $E_D$ come from variations in the water depths $h_1$ and $h_2$, either because of non-uniformities in the bed, or because of variations along the wave crest. The effect of bed non-uniformities is discussed here. Peregrine (1999) discusses the effect of crest variations for finite length breaking wave crests.

**Longshore currents**

Figure 1 is a sketch of regular waves incident at an angle on a gently sloping beach which is uniform in the longshore direction; the slightly irregular lines indicate the bores and runup. The $x$-direction is on shore, and the $y$-direction along shore. The standard approach to considering the generation of longshore currents, from Longuet-Higgins (1970), is to average over the waves and consider the momentum flux or radiation stress. A short straight line is drawn to illustrate this. Through such a shore-parallel surface the flux of $x$ momentum carried shorewards by the waves, $S_{xx}$, is reducing towards the shore as the bores dissipate wave energy. The resulting gradient of momentum flux is balanced, in the simplest case by a corresponding gradient of the mean surface giving a set up towards the shoreline.

On the other hand, the flux of $y$ momentum carried shorewards by the waves, $S_{yx}$, is also reducing, but with no pressure gradient to balance it. Since the momentum must be conserved it thus contributes to a longshore current. In fact a balance is reached, either by direct bed friction, or, more likely, by the horizontal eddy viscosity which is enhanced by the long life of almost two-dimensional eddies which are generated by instabilities in the flow, bed irregularities, and/or irregularities in the incident waves.

The vorticity view of the longshore current generation depends on vorticity generation. Again this results from the shoreward diminution of the waves, but now we focus on the bores. Each bore starts abruptly as a wave breaks so that it is at its strongest when created and decays to zero where it meets the shoreline. Thus $E_D$ is continually diminishing shorewards and its gradient leads to vorticity generation as described above. This vorticity is the gradient of the longshore current profile.

The most interesting aspect of this viewpoint comes when we look at the offshore end of the bore where it is created by the initial breaking of a wave crest. Here the bore
Figure 1. The irregular heavy lines sketch the positions of bores due to regular obliquely incident waves approaching a shoreline on the right. The flux of both x- and y-momentum past a shore-parallel line is indicated by arrows. The dashed line is an estimate of the edge of the region of vorticity as it is displaced by the wave motion. The lower profile is a sketch of a longshore current profile in the absence of horizontal mixing.
dissipation has its greatest value and also its greatest gradient, that is from zero offshore from breaking up to its maximum at breaking. This results in generation of vorticity of the opposite sense to that of the rest of the surf zone, as is needed for the longshore current to diminish to zero offshore. This draws attention to the localised generation of vorticity, and hence to a feature that appears to have been overlooked in discussions about the offshore profile of longshore currents. As may be seen in the computational example described in the next section, any vorticity that is generated is convected with the water motions. In particular the horizontal displacements of the incident wave motion are not generally negligible.

As an example consider linear long wave theory on water of constant depth \( h \). For a sinusoidal wave of height \( H \), the total horizontal displacement of the water is \( HL/2\pi h \), where \( L \) is the wavelength. Note \( L/h \) is large for long waves, and \( H \) is not small when a wave breaks. The trajectory of the vorticity due to this displacement is sketched with a dashed line in figure 1. Thus any velocity sensor at a fixed position near the breaking point is affected by the vorticity for only part of the wave period. This means that even for perfectly regular waves with no horizontal eddy viscosity, the measured velocity profile could not show the very steep reduction to zero current offshore that the wave averaged approach predicts. This feature of the problem has yet to be studied quantitatively, but a sketch of the velocity profile that would be measured is included in figure 1.

**Eddies generated by a non-uniform bar**

Vorticity can be generated at a bore because the dissipation, \( E_D \), varies due to variation in the level of the bed. As an illustration we present results from computation of a uniform wave incident normally on a plane beach with a bar. Bed non-uniformity is introduced by having a dip in the elevation of the bar. The contours of the bed and the numerical domain of integration are shown in figure 2. The domain is taken to be periodic in the long-shore direction. A single large wave of elevation propagating towards the shore constitutes the initial condition.

The wave and current motions are modelled by the finite-amplitude shallow-water equations in the dimensionless form:

\[
\begin{align*}
&u_t + uu_x + vu_y + h_x = d_x, \\
&v_t + uv_x + vv_y + h_y = d_y, \\
&h_t + (hu)_x + (hv)_y = 0.
\end{align*}
\]

where the coordinates \((x, y, t)\), depth to bed, \(d(x, y)\), total water depth, \(h(x, y, t)\) and horizontal velocity components, \((u, v)\) are related to the corresponding dimensional variables, starred, by

\[
x = x'/D, \quad y = y'/D, \quad t = t'(\alpha g/D)^{1/2}, \quad d = d'/\alpha D, \quad h = h'/D, \quad u = u'/(\alpha g D)^{1/2}, \quad v = v'/(\alpha g D)^{1/2}.
\]
Figure 2: Contour plot of the bed, $d(x,y)$. Those above the initial still water level are shown with dashed lines. Contour interval: 0.1.

Figure 3: Examples of grid refinement at $t = 0$ and $t = 0.8$. 
Here $D$ and $\alpha$ are a reference depth and beach slope respectively; e.g. for a beach of constant slope rising from a horizontal bed, $D$ could be chosen equal to the depth of undisturbed water over the horizontal bed, and $\alpha$ equal to the bed slope. This distortion of variables is used to scale out the beach slope, as is possible when no friction terms are included, see Brocchini & Peregrine (1996) or Hibberd & Peregrine (1979) where a slightly different scaling has the same effect.

The computational domain has a bed that is horizontal and constant unit depth for $x < 0.8$, at which point the bed rises with $x$ with a slope 1. The bar is between $x = 1.05$ and 1.383, formed by adding a the positive sinusoid of amplitude 0.125. The dip is formed by multiplying the bar height by a suitable factor varying in the alongshore direction. Thus the bed is given by:

$$d = 1 - (x - 0.8) - 0.125 f(y)[1 + \sin(6\pi(x - 1.05) - \pi/2)]$$

where

$$f(y) = 1 + \cos(2\pi y/L)[\exp\left\{- (y - L/2)^2 / a^2\right\} + \exp\left\{- (y - 3L/2)^2 / a^2\right\}].$$

The width of the domain is $L = 2.5$, and $a = 0.3$. A plot of bed contours is given in figure 2.

The initial conditions are to have water at rest except over the horizontal bed, $0 < x < 0.8$ where

$$u(x,0) = 0.3 \left[ 1 + \sin(2\pi x/0.8 - \pi/2) \right]$$

$$h(x,0) = \frac{1}{4} u(x,0)^2 + u(x,0).$$

The relationship between $u$ and $h$ is chosen from the properties of simple unidirectional waves to give only onshore propagation initially.

The numerical scheme used is one due to Quirk, "AMRITA", which has adaptive mesh refinement, with a Roe type solver, conserving mass and momentum, and a total variation diminishing scheme that can accurately represent the initiation and propagation of the discontinuities in the solutions that represent bores. It is very similar to the gas dynamic code incorporated in the same program package that is described in Quirk & Karni (1996). The computation reported here includes no dissipation other than that which occurs at bores. The mesh refinement criterion are specified by the user. Refinement is clearly needed at bores, but our preliminary studies of accuracy showed that it is also needed at the shoreline and in regions with vorticity. An important feature for checking is that potential vorticity is conserved following a fluid particle. Figure 3 shows the numerical mesh at the initial time, where only the shore line has refinement since we start with a smooth wave, and as the wave meets the shoreline where much refinement is needed for the more complex flow.
Figure 4: Contours of water surface height, $h - d$, with 25 contours in each of the intervals $[-1.0, -0.04]$ and $[0.04, 1.0]$. Contours of the exposed beach are also included.
Figure 5: Onshore velocity component, $u$, with 12 contours in $[-2.5, -0.2]$ and $[0.2, 2.5]$. 
Figure 6: Alongshore velocity component, $v$, with 20 contours in $[-0.03, -0.015]$ and $[0.015, 0.03]$. 
The primary results are shown as contour plots of the surface elevation, and the onshore and alongshore velocity components in figures 4, 5 and 6. As may be seen the bore, the following wave’s elevation and the onshore water velocity all become lower over the dip in the bar than they are elsewhere. The alongshore velocity component would be zero if the bar were uniform, so its values give a clear view of the disturbance caused by the dip in the bar.

Potential vorticity at four different times is displayed in figure 7. Since vorticity is obtained from the primary variables by differentiation an increase in numerical noise is likely, and occurs. We have not smoothed the results, some of the noise is closely related to the steep front of the bore and although it mainly translates with the bore some small mesh-scale disturbances appear to be left behind. However, the generated vorticity shows up clearly. In the first frame, at \( t = 0.4 \), the bore is in the process of passing over the bar and the effect of the dip in generating vorticity at its sides where \( E_D \) has a significant gradient is clear. Only part of the vorticity generation has occurred at this time. Note figure 4 shows little discernible deviation in the line of the bore front at any time despite the gradient of its strength induced by the dip in the bar.

By time \( t = 0.6 \) the bore has passed over the bar and two narrow regions of vorticity have been generated. The bore’s position can be seen by the thin spurious contour line just in front of these new eddies. The subsequent frames at later times show how the vorticity is convected shorewards by the forward motion of the water in the wave. The area over which the vorticity is spread increases substantially. This is because the vorticity moves with the water into a shallower region where the water has to spread out. As can be seen the values of the potential vorticity appear to be well conserved, e.g. the peak value hardly changes.

**Conclusion**

The interpretation of surf zone currents and their generation by considerations of vorticity and potential vorticity are illustrated and discussed here. They give a picture of the currents which is more directly related to the dissipative structure in surf zone waves where almost all the dissipation occurs in breaking and bores. We demonstrate the generation of discrete eddies by relatively small non-uniformities in the bed profile. Also evident in the numerical solutions is a large horizontal convection of the eddies by the wave motion following the bore. This horizontal motion is also relevant to the interpretation of the generation of longshore current profiles by regular waves, and appears to be a matter that should be borne in mind when interpreting velocity measurements from fixed velocity sensors.

Experimental Study of Wave Breaking and Blocking on Opposing Currents

Arun Chawla and James T. Kirby

Abstract

A series of experiments on monochromatic waves being blocked by opposing currents are presented in this paper. A hierarchical pattern in the wave field characteristics was observed with increasing wave amplitude. A shoaling model using a bore dissipation formulation to simulate current limited breaking is compared with the data. It is observed that amplitude dispersion plays an important role in wave blocking and cannot be ignored. For the large amplitude waves side band instabilities radically affect the wave field and prevent wave blocking.

Introduction

Wave blocking occurs in regions (e.g. mouths of river inlets) where the currents are opposing the waves. The opposing current slows down the waves leading to an increase in the wave steepness, which sometimes leads to wave breaking. The waves get blocked when the current is strong enough to prevent the wave energy from traveling upstream. That is when the group velocity $C_g$ goes to zero. The steep waves in front of the blocking point cause considerable navigational hazards and can also affect sediment transport. Since the wave field is dramatically altered through the blocking region, it becomes important for the coastal engineer to be able to quantify under which conditions wave blocking will occur. There is also a limited understanding of energy dissipation due to current limited wave breaking. Thus, from an engineering viewpoint a study of wave blocking and the evolution of the wave field through these blocking points is very important.

Before progressing into the dynamics of wave blocking, it is important to know the conditions under which wave blocking occurs. Consider a two dimensional wave moving on a depth-uniform current $U$. Then in a frame of reference moving with the current, the equations and solutions for water wave motion are identical to the case of no current. If $\omega$ is the wave frequency in a stationary reference frame, and $\sigma$ is the wave frequency in a reference frame moving with the current, then the phase speed of the wave in the moving reference frame can be related to the phase speed in a...
stationary reference frame by

\[ \frac{\omega}{k} = \frac{\sigma}{k} + U \tag{1} \]

or

\[ \omega - kU = \sigma \tag{2} \]

where \( k \) is the wave number and remains unchanged in the two reference frames. The expression for \( \sigma \) depends upon the theory used to obtain the dispersion relation from the equations. Differentiating (2), and setting \( C_g = \frac{\partial \sigma}{\partial C_g} \) to zero we then get the condition for wave blocking as

\[ \frac{\partial \sigma}{\partial k} = -U \tag{3} \]

From (3) it is obvious that wave blocking can only occur if the wave and current are moving in opposite directions.

A linear uniform asymptotic solution for the waves close to the blocking point was first obtained by Smith (1975), who showed that, for small wave amplitudes, the waves are reflected from the blocking point. These reflected waves get shorter and shorter as they move away from the blocking point. Stiassnie and Dagan (1979) showed that when the required blocking current is close to the maximum current then partial wave reflection occurs. Their solution provided the transition region from no reflection to total reflection of wave energy. Some nonlinear aspects of the waves at the blocking points were also studied by Peregrine and Smith (1979). Both Shyu and Phillips (1990) and Trulsen and Mei (1993) further enhanced the theory of wave blocking by including the effects of surface tension. They showed the existence of a second blocking point which occurs when the reflected waves get so small that surface tension effects become predominant in the dispersion relation.

All the references cited above have concentrated on the study of wave reflection from the blocking point. But wave reflection occurs only if the initial wave amplitude is fairly small. For most practical problems the waves become steep enough to break as they approach the blocking point with very little to no wave reflection. The process is complex and requires an extensive experimental study. Unfortunately there are very few references in the literature to experimental studies of wave blocking. Lai et al. (1989) have conducted laboratory studies of the kinematics of the wave-current interaction under blocking conditions but do not discuss any of the dynamics. Sakai and Saeki (1984) have also conducted experiments of waves on opposing currents, but their experimental setup also includes a sloping sea bed. The focus of their study was the combined effect of opposing currents and sloping sea bed on wave transformation and breaking. In their experiments wave breaking occurs in shallow water, and it thus becomes difficult to isolate current limited wave breaking from depth limited wave breaking. There are still a number of unanswered questions, including what are the factors affecting wave blocking, how do waves break and dissipate energy under strong opposing current, and how do the wave field characteristics change with increasing nonlinearity. Therefore, we need further experimental studies to get a better understanding of the evolution of the wave field through the blocking region and
the dynamics of the wave-current interaction. Keeping this aim in mind the present study was carried out. A series of experiments have been conducted with monochromatic waves to provide some useful insights into the characteristics of the wave field in blocking currents, and the conditions under which the waves get blocked. The experiments have been conducted in relatively deep water so as to minimize the interaction between the bottom bathymetry and the waves. A simple shoaling model for waves on currents combined with a bore dissipation model to simulate wave breaking has also been compared with the data. This has been done with an attempt to quantify current limited wave breaking.

Experimental Setup

The experiments were conducted in the recirculating flume at the Center for Applied Coastal Research. A schematic plan view of the setup is shown in Figure 1. The flume is 30 m long and 0.60 m wide. All the tests were conducted in a water depth of $h = 0.50$ m. Currents are generated with the help of a pump which removes the water from behind the wavemaker and puts it back at the far end. A narrow channel has been created with the help of a false wall so as to be able to generate faster currents in the middle of the flume. A perforated wave paddle is used to generate waves so that the current can be allowed to go through the paddle. Porous beaches have been placed at the two ends of the flume to absorb the waves. All measurements in the $x-$direction are made from the still position of the wave paddle.

Data was recorded in the form of a time series of the water surface at 29 different locations extending through the channel. Capacitance-type wave gages were used for this purpose. The gage locations are shown by open circles in Figure 1. At each location data was collected for 600 wave periods and wave height estimates obtained using a zero-up crossing method. The current field was measured using an acoustic doppler velocimeter. Figure 2 shows the vertical profile of the mean current (averaged over 330 seconds) at 5 different locations in the flume. Due to the development of
a bottom boundary layer there is a slight shear in the current profile, specially in the region closer to the wavemaker. But inside the channel the current is more or less depth uniform. Thus, for the remainder of the paper we shall consider a depth averaged value of the current only. As a result of the constriction caused by the narrowing of the channel, the depth averaged current varies from 0.32 m/s at $x = 12.4$ m to its maximum value of 0.53 m/s at $x = 15.2$ m.

Various tests were conducted of which 6 cases will be shown here. The particulars about the tests are given in Table 1. In these cases the blocking point (according to linear dispersion) for the given wave period occurs close to the narrow part of the channel ($x = 14.6$ m). The incident wave amplitude was increased from test 1 to 6 and the characteristics of the wave field observed.

Theoretical Model
Bretherton and Garrett (1969) showed that in the presence of currents it is the wave action that is conserved and not the wave energy. Their conservation principle is given by

\[ \frac{\partial}{\partial t} \left( \frac{E}{\sigma} \right) + \nabla \cdot \left( \left( \frac{E}{\sigma} \right) \frac{\tilde{k}}{k} \right) = 0 \]  

(4)

where \( \frac{E}{\sigma} \) is the wave action and \( E \) is defined by linear theory as

\[ E = \frac{1}{8} \rho g H^2 \]

\( H \) being the wave height.

Since we are considering only steady wave conditions, we can neglect the first term in (4). Allowing for the variation of the channel width, integrating across the channel and providing a dissipation function for wave breaking, we get

\[ \frac{1}{b} \frac{\partial}{\partial x} \left( \frac{bEC_q}{\sigma} \right) = \frac{D'}{\sigma} \]  

(5)

where \( b \) is the channel width. \( D' \) is defined according to the bore dissipation model of Battjes and Janssen (1978), and is given by

\[ D' = -\frac{\beta}{\pi} \left( \sqrt{\frac{8}{\rho g}} \right) kE^{3/2} \]  

(6)

where \( \beta \) is a parameter. To match this dissipation rate with our data we take \( \beta = 0.20 \). It should be kept in mind that this is ten times lower in magnitude than the value used for modeling waves breaking on a sloping beach (Battjes and Janssen, 1978). This is due to the fact that current limited wave breaking is very different from depth limited wave breaking even though we are using the same formulation to model the two processes. Figure 3 shows a picture of waves breaking on the current. From the picture we can see that the breaking is weak and unsaturated as opposed to the saturated breakers observed in depth limited breaking.

The onset of wave breaking is predicted by Miche’s criterion given by

\[ H_m = \frac{\alpha}{k} \tanh kh \]  

(7)
where $\alpha$ is a parameter. By taking the Stokes wave solution and assuming that at
the onset of breaking the fluid velocity at the crest of the wave is equal to the phase
velocity, Miche got $\alpha = 0.88$. This value of $\alpha$ has been used in the literature to
predict the onset of depth limited breaking (Battjes and Janssen, 1978). However,
based on our observations $\alpha$ has a lower value ($\alpha = 0.60$) for current limited wave
breaking. Sakai and Saecki (1984) have shown through their experimental results that
$\alpha = 0.88$ works reasonably well when there are no opposing currents, but it decreases
with increase in the opposing current. The smallest value of $\alpha$ that they got was
approximately 0.7. It should be kept in mind that their experiments were carried
out in shallow water ($kh \approx 0.63$) where both depth and current play a part in wave
breaking, while our experiments were carried out in much deeper water ($kh \geq 2.4$)
where the wave breaking is caused only by the opposing current.

Eq. (5) together with (6) gives a model for a wave shoaling and breaking on a
current. The model does not account for wave reflection, and thus cannot be used in
cases where the waves are reflected from the blocking point. Also, it can be seen from
(4) that at the blocking point ($C_\theta = 0$) the model becomes singular. Thus the model
can only be used until the blocking point.

The dispersion relation is given by (2) together with an expression for $\sigma$ which
depends upon the wave theory used. According to linear wave theory we have

$$\sigma = \pm \sqrt{gk \tanh kh}$$

(8)

and according to a third order Stokes wave theory (Bowden, 1948) we have

$$\sigma = \pm \sqrt{gk \tanh kh \left[ 1 + (ka)^2 \left( \frac{8 + \cosh 4kh - 2 \tanh^2 kh}{8 \sinh^4 kh} \right) \right]}$$

(9)

To determine the importance of amplitude dispersion in wave blocking, the model shall be compared with data using both the dispersion relations. From (3) and (9) we can already see that amplitude dispersion tends to increase the required blocking current, by increasing the relative wave frequency $\sigma$ at a fixed $k$.

**Observations**

Out of the 6 test cases, only in test 1 was the incident wave height small enough for the waves to be reflected from the blocking point. Since the gages were too far apart to obtain the envelope of the partial standing waves, the experiments were repeated for this case with the gages densely spaced between $x = 13.7$ m and $x = 16$ m.

Smith (1975) and all subsequent references in the literature on wave reflection from a blocking point have shown that the envelope of the waves through the blocking point is represented by an Airy function, within the context of the linearized theory. From Trulsen and Mei (1993), the wave amplitude near the reflection point is given by

$$a = b_0 \text{Ai}(-\alpha^{2/3}(x - x_{st}))$$

(10)

where, $x_{st}$ is the location of the blocking point (for our test case $x_{st} = 14.6$ m), $b_0$ is a constant related to the incident wave amplitude, and $\alpha$ is given by

$$\alpha = \sqrt{-\left( \frac{-2 \partial U \partial x \, k\sigma}{3U^2} \right)} |_{x=x_{st}}$$

(11)

Matching the data to (10) at $x = 13.7m$ and then comparing the amplitude envelope to the Airy function (Figure 4) we find that (10), which is based on linear theory, gives a good estimate of the actual shape of the amplitude envelope but underestimates the first peak. The accentuation in the wave envelope occurs because the larger wave amplitude close to the blocking point makes nonlinear effects important. The nonlinear term in a cubic Schroedinger equation for a modulating wave-train changes sign at $kh = 1.36$, leading to a self-focusing modulation for $kh > 1.36$, and a defocusing modulation for $kh < 1.36$. The result of the self-focusing mechanism, expected to be dominant here, is to accentuate the height of envelope modulations. A similar effect occurs in the case of an evolving sinusoidal wave front, where in deep water, linear theory again underestimates the first peak of the amplitude envelope in the front (Mei, 1992, page 57, Figure 4.2). It should be noted that these are just
the preliminary findings and a thorough analysis of wave reflection from the blocking point is currently being carried out.

Tests 2 to 6 all have wave breaking with no apparent wave reflection. We can thus compare the data with the numerical model. The comparison is shown in Figure 5. In each of the test cases the wave heights have been normalized by their corresponding incident wave height. The depth averaged velocity distribution is also shown as a function of x. In the case of test 2 the wave shoals as the opposing current is increased and gets blocked before it can reach the maximum limit of the current. Test 3 shows a similar trend but now the blocking point is shifted back further from the wave paddle due to amplitude dispersion caused by the larger wave height. Wave blocking now occurs at the maximum current. In test 4, due to an even larger wave height, the wave reaches the maximum current without getting blocked. At this point, if the wave height does not reduce, the wave will travel right through the channel. But the wave is breaking and thus continues losing energy until the magnitude of the current in the narrow channel is enough to block it. In these three cases we find that the model works very well in predicting the blocking point when using Stokes third order dispersion as opposed to linear dispersion. The model also performs better in estimating the shoaling of the waves before blocking when taking amplitude dispersion into account.

Tests 2 to 4 are similar in the sense that the waves break and get blocked. But
Figure 5: Model to data comparisons of the wave height distribution. 'Solid line' Bore model with Stokes third order dispersion, 'dashed line' Bore model with linear dispersion, 'circles' Data

tests 5 and 6 show a different pattern. From Figure 5 it can be seen that in both cases the waves reach the maximum current, and just as in test 4, propagate into the channel and continue dissipating energy due to wave breaking. However, the waves do not get blocked even when the blocking condition is satisfied for the model. Why? To get a better idea let us consider the wave period distribution as a function of $x$ for the different test cases. From Figure 6 it can be seen that for tests 5 and 6 the wave energy shifts to a lower frequency as it propagates through the channel. For these
The shift in the wave energy to a different frequency is explained by the growth of lower side bands. Benjamin and Feir (1967) showed that in deep water, steep waves
Figure 7: Frequency Spectra for Test 6 at various locations in the channel. Energy is transferred to the lower side band while the primary wave is blocked.

are unstable to disturbances at some frequencies $\delta f$ away from their fundamental frequency (where $\delta f$ is a small number). This leads to the growth of bands of energy on either side of the fundamental frequency in the frequency spectra, which are referred to as side bands. The growth of these side band instabilities depends upon the wave steepness and water depth. They become highly pronounced when the waves are riding on opposing currents and have been observed in the laboratory (Lai et al., 1989). As the waves approach the blocking point the group velocity $C_g$ tends to zero and the wave energy travels very slowly. Thus, a significant amount of energy
could be transferred from the fundamental frequency to the side bands even through small spatial distances, as the time of passage of a given wave energy packet through the transition region is relatively long. Since the lower side band requires a stronger blocking current than the primary wave or the upper side band, it could then continue to propagate forward while the other two are blocked.

This is clearly evident in test 6. The frequency spectra at six different gage locations are shown in Figure 7. At \( x = 10 \) m the wave is away from the channel but the side bands are clearly visible. The fundamental frequency is \( f = 0.833 \text{Hz} \) while the most prominent lower and upper side bands occur at \( f = 0.688 \text{Hz} \) and \( f = 0.978 \text{Hz} \) respectively. As the waves propagate into the channel the growth of these side bands is clearly evident. Going from \( x = 14.7 \) m to \( x = 15.17 \) m the energy in the lower side band increases by almost 10 times in less than 0.5 m. In the narrow part of the channel, first the upper side band and a little later the primary wave get blocked. But the wave energy continues to propagate through via the lower side band. A plot of the corresponding time series (Figure 8) shows the shift to a longer wave period. During the transfer of energy to the longer wave period the waves become very groupy. This increases the complexity of the breaking process as the waves tend to break at the crests of the wave groups. A similar pattern was also seen in test 5. Tests 2 to 4 showed no side band instabilities due to the smaller wave steepness.

Conclusions

In this work we have studied a series of monochromatic waves on an opposing blocking current. The wave amplitudes considered varied from small to large. For the smallest wave amplitudes, wave reflection from the blocking point was observed. Preliminary results show that though the amplitude envelope confirms well with the theoretical predictions, discrepancies between the data and theory show up close to the blocking point due to nonlinear effects.

A simple wave action conservation model together with a bore dissipation breaking model is used to simulate the data. Comparisons show that amplitude dispersion plays an important role in wave blocking. A third order Stokes dispersion relation works much better than a linear dispersion relation in predicting the blocking point. Also the predictions of energy decay from the bore model are reasonably accurate upto the blocking point.

For the largest wave amplitudes the wave energy shifts to a lower frequency due to side band instabilities and the waves do not get blocked, while the model predicts wave blocking. The growth of side bands also makes the waves very groupy, and thus in turn increases the complexity of wave breaking. It is clear that side bands in a carrier wave play an important role in determining whether waves are blocked or not, and ignoring them could lead to significant errors in wave modeling. This phenomenon requires further study and efforts are underway to try and predict the growth of these instabilities using a Schrodinger's equation.

A hierarchy in the wave field characteristics has been observed as the wave amplitude is increased. Depending upon the initial wave amplitude and frequency a monochromatic wave on an opposing current could
Figure 8: Time series for Test 6 at various locations in the channel.

1. be blocked and reflected,
2. be blocked and break at the blocking point,
3. pass through the maximum current due to amplitude dispersion but break and still get blocked, or
4. transfer significant energy to a lower side band which does not get blocked while the primary wave and the upper side band do.

In a random sea all these different phenomena could be occurring at the same time
making dissipation modeling all the more difficult. Thus the next step is to study wave breaking in groupy and random waves.

Tidal ellipses in the near-shore zone (-3 to -10 m); modelling and observations

Klaas T. Houwman and Piet Hoekstra

Abstract

Based on theoretical considerations it is demonstrated that in the near-shore zone the tidal water level fluctuations are mainly caused by cross-shore volume fluxes. Phase differences between the tidal wave propagating on the shelf and in the shallow near-shore zone create cross-shore surface gradients which result in an onshore directed flow during rising water and an offshore directed flow during falling water. Observations of near bed velocities in the near-shore zone confirm the presence of these currents. It results in an anti clockwise rotating current vector at a water depth of about 10m. Comparisons of these observations with results obtained from a 1-D flow model show that the tidal ellipses are not the result of Coriolis forces but are generated by the alternating cross-shore water fluxes due to the tide.

Introduction

Generally, in the near-shore zone several mechanism are present which are capable of driving a mean flow, e.g. waves, wind and tides. In literature many studies are focussing on wave driven currents, but hardly any study can be found describing the tidal phenomena in the near-shore zone. In this study we will focus on tidal flow phenomena which can be found in the near-shore zone of the barrier island of Terschelling, the Netherlands. Houwman and Uittenbogaard (1998) investigated the longshore tidal flow at this location by combining modelling and observations. Here emphasis will be given to the tide induced cross-shore flow. Measurements as well as model results will be used to investigate the origin of these currents.

Description of the field site and measurements

1 Institute for Marine and Atmospheric Research, Utrecht University, Department of Physical Geography, P.O.Box 80.115, 3508 TC Utrecht, The Netherlands.
For the analysis presented in this paper, data will be used obtained from measurements made in the multiple bar system of the barrier island of Terschelling, the Netherlands. These measurements were carried out in the framework of the NOURTEC project (Hockstra et al., 1994). The field site is fully exposed to the North Sea, with an average annual offshore significant wave height of 1.1 m. Tides are semi diurnal with a neap tidal range of about 1.5 m and a spring tidal range of ca. 2.5 m. The tidal wave propagates along the coast from the west to the east with an almost constant speed and shape within several tens of km’s at either side of the measurement site. In a cross-shore direction, the inner near shore zone is characterized by several breaker bars parallel to the shoreline (see figure 1).

Figure 1: Cross-shore profile with instrumented positions.

The bars are more or less uniform in longshore direction in the area of interest. Several instrumented tripods were placed in a cross-shore transect at position P1, P2, P3 and P4 (see Figure 1) and data was collected over a time period of 2 years during three successive campaigns. All tripods were equipped with two Electro Magnetic Flow meters (EMF) at (nominal) heights of 0.3 m and 1.2 m above the bed and a pressure sensor at 2.2 m above the bed. Each tripod collected data with a sampling frequency of 2 Hz with a burst length of 2048 s and starting at every full hour. These bursts were split up in four subseries of 512 s each and averaged values of these subseries were used for the analyses presented here. Furthermore, from this data set two calm weather events, with a length of about 140 hours each, were selected. The wave height during these periods was in the range of 0.3-0.8 m and wave breaking occurred only landwards of P4. The wind speed during both periods was about 6 m/s.

Flow model

In this study, a one dimensional vertical flow model (1-DV) will be used to support the analysis of measurements. Here the outline of this model will be described briefly. More details, and an evaluation of this model are presented in Houwman and Uittenbogaard (1998). This 1-DV flow model, describes the distribution of the horizontal velocity vector over depth at a single location in the horizontal plane. The equations of motion in cross-shore $x$ and longshore $y$ direction at a particular height $z$ above the bottom are respectively given by:
In this $U$ and $V$ are the orthogonal velocity components in $x$ and $y$ direction respectively. The first left-hand terms describe the rate of change of the velocities. The horizontal pressure gradient is represented by the first right-hand term, with $\zeta$ being the water level fluctuation around mean sea level. The Coriolis force is given by the second right-hand term, with the Coriolis parameter $f = 2\Omega \sin \Phi$ representing the influence of the earth's rotation. The last right-hand term describes the vertical exchange of horizontal momentum due to the turbulent forces. The eddy viscosity $v_r$ is calculated from the Kolmogorov-Prandtl expression, using a standard $k$-$\varepsilon$ turbulence model. The equations of this turbulence model, with their constant settings, are adopted from Launder and Spalding (1974). Assuming a logarithmic velocity profile in the near-bed region and in the region near the air-water interface leads to the boundary conditions for this $k$-$\varepsilon$ turbulence model.

The boundary conditions for the flow equations (1) and (2) can be deduced making the same assumption. The bottom boundary condition for eq.(1) reads:

$$v_r \frac{\partial U}{\partial z} |_{z=z_0} = S^2 U \sqrt{U^2 + V^2}$$

The parameter $S$ is given by $S = \kappa \ln(z/z_0)$, with the Von Kármán' constant $\kappa$ and roughness length $z_0$. Similar conditions are used at the upper boundary and for eq. (2). The cross-shore water surface gradient $\partial \zeta/\partial x$ is obtained from a method given by Uittenbogaard and Van Kester (1996). They used the depth-integrated version of the equation of motion to calculate the surface gradient. Here this method is applied to calculate the cross-shore surface gradient $\partial \zeta/\partial x$:

$$g \frac{\partial \zeta}{\partial x} |_t = \frac{\tau_{sx} - \tau_{bx}}{\rho h} + \frac{\overline{U(t - T_{rl})} - \overline{U_0}}{T_{rl}} + f \overline{V}$$

with:

- $\tau_{sx}$ = surface shear stress in cross-shore direction
- $\tau_{bx}$ = bottom shear stress in cross-shore direction
- $\rho h$ = water depth
- $T_{rl}$ = some relaxation time span
- $\overline{U(t - T_{rl})}$ = depth averaged cross-shore velocity solution at time $t - \Delta t$
\( \overline{U_0} \) = given depth averaged cross-shore velocity at time \( t \)
\( \overline{V} \) = depth averaged longshore velocity solved

The cross-shore surface gradient can be calculated from eq. (4) using information about the shear stresses at the boundaries and the depth averaged currents. The shear stress \( \tau_{ss} \) and the depth averaged currents \( \overline{U}(t-T_{rl}) \) and \( \overline{V} \) are obtained from the solution of eq. (1) and (2) while the surface stress component \( \tau_{ss} \) is an input term of the model (wind stress). The depth averaged velocity \( \overline{U_0} \) must be specified and is an input parameter for the model. Using alternatingly eq. (1), (2) and (4), the depth averaged velocity \( \overline{U} \) at time \( t - T_{rl} \) approaches the velocity \( \overline{U_0} \). The surface gradient then balances the shear stresses at the surface \( \tau_{sx} \) and the bottom \( \tau_{bx} \) and the (small) contribution of the Coriolis force. The time step \( T_{rl} \) is taken equal to two times the numerical time step which results in a stable and accurate solution.

The prescribed depth averaged (cross-shore) velocity \( \overline{U_0} \) is set to zero for the entire tidal cycle. Note that this does not mean that the cross-shore velocity at each position in the vertical is zero. Finally, specification of the longshore surface gradient \( \partial \zeta / \partial y \) and the roughness length \( z_0 \) is needed, to apply the model. Here the longshore surface gradient, obtained from measured water levels at two locations along the coast, is used to drive the model. A fixed roughness length \( z_0 \) of 0.0033 m was used for all computations, based on the findings of Houwman and Van Rijn (1998) for the same site. All computations were carried out, using 100 grid points equally distributed over the vertical, and 16 time steps in an hour. The model is capable to reproduce the observed longshore velocities accurately as shown by Houwman and Uittenbogaard (1998).

**Results**

The model was run for the first selected period of 140 hours at position P1 and the calculated flow pattern at 1.2 m above the bed is shown in figure 2. The calculated current ellipse is almost flat and is orientated parallel to the coast. Note that the horizontal and vertical axes are different in this diagram. In principle the combination of the Coriolis force and the cross-shore pressure gradient should produce a clockwise rotating current vector at the surface and an anticlockwise sense of rotation for the current ellipse at the bottom. But at this water depth of about 10 m, the vertical gradient of the Coriolis forcing term is rather small. The depth averaged contribution of the Coriolis force in cross-shore direction \( f \overline{V} \) is balanced by the cross-shore water surface gradient. So, the difference between the Coriolis force \( f \overline{V} \) and the depth averaged Coriolis force \( f \overline{V} \) is the only net driving force left for the cross-shore flow. The combination of this small driving force and a strong friction in the vertical results in an almost rectilinear flow pattern. Figure 2 also presents the measured flow pattern for the same period and location. In contrast to the predicted flow pattern, the observations show a clear developed ellipse. This ellipse is apparently not caused by Coriolis forces because these were taken into account in the model. The difference between predicted and observed cross-shore velocities can be explained in the following way: In the model the depth averaged cross-shore flow is taken equal to zero. Using this condition one assumes
implicitly that at each location the volume of water involved in the rising or falling of the water level is fully delivered by the longshore tidal flow. This can easily be seen from the continuity equation (5). Taking $U = 0$ implies that the first term is balanced by the third term.

$$\frac{\partial \zeta}{\partial t} + \frac{\partial h U}{\partial x} + \frac{\partial h V}{\partial y} = 0$$

Figure 2: Calculated and measured flow pattern at P1, 1.2 m above the bed.

A scale analysis however, shows that this is not the case in the near-shore zone. Assuming a tidal wave with amplitude $\zeta$, period $T$, wavelength $L$ and depth averaged longshore velocity $V_1$, the first and last term in the continuity equation have the following order of magnitude:

$$\frac{\partial \zeta}{\partial t} = O\left(\frac{\zeta_1}{T}\right)$$

$$\frac{\partial V h}{\partial y} = h \frac{\partial V}{\partial y} + V \frac{\partial h}{\partial y} = O\left(\frac{V_1}{L} + \frac{V_1 \zeta_1}{L}\right)$$

The magnitude of these terms becomes comparable at a mean water depth $d = 24$ m, when typical values for the tidal regime at Terschelling are used. At smaller water depths $\partial \zeta/\partial t$ is significant larger than the $\partial V h/\partial y$ term. So, at these water depths a cross-shore flux must be present. The actual magnitude of the $\partial \zeta/\partial t$ and $\partial V h/\partial y$ terms can more accurately be deduced using the flow model. The magnitude of the $\partial V h/\partial y$ term can be calculated assuming a longshore uniform topography and using the propagation speed of the tidal wave. These computations demonstrate that the term $\partial V h/\partial y$ is significant smaller than the $\partial \zeta/\partial t$ term at a mean water depth of 10 m. Averaged over a half tidal cycle, about 22% of the volume of water is delivered by this longshore term at this water depth. At smaller water depths the importance of the $\partial V h/\partial y$ term decreases rapidly. For example, at a water depth of 5 m approximately 6% of the volume flux is delivered by the longshore term and at 2 m water depth only 1% can be explained from this. This implies that in the near shore zone the second term in the continuity equation $\partial U h/\partial x$, is non-
zero and is mainly responsible for delivering the volume of water associated with the tidal water level fluctuations in the coastal zone. The relative importance of this cross-shore term grows for a decreasing water depth. The underlying reason for this cross-shore flux is the difference in water depth on the shelf and in the near-shore zone. The tidal wave propagates along the coast with a speed determined by the (average) water depth at the shelf. In the shallow near-shore zone the propagation speed would have been less as a result of the smaller water depth, which is of course not possible. The tide in the near-shore zone lags the propagation of the tidal wave at the shelf only slightly. But, this results in co-tidal lines which are not entirely perpendicular to the coast. This is schematically illustrated in figure 3.

![Figure 3: Cotidal lines on the shelf and shoreface.](image)

During rising water the water level in deep water rises faster than in the shallow near-shore zone. This results in a cross-shore water surface gradient which drives an onshore directed, cross-shore flow (see figure 4). This flow is (mainly) responsible for increasing the water level in the shallow near-shore zone. During falling water the reversed process will take place and an offshore directed flow will be present, as indicated in figure 4.

![Figure 4: Cross-shore flow due to tide induced surface gradients.](image)

So, in colour full terms spoken, the tidal wave in the near-shore zone is drawn along the coast by the tidal wave travelling on the shelf. The principle of this tide induced cross-shore flow is also described by Pugh (1987). Unfortunately, the magnitude of this cross-shore flow can not be deduced from a 1-DV model, at least a 2-DH model is required. But in the near-shore zone the third term in the continuity equation is relatively small as shown above. Therefore a reasonable approximation of the magnitude of the cross-shore flow can be found after neglecting this longshore term in the continuity equation. After integration in cross-shore direction from a position $x_0$ to the waterline, see figure 5, the
following expression is found:

\[ \overline{U_0} = \frac{x_0 \partial \zeta}{h \partial t} \]  (7)

So, the depth averaged flow at a particular position in the near shore-zone depends on the distance to the waterline \( x_0 \), the local water depth \( h \) and the rate of fluctuation of the water level. The flow \( \overline{U_0} \) delivers a water volume to the landwards located zone, equal to the dotted area presented in figure 5.

![Figure 5: The tide induced cross-shore flow in the near-shore zone.](image)

The distance to the water line \( x_0 \) depends on the actual water level and is thus a function of time. It can be calculated from: \( x_0 = x_1 + \zeta \tan \beta \). In this \( x_1 \) is the distance to the waterline when \( z = 0 \) (mean sea level) and \( \tan \beta \) is the slope of the beach, which is 0.014 m/m in the Terschelling case. Figure 6 shows the computed cross-shore distribution of the depth averaged cross-shore flow during one tidal cycle. During falling water (time 0 to 5) an offshore (negative) flow is present at all positions and during rising water (time 6 to 11) an onshore (positive) flow exists at each position. Due to the asymmetry of the water elevation curve, the onshore directed currents are larger than the offshore directed ones, but the duration of this latter period is longer. The largest velocities are found just after low tide. At that time the most rapid variation of the water level takes place. The cross-shore distribution of the tidal flow clearly shows a relationship with the morphology. The largest velocities can be found on top of the bars and local minima in the spatial flow distribution coincide with the troughs. Further offshore also rather strong velocities are predicted. But, one has to keep in mind that at water depths larger then \(~8\) m the contribution of the longshore term in the continuity equation becomes significant resulting in a reduction of \( \overline{U_0} \). The magnitude of the cross-shore flow depends on the speed in which the water level is changing. The largest flow velocities coincide with the steepest parts of the tidal elevation curve. For these periods the longshore surface slope is also maximal. Without inertia, this would result in maximum cross-shore and longshore flow at the same time, creating a rectilinear flow pattern oblique to the coast. The influence of the inertia is however significant for the longshore flow, which results in a phase lag between cross-shore and longshore flow. Therefore an anticlockwise rotating current vector can be expected at locations where inertia plays a significant role, see figure 2. In contrast to velocity profiles affected by Coriolis forces this mechanism creates a current vector which rotates in the same direction at every position in the vertical. The direction of rotation has of course nothing to do with Coriolis forces, it is determined by
Figure 6: Cross-shore distribution of the tide induced depth averaged cross-shore flow.

the position of the coast, left or right relative to the progressive tidal wave.

This mechanism, generation of a tide induced cross-shore flow, can easily be implemented into the flow model simply using eq. (7) to calculate the model input parameter $U_0$ for every time step.

Computations were carried out, using this condition, for the two selected periods of 140 hours each. Figure 7 shows the observed and calculated tidal ellipses during the first period at P1 at 1.2 m and 0.3 m above the bed. The computed as well as the observed flow patterns show ellipses created by an anticlockwise rotating current vector. The predictions agree well with the observations. The tide induced cross-shore velocities at these levels are rather small, with a typical maximum value of about 0.05 m/s at 1.2 m above the bed. Figure 8 shows the flow pattern at P1 during the second period of 140 hours. The computed velocities during this period form an anticlockwise rotating current vector similar to the previous period. The measured velocities however do not show a clear ellipsoidal form. Unfortunately, the orientation of the measured flow pattern is not accurately known due to inaccuracies in the determination of the direction of the flow meter in the frame. So, it is not clear if the phase lag between long and cross-shore flow has become less or that the cross-shore flow is diminished during this period. It is also
Figure 7a: Measured flow pattern at PI during the first period.

Figure 8a: Measured flow pattern at PI during the second period.

Figure 8b: Predicted flow pattern at PI during the second period.
unclear why in the second period the observed ellipses are flat, contrary to the ones in the first period, but at station P2 the same phenomena occurred. During the second period the observed velocities at P2 do not form an ellipse in contrast to the predicted ones. The ellipses observed during the first period are shown in figure 9 together with the calculated ones.

Although the observed ellipses are less “open” as the computed ones, they both display similar trends. The onshore velocities are larger than the offshore directed velocities, which is also visible in figure 7 and 8. The shape of the predicted tidal ellipses at P1 and P2 is different, which is the result of a decrease of the phase lag between the longshore and cross-shore flow. The influence of the inertia on the flow at P2 is smaller than at P1 resulting in a reduction of this phase lag. The measured and predicted tidal ellipses during the second period at this position P2 are shown in figure 10. At position P3 and P4 only data from the second period is available. The measured and computed ellipses at station P3 for this period are shown in figure 11. Also here the current vectors predicted by the model rotate in an anticlockwise sense. And again, onshore directed current velocities are larger than the offshore directed ones. At this position with a mean water depth of about 4 m the influence of the inertia on the flow is small, which results in an almost flat ellipse. The main axis of this ellipse makes an angle with the coast line. The predictions and observations do not deviate significantly from each other, taking into account the error band in the orientation of the flow meter.
Figure 10a: Measured flow pattern at P2 during the second period.

Figure 10b: Predicted flow pattern at P2 during the second period.

Figure 11a: Measured flow pattern at P3 during the second period.

Figure 11b: Predicted flow pattern at P3 during the second period.
Figure 12 shows the measured and predicted current ellipses in the trough at station P4. The observations and the model results indicate that no clear ellipses are developed at this position. This can be explained by the combination of a relative large water depth at this position and the rather small distance to the shore. The measured velocities are somewhat scattered and the flood current at 0.3 m above the bed seems to be deflected. The reason for this is not clear.

![Figure 12b: Predicted flow pattern at P4 during the second period.](image)

Discussion and conclusions

Based on theoretical considerations it is demonstrated that small but persistent cross-shore flows are generated in the near-shore zone due to tidal water level fluctuations. This is confirmed by the comparison between model computations and flow observations. A phase difference between the tidal wave in the near-shore zone and on the shelf creates cross-shore surface gradients which drives a cross-shore flow. At this site the volume flux involved in the tidal fluctuation of the water level in the near-shore zone, at water depths less than 10 m, is mainly delivered by the cross-shore flow. Neglecting the contribution of the longshore flow to this volume flux makes it possible to determine this cross-shore flow. The magnitude of the tide induced cross-shore flow depends on the tidal range, the shape of the tidal curve, the local water depth, the distance to the water line and the slope of the beach. Furthermore, the propagation speed of the tidal wave is important, if one takes the longshore term, the third term in eq. (5), into account.

Based on this, it can be expected that this mechanism is important only for coastal areas
dealing with a meso or macro tide and a gentle sloping beach-shoreface system such as the coast of Terschelling.

The comparison of observed and predicted tidal ellipses demonstrates that the tide induced cross-shore currents can be detected in the field. Predictions of the near bed flow at a water depth of about 10m (location P1) indicate that ellipses can be expected, which were also observed in the field during the first period. But, in contrast to the predictions, no clear ellipse was observed during the second period. A similar result was found at P2. Apparently, the flow pattern can easily be disturbed by other mechanisms. 

Non-uniformity of the morphology in longshore direction could be an explanation for the difference between measured and predicted ellipses during the second period. But, particular at position P1, the large scale morphology is uniform over several kilometres in longshore direction and is almost identical for both periods. So, it is unlikely that this is the reason for the observed differences. Perhaps wind effects play a role in this, although no significant differences were present during the first and second period. A decrease of the phase differences between longshore and cross-shore velocities, which are small, could explain the diminishing of the open ellipses. A time shift, for any reason whatsoever, in the order of 20 minutes would already give a flat ellipse which makes an angle to the coastline. These flat ellipses have been observed, but the magnitude of the cross-shore flow in those cases can not be determined due to the inaccuracies in the direction of the measured flow vector. At this stage, it remains unclear what the reason is for the disturbance of the ellipse. It is clear though persistent, tide induced cross-shore currents exist. Going from P1 further inshore, the phase difference between longshore and cross-shore near bed flow decreases, resulting in a change of the shape of the tidal ellipse. At P3, the major axis of predicted ellipses is oblique orientated to the coast and the minor axis is only small compared to the one at P1.

Finally, at P4 a rectilinear flow pattern is predicted, orientated shore parallel, which is the result of the rather large water depth and the short distance to the shore line.

ADCP Observation of Nearshore Current Structure in the Surf Zone

Takao Yamashita*, Hiroshi Yoshioka*, Shigeru Kato*, Lu Ming* and Chikara Shimoda**

Abstract

Coastal current in the nearshore zone is generated by both breaking waves inside the surf zone and by the wind over the extended area of the coastal and offshore zones. Wind-induced currents as well as wave-induced currents are characterized by strong shear flows and complicated turbulence flow fields. In order to develop mathematical models for these currents, it is essential to formulate wind and wave stresses acting on the sea surface. Unfortunately, there has been no reliable observation of current profile in the surf zone under the condition of strong wind. No extensive information on wind stresses inside the nearshore zone has been made available, primarily because of the challenge of recording these data without facilities such as observation pier or towers.

In this paper we conducted a continuous recording of nearshore current profile and wind stresses in/out the surf zone by using high frequency ADCP (Acoustic Doppler Current Profiler, 1200kHz) installed on the sea bottom under the observation pier of Ogata Wave Observatory, together with 3-component ultrasonic anemometer. This two and half months observation revealed part of the structure of nearshore currents and some characteristics of the wind drag coefficient in the nearshore zone.

1. Introduction

Causes of beach erosion may be natural, as for example entrainment by storm waves or nearshore currents, or they may result from human activity, as for example from coastal structures, which affect waves and currents patterns, from hinterland development which reduced sediment yield, or from the global warming of the atmosphere which produces a rise of sea level. As a consequence, beaches become smaller and smaller. Management and use of the seashore may also affect water quality and the entire ecological system with its natural resources. Beaches play an important role in the global environment, yet beaches are so fragile.

Maybe, all over the world, intensively both in the United States and in European countries, the role of beaches as a regulator of the coastal environment, as well as their function as wave absorbers (disaster prevention function) have been recognized for several decades. Soft beach construction by sand nourishment and simple structures seems to be the best choice of beach preservation. A new field, so called "Beach Engineering", emerged, in which beach protection, maintenance, and environmental and economic evaluation have been extensively examined. An interdisciplinary research on coastal environment keeps developing.

Part of this research consists of predicting the evolution of both natural and artificial beaches, and numerical simulations can be used for this purpose. Beach changes result from sediment transport which is controlled by several factors; sediments are moved away by ocean currents and nearshore currents, originated by external forces such as waves and winds. Therefore, numerical models need to combine a model for wind, a model for wave propagation and a model for sediment entrainment. Most nearshore current models have been written as horizontally two dimensional models, assuming the driving shear forces to be originated by the gradient of radiation stresses. However, these models are incomplete because it is assumed that the current profile is uniform in the vertical direction. Although the three-dimensional nature of nearshore currents has been recently studied by numerical simulations, their dynamics is not yet fully understood and their modeling remains a difficult task; to avoid the complexity of three-dimensional models which require long calculations, quasi three-dimensional models have been proposed instead. Whereas models can be run to simulate changes of sea bottom topographies induced by natural factors as well as by nearshore constructions, because of the variety of beaches, of wave and current conditions, and because of the complexity of the processes involved, the results of these simulations lack accuracy. Field observations can then be used as a complementary source of information to understand current mechanisms, long-term beach evolution, and to calibrate the models in each particular case. This requires a substantial amount of data simultaneously for winds, waves and currents in order to calibrate each part of the code - wind module, wave module and current module - as well as the whole coherence of the model. For example, test runs can be performed and model parameters adjusted until numerical results fit field data.

Such a long term observation was carried out by Yamashita et al. (1997) to investigate the structure of nearshore currents in the surf zone along the Ōgata coast facing the Japan Sea. Since most erosion occurs in presence of large waves and strong winds, data were recorded during winter time, under such conditions. After an observation of two months, the following characteristics were revealed: (1) nearshore currents have almost uniform vertical distribution in the surf zone, (2) nearshore currents are strongly influenced by the wind, and wind-induced currents are of the same order as wave-induced currents. It was also observed that features of waves, currents and turbulence differ significantly from shallow waters to deep waters. Therefore, mechanisms of momentum transfer between atmosphere and sea deserve further investigations. Effects of both waves and winds need to be taken into account in any nearshore current simulation along this coast.

It is the goal of this study to discuss some aspects of winds, waves and currents...
recorded in the surf zone and to get a better understanding of their mutual interaction; the observation was made possible by the presence of the T-shaped observation pier (TOP) of Ogata Wave Observatory, a research facility of the Disaster Prevention Institute (DPRI), Kyoto University. This pier extends from the shoreline into the surf zone and permits continuous and methodic recordings of nearshore data in an area inaccessible by boat under severe winter conditions. The pier also enables constant check out and maintenance of all instruments. Nearshore currents were recorded by two ADCPs. Winds were recorded by a three-components anemometer at a 10m elevation above mean sea level. The influence of wind and waves on current intensity and direction were investigated. A drag coefficient was derived to characterize wind stresses over the surf zone. The drag coefficient was deduced from wind data using the Turbulence Dissipation Method (TDM).

2. Observation of Currents, Waves and Winds in the Nearshore Zone

During winter time, severe erosion is caused by offshore sediment transport along the Japan's coast facing the Japan Sea. It is believed that the strong winds and waves take a significant role in this process, but the mechanisms involved are not yet understood. In this study, the interdependence between winds, waves and currents is examined, based on a set of data recorded in/out the surf zone in order to get a preliminary idea on nearshore-currents structure and dynamics. The observation was carried out using the pier (TOP) with the following instruments: 3-component ultrasonic anemometer for wind shear stresses, seven ultrasonic wave gauges for water surface elevation and wave characteristics and two 1200KHz ADCP set on 1.3m above the sea bottom underneath the pier for current profiles. Dimension and location of instruments are shown in Fig.1.

Figure 1 T-shaped observation pier, beach profile and location of instruments
Figure 2 shows (a) the significant wave height of the wave gauge ch.4 and 5, (b) offshore and (c) longshore velocities (4-6m depth average of west ADCP) during the entire observation period. As been shown in Fig.2(b), seven winter storms which generated strong offshore-going currents were recorded. Five cases of them, Case A (Jan. 4-5), Case B (Jan. 6-7), Case C (Jan.18-20), Case D (Jan.31-Feb.1) and Case E (Feb.9-10), are selected to investigate the interdependence between nearshore currents and wind-wave climate. It is observed that strong offshore currents arise only during short periods of less than 24hrs and longshore currents going eastwards are dominant.

Figure 2 Significant wave height (ch.4 and 5), and 4-6m depth averaged currents of the west ADCP recorded during the entire observation period. Cases A-E indicate the selected events in which strong offshore going currents observed.

Top: significant wave height of the wave gauge ch.4 and 5, Middle: offshore velocity (going offshore is positive), Bottom: longshore velocity (going eastwards is positive)
3. Interdependence between Nearshore Currents and Wind-Wave Climate

Figures 3 - 7 show interdependence between nearshore currents and wind/wave climate of five selected winter storms (Case A-E in Fig.2(b)). Sub figures refer respectively to time (a) wave climate, (b) wind climate, (c) longshore current profiles, (d) offshore current profiles and (e) nearshore current profiles by vector. As TOP is oriented north-west (48deg from the north, shore-normal), winds blowing from a direction westwards relative to TOP will be referred to as westerly winds. During winter storm winds typically blow from the west, i.e. they are westerly relative to the pier. From these figures, it can be recognized that there are two types of wind/wave climates which cause strong offshore-going currents. One is the type called "end-storm undertow" which is defined that sudden bursts of current occur with changes in wind directions from westerly to easterly with reduction of wind velocity at the end of the winter storms (Cases A, B, E). The other is the type called "mid-storm undertow" which is defined that continuous strong shore-normal(NW) winds generate strong undertow in the midst of storm (Cases C, D). It has been recognized at TOP that when the significant wave height at the gauge ch.4 exceeds 2.5m, TOP is completely inside the surf zone, and when being the range of 2.0-2.5m, breaker point exists in the area of gauge ch.4 to ch.6. If the obvious reduction in the significant wave height between ch.5 and ch.6 is observed, we judge that wave breaking occurred between ch.5 to ch.6. Following are significant nearshore-current characteristics revealed by the 1998 observation:

(a) Velocity profile : Sub figures (c) and (d) in Figs. 3-7 indicate that both longshore and offshore current profiles in the vertical direction are almost uniform in the region under the wave trough level and above the boundary layer when wave and wind climates are stable. Figure 8 shows the hourly changes in vertical profiles of on-offshore (left) and longshore (right) in Case B. Phases A, B and C in the figure are indicated in Fig.4, which are corresponding to before, middle and after the sudden bursts of offshore-going currents.

(b) Longshore currents : Direction of longshore currents is much more sensitive to the wind direction than waves. Its intensity is much stronger than that of on-offshore component except the phase of the sudden bursts of offshore-going currents. These observation facts may indicate that strong longshore current is mainly induced by winds in the wide area of nearshore zone and its direction is shore-parallel. Wave-induced longshore current is much smaller than wind-induced one. This fact suggest us that wind-induced current near the surf zone is the dominant factor of sediment transport under the storm conditions such as typhoon, hurricane and winter monsoon. This effect should be taken into consideration when beach changes and depth of closure are discussed.

(c) On-offshore currents : As mentioned before there are two types of wind climate which cause a strong offshore-going current, those are called here "end-storm undertow" and "mid-storm undertow". These cross shore currents may be generated by unbalance of mean water surface gradient and shear stresses due to both winds and
Figure 3 Interdependence between nearshore currents and wind/wave climate of winter storms (Case A).

Figure 6 Interdependence between nearshore currents and wind/wave climate of winter storms (Case D).
Figure 7 Interdependence between nearshore currents and wind/wave climate of winter storms (Case E).
breaking waves. When wind direction changes and/or wind velocity decreases at the end of winter storm, the type of "end-storm undertow" occurs. When the water surface gradient which is generated by wind and wave-induced cross shore currents loses its balance in the midst of the storm, the type of "mid-storm undertow" occurs. Wave-induced cross shore currents is mainly generated in the surf zone by wave breaking, which may form the velocity profile of the so-called undertow together with wind-induced cross shore currents. Note that the mechanism of this undertow is different from two types of strong offshore-going currents. The intensity of offshore-going sediment transport by "end-storm undertow" and "mid-storm undertow" may have to be made clear to evaluate the total volume of losing sand by storms.

4. Wind Stresses in the Nearshore Zone

As wind-induced current is the main factor of sediment transport, especially longshore transport, evaluation of wind stresses in the nearshore zone is one of the most important tasks of beach change prediction under the storm condition. Stress factors represent the exchange of momentum between atmosphere and ocean, and between ocean and sea bed. Air-sea momentum exchange is controlled by the waves; it is a complex process involving turbulent boundary-layer flow over a moving rough surface, wave generation, non-linear energy transfer between wave components, and wave breaking. Besides, waves also affect the bottom stress by increasing turbulence in the bottom boundary layer and eddy viscosity, hence facilitating momentum transfer. These processes are not very well understood theoretically, especially under strong winds and high waves, and therefore they are not incorporated into the models. If they could be better explained, then, in principle, the accuracy of the corresponding forcing terms in the equations of motion for nearshore currents could be improved.

Following is an analysis of wind data over the surf zone aimed to formulate wind stresses in terms of a drag coefficient. Wind turbulence was measured by a three-components ultrasonic anemometer, located on top of the observation pier, 10m above the mean sea level. Wind data were continuously recorded at a 10Hz sampling frequency, and analyzed by means of the Turbulence Dissipation Method (Yelland et al., 1996). Wind data observed have been classified into four types according to the wind direction relative to the pier (TOP), as defined in Fig. 9. Almost all winds stronger than 10m/s are from the direction of south-west to north-west (Type I), in which the drag coefficient, $C_D$, estimated by TDM (10min in every hour) and the average wind speed at 10m, $U$, obey a linear relationship in a semi-log plot as shown in Fig. 10. The following fitting formula has been obtained:

$$C_D = 0.0223 \left( \frac{10}{3} \right)^{15} U$$ (1)

The drag coefficient usually increases with the wind speed in the ocean, but observed drag coefficient indicates the opposite tendency in the nearshore zone. The effect of long-crestedness and steepness of waves in the shallow water may cause larger drag coefficient and wave breaking may cause such an inverse trend vs wind speeds.
Figure 8: The hourly changes in vertical profiles of on-offshore (left) and longshore (right) in Case B.

Figure 9: Wind data classification (four types) according to the wind direction relative to the pier (TOP).
5. Conclusions

This study is a screening of a set of wind and current data recorded in the surf zone during a two and half months period from an observation pier. Winds and waves were observed simultaneously and continuously in the nearshore zone, at a location alternately inside the surf zone and outside, depending on the state of the sea. This long-term observation revealed the structure of currents and the characteristics of the wind drag in the nearshore zone; main results are summarized below:

(1) There are two types of wind/wave climates which cause strong offshore-going currents. One is the type called "end-storm undertow" which is defined that sudden bursts of current occur with changes in wind directions from westerly to easterly with reduction of wind velocity at the end of the winter storms. The other is the type called "mid-storm undertow" which is defined that continuous strong shore-normal(NW) winds generate strong undertow in the midst of storm.

(2) Both offshore and longshore current profiles are vertically uniform underneath the wave trough level.

(3) Direction of longshore currents is much more sensitive to the wind direction than waves. Strong longshore current is mainly induced by winds in the wide area of nearshore zone and its direction is shore-parallel. Wave-induced longshore current is much smaller than wind-induced one.
Wave-induced cross shore currents is mainly generated in the surf zone by wave breaking, which may form the velocity profile of the so-called undertow together with wind-induced cross shore currents.

Drag coefficient in the near shore zone was empirically formulated with relation to the wind speed in the range of over 10m/s, which shows the opposite tendency to that in deep waters.

Acknowledgements

The authors would like to express our thanks to Mr. Kiyoshi Uchiyama, technician in Ogata Wave Observatory, for his kind help in observations. This study was funded by the Ministry of Education, Science, Sports and Culture of Japan as the Research Project, Grant-in-aid for Scientific Research (1997-1998), contract No.09555157, (the chief researcher, Takao Yamashita, Kyoto University). Support for a part of observation was also received from the NEWJEC Consultants Inc, Osaka, Japan.

Numerical Modeling of Nearshore Circulation on a Barred Beach with Rip Channels

K.A. Haas, I.A. Svendsen and M.C. Haller

Abstract

A nearshore circulation modeling system has been applied to a closed wave basin with a longshore bar and two rip channels. The major characteristics of the flow pattern have been established by the model including the recirculation cells, the feeder currents and the bias of the rip current toward the center of the basin. Wave current interaction is established as one of the significant mechanisms in the flow. The parameters for the eddy viscosity and the bottom friction have been shown to influence the stability of the flow. The flow is generally fluctuating and large vortex systems are formed. The model results are compared with the experimental data matching magnitudes of mean velocities as well as trends of oscillations.

Introduction

The concept of rip currents was first introduced by Shepard (1936). Since then there have been many attempts to observe rip currents in the field, such as the observations by Shepard et al. (1941), Shepard and Inman (1951), McKenzie (1958), and Sonu (1972) to name a few. All of these studies noted that the rip currents were not steady but were transient in nature which contributed to the difficulty in obtaining accurate measurements in the field. Shepard and Inman (1951) noted that the rip current seemed to be pulsating and that eddies were being generated. Rip currents usually are described to be fed by feeder currents, although flow entrainment can be important or even dominate as described by Shepard et al. (1941) and McKenzie (1958).

There have also been several theoretical studies of rip currents, such as Arthur (1962) who showed that the conservation of potential vorticity requires the rip currents to become more narrow as they flow offshore. The flow across and behind

longshore bars was analyzed by Dalrymple (1978) using a simple linear model. The cross-shore flow was analyzed by the theoretical and experimental work of Svendsen and Hansen (1986) and Hansen and Svendsen (1986). These works addressed the issue of interaction between the breaking waves and circulation currents and the driving mechanisms for those currents. Computational results of a simplified version of the present model for flow over a rip channel and barred beach showed that on barred beaches with rip channels the longshore variations are important (Sancho et al, 1995). Particularly, the longshore pressure gradients strongly contribute to the longshore momentum balance.

**Present Problem**

Dalrymple (1978) provided two classifications of the generating mechanisms for rip currents, wave interaction and structural interaction. In this study we look at rip currents in the structural interaction class. Specifically, we are modeling the experiment of normal incident waves in a closed wave basin with a longshore bar and two rip channels as outlined by Haller et al. (1997a,b). The bathymetry used in the model was taken from a detailed survey of the wave basin and is shown in figure (1). The two rip channels were intended to be symmetric to each other although they clearly have some differences. The bars also exhibit longshore non-uniformities which will have an impact on the circulation.
Figure (2) shows a schematic diagram outlining the general flow patterns for the nearshore region of the basin. The short waves are normally incident with a period of 1 s and an off-shore wave height of 4.8 cm. These waves propagate toward the shore and start breaking over the bars, as indicated in the drawing, creating a setup in the mean water level. The waves are not breaking as much in the channels, therefore the mean water level is lower in the channels, which creates a longshore pressure gradient from the bars directed toward the channels. This pressure gradient is driving the currents towards the channels, creating the feeder currents for the rips.

Because the waves have not broken as much in the channels, these waves will be larger and therefore break earlier than the waves behind the bar as they approach the shoreline. This will create a larger setup, or a bump in the mean water level, close to the shoreline behind the channel. Therefore, a longshore pressure gradient will drive flow away from the channels creating secondary or recirculation cells close to the shoreline. Note that the circulation is highly dependent on the breaking pattern; if the waves did not break on the bar then there would be no recirculation cells and the feeder currents for the rips would be much smaller.

**Model Equations**

The model system is the SHORECIRC which consists of a short wave transformation component ("wave driver") and a short wave-averaged component, working
simultaneously to simulate the short and long wave motions, and their interactions, in the nearshore regions. The short wave model REF/DIF (Kirby and Dalrymple, 1994) is used as the wave driver accounting for the effects of bottom induced refraction-diffraction, current induced refraction and wave breaking dissipation by solving the parabolic equation initially developed by Kirby and Dalrymple (1983).

The nearshore circulation model used is SHORECIRC, as described in Van Dongeren et al. (1994) and Van Dongeren and Svendsen (1997), which determines the flow pattern by solving the quasi-3D short wave-averaged hydrodynamic equations given below.

\[
\frac{\partial \bar{Q}_x}{\partial t} + \frac{\partial \bar{Q}_x}{\partial x} + \frac{\partial \bar{Q}_y}{\partial y} = 0
\]  

\[
\frac{\partial \bar{Q}_x}{\partial t} + \rho \frac{\partial}{\partial x} \left( \frac{\bar{Q}_x^2}{h_o + \bar{\zeta}} \right) + \frac{\partial}{\partial y} \left( \frac{\bar{Q}_x \bar{Q}_y}{h_o + \bar{\zeta}} \right) + \rho g \left( h_o + \bar{\zeta} \right) \frac{\partial \bar{\zeta}}{\partial x} 
+ \frac{\partial}{\partial x} \left( \frac{S_{xx}}{h_o + \bar{\zeta}} - \int_{-h_o}^{\zeta} \tau_{xx} dz \right) + \frac{\partial}{\partial y} \left( \frac{S_{xy}}{h_o + \bar{\zeta}} - \int_{-h_o}^{\zeta} \tau_{xy} dz \right) - \tau_S^x - \tau_B^x 
+ \rho \frac{\partial}{\partial x} \int_{-h_o}^{\zeta} V_{1x} V_{1x} \, dz + \rho \frac{\partial}{\partial y} \int_{-h_o}^{\zeta} V_{1y} V_{1x} \, dz 
+ \rho \frac{\partial}{\partial x} \int_{-h_o}^{\zeta} u_{wx} V_{1x} + u_{wx} V_{1x} \, dz + \rho \frac{\partial}{\partial y} \int_{-h_o}^{\zeta} u_{wy} V_{1x} + u_{wy} V_{1x} \, dz = 0
\]  

\[
\frac{\partial \bar{Q}_y}{\partial t} + \rho \frac{\partial}{\partial y} \left( \frac{\bar{Q}_y^2}{h_o + \bar{\zeta}} \right) + \frac{\partial}{\partial x} \left( \frac{\bar{Q}_x \bar{Q}_y}{h_o + \bar{\zeta}} \right) + \rho g \left( h_o + \bar{\zeta} \right) \frac{\partial \bar{\zeta}}{\partial y} 
+ \frac{\partial}{\partial x} \left( \frac{S_{xy}}{h_o + \bar{\zeta}} - \int_{-h_o}^{\zeta} \tau_{xy} dz \right) + \frac{\partial}{\partial y} \left( \frac{S_{yy}}{h_o + \bar{\zeta}} - \int_{-h_o}^{\zeta} \tau_{yy} dz \right) - \tau_S^y - \tau_B^y 
+ \rho \frac{\partial}{\partial x} \int_{-h_o}^{\zeta} V_{1y} V_{1y} \, dz + \rho \frac{\partial}{\partial y} \int_{-h_o}^{\zeta} V_{1y} V_{1y} \, dz 
+ \rho \frac{\partial}{\partial x} \int_{-h_o}^{\zeta} u_{wx} V_{1y} + u_{wx} V_{1y} \, dz + \rho \frac{\partial}{\partial y} \int_{-h_o}^{\zeta} u_{wy} V_{1y} + u_{wy} V_{1y} \, dz = 0
\]

where \( x \) and \( y \) are the cross-shore and longshore directions, the overbar represents wave-averaging, \( \bar{\zeta} \) is the mean water level, \( \bar{Q}_x \) is the wave-averaged volume flux in the \( \alpha \) direction, \( \rho \) is the water density, \( h_o \) is the still water depth, \( S_{\alpha\beta} \) is the radiation stress, \( \tau_{\alpha\beta} \) is the turbulent stress, \( \tau_S^x \) and \( \tau_B^x \) are the surface and bottom shear stresses in the \( \alpha \) direction, \( V_{1\alpha} \) is the depth varying portion of the currents and \( u_{wx} \) is the short wave velocity. Equation (1) is the conservation of mass, equation (2) the cross-shore or \( x \)-momentum balance and equation (3) the longshore or \( y \)-momentum balance.

The first three terms in the momentum balances (equations (2) and (3)) are the local accelerations and the convective accelerations. The next term is the pressure
gradient followed by the gradient of the radiation and turbulent stresses. In this study the turbulent normal stresses are neglected (i.e. the terms $\tau_{xx}$ and $\tau_{yy}$) because they are usually considered small compared to the turbulent shear stresses. The surface shear stresses are also neglected since we are modeling a closed basin inside a laboratory. The last four terms on the left-hand side are the quasi-3D terms which act as a dispersive mixing mechanism. Traditional nearshore circulation models assume depth uniform currents which would mostly eliminate those four terms. Because this is the beginning of the study, we will also assume depth uniform currents, although, in future studies the importance of depth varying currents will be analyzed in greater detail.

The turbulent shear stresses are modeled by utilizing an eddy viscosity approach given by the following expressions, (Sancho, 1997),

$$
\tau_{xy} = \rho \nu_t \left( \frac{\partial V_y}{\partial x} + \frac{\partial V_x}{\partial y} \right)
$$

(4)

where $\nu_t$ is the eddy viscosity given by

$$
\nu_t = C_1 u_o h + M h \left( \frac{D}{\rho} \right)^{\frac{1}{2}}.
$$

(5)

Here $C_1$ is a constant coefficient, $u_o$ the bottom orbital velocity, $h$ the total water depth, $D$ the energy dissipation rate per unit area of the short waves, and $M$ a constant taken to be 0.1. This eddy viscosity formulation accounts for both bottom induced and wave breaking turbulence. The first term in equation (5) represents the bottom induced turbulence which is always present and the second term represents the wave breaking turbulence which is only present in the surf zone.

The bottom shear stress is modeled using the generalized friction factor approach for waves and currents as outlined by Svendsen and Putrevu (1993),

$$
\tau^B_\alpha = \frac{1}{2} \rho f_{cw} u_o (\beta_1 V_{0x} + \beta_2 u_{0x})
$$

(6)

where $\beta_1$ and $\beta_2$ are given by

$$
\beta_1 = \left[ \left( \frac{V_b}{u_o} \right)^2 + 2 \frac{V_b}{u_o} \cos \theta \cos \mu + \cos^2 \theta \right]^{\frac{1}{2}}
$$

(7)

$$
\beta_2 = \cos \theta \left[ \left( \frac{V_b}{u_o} \right)^2 + 2 \frac{V_b}{u_o} \cos \theta \cos \mu + \cos^2 \theta \right]^{\frac{1}{2}}.
$$

(8)

$\beta_1$ and $\beta_2$ are weight factors for the current and wave motion respectively and $f_{cw}$ is the bottom friction factor.
Figure 3: Time-averaged below-trough velocity vectors from (A) experimental data (described by Haller et al. (1997b)) and (B) SHORECIRC.

**Qualitative Results**

Figure (3) shows the below-trough velocity vectors for the experimental data on the left-hand side and the model results on the right-hand side. The experimental data was time-averaged for 819 seconds over the last half of the experiment. Only three velocity gauges were used at a time, however, there was a high rate of repeatability allowing all the time-averaged properties to be examined simultaneously. The model results were time-averaged over 750 seconds after beginning from a cold start for 200 seconds. The model data results from a single model run in which the velocities were the qualitative best fit with the experimental data.

The majority of the experimental data is gathered around the upper rip channel so we will primarily focus on the flow around that rip channel. The rip currents are easily identifiable in the channels for both the experiment and model. In both diagrams of figure (3), the rip currents vanish just seaward of the channel. The rips are also biased toward the center of the basin in both the experiment and the model. The flow leaving the rip channel in the model turns toward the center of the basin and flows back onto the bar and then runs shore parallel, similar to the experimental
results. The magnitude of the rip currents in the channel also are similar. The rip in
the model has flow entrainment which causes the rip to widen offshore. The model
from Arthur (1962) predicts that the rips should become narrower but that model
does not allow for flow entrainment.

The recirculation cells discussed earlier are clearly evident in both the experiment-
tal and the model results. However, the experiment shows a stronger shoreward flow
behind the channel close to the shoreline, which is not present in the model results.
This will be discussed in greater detail later. The two recirculation cells for the upper
rip in the model are unequal due to the irregularities in the bathymetry previously
mentioned. The flow around the two rip channels also exhibit many differences which
is a result of the seemingly minor differences in the bathymetry of the channels. We
also noticed that the feeder currents are similar between the two figures with the
upper feeder currents being at a slight angle toward the channel and the lower feeder
currents being shore parallel. The magnitude of the currents behind the bar are
similar between the two cases.

Wave Current Interaction

The wave current interaction is accounted for in the model system and proves to be
an important mechanism, particularly around the strong rip currents. The governing
equation in REF/DIF accounts for the effect of large currents including the doppler
shift due to currents.

The wave current interaction is modeled interactively by initially determining
the short waves without currents and then calculating the resulting currents with
SHORECIRC. The currents and mean water level are fed back into REF/DIF to
determine the new wave field. This process is constantly repeated to provide for the
wave current interaction. In the present study the short waves are calculated approx-
imately once every short wave period. The wave field, and therefore the forcing, only
has small changes over this short time scale, providing smooth transitions between
the different forcings.

The effect of including the wave current interaction is shown in figures (4), (5) and
(6). Figure (4) shows the cross-shore sections of the short wave height across the center
bar and through the channel for cases with and without wave current interaction. In
general, the waves over the bar shoal and break on the bar (as indicated by the steep
decline in wave height), then reform, shoal and break at the shoreline. On the other
hand, the waves in the channel only have a single break point and, therefore, tend
to start breaking earlier as they approach the shoreline. We see that inclusion of the
currents causes the wave heights in the channel to increase slightly and the onset of
breaking occurs farther offshore in the channel. The comparisons with experimental
data shows that these trends, if not the exact magnitudes, are matched. It is more
important to match the gradient of the wave heights because the forcing is due to the
gradient of the radiation stresses which is proportional to the gradient of the wave
height.

Figure (5) shows the mean water level for the same two cross-shore sections with
Figure 4: Comparison of time-averaged modeled short-wave height with and without wave current (w/c) interaction to experimental data (described by Haller et al. (1997b)).

and without wave current interaction again. The longshore pressure gradient between the channel and the bar is evident between $x = 12 - 13.5$ m. This longshore pressure gradient is reversed, although much smaller, closer to the shoreline. The effect of the wave current interaction on the mean water level is most evident in the channel around $x = 12 - 13.5$ m where the water level is significantly reduced. Everywhere else the differences appear to be insignificant. In particular, the changes along the center of the channel due to the currents turn out to be important, even though they may appear small. However, it is emphasized that although the sine wave theory of REF/DIF has been modified, it does not model the forcing of breaking waves accurately.

Finally, figure (6) shows the vorticity and below trough velocity vectors demonstrating the most significant impact of the wave current interaction on the circulation pattern. The most significant change is that with the wave current interaction included, the rip current does not extend very far offshore of the channel and is biased toward the center of the basin. The recirculation cells are smaller and do not extend over the bar as they do for the case without wave current interaction. The experimental data in figure (3) also shows that the rip vanishes and is biased toward the center of the basin. We have found that this effect is only achieved in the model if we include the wave current interaction.

Selection of Parameters

The important flow parameters which have been adjusted to fit the experimental data are the eddy viscosity coefficient (C_1) and the bottom friction factor (f_w). The parameter C_1 is varied between 0.001 and 0.01. This parameter will change the eddy viscosity due to the bottom induced turbulence. Therefore, changing the parameter will primarily affect the flow outside the surfzone because the term representing breaking wave conditions will dominate inside the surfzone. The friction factor is estimated from Jonsson (1966) and has a range from 0.01 to 0.035 accounting for the uncertainty in bottom roughness and the variable flow conditions.

Figure (7) shows velocity profiles for longshore sections at four cross-shore locations; moving down, at the shoreline (x = 14 m), in the trough (x = 13 m), over the bar (x = 11.25 m) and seaward of the bar (x = 10 m). This figure shows two cases with an eddy viscosity coefficient, C_1, of 0.001 and 0.01 and the friction factor being held constant at f_w = 0.03. The most significant change occurs in the longshore velocity offshore of the bar, where the velocity for the higher eddy viscosity is slightly reduced. The increased eddy viscosity tends to help stabilize the flow, therefore significantly reducing the meandering of the rip current. Less meandering of the rip current will produce less time-averaged longshore velocity in the rip.

Figure (8) shows velocity profiles of the same longshore sections for f_w = 0.015 and f_w = 0.03 and C_1 being held constant at 0.001. The variation between the two
Figure 8: Comparison of time-averaged below-trough velocity for cross-shore (Um) and longshore (Vm) flow with experimental data (described by Haller et al. (1997b)). Solid line (-) is for \( f_w = 0.03 \), dashed line (- -) is for \( f_w = 0.015 \) and asterix (*) is the experimental data.

Cases is much more significant. As with the eddy viscosity, increasing the bottom friction tends to stabilize the flow. The time-averaged cross-shore velocity in the rip current tends to be larger for higher friction factors because less meandering of the current produces less mixing. The longshore velocity for the lower friction case for the farthest offshore sections tends to be antisymmetric (i.e. the current is positive on one side of the rip channel and negative on the other), whereas the higher friction tends to have the longshore current in one direction. The lower friction factor allows the rip to meander fairly equally in both directions whereas the higher friction factor, and experimental data, shows a bias toward the inside of the basin. Even though the higher friction case has smaller instantaneous velocities, the time-averaged velocities in the rip are higher because the flow is more stable with less mixing.

Multiple cases for the range of the eddy viscosity coefficient, \( C_1 \) between 0.001 and 0.01, and the bottom friction factor, between \( f_w = 0.015 \) and 0.03 were run to obtain the best fit with the experiments. From these different cases the best visual match of the currents with the experimental data was selected. The parameters that best fit the data turned out to be \( C_1 = 0.001 \) and \( f_w = 0.03 \). These are the same parameters used for the model results in figure (3). The relatively high \( f_w \) is in conjunction with the small scale experiment where the boundary layer is in the laminar-turbulent transition region. Figure (9) shows the currents for the final selection of parameters for cases with and without wave current interaction in the same longshore sections as figures (7) and (8). This figure demonstrates that the inclusion of the wave current
interaction improved match with the measured data, particularly the flow around the rips.

Close to the shoreline, the top panels in figure (9), the cross-shore velocity is too small and the longshore velocity is too large. This is probably a result of the recirculation cells in the model being shifted seaward relative to the experiments because the shoreline boundary condition is a wall with an average still water depth around 6 mm. Presumably, utilizing a moving shoreline condition could improve the match with data close to the shoreline. The recirculation cells being shifted seaward could also explain why the cross-shore velocity in the trough (second panel on the left) is less accurately predicted.

Some of the inaccuracies around the rip channels and in the trough region between the bar and the shoreline could be a result of incorrect breaking patterns. The short wave driver uses a bottom induced breaking criteria which causes the waves in the channel to break closer to the shoreline. Visual observation of the experiments showed that the waves in the channels were breaking somewhat earlier due to the increased short wave steepness from the opposing current. Correctly predicting the breaking pattern and the forcing due to the breaking waves would also improve the comparison with the data, although, in general, the magnitudes of the currents from the model match fairly well with the experimental data.

Finally it may be noticed that only the time-averaged properties of the flow field are presented here because they provide the best means of comparison with the experiments. The time varying properties of the currents and mean water level show many similarities with the experiments. The flow for both cases is unstable. The rip has instabilities on several time scales, typically a faster scale \(\sim 20 \text{ seconds}\), which appears to be related to the instability of a jet and slower motions with scales \(\sim 100 - 300 \text{ seconds}\). The experiments (Haller et al., 1997b) have shown similar trends. The model also shows eddies being created and shed from the rips as well as from the flow behind the bar. The time series from the experiments show some evidence of eddies passing through the sensors in a similar fashion.

**Conclusions**

A study on rip currents has been performed by applying a numerical nearshore circulation model system to an experiment in a closed wave basin with a barred beach containing two rip channels. The breaking pattern resulting from this bathymetry has been identified to be an important driving mechanism of the nearshore currents. Significant changes occur when the wave current interaction is included in the model system such as the rip current vanishing quickly offshore and being biased toward one side as is also found in the experiments. In general, the model and experiments are in agreement.

The effect of several flow parameters has been analyzed including the eddy viscosity and the bottom stress. Both parameters are a factor in controlling the stability of the flow. Decreasing either parameter causes the flow to become more unstable. These parameters can be varied to give a qualitative best fit of the modeled cur-
Figure 9: Comparison of time-averaged below-trough velocity for cross-shore (Um) and longshore (Vm) flow with experimental data (described by Haller et al. (1997b)). Solid line (-) is with wave current interaction, dashed line (- -) is without wave current interaction and asterix (*) is the experimental data.

rents to the experimental data. Changes in the eddy viscosity does not produce large changes in the flow pattern. Variations in the bottom stress are more important. The values of the two coefficients selected for matching the experimental data are physically realistic. Currents have been assumed depth uniform in this preliminary study.

APPLICABILITY OF A QUASI-THREE DIMENSIONAL NUMERICAL MODEL TO NEARSHORE CURRENTS

Masamitsu Kuroiwa¹, Hideaki Noda² and Yuhei Matsubara³

ABSTRACT

This paper presents a quasi-three dimensional numerical model of wave-induced current due to wave breaking so as to make it applicable to the coastal region with the coastal structures. First, applicability of the present model to undertow velocity and longshore current field was investigated. Secondly, laboratory tests were carried out to examine the characteristics of nearshore currents around the detached breakwater. Thirdly, nearshore currents around the breakwater were computed using the present numerical model. Finally, the results of computation were compared with those of laboratory tests and the applicability of the numerical model was discussed.

INTRODUCTION

The objective of this study is to develop a simple quasi-three dimensional model (Q-3D model) of nearshore currents so as to make it applicable to the coastal region with the coastal structures.

The nearshore currents have been previously predicted by using two-dimensional model in the horizontal plane (2DH model). However, in the surf zone the direction of current vectors near water surface is different from that at sea bottom because of effect of undertow velocities. The currents have spiral profiles in the vertical direction. In order to predict the change of beach profile and dispersion of pollutants exactly, it is very important to determine the three dimensional distribution of nearshore currents.

Recently, some models for determining the three dimensional currents have been proposed. Svendsen et al. (1989) presented an analytical model composed of cross-shore and alongshore current velocities. Sanchez et al. (1992) proposed a Q-3D numerical model by combining 2-DH model and one-dimensional model in the vertical direction (1-DV model). Okayasu et al. (1994) proposed a Q-3D numerical model with the effect of the momentum flux due to the large vortexes formed on

the front face of breaking waves. These models have been only applied to straight coast without coastal structures. On the other hand, Pechon et al. (1994) have proposed a quasi-three dimensional numerical model and tried to calculate the nearshore current around the coastal structures. However, comparison with measured data has not been done. The applicability of these models should be confirmed by comparing with the measured data and a predicted model on nearshore currents must be completed by above mentioned procedure.

In this study, a Q-3D numerical model based on the solution method by developed Koutitas et al. (1980) is proposed. The applicability of the Q-3D model to undertow, longshore currents and nearshore currents around the coastal structures is investigated by comparing with the experimental results.

**NUMERICAL MODEL**

The present model consists of two modules. Wave and steady current velocity field are determined separately without wave-current interaction.

**Wave field module**

Wave field can be obtained from the time-dependent mild slope equations proposed by Watanabe et al. (1984). The governing equations are as follows:

\[
\frac{\partial Q_x}{\partial t} + \frac{1}{n} C^2 \frac{\partial n \eta}{\partial x} + f_D Q_x = 0 \quad \text{---------------------------(1)}
\]

\[
\frac{\partial Q_y}{\partial t} + \frac{1}{n} C^2 \frac{\partial n \eta}{\partial y} + f_D Q_y = 0 \quad \text{---------------------------(2)}
\]

\[
\frac{\partial \eta}{\partial t} + \frac{\partial Q_x}{\partial x} + \frac{\partial Q_y}{\partial y} = 0 \quad \text{---------------------------(3)}
\]

where \( Q_x \) and \( Q_y \) are the depth-integrated flow rates per unit width by waves in the cross-shore (x) and alongshore direction (y) respectively, \( t \) the time, \( C \) the wave celerity, \( \eta \) the surface elevation, \( n \) the ratio of group velocity to \( C \), \( f_D \) the attenuation factor by wave breaking. The attenuation factor \( f_D \) is estimated as follows:

\[
f_D = \alpha_D \tan \beta \sqrt{\frac{g}{h} \left( \frac{\hat{Q}}{Q_r} - 1 \right)} \quad \text{---------------------------(4)}
\]

\[
\hat{Q} = \sqrt{\hat{Q}_x^2 + \hat{Q}_y^2} \quad \text{---------------------------(5)}
\]

\[
Q_r = 0.25 \sqrt{gh^3} \quad \text{---------------------------(6)}
\]

where \( \alpha_D \) is the non-dimensional coefficient, which is 2.5. \( \tan \beta \) is the bottom slope, \( \hat{Q} \) is the amplitude of flow rate, \( Q_r \) is the amplitude of the flow rate of recovered waves.

The governing equations for wave field are solved by using the explicit finite difference method on a staggered rectangular grid region.
Nearshore current module

Governing equations

The governing equations are derived from the 3-D Navier-Stokes equations. The equations of motion for Q-3D nearshore currents proposed by Svendsen et al. (1989) may be expressed as

\[
\begin{align*}
\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} + W \frac{\partial U}{\partial z} &= -g \frac{\partial \zeta}{\partial x} - \frac{\partial S_{xx}}{\partial x} - \frac{\partial S_{xy}}{\partial y} \\
&+ \frac{\partial}{\partial x} \left( v_h \frac{\partial U}{\partial x} \right) + \frac{\partial}{\partial y} \left( v_h \frac{\partial U}{\partial y} \right) + \frac{\partial}{\partial z} \left( v_v \frac{\partial U}{\partial z} \right) \\
\end{align*}
\]

\[(7)\]

\[
\begin{align*}
\frac{\partial V}{\partial t} + U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} + W \frac{\partial V}{\partial z} &= -g \frac{\partial \zeta}{\partial y} - \frac{\partial S_{yy}}{\partial y} - \frac{\partial S_{yx}}{\partial x} \\
&+ \frac{\partial}{\partial x} \left( v_h \frac{\partial V}{\partial x} \right) + \frac{\partial}{\partial y} \left( v_h \frac{\partial V}{\partial y} \right) + \frac{\partial}{\partial z} \left( v_v \frac{\partial V}{\partial z} \right) \\
\end{align*}
\]

\[(8)\]

where \( U, V \) and \( W \) are steady current velocities in the \( x, y \) and \( z \) directions, respectively as shown in Figure 1. \( \zeta \) is the mean water level, \( S_{xx}, S_{xy}, S_{yx} \) and \( S_{yy} \) represent the excess momentum fluxes (radiation stresses) due to waves. These values are estimated by solving the time-dependent mild slope equations (1)-(6), which include the effect of reflection and diffraction around the coastal structures such as detached breakwaters. \( v_v \) and \( v_h \) represent the turbulent eddy viscosity coefficients in the vertical and horizontal direction, respectively. \( v_h \) is estimated by using the method presented by Longuet-Higgins (1970). The eddy viscosity coefficient \( v_v \) plays a very important roll in the determination of the vertical distribution of nearshore currents. The effects of the eddy viscosity coefficients must be examined. Two types of the coefficients are proposed. One is assumed that the value is constant in the vertical distribution. A simple method proposed by Tsuchiya et al. (1986) is used, according to the following relationship:

\[
v_v = ACH \quad (9)
\]

where \( C \) is the wave celerity, \( H \) is the wave height and \( A \) is the non-dimensional constant. \( A \) is set to be 0.01. The other is assumed that the coefficient is quadratic function as follows;

\[
v_v = A_v CH \left( \frac{z + h}{h} \right)^2 + B_v CH \quad (10)
\]

where \( A_v = 0.01, B_v = 0.001 \).

The continuity equation is as follow:
\[
\frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} + \frac{\partial W}{\partial z} = 0 \quad \text{(11)}
\]

and the depth-integrated continuity equation is:

\[
\frac{\partial \bar{z}}{\partial t} + \frac{\partial \bar{U}(h + \bar{z})}{\partial x} + \frac{\partial \bar{V}(h + \bar{z})}{\partial y} = 0 \quad \text{(12)}
\]

where \( \bar{U} \) and \( \bar{V} \) are the depth-averaged steady currents. The steady current velocity \( W \) in the vertical direction is determined from Eq. (11) and the mean water level \( \bar{z} \) is determined from Eq. (12).

**Boundary conditions and solving method**

In this study, shoreline, offshore and side wall in the small basin are assumed fixed boundaries, namely, the velocity components normal to those boundaries can be taken as zero.

The boundary conditions in the mean water surface and bottom are needed to determine the vertical distribution of the currents. In general, the boundary condition at the free surface is the no-flux condition. However, in the case that mass transport due to wave breaking is dominant in the surf zone, shear stress due to water surface rollers must be considered. The stress is given by taking account of the effect of surface roller based on Svendsen's model (1989) as follows

\[
\tau_s = A_s \rho gh \tan \beta \left( \frac{H}{h} \right)^2 \left( 2.7 \frac{h}{L} \right) \quad \text{(13)}
\]

where \( H \) is the wave height, \( h \) the water depth and \( L \) the wave length, \( \tan \beta \) is bottom slope. \( A_s \) is constant value, which is determined empirically by comparing computed nearshore currents with experimental data, that is, \( A_s = 0.5 \sim 1.0 \). The boundary conditions at mean water level are given by

\[
V, \left. \frac{\partial U}{\partial z} \right|_{z = \bar{z}} \cos \alpha / \rho \quad V, \left. \frac{\partial V}{\partial z} \right|_{z = \bar{z}} \sin \alpha / \rho \quad \text{(14)}
\]

where \( \alpha \) is the wave direction.

The boundary conditions at bottom level are given as

\[
V, \left. \frac{\partial U}{\partial z} \right|_{z = -h} = \tau_{bx} / \rho \quad V, \left. \frac{\partial V}{\partial z} \right|_{z = -h} = \tau_{by} / \rho \quad \text{(15)}
\]

in which \( \tau_{bx} \) and \( \tau_{by} \) are the shear stresses due to bottom friction, which include the effect of interaction between the steady current and wave oscillatory motion.

The equations (7) to (12) are solved by using the hybrid method proposed by Koutitas et al. (1980), which combines the fractional step finite difference method in the horizontal plane with the Galerkin finite element method in the vertical direction.

**RESULTS AND DISCUSSIONS**

**Undertow under spilling breaker**
Experimental Apparatus

The laboratory tests under the spilling breaker were carried out in two-dimensional wave tank with beach slope of 1:15. The incident wave height in horizontal bottom where is 40 cm deep was 13.1 cm and the wave period was 1.01 sec. The water particle velocities in the surf zone were measured by using the two components Laser Doppler Anemometer (LDA). Measurement points were set at the interval of 1-2 cm distance from 2 mm above the bottom to trough level in the vertical direction and 3 cm distance in the cross-shore direction.

Computed results and comparisons with measured data

Figure 2 shows an example of the computed results of velocity field in the vertical plane. The present model can predict the wave set-up and circulation flow in the surf zone. It is confirmed that undertow velocities can be reproduced in lower layer. If $A_s=0$ in Eq. (13), which shows $\tau_s=0$ at mean water surface level in the surf zone, circulation flow may not be generated. Therefore, the shear stress due to surface roller plays an important role in the production of the undertow velocities.

Figure 3 shows the comparison of vertical distribution of undertow velocities between the calculated results and measured data. The effect of eddy viscosity coefficient to the vertical distribution of nearshore currents was examined. In this figure, solid line and dotted line are the computed results by using the eddy viscosity coefficient of quadratic (referenced Eq. (10)) and constant types (referenced Eq. (9)), respectively, and symbol circle shows experimental results. From these figures, both computed curves which describe the vertical distribution of undertow velocity are coincident, although the eddy viscosity coefficients used are different in both curves, and then, the constant type of eddy viscosity coefficient is used because constant type is simpler than quadratic one. Finally, it is clear that computed curves show good agreement with measured data.

![Figure 2 Example of flow pattern in the surf zone obtained from the present model](image-url)
Figure 3 Comparison of vertical distributions of undertow velocities between computed and measured results

**Longshore Currents**

The present model is applied to determine the vertical profile of longshore currents. The results of calculation are compared with those of laboratory tests conducted by Visser (1991). The wave condition is shown in Table 1. Figure 4 shows the comparison of the depth-integrated longshore current between the computed results and measured data. In this figure, solid line and symbol circles are the computed results and the measured data, respectively. It is found that the computed results agree with the measured data. Figure 5 shows the comparisons of vertical distribution of longshore currents between the computed results and measured data. Figures 5 (a), (b) and (c) correspond to the points as shown in Figure 4. In these figures, solid lines and dotted lines are the computed alongshore components \( V \) and cross-shore components \( U \), respectively. Combining the cross-shore and alongshore components, it is clear that the longshore currents have spiral profile in the vertical direction. The computed velocities \( V \) agree with the measured longshore velocities.

Nearshore Currents around Detached Breakwater

Experimental Apparatus

The laboratory tests under two regular wave conditions were carried out in the small wave basin (12m × 5.0m × 0.6m) with the beach slope of 1:10 as shown in Figure 6. The water depth adopted in this experiment was 0.3m at the toe of beach slope. Steel wave-guides along direction of the wave propagation were placed in the basin. The half-detached breakwater model in a width of 1m normal to the incident wave was installed at 0.15m deep on the beach slope.
The wave condition is shown in Table 2. The surface elevations behind the breakwater model were measured using capacitance type wave gages. Cross-shore and longshore components of water particle velocities below the trough level behind the breakwater model were measured by using bi-axial electro-magnetic velocity meters. The measuring points were arranged with every 20 cm long in the horizontal direction and 2 cm high in the vertical one. The velocity data were sampled at interval of 0.02 second. Steady current velocities were determined by time-averaged water particle velocity components.

Computed results and comparison with measured data

Figure 7 shows the domain of calculation and an example of distribution of wave height around the detached breakwater calculated from the mild-slope equations. In this figure, dotted line represents breaking line, which is determined as the ratio of water particle velocity to wave celerity, \( u_p/C > 0.45 \).
Figure 7 Domain of calculation and an example of wave field calculated from the mild-slope equations (Case 1; H_o=7.53cm, T=1.0s)

Figure 8 shows the comparison of the distribution of wave heights in the cross-shore direction between computed results and measured data for Case1. The computed results show good agreement with the experimental data.

Figures 9(a) and (b) show examples of the computed current vectors at mean water surface level and those at bottom level, respectively. In both figures, it is found that the magnitudes and directions of current vectors at mean water surface level are obviously different from those at bottom. Undertow velocities in the surf zone can be reproduced in the opening of the detached breakwater, and the spiral profiles can be reproduced in the surf zone.

Figures 10(a) and (b) show the vectors of steady current velocity behind the detached breakwater at 2cm above bottom for the experiments of Case1 and 2, respectively. In these figures, solid line and dotted line are breaker line obtained from the experiments and dotted one obtained from the computations. From the result for Case1 it is found that a circulation flow is generated behind the breakwater. On the other hand, the flow pattern for Case2 is non-closed circulation. The distribution of the steady current velocities for Case2 is different from that for Case1, and the magnitude of current velocity for Case2 is larger than that for Case1. It is clarified that the flow pattern depends on the wave condition.

Figures 11(a) and (b) show the computed vectors of steady current velocity at 2cm above bottom for Case1 and 2, respectively. It is found that the results of computations show qualitative agreement with those of experiments in Figures 9(a) and (b).
Figure 8 Comparison of wave height distribution between computation and experiment for Case1 (H_o=7.53cm, T=1.0sec)

Figure 9 Distribution of steady current vectors obtained from the present Q-3D model (Case1; H_o=7.53cm, T=1.0sec)
Figure 10 Distribution of current vectors at 2cm above bottom obtained from the laboratory tests.

Figure 11 Distribution of current vectors at 2cm above bottom obtained from the present Q-3D model.

Figures 12 and 13 show the comparisons between the vertical profiles of the computed results and those of the measured data for Case1 and Case2, respectively. Notations (a),(b),(c) and (d) in these figures correspond to results at the stations A,B,C and D behind the detached breakwater. In these figures, $U$ and $V$ represent cross-shore and alongshore components of steady current, respectively. From the results of measurement for Case1, cross-shore and alongshore current velocities at St.A,C and
D are almost constant over the depth. It is found that the computed results coincide with the measured data. From the results of experiments at St. B, the magnitude and direction of the cross-shore current $U$ near water surface is different from that near bottom. It is found that nearshore currents in the vicinity of the detached breakwater have spiral distribution in the vertical direction. The computed results for the cross-shore steady current $U$ show good agreement with the measured data. On the other hand, the computed $V$ are overestimated.

From the comparison for Case2 in Figure 13, it is found that the computed current velocities $U$ and $V$ at St. A, B, and D show qualitative agreement with the measured data, and the computed velocity $U$ at St. C in the opening of the breakwater is different from the measured data.
Figure 13 Comparisons of vertical distribution of nearshore currents behind the detached breakwater for CASE2 (H_o=12.25 cm, T=1.0s)

Most computed results show qualitative agreement with the laboratory tests. It was confirmed that the present Q-3D numerical model could apply to the prediction of nearshore currents around the coastal structures such as the detached breakwater.

CONCLUSIONS

This paper presented a numerical model for estimating the vertical profile of nearshore currents. The computed results were compared with the measured data. The applicability of the Q-3D model to nearshore currents was investigated. The main conclusions of this study are summarized as follows:
1) A quasi-three dimensional numerical model of nearshore currents was developed.
2) Undertow velocity and spiral profile in the surf zone can be reproduced by taking account of the shear stress due to breaking wave.
3) The vertical distribution of longshore currents was computed. The results were compared with the results of the laboratory tests conducted by Visser(1991). The computed results agreed with the measured data.
4) From the laboratory tests of the detached breakwater, it was found that the flow patterns behind the breakwater depend on the wave conditions.
5) From the experimental results in the vicinity of the detached breakwater, it was found that the magnitude and direction of nearshore currents near water surface is different from those near bottom from the experiments and it shows spiral distribution in the vertical direction.
6) The results of computation of nearshore currents around the breakwater using present Q-3D model show good agreement with those of experiments. The spiral profiles in the vicinity of the breakwater was computed.

It was confirmed that the numerical model could be applied to the determination of the distribution of currents around coastal structures.

Three-Dimensional Nearshore Currents Model Based on Vertical Distribution of Radiation Stress

Hisamichi Nobuoka¹, Nobuo Mimura² and Hajime Kato³

Abstract

Wave-induced currents in a surf zone must be explained by the change of wave motion. The driving force for nearshore currents is the radiation stresses which are defined as the excess momentum flux due to wave motion. However, there is no model which can describe the three-dimensional structure of the nearshore currents. This study aims to develop a model of this kind, in which only wave motion is taken as the driving force to the currents. Governing equations are derived from the Navier-Stokes equations. This model is proved to reproduce the currents measured in the experiments.

1. Introduction

Nearshore currents in a surf zone have a three-dimensional structure (e.g., Svendsen et al., 1989). They have been dealt with by the combination of horizontal and vertical circulations. The generation of the horizontal circulation has been expressed with radiation stresses averaged over a water depth. On the other hand, it is suggested that the vertical circulation including undertow is caused by the imbalance between the momentum flux of wave motion and pressure force in a vertical plane (Dyhr-Nielsen et al., 1970).

Some models for the vertical circulation including undertow take into account the role of rollers associated with wave breaking. These models are classified into two types. One is an undertow model proposed by Svendsen (1984). The undertow model needs to empirically assume the volume rate of the undertow compensating the onshore

¹ Research Associate and ³ Professor, Dept. of Urban & Civil Eng. Faculty of Eng., Ibaraki Univ., Nakanarusawa, Hitachi, Ibaraki, 316, Japan    (e-mail hnob@hit.ipc.ibaraki.ac.jp)
² Professor, Center for Water Environmental Studies, Ibaraki Univ., Nakanarusawa, Hitachi, Ibaraki, 316, Japan
flux above the wave trough. In a three-dimensional beach, however, the estimation of compensating flow is very difficult, for onshore and offshore flow rates are not necessary balanced in a vertical section. The other type is a model which considers the momentum flux of surface roller as driving force for the vertical circulation. It is not clear, however, how the momentum of surface roller occur.

This study aims to propose a new type of three-dimensional nearshore currents model on the basis of two concepts; i.e., the flux of onshore flow above the trough level and offshore flow under the trough level themselves are variable to be obtain, and a driving force for currents is only wave motion. At first, governing equations are derived from the Navier-Stokes equation. Then, the mechanism to generate time-mean currents are discussed. The predictive capacity in this model is also examined by comparing the computational results with measurements of cross- and long-shore currents in different settings.

2. Governing Equations and Numerical Solution

Basic equations to derive the time-mean equations are the Navier-Stokes equations of continuity (Eq. (1)) and momentum conservation (Eq. (2) and (3)).

\[ \frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \]  
\[ \frac{\partial u}{\partial t} + \frac{\partial u^2}{\partial x} + \frac{\partial uw}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial x} \]  
\[ \frac{\partial w}{\partial t} + \frac{\partial uw}{\partial x} + \frac{\partial w^2}{\partial z} = -g - \frac{1}{\rho} \frac{\partial p}{\partial z} \]

where \( u, w \) are the total instantaneous fluid particle velocity in the \( x \) and \( z \) directions, \( p \) is pressure, \( \rho \) is the mass density and \( g \) is gravity. The terms in \( y \) direction are similar to the \( x \) terms, but are not presented here for the sake of brevity. Furthermore viscous terms are not expressed now as they will be small except in the bottom boundary.

Equations (1), (2) and (3) are transformed into the Reynolds equations by dividing the velocity components and pressure into three components (Eq. (4)).

\[ u = \bar{u} + u' \]
\[ w = \bar{w} + w' \]
\[ p = \bar{p} + p' \]

\[ u' = \frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} \]
\[ w' = \frac{\partial w}{\partial t} + \frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} \]
\[ p' = -\frac{\partial \bar{p}}{\partial x} - g - \frac{1}{\rho} \frac{\partial \bar{p}}{\partial z} - \frac{1}{\rho} \frac{\partial p'}{\partial x} \]
where $\bar{u}, \bar{w}, \bar{p}$ are time-mean components, $u_w, w_w, p_w$ are periodic components associated with wave motion, $u', w', p'$ are turbulent fluctuating components. The time-mean quantities in Eq. (4) satisfy the following relation:

$$\begin{align*}
\bar{u}', \bar{w}' &= 0 \\
\bar{u}_w, \bar{w}_w &= 0 \text{ (except above trough level)} \quad (5)
\end{align*}$$

We obtain Eq. (6), (7) and (8) substituting Eq. (4) to Eq. (1), (2) and (3).

$$\begin{align*}
\frac{\partial (\bar{u} + u_w + u')}{\partial x} + \frac{\partial (\bar{w} + w_w + w')}{\partial z} &= 0 \quad (6) \\
\frac{\partial (\bar{u} + u_w + u')}{\partial t} + \frac{\partial (\bar{u} + u_w + u')^2}{\partial x} + \frac{\partial (\bar{u} + u_w + u')(\bar{w} + w_w + w')}{\partial z} &= -\frac{1}{\rho} \frac{\partial (\bar{p} + p_w + p')}{\partial x} \quad (7) \\
\frac{\partial (\bar{w} + w_w + w')}{\partial t} + \frac{\partial (\bar{u} + u_w + u')(\bar{w} + w_w + w')}{\partial x} + \frac{\partial (\bar{w} + w_w + w')^2}{\partial z} &= -g - \frac{1}{\rho} \frac{\partial (\bar{p} + p_w + p')}{\partial z} \quad (8)
\end{align*}$$

The pressure $p$ at arbitrary height $z$ can be calculated after integrating vertical momentum equation (Eq. (8)) between water surface $\eta$ and $z$. The following equation is obtained assuming that interaction between the components is not exist (Assumption-1) and that pressure at the water surface is zero.

$$\begin{align*}
\frac{1}{\rho} (\bar{p} + p_w + p') &= g(\eta + \eta_w + \eta' - z) \\
&+ \frac{\partial}{\partial t} \int_{\eta}^{z} (\bar{w} + w_w + w') dz \\
&+ \frac{\partial}{\partial x} \int_{\eta}^{z} (\bar{u}w + u_ww_w + u'w') dz \\
&- (\bar{w}^2 + w_w^2 + w'^2) \quad (9)
\end{align*}$$

When Eq. (9) is substituted to Eq. (7) with Assumption -1, we can obtain Eq. (10).
\[
\frac{\partial \bar{u}}{\partial t} + \frac{\partial \bar{u}^2}{\partial x} + \frac{\partial \bar{w} \bar{w}}{\partial z} = -\frac{\partial}{\partial x} \left[ g(\bar{\eta} - z) + \int_{\bar{z}}^{\eta} \frac{\partial \bar{w} \bar{w} dz}{\partial x} \right] - \frac{\partial}{\partial x} \left[ \frac{\partial \bar{u} \bar{w}}{\partial \bar{z}} \right] - \frac{\partial}{\partial \bar{z}} \left[ \frac{\partial \bar{u} \bar{w}}{\partial \bar{z}} \right]
\]

After averaging the Eq. (10) over a wave period, Eq. (11) is finally obtained.

\[
\left( \frac{\partial \bar{u}}{\partial t} + \frac{\partial \bar{u}^2}{\partial x} + \frac{\partial \bar{w} \bar{w}}{\partial z} \right) = -\frac{\partial}{\partial x} \left[ g(\bar{\eta} - z) + \int_{0}^{T} \frac{1}{T} \int_{\bar{z}}^{\eta} \left[ \frac{\partial}{\partial x} \left( \frac{\partial \bar{w} \bar{w} dz}{\partial x} \right) \right] dt \right] - \frac{\partial}{\partial \bar{z}} \left[ \frac{\partial \bar{u} \bar{w}'}{\partial \bar{z}} \right]
\]

Here some assumptions are added; the wave components are expressed by small amplitude wave theory (Assumption-2), third-order terms of wave height are sufficiently small and can be neglected (Assumption-3), the gradient of the Reynolds stress in the horizontal direction is much smaller than that of radiation stress based on the Stive et al. (1982) (Assumption-4) and the vertical acceleration of time-mean component is small (Assumption-5). Adding these assumptions, the Eq. (11) for the momentum conservation of the time-mean components becomes the following equation.

From the still water level to the bottom \((-h \leq z \leq 0)\),

\[
\left( \frac{\partial \bar{u}}{\partial t} + \frac{\partial \bar{u}^2}{\partial x} + \frac{\partial \bar{w} \bar{w}}{\partial z} \right) = -\frac{\partial}{\partial x} \left[ g(\bar{\eta} - z) - \frac{\partial}{\partial \bar{z}} \left( \bar{u}^2 - \bar{w}^2 \right) - \frac{\partial \bar{u}' \bar{w}'}{\partial \bar{z}} \right]
\]

and, for above the still water level \((0 \leq z \leq \eta)\),

\[
\left( \frac{\partial \bar{u}}{\partial t} + \frac{\partial \bar{u}^2}{\partial x} + \frac{\partial \bar{w} \bar{w}}{\partial z} \right) = -\frac{\partial}{\partial x} \left[ g(\bar{\eta} - z) - \frac{1}{T} \int_{0}^{T} \frac{\partial}{\partial \bar{x}} g(\bar{\eta}) dt - \frac{\partial \bar{u}' \bar{w}'}{\partial \bar{z}} \right]
\]

Equation (12) and (13) consist of four terms; acceleration, hydrostatic pressure, radiation stress and the Reynolds stress terms.
The continuity equation (1) becomes Eq. (14) by following the similar process.

\[
\frac{\partial \bar{u}}{\partial x} + \frac{\partial \bar{w}}{\partial z} = 0
\]  \hspace{1cm} (14)

The water depth is divided into an appropriate number of the horizontal layers. The sketch of layer is shown in Fig. 1. The layer are numbered from top to bottom. The \( h_i \) indicates the depth at the lower boundary of the number \( i \) th layer. The surface of the first layer is the mean water level \( \bar{\eta} \) and the lowest boundary is the bottom surface.

\[
\begin{align*}
\text{z} = \bar{\eta} & \quad \text{z} = 0 & \quad \text{z} = -h_1 & \quad \text{z} = -h_2 & \quad \cdots & \quad \text{z} = -h_b \quad \text{z} = -h, \\
\text{z} = -hb & \quad \text{z} = -hb-1 & \quad \cdots & \quad \text{z} = -hb-i & \quad \cdots & \quad \text{z} = -hb \quad \text{z} = -hb \quad \text{z} = -hb \quad \text{z} = -hb \quad \text{z} = -hb \quad \text{z} = -hb \quad \text{z} = -hb
\end{align*}
\]

\( K = 1 \)
\( K = 2 \)
\( \cdots \)
\( K = b \)

\text{Figure-1 Lay-out of Multi-Layer}

In order to obtained the governing equations for each layer, Eq. (12), (13) and (14) are integrated between the upper and lower boundary of each layer with an assumption that the time-mean horizontal velocity \( \bar{u} \) is constant in each layer (Assumption-6).

\text{<Momentum Equation>}

\text{The Top Layer (k=1)}

\[
\begin{align*}
\frac{\partial \bar{P}}{\partial t} + \frac{\partial \bar{P} \bar{u}}{\partial x} - \bar{u} \bar{w} & \bigg|_{z=-h_1} \\
& = -g(\bar{\eta} - (-h_1)) \frac{\partial \bar{\eta}}{\partial x} - \frac{\partial}{\partial x} \left( \frac{1}{2} \bar{\eta}^2 + \int_{h_1}^{0} (\bar{u}_w^2 - \bar{w}_w^2) dz \right) + u'w' \bigg|_{z=-h_1} \\
& \hspace{1cm} (15)
\end{align*}
\]

\text{The Middle Layer (k= i)}

\[
\begin{align*}
\frac{\partial \bar{P}}{\partial t} + \frac{\partial \bar{P} \bar{u}}{\partial x} + \bar{u} \bar{w} & \bigg|_{z=-h_i-1} - \bar{u} \bar{w} \bigg|_{z=-h_i} \\
& = -g((-h_i-1) - (-h_i)) \frac{\partial \bar{\eta}}{\partial x} - \frac{\partial}{\partial x} \left( \int_{-h_i}^{-h_i-1} (\bar{u}_w^2 - \bar{w}_w^2) dz \right) + u'w' \bigg|_{z=-h_i-1} - u'w' \bigg|_{z=-h_i} \\
& \hspace{1cm} (16)
\end{align*}
\]
The Bottom Layer \((k=b)\)

\[
\frac{\partial P_b}{\partial t} + \frac{\partial P_b}{\partial x} \vec{u}_b + \vec{u}_b \vec{w}_b \bigg|_{x=-h_b-1} \\
= -g((-h_{b-1}) - (-h_b)) \frac{\partial \bar{\eta}}{\partial x} - \frac{\partial}{\partial x} \left( \int_{h_b}^{h_{b-1}} \left( \bar{u}_w^2 - \bar{w}_w^2 \right) dz \right) + \vec{u}_w \vec{w}_w \bigg|_{x=-h_b}
\]  

(17)

<Continuity Equation>

The Top Layer \((k=1)\)

\[
\left( \frac{\partial \bar{\eta}}{\partial t} \right) + \frac{\partial P_1}{\partial x} - \bar{w}_1 = 0
\]  

(18)

The Middle Layer \((k=i)\)

\[
\frac{\partial P_i}{\partial x} + \bar{w}_{i-1} - \bar{w}_i = 0
\]  

(19)

The Bottom Layer \((k=b)\)

\[
\frac{\partial P_b}{\partial x} + \bar{w}_b = 0
\]  

(20)

where,

\[
\bar{P}_i = \int_{-h_i}^{-h_i} u_i dz
\]  

(21)

The governing equations in the present model are from Eq. (15) to (20). A bottom friction term is added to Eq. (17).

These governing equations are solved numerically with a modified ADI method (Maa, 1990; Sato et al., 1992). The variables to be obtained are time-mean velocity \(\bar{u}, \bar{w}\) in each layer and time-mean water level \(\bar{\eta}\) at the top layer. The radiation stress in each layer is calculated using water particle velocities and water surface elevation calculated by the small amplitude wave theory. The total amount of this stress over the water depth is the same as the conventional radiation stress introduced by Louguet-Higgins et al. (1964). The Reynolds stresses are represented by the eddy viscosity model. The eddy viscosity coefficients are estimated by the empirical formula introduced by Okayasu et al. (1988), for the onshore area between plunging point and shoreline. For the area off the breaking point, this coefficient is set to be zero. In the area between plunging and breaking points, the coefficient is calculated by linear interpolation. The bottom friction is expressed with a term proportional to the square of time-mean velocity.
3. Theoretical Consideration on the Present Model

As waves approach to the shore, a part of the momentum of wave motion is transferred to a flow. Since the total momentum of water motion in the surf zone is conserved, changes in wave momentum in the horizontal direction should balance with the momentum of time-mean currents. This phenomenon is expressed in the Navier-Stokes momentum equations. Equation (22) is the Navier-Stokes equation expressed by the time-mean and wave components, and is same as Eq. (10) excluding the turbulent term.

\[
\frac{\partial \mathbf{u}}{\partial t} + \nabla \cdot \mathbf{u} = -\mathbf{u} \cdot \nabla \mathbf{u} + 1 \frac{\partial p}{\partial x} = -\left( \frac{\partial u_w}{\partial t} + \frac{\partial u_w^2}{\partial x} + \frac{\partial u_w w_w}{\partial z} + \frac{1}{\rho} \frac{\partial p_w}{\partial x} \right)
\]

(22)

The left side shows the balance of the time-mean component while the right side is for the wave component. If the wave momentum decreases, the momentum of flow must increase for conserving the total momentum. The transferred momentum in an averaged wave period is expressed as the difference in the radiation stresses.

When a wave breaks and jet and large vortexes occur, the momentum of jet and vortexes must be supplied from the wave motion. The source of the time-mean momentum of the vortex is also the difference in the radiation stress. In the models for the vertical circulation, the vortex is often dealt as outer source of force to the time-mean flow (e.g. Péchon et al., 1994). However, from the above-mentioned consideration, it is sufficient to take only change in the radiation stress as driving force of the time-mean flow. This is the basic concept of this model.

As the radiation stress is dealt with as an integrated form over a water depth until now, we can not take into consideration its vertical distribution. However, it is needed to express the strong transfer by wave breaking around the water surface. Figure-2(a) shows an example of calculated result for the gradient of radiation stress after wave breaking. The gradient around the surface is the steepest throughout the depth. This result expresses that the momentum is transferred from wave to large vortexes in a wave period. Figure-2(b) shows hydrostatic time-mean pressure at the same point. Comparing the pressure force and radiation stresses, onshore force induced
by the radiation stress is stronger than offshore pressure force at the top layer. On the other hand, they are opposite in other layers i.e.; offshore force induced by pressure is stronger. This means that the present model can represent the vertical distribution of driving forces and their local imbalance.

These local imbalances of radiation stress and time-mean hydrostatic pressure force indicate how the vertical circulation is generated. The distribution of time-mean water level which causes the gradient of hydrostatic pressure force can be explained by the radiation stress. Then, we can explain the generation of the vertical circulation with radiation stresses as a source of driving force.

4. Comparisons of Results between Simulations and Experiments.

The present model was applied to predict time-mean water level and vertical distribution of on- and off-shore time-mean currents. The following three experiments were chosen for the comparison.

(Case-a) Vertical Circulation and Wave Set-up/Set-down in Wave Flume (2-DV)

In this case, the experiments were divided two sorts. First one was designed to compare the distribution of mean water level and pattern of vertical circulation in a surf zone. The wave flume was 20 m long and 0.6 m wide with a beach of 1/20 slope. The water depth in the uniform area was 35 cm. Two different wave conditions were used; spilling breaker (Case-a-1) and plunging breaker (Case-a-2). Surface elevations and velocity were measured by capacitance-type wave gauge and electromagnetic current meter respectively.

The other experiment was performed by Okayasu et al.(1988), in which vertical distribution of cross-shore current was measured in detail by laser-Doppler velocimeter. The wave flume was 23 m long and 0.4m wide with a 1/20 slope. Water depth in the uniform area is 40 cm. Six lines were chosen to measure the currents. Line-1 is at the breaking point and Line-6 is on the still water shore line. Two conditions of incident wave were chosen; plunging breaker (Case-a-3) and spilling breaker (Case-a-4).

(Case-b') Weak Three-Dimensional Nearshore Currents in Wave Basin

This case was chosen to check the capacity of this model to predict the vertical distribution of long- and cross-shore currents. This experiment was performed by Okayasu et al.(1994), and the currents observed in the experiments was not strong. The condition of the experiment and simulation are shown in Fig.-3. The wave basin has a 1/20 uniform slope which is uniform in the long-shore direction. Wave enters at an angle of 10 degree to cross-shore line.
(Case-c) Strong Three-Dimensional Nearshore Currents Around a Step

This case was selected to examine the capacity to predict the three-dimensional nearshore fast currents. Figure-4 shows a schematic diagram of the wave flume. The width of the step were three fifth of the flume width in order to cause three-dimensional currents.

Table-1 shows the conditions of these cases, where $H_i$ and $T$ are height and period of incident waves, and $h$ is the water depth in the offshore.
(1) Results of Vertical Circulation and Wave Set-up/Set-down (Case-a)

Figure-5(a) and 5(b) show the results of Case-a-1 and Case-a-2 respectively. The line and marks in each figure indicate the mean-water level obtained by the simulation and experiment respectively. Both results of the simulation show good agreement with the experimental results, though wave set-down are slightly overestimated around the wave breaking point. Simulated and measured cross-shore currents are shown by arrows with solid line and broken line respectively. The direction of vertical circulation of both simulated results is onshore at the uppermost level and offshore below the second level which is nearly equal to wave trough level. These patterns correspond to the experimental results.

The calculated results and experimental data measured by laser-Doppler velocimeter are compared in Figure-6(a) and 6(b) in order to examine the vertical distribution of cross-shore current in detail. Simulation results are indicated by filled circles with line and experimental results are by broken lines. From Line-3 to Line-5, where large vortexes progress, simulated vertical distribution show good agreement with experiments. On the other hand, the agreement is not so good at Line-2 and 6, which are near the breaking point and the shore line, respectively.

(2) Results of Weak 3-D Currents (Case-b)

It is important to properly predict time-mean water level, since the gradient of the water level is one of the driving force of currents. Figure-7 shows the comparison for the water level. The results by the present multi-layer model and single layer model which have been used conventionally are indicated by a circle and a triangle respectively. The results of both simulations are in close agreement with that of experiments.

Figure-8(a) shows the vertical distribution of currents simulated simultaneously with the water level. The vertical axis shows the water depth. The horizontal axes show the cross- and long-shore directions. The solid lines show the calculated cross- and long-
shore current velocities, and the solid lines with filled circle show the sum of these velocities. On the other hand, the broken lines show the measured currents.

In both results of simulation and experiment, cross-shore currents are onshore above the wave trough level and offshore under the trough level. In the long-shore direction, there is a vertical distribution of the current velocity i.e.; it is slow near the surface, fast in the middle, and slow again near the bottom. The simulated currents velocities agree approximately with experiments in the area where the water depth is a comparatively large as Line-22. On the other hand, in the area where the depth is small as Line-42, the simulated velocities are far slower than experiment. This reason may be that the present model can not yet express the distribution of radiation stress well in the shallow region.

Next, the present multi-layer model is compared with a single layer model which have been used conventionally. For the result of single layer model (Fig.-8(b)), cross-shore current dose not appear and long shore currents are of course uniform over the depth. Such comparison shows the effectiveness of the multi-layer model for the simulation of the three-dimensional structure of the nearshore currents.

![Diagram](image)

**Figure-8** Vertical Distribution of Cross- and Long-Shore Currents (Case-b)
(a) Numerical Simulation

(b) Experiment

Figure-9 Three-dimensional currents around the step (Case-c)

(3) Results of Strong 3-D Currents (Case-c)

Figure-9(a) and (b) show the simulated and measured results of the near-shore currents around the step. The currents were measured only under wave trough by a electromagnetic current meter. In the results of simulation, there are circulations around the step and near the shore line respectively. The circulation around the step is anti-clockwise; i.e., it directs onshore above the step and offshore at the gap of structure. The other circulation show the reverse rotation. Detailed examination of simulated results shows that flow moves from one to another circulation and vice versa. Part of streamlines forms a “8” shape with a two-level crossing. The measured and observed result showed a similar pattern of circulation.

Another remarkable three-dimensional structure is that offshore currents near the bottom of the gap turn to a rising current along the step in the vicinity of $x=300$ line. This pattern of current is also reproduced in the simulation.

5. Conclusion

In this study, a three-dimensional nearshore current model based on the vertical distribution of the radiation stresses was developed. As the driving force of this model is only radiation stresses, it is comparatively easy to calculate the time mean flow for the
three-dimensional beach. Simulated results for wave set-up/set-down and vertical
distribution of cross- and long-shore currents show good agreement with measured data.
The above results confirm that this model is effective to estimate three-dimensional
nearshore current in the surf zone.

Numerical Simulation of Wave Fields around
The Submerged Breakwater with SOLA-SURF Method

Norio Hayakawa, Member*, Tokuzo Hosoyamada*, Shigeru Yoshida**
and Gozo Tsujimoto*

Abstract

Both two and three dimensional numerical simulation of wave fields around the submerged breakwater is carried out using the SOLA-SURF method. The results of the calculation are compared with the laboratory experiment. It is shown that the side wall boundary condition for the three dimensional calculation of the laboratory tank should be nonviscous (slip-type) to reproduce the experimental data. The calculation method is easily extendible to a field scale case.

Introduction

Numerical simulation of wave fields based on the Navier Stokes (NS) equation has been known to be time-consuming. It has been customarily carried out with some kind of simplifications such as irrotationality for the Boundary Element Method, mild slope hypothesis for the long wave approximation, etc. The advancement of the computer technology in recent years, however, has made numerical simulation method based on the NS equation remarkably amenable. It is now possible to integrate the NS equation directly for the simulation of wave fields within a reasonable CPU time.

Also, there is a need for such a study in designing coastal engineering structures of the advanced type. A good example is found in the design of a submerged breakwater around which the flow is quite complicated and the mechanism and extent of scour is not fully understood. In this respect, the need to develop the simulation method of the three dimensional flow structure is quite apparent.

The objective of this study is to develop a three dimensional simulation method of the wave and flow field around a submerged breakwater. The result will be tested with the experimental study in a laboratory wave tank. The numerical simulation method adopted in this study is the SOLA-SURF method (Hirt et al. 1975, Bulgarelli et al. 1984).

SOLA-SURF Method

Numerical schemes to integrate the NS equations can be characterized in the way to treat time development of the water surface. In the SOLA-SURF method, the kinematic condition of water surface is integrated for prediction of the position of water surface for the successive time step. Then the pressure and velocity are adjusted at the same time to satisfy the set of the governing equations, rendering this method quite effective and versatile. With this method, unfortunately, it is impossible to simulate the breaking wave. Aside for the breaking wave, SOLA-SURF method appears to be quite versatile as it directly deals with the NS equations and can be easily extended to the three dimensional wave field.

The formulation of the SOLA-SURF algorithm is given in the reference and will not be repeated here. The basic equations to be solved are three dimensional equation of continuity and Navier-Stokes equations for the incompressible, viscous fluid and these are not listed herein. In this study, the flow inside the permeable breakwater is also analyzed and the basic equations of motion in this case are linear equations of the Darcy flow given as

\[ \frac{\partial \vec{v}}{\partial t} = -\vec{\nabla}(p + gz) - \frac{\varepsilon v}{k} \vec{v} \]  

(1)

\[ \nabla \cdot \vec{v} = 0 \]  

(2)

where \( \vec{v} \) is the three dimensional velocity vector, \( t \) is time, \( \varepsilon \) is the porosity, \( k \) is the permeability, \( p \) is pressure, \( g \) is the gravitational acceleration, \( z \) is the elevation, and \( \nu \) is the kinematic viscosity. Incorporation of Eqs. (1) and (2) into the SOLA-SURF method is easy since these equations are simplified form of the NS equations. At the boundary of the submerged breakwater with water, continuity conditions of velocity and stress components are applied.

Experimental Condition

Laboratory experiments are carried out with a wave tank, 15m long and 0.6m wide. In this tank a model submerged breakwater is placed piling up model blocks of hexa-pod shape for the case of the permeable breakwater. Fig. 1 shows the wave tank set up of this study. The numerical calculation of this study is carried out under the same conditions as the laboratory experiment.
Fig. 1 Wave tank

Fig. 2 Comparison of velocity vectors for 2D calculation and lab experiment
The results of the lab study is then compared with the numerical calculation using the SOLA-SURF method. For two dimensional study submerged breakwater is placed uniformly over the width, while for three dimensional study the breakwater is placed over the half width of the tank.

The experimental conditions are as follows: incident wave height $H$ of 0.135m, wave period $T$ of 0.15s and water depth $h$ of 0.6m. In the lab experiment, detailed measurement of the velocity vectors is carried out using an electromagnetic current meter to obtain the data that can be compared with the numerical simulation.

**Calculation with 2D Breakwater**

In this chapter is presented the result with the two dimensional (2D) breakwater, which means that the breakwater is placed to fill the whole width of the wave tank. The objective is to investigate the flow structure around the breakwater in detail and to test the validity of the three dimensional calculation.

**Flow structure around 2D breakwater:** Figure 2 shows the velocity vector around the submerged breakwater. In this figure, the top two charts indicate the results of simulation with SOLA-SURF method, while the bottom two charts those for the laboratory experiments. The development of wave vector is simulated reasonably well. In the laboratory experiments, the return flow to the offshore direction is observed. This is probably related to the phase difference of wave and horizontal velocity. In the SOLA-SURF method, on the other hand, the return flow is not observed probably because the Sommerfeld's radiation condition for the onshore boundary is effective.

**Side wall boundary condition for 3D calculation:** Next the three dimensional SOLA-SURF calculation is performed on this 2D breakwater. Fig. 3 gives the resulting water surface elevation. In this calculation, the boundary condition at the side wall of the water tank is set at first as non-slip type, i.e. viscous, condition. It is then observed that there is a considerable gradient in the water surface along the wave ridge, a situation which is not found in the laboratory experiment. This is probably because this calculation is essentially the laminar flow calculation, whereas the flow in the wave tank is at least to some degree turbulent. Therefore, the slip (inviscid) condition for the side wall is adopted for the further calculation. The top and bottom charts of Figure 3 give the calculation result with, respectively, no-slip and slip boundary conditions.

**Calculation with 3D Breakwater**

To test the validity of the three dimensional SOLA-SURF calculation, it is applied to the three dimensional (3D) breakwater. The 3D breakwater occupies half width of the wave tank with the other half free of breakwater. Fig. 4a and 4b give the water surface profile and Fig. 5 and 6 give velocity vectors for both permeable and impermeable submerged
breakwaters. In these figures the submerged breakwater is placed to the left half of the wave tank looking in the direction of the wave propagation, occupying from 6.6 to 7.4 m in the across-shore distance and 0.0 to 0.3 m in the long-shore distance.

Figure 4 shows that the wave profile is deformed over the submerged breakwater section, with somewhat less deformation above the half width over which the breakwater is not present, showing the effect of the 3D calculation. The wave deformation around the impervious breakwater (Fig. 4a) is more remarkable than that for the permeable breakwater (Fig. 4b).

Fig. 5 and 6 give the comparison of velocity vectors at the plane 2.5 cm over and 17.5 cm under the top surface of the submerged breakwater, respectively. Fig. 5 indicates that the water over the breakwater flows out to the part free of breakwater, which corresponds to the phase of the water surface elevation between these two areas observed in Fig. 4. The impervious breakwater, compared to the permeable breakwater, tends to give more pronounced difference in velocity vectors. Fig. 6 shows that the flow tends to turn around the corner of the breakwater. It is also remarkable that there exists significant amount of flow inside of the permeable breakwater.

**Conclusion**

It is shown that numerical simulation of three dimensional wave field over a submerged breakwater is possible with the SOLA-SURF method. The breakwater in this case can be impervious or permeable. Simulation results are, on comparison with the laboratory experiments, qualitatively satisfactory.

NUMERICAL ANALYSIS OF WAVE BREAKING DUE TO SUBMERGED BREAKWATER IN THREE-DIMENSIONAL WAVE FIELD

Koji KAWASAKI¹ and Koichiro IWATA²

ABSTRACT

The wave breaking and post-breaking wave deformation due to a submerged breakwater in a three-dimensional wave field have been investigated numerically and experimentally in this study. The calculated and measured results have revealed that the breaking limit and the breaker types are almost independent of the relative structure length \( W/L_t \) (0.5 \( \leq \) \( W/L_t \) \( \leq \) 2.5), and that the horizontal and vertical circulation flows are formed around the submerged breakwater. It is also found that the wave breaking in three-dimensional wave field is affected strongly by the wave refraction, different from the two-dimensional case. The numerical calculation method based on a SOLA-VOF method has been developed and has reproduced well laboratory experiments in case of a weak breaker such as the Spilling breaker.

INTRODUCTION

Accurate prediction and evaluation of wave breaking process due to a submerged breakwater are important in view of multi-purpose utilization of coastal sea area as well as the wave dynamics. Researches have ever been conducted to evaluate numerically and experimentally the wave breaking and its deformation due to the submerged breakwater. Most of these researches are, however, limited to a two-dimensional wave field (for examples, Petit et al., 1994; van Gent et al., 1994; Sabeur et al., 1996; Iwata et al., 1996).

The main purpose of this study is to discuss numerically and experimentally the wave breaking process due to a submerged breakwater in a three-dimensional wave field.

dimensional wave field. First, elaborate three-dimensional laboratory experiment was conducted to study the breaking limit, the breaker type, the breaking position and the wave deformation after breaking in the regular wave field, in relation to the relative dimensions of submerged breakwater to the waves. Next, the numerical calculation method based on the SOLA-VOF method (Hirt and Nichols, 1981) is developed to investigate the wave breaking process due to the submerged breakwater. The validity of the present method is verified by comparing with the experimental results.

LABORATORY EXPERIMENTS

Three kinds of laboratory experiments, such as Series I on the breaking limit, breaker type and breaking position, and Series II and III regarding the wave deformation and the water particle velocity field after breaking, were carried out in a three-dimensional wave basin (28m in length, 8m in width and 0.8m in depth) at Nagoya University. In the experiments, the relative width \( B/L_i \), the relative submerged depth \( R/h \) and the relative height \( D/h \) of the submerged breakwater were fixed as \( B/L_i=0.3 \), \( R/h=0.4 \) and \( D/h=0.6 \), where \( B \) is the structure width, \( R \) the submerged depth, \( D \) the structure height, and \( L_i \) the wavelength at the still water depth \( h \). The still water depth was kept constant at 40cm. The relative submerged breakwater length \( W/L_i \) was as-

![Fig. 1 Definition sketch of wave basin](image-url)
signed as $W/L_i = 0.5, 1.0, 1.5, 2.0$ and $2.5$. The regular waves with different wave periods $T_i = 0.8, 1.2$ and $1.68$s were generated so as to propagate perpendicularly to the submerged breakwater. The incident wave height $H_i$ was, in Series I, carefully changed to find out the breaking limit and the breaker types. On the other hand, $H_i$ in Series II and III were chosen so that the following non-linearity parameter $\Pi$ (Goda, 1983) was 0.08 and 0.09 for three different wave periods.

$$\Pi = \frac{H_i}{L_i} \coth^2 \left( \frac{2\pi h}{L_i} \right)$$ (1)

Note that the above-stated conditions were selected so that the breaker type became the Spilling breaker.

For each experimental condition, the water surface profile $\eta$ was measured with capacitance-type wave gages at 0.1$L_i$ interval mesh points within the square region of 2.0$L_i$ in $x$-axis and 1.5$L_i$ in $y$-axis, as shown in Fig. 1. The horizontal water particle velocities $u$ and $v$ at three different depths on each mesh point were also measured with electromagnetic type velocimeters. Moreover, the wave breaking process was recorded using a video tape recorder.

**NUMERICAL CALCULATION METHOD**

A numerical model has been developed to study the wave breaking process due to the submerged breakwater in the three-dimensional wave field (Kawasaki, 1998). The model utilizes a SOLA-VOF method (Hirt and Nichols, 1981) as well as a non-reflective wave generator (Brorsen and Larsen, 1987). Further, an added dissipation zone is adopted to treat the open boundaries (Hinatsu, 1992).

The wave field is governed by the continuity equation (Eq.(2)) and Navier-Stokes equations (Eq.(3) ~ (5)) for incompressible fluid. The free surface is treated by introducing a function $F$ that represents the fractional volume of the cell occupied by the fluid, as in Eq.(6).

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = q = \begin{cases} q^*/\Delta x_s & \text{at } x = x_s \\ 0 & \text{at } x \neq x_s \end{cases}$$ (2)

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \nu \nabla^2 u$$ (3)

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial y} + \nu \nabla^2 v + \frac{\nu}{3} \frac{\partial q}{\partial y}$$ (4)

$$\frac{\partial w}{\partial t} + u \frac{\partial w}{\partial x} + v \frac{\partial w}{\partial y} + w \frac{\partial w}{\partial z} = -g - \frac{1}{\rho} \frac{\partial p}{\partial z} + \nu \nabla^2 w + \frac{\nu}{3} \frac{\partial q}{\partial z} - \gamma w$$ (5)
Fig. 2  Definition sketch of computational domain

\[
\frac{\partial F}{\partial t} + \frac{\partial (F_u)}{\partial x} + \frac{\partial (F_v)}{\partial y} + \frac{\partial (F_w)}{\partial z} = Fq
\]

(6)

where the Cartesian coordinate system \((x, y, z)\) is used. \(u, v\) and \(w\) are the velocity components in respective direction of \(x, y\) and \(z\). \(q\) is the wave generation source with its strength \(q^* / \Delta x_s\) only assigned at source line \((x = x_s)\), in which \(q^*\) is twice horizontal velocity component of the generated wave (the third-order Stokes wave in this study), and \(\Delta x_s\) is the mesh size in \(x\)-direction at \(x = x_s\). \(t\) is the time, \(p\) the pressure, \(\rho\) the fluid density, \(\nu\) the kinematic viscosity, \(g\) the gravitational acceleration, and \(\nabla = (\partial / \partial x, \partial / \partial y, \partial / \partial z)\). \(\gamma\) is the positive wave dissipation factor and equals 0 except for the added dissipation zone.

As shown in Fig. 2, the computational domain (shaded portion) is the half side of total region because it was confirmed from laboratory experiments that the wave breaking phenomenon was almost symmetrical for the center line of the submerged breakwater. The computational domain is \(16.0L_i \times 4.0L_i \times 1.5h\) in the respective directions of \(x, y\) and \(z\). The positive \(x\)-direction is onshoreward. The vertical \(z\)-axis is taken positive upward with its origin being on the still water level. The mesh sizes \(\Delta x, \Delta y\) and \(\Delta z\) are

Fig. 3 Flow chart of numerical calculation

The flow chart of the present numerical scheme is shown in Fig. 3. The Navier-Stokes equations (Eqs.(3) ~ (5)) are used to calculate the first approximation of the velocities at the next time step. However, the calculated velocities do not satisfy, in general, the continuity equation Eq.(2). Therefore, to satisfy the continuity equation completely, the velocities and the pressure are repeatedly adjusted. Next, using the thus obtained velocities, the behavior of the free-surface is evaluated by calculating the advection equation Eq.(6).

Stable numerical computation is carried out by repeating the above-mentioned procedures under suitable boundary conditions at each time step.

RESULTS AND DISCUSSIONS

(a) Breaking Limit, Breaker Types and Breaking Position

Figure 4(a) and (b) illustrate the critical relative wave height for the wave breaking \((H_i/L_i)_c\) or \((H_i/R)_c\) in relation to the relative structure length \(W/L_i\), in which \(W/L_i=\infty\) means the two-dimensional experimental results.
(Iwata et al., 1996). The breaking limit Eq. (7) at the constant depth derived by Miche (1944) is also shown for comparison. In this study, the wave breaking is defined as the instance when the wave front became vertical.

\[
\left( \frac{H_i}{L_i} \right)_c = 0.142 \tanh \left( \frac{2\pi h}{L_i} \right)
\]  

(7)

The wave breaking first occurs, in general, at both side edges of the submerged breakwater and then spreads, with wave propagation, to the onshore center line of the structure. As shown in Fig. 4(a) and (b), \( W/L_i \) little effects the breaking limit under \( 1.0 \leq W/L_i \leq 2.5 \). According to Fig. 4(b), the critical relative wave height \( (H_i/R)_c \) is 0.35 for \( h/L_i=0.2 \) and 0.41 for \( h/L_i=0.4 \), which are smaller than their respective two-dimensional values \( (W/L_i=\infty) ; \ (H_i/R)_c \cong 0.39 \) for \( h/L_i=0.2 \) and \( (H_i/R)_c \cong 0.49 \) for \( h/L_i=0.4 \). In other words, the wave in three-dimensional wave field is likely to break under smaller incident wave height than the case of two-dimensional field. This is thought to be largely attributed to the wave refraction by the abrupt change of water

(a) Relation of \( (H_i/L_i)_c \) and \( W/L_i \)  
(b) Relation of \( (H_i/R)_c \) and \( W/L_i \)  

Fig. 4 Breaking limit

(a) \( h/L_i=0.2 \)  
(b) \( h/L_i=0.4 \)  

Fig. 5 Breaker types
Laboratory experiments reveal, as shown in Fig. 5, that the breaker types are classified into Spilling breaker (□), S-P breaker which means an intermediate type between Spilling and Plunging breakers (○), and Double breaker (△). The Double breaker is defined as twice breaking in front of and above the structure due to the wave-induced return flow (Katano et al., 1992). It is also found out from Fig. 5 that regardless of $W/L_i$, the breaker type changes from Spilling to S-P breaker with an increment of $H_i/R$ under $0.5 < W/L_i < 2.5$. The occurrence range of each breaker type can be graphically given in Fig. 5(a) and (b). This would show that the magnitude of the wave-submerged breakwater interaction becomes smaller with an increment of $h/L_i$.

Figure 6 shows the relationship between $x_b/L_i$ and $H_i/R$ with parameter of $W/L_i$ in case of $h/L_i=0.2$ and 0.4, where $x_b$ is the distance from the front face of the submerged breakwater to the breaking point. Regardless of $W/L_i$, the breaking point shifts to the offshore side with an increase of $H_i/R$. In Fig. 6(a), $x_b/L_i=-0.05$ is attained for $H_i/R \geq 0.7$ because of forming the partial standing wave. Moreover, the breaking point in the three-dimensional case shifts to the offshore side as compared with the two-dimensional case.

(b) Wave Deformation

Figure 7 indicates one example of the wave height distribution, in which the breaker type is a weak Spilling breaker. The wave height above the submerged breakwater becomes larger than the incident wave height ($H/H_i \geq 1.0$), especially the wave height at the side edge of the submerged breakwater ($y/L_i=0.3$) is much larger.
Fig. 7  Comparison of wave height variation between computation and laboratory experiment ($H_i/L_i=0.05$, $h/L_i=0.2$, $W/L_i=1.0$)

Fig. 8  Water Particle Velocity around Submerged Breakwater
($h/L_i=0.2$, $H_i/L_i=0.05$, $W/L_i=1.0$; $z/h=-0.15$, $t/T_i=7.0$)

The reason of this can be explained from Fig. 8, which shows the water particle velocity at $z/h=-0.15$ when the free-surface at the side edge of the structure becomes extremely large. According to this figure, the direction of the velocity is converged near the side edge of the structure due to the wave refraction by an abrupt change of the water depth. Therefore, as already mentioned, it can be thought that the wave height at the side edge of the submerged breakwater becomes extremely large mainly by the effect of the
wave refraction.

As shown in Figs. 7 and 9, the water surface profiles as well as the wave height before and after wave breaking, computed with the present numerical calculation method, are in good agreement with those of the laboratory experiments. In addition, as shown in Fig. 10 (the case of a weak Spilling breaker), the computed water particle velocities agree well with the experimental values. Therefore, the present numerical calculation method can evaluate well the breaking wave deformation in case of the Spilling breaker.

The calculation results, as demonstrated in Fig. 11, reveals that the diffracted wave is generated around the structure and that the partial standing wave is formed in front of the structure. It is also found that the relative structure length $W/L_i$ affects the wave height above the structure.

(c) Wave Spectra

Figure 12 shows the spatial distribution of the non-dimensional wave height spectrum $2A(f)/H_i$, where $A(f)$ is the amplitude spectrum and $f$ is the wave frequency. It is obvious that the decreasing region of the fundamental harmonic component coincides with the increasing region of the second harmonic component. This would indicate the shift of the wave energy of the fundamental harmonic component to that of the second harmonic component. The fundamental harmonic component increases again in the range of the non-breaking reformed wave (roughly $x/L_i \geq 1.0$), while the second harmonic component is decaying with wave propagation. The amplitude variation of the second harmonic component is seen to be periodic at the onshore side of the structure. Therefore, similar to Massel's results (1983) for non-breaking waves in two-dimensional wave field, it can be judged that the free second harmonic component wave is generated even under the condition of wave breaking.

(d) Mean Velocity Field

Figure 13 shows the numerical and experimental results for the mean velocity field around the submerged breakwater. It is recognized from Fig. 13(i) and (ii) that there is the strong mean onshore velocity near the free-surface at onshore side of the submerged breakwater. This is due to the wave breaking above the submerged breakwater. The mean offshore velocity, i.e. the return flow is also found to be caused near both the side of the structure ($0.5 \leq y/L_i \leq 1.0$) and the bottom. Thus, it is clear that the return flow takes place to compensate the onshore mass transport around the still water level caused by wave breaking. Judging from the above-stated, it can be said that
Fig. 9  Time history of the water surface profile

two circulation flows, that is, the horizontal and vertical circulation flows are formed around the submerged breakwater.

CONCLUSIONS

Main conclusions in this study are summarized as follows:

1) The breaking limit and the breaker types are almost independent of the relative structure length $W/L_i$ in the range of $0.5 \leq W/L_i \leq 2.5$.

2) The breaker type changes from Spilling to an intermediate breaker between Spilling and Plunging breakers (S-P breaker) with an increment of the relative incident wave height $H_i/R$.

3) The breaking position shifts to the offshore side as $H_i/R$ becomes larger.

4) The free second harmonic component wave is possibly generated from the edge side of the submerged breakwater.

5) The horizontal and vertical circulation flows are formed around the submerged breakwater.

6) The present numerical calculation model with the SOLA-VOF method has been found to evaluate well the wave deformation before and after breaking in case of weak breakers like the Spilling breaker.

CLASSIFICATION OF WAVE LOADING ON MONOLITHIC COASTAL STRUCTURES

Andreas Kortenhaus¹, Hocine Oumeraci²

Abstract

The paper uses the 'parameter map' which has been developed under PROVERBS (Probabilistic Design Tools for Vertical Breakwaters) in the frame of the ongoing MAST III programme of the European Union (EU contract no. MAS3-CT95-0041) to classify the wave loading on monolithic coastal structures and to identify the conditions leading to wave impacts. Data from four different hydraulic model tests have been used to verify and extend the parameter map. As a result an updated version is proposed for further design purposes.

1. Introduction

Waves approaching the shoreline from the open sea are transformed by various processes like shoaling, diffraction and refraction before they eventually break on the sloped foreshore. In conjunction with any coastal structure at the shoreline wave breaking is more complex to estimate and various methods have been developed to account for this phenomenon.

One of the most recent studies on this topic is conducted by a multinational European research group under the MAST III programme of the European Union within the PROVERBS project ('Probabilistic Design Tools for Vertical Breakwaters'). Within PROVERBS a parametric decision map has been developed to provide an easy-to-use guidance for the breaker type to be expected in front of vertical structures as a function of various geometric and wave parameters (Allsop et al., 1996; Oumeraci, 1997).

¹ Dipl.-Ing., Research Assistant, Leichtweiß-Institut, TU Braunschweig, Beethovenstr. 51a, 38106 Braunschweig, Germany, e-mail: a.kortenhaus@tu-bs.de
² Prof. Dr.-Ing., University Professor, Managing Director of Leichtweiß-Institut, TU Braunschweig
This parameter map (Fig. 1) has been cross-checked against various structures and parameter variations but is still under further development. More work is needed to fill the gaps and add possible modifications of parameters. A contribution into this direction was made by Kortenhaus and Oumeraci (1997) who summarized small- and large-scale model tests and gave some advice on the use of slightly varied parameters and parameter ranges.

Very little information within the parameter map is yet available for composite type breakwaters with a very high mound. The aim of this paper is to feed and extend the aforementioned map with more detailed information obtained from large-scale model tests on innovative high mound composite breakwaters (HMCB) performed in the Large Wave Flume (GWK) of Hannover, Germany.

2. The Parameter Map Concept

The parameter map is a simple, easy-to-use map to identify wave loading on monolithic coastal structures. In the following some parameters and notations are defined. Furthermore, the input of the map (structure types) and the output (breaker types) are described in more detail.
(a) Governing Parameter

All parameters related to the various structure types are defined in Fig. 2. Three dimensionless parameters are needed to use the map and identify the breaker type at the structure. The occurrence or non-occurrence of impact breakers at the wall can be predicted by these parameters at the following three decision levels:

1. Relative berm height \( h_b^* = h_b/h_s \); \( h_b \) is the height of the berm and \( h_s \) is the water depth at the toe of the rubble foundation; \( h_b^* \) represents the most important input parameter for the depth limited wave breaking in front of the breakwater, but also defines the type of structure (vertical breakwater, low or high mound breakwater, crown wall).

2. Relative wave height \( H_s^* = H_s/h_s \); \( H_s \) is the significant wave height at the toe of the rubble foundation. \( H_s^* \) was found to be decisive for wave breaking where waves with small \( H_s \) do not break whereas higher waves could break at the structure thus inducing extreme impact pressures and forces. If \( H_s^* \) exceeds a certain maximum value (for details see Muttray et al., 1998) the wave breaks on the berm and only broken waves will reach the structure.

3. Relative berm width \( B_{eq}^* = B_{eq}/L_{hs} \); \( B_{eq} \) is the equivalent berm width in front of the structure which is defined as \( B_{eq} = B_b + (0.5 \cdot h_b \cdot \text{m}) \). The wave length \( L_{hs} \) is the local wave length in the water depth \( h_s \) determined by the peak period of the waves. \( B_{eq}^* \) describes the effect of the berm width on the occurrence of the impact loading.

(b) Main Structure Types

Principally, four types of breakwaters can be distinguished. These types can be characterised by \( h_b^* \), together with the most typical type of waves in front of these walls.
Vertical Wall Breakwater (VWB): this type is characterised by a very low bedding layer without any mound. The relative berm height $h_b^*$ varies from 0.0 to 0.3. There is almost no wave breaking in front of these vertical breakwaters but mostly standing or slightly breaking waves occur. Under extreme wave height conditions wave may break at the wall (wave - wave interaction).

Low and High Mound Breakwaters (LMB and HMB): they consist of a rubble mound layer of various thickness and a caisson structure sitting on top of this mound. The relative berm height $h_b^*$ varies from 0.3 to 0.9. Low mound breakwater (LMB, $h_b^* = 0.3 \div 0.6$) and high mound breakwater (HMB, $h_b^* = 0.6 \div 0.9$) can be distinguished. This type of breakwater can cause severe breaking at the wall and high loads at the structure.

High Mound Composite Breakwater (HMCB): a new type of composite type breakwater developed at PHRI, Japan with a very high rubble foundation and a smaller superstructure than standard vertical breakwaters is characterized by $h_b^* \approx 0.9 \div 1.0$. Depending on the water level at the structure only breaking waves or already broken waves can be observed at the structure, i.e. it represents a transition between a caisson breakeater and a crown wall of a rubble mound breakwater.

Crown walls (CW): crown walls are located on top of a rubble mound layer and usually the water level is below the berm so that generally $h_b^* > 1$. Most crown walls are designed for broken waves only.

(c) Main Breaker Types

From the parameter map four different breaker types may be distinguished. These types are classified by typical force time series showing their characteristics (Oumeraci and Kortenhaus, 1997).

Quasi-standing waves in front of vertical structures can be observed for smaller wave heights so that the incident waves are more or less fully reflected by the wall and do not break. The typical force history does not show significant peaks but alters slowly over time (quasi-static force).

Slightly breaking waves occur when the wave height is slightly increased and the waves start to break in front of a breakwater. Sometimes this breaking occurs at the wall, thus inducing a first peak in the force time series which is higher than the second (quasi-static) peak.

Wave impacts generally occur when the berm in front of the structure induces a breaker with the breaking point just in front of the wall. Many different types of impact breakers were already described (Oumeraci and Kortenhaus, 1997)
but they are very difficult to be classified only by means of wave and geometric parameters. Therefore, the parameter map does not give any detail on the type of breaker or on the frequency of its occurrence. In all cases the force history shows a clear and high first peak which is significantly higher than the second 'quasi-static' peak.

If the breaking point is far enough in front of the wall (e.g. in case of a wide berm or extremely shallow water in front of the structure) only a broken wave will reach the structure. In this case a force history is obtained which is generally superimposed by high frequency oscillations due to a large air content in the water. The order of magnitude of the forces is the same as for slightly breaking waves.

3. Experimental Setup

In a joint research project between Port and Harbour Research Institute (PHRI), Japan and Leichtweiß-Institut (LWI), Germany the wave load and hydraulic performance and the loading of an innovative high mound composite type breakwater have been investigated.

The most important dimensions, locations of measurement devices, information about the test setup and results of these tests can be found in Muttray et al. (1998). A slit-type breakwater and a solid wall breakwater on a very high mound have been tested. Within this study results of the solid wall breakwater have been used only (acronym: CERI) to assure comparison with other data sets on vertical breakwaters.

Fig. 3 shows the front view of the model breakwater in the Large Wave Flume (GWK) where the fore-shore, the rubble foundation and the caisson structure can easily be identified. The rubble foundation consists of rock of 0.5 to 5.0 kgs with an armour layer of 40 kg Accropodes. The caisson structure is made of reinforced concrete with a solid wall and a slit-type wall (pillars).

Three more data sets on composite type breakwaters have been used in this paper. These additional data sets were taken from the following large-scale and small-scale investigations performed at various institutes in the U.K. and Germany:
Random waves have been used on a composite type breakwater in a small-scale 2D flume at HR Wallingford. Various modifications of rubble mound geometry have been tested representing the most comprehensive data set (more than 200 tests) to support the parameter map (acronym: HR). These tests have been described in more detail in Allsop et al. (1996).

Regular and random waves have been tested in large-scale model tests performed in 1993 and 1994 in the Large Wave Flume of the 'Coastal Research Center', a joint institution of the University of Hannover and the Technical University of Braunschweig, Germany. Due to the large scale only one geometry has been tested but water level and wave parameters were varied extensively thus resulting in about 80 tests with random waves and 60 tests with regular waves (acronym: GWK). For more details on test setup see Kortenhaus and Oumeraci (1997).

Regular and random waves have also been used for small-scale model tests performed at the Franzius-Institute of University of Hannover, Germany in 1993 (Oumeraci et al., 1995). About 80 tests with regular waves and 120 tests with wave spectra have been conducted which were all used for feeding the parameter map (acronym: WKS).

The type of waves and the range of relative parameters for all tests are summarized in Tab. 1.

### 4. Classification of Breaker Types

The breaker types classified in section 2 are sometimes very difficult to distinguish from the force or pressure time series they induce at the wall. Therefore, a procedure had to be found to identify these breakers by means of both video observation and analysis of force histories.

In Fig. 4 a slightly breaking wave is shown when it breaks at the wall. Fig. 5 shows a wave breaking in a reasonable distance before reaching the wall so that this may be classified as 'broken wave' whereas Fig. 6 shows a wave breaking directly at the structure thus inducing high pressure and force peaks. From photos like this and video frames of all of the tests an identification of the respective breaker type was performed. However, it has been found from the analysis that the procedure to classify the breaker types is different for regular and random waves. This will be described in more detail in the following sections.
Regular waves are generally easier to handle than random waves as they generate regular signals at wave gauges and pressure transducers given that a wave absorber is available behind the structure and the wave reflection control at the wave paddle works properly. In this case, these waves can easily be characterised by mean values of pressures and forces and only one breaker type exists.

As already mentioned the distinction of breaker types could be very difficult from force histories only, particularly, if complex berm geometries are involved as this is the case for high mound breakwaters. It is therefore strongly recommended (i) to use video analysis of the tests for distinction of breaker types and (ii) to use available time series of pressures (preferably in the vicinity of the still water level) or horizontal forces to check the breaker type identification. The latter step is required because very often it cannot be observed from the video whether a wave breaks as a slightly breaking wave or as an impact breaker. This, however, can easily be identified by the force or pressure signal showing a clear sharp peak in the case of an impact breaker.
(b) Random Waves

(i) Flow Chart Procedure

For random waves it is not practicable to identify each single wave in a wave test by means of video analysis. Furthermore, each breaker type may occur in a single test. The main goal, however, is to identify a characteristic breaker type for each of the tests performed. Therefore, a different approach is needed which may be summarized as follows:

In Fig. 7 the analysis starts with a time series analysis of the random wave test. From this the occurrence probability of impact breakers $P_{Fh}$ can be obtained which is described in more detail within the next section. If $P_{Fh}$ is higher than 5% of all waves in the test, it is assumed to be sufficiently large to design the breakwater for impact breakers. If this is not the case, videos from the test are needed to identify the prevailing characteristics of the waves in the individual test. This allows for a fast video analysis so that a minimum of time is needed.

![Flow Chart for Identification of Breaker Types for Random Wave Tests](image)

**Figure 7.** Flow Chart for Identification of Breaker Types for Random Wave Tests

If the video analysis shows some breaking waves at the structure the time series analysis ($P_{Fh}$) is needed again to distinguish between 'quasi-standing' waves ($P_{Fh} < 1\%$) and 'slightly breaking' waves ($P_{Fh} \geq 1\%$). Thus, the principal breaker type of the test has been found and will be assigned to the related test.

(ii) Time Series Analysis of Impact Breakers

Impact breakers can be identified from horizontal force histories integrated at the front wall of the breakwater. Therefore, an automatic procedure has been set up to identify these impacts.

In Fig. 8 a typical force time series of random waves is shown where the left vertical axis represents the horizontal force in model units and the right axis the relative horizontal force (non dimensionalised by $\rho g H_{Sl}^2$); the horizontal
Figure 8. Definition of Impact Breakers from Force Time Series

axis is the time in model units. Two criteria were adopted to identify impact breakers:

1. the relative horizontal force $F_h / \rho g H_{si}^2$ should be larger than 2.5; and
2. the ratio of the maximum horizontal force $F_{h, \text{max}} / F_{h, q}$ (first peak over second peak for each single event) must be larger than 2.5 as well.

If these criteria are applied to force time series the number of impact breakers can be found by simply counting the number of impacts and dividing by the number of all events (waves) in one test.

5. Results

All data from the various data sets have been analysed as described above and breaker types have been assigned to each of the tests. Therefore, the next step is to identify the areas of the parameter map where these data fit. For this purpose the first two relative parameters $h_b^*$ and $H_s^*$ described in section (b) are plotted against each other (Fig. 9).

The boxes in Fig. 9 indicate the branches of the parameter map as given in Fig. 1. Each box is labelled by the type of breaker which has to be expected for these relative parameter. All observed breaker types for each data point are indicated by different symbols and a second symbol for each point gives the type of tests in which it has been observed.

Following the parameter map for most data points the breaker type seems to be dependent on the relative berm width $B_{eq}$. Within this box all breaker types were observed thus indicating that the relative berm height and the relative wave height are not sufficient to classify the breaker type. However, outside this box some data points can be found with $h_b^* = 1.0$ (i.e. water level in height of the
berm level) which fall in the box of 'broken waves'. The observed breaker types match the parameter map prediction very well so that the map is verified in this region.

For $H_s^* > 0.6$ the data points indicate that the waves will break before reaching the structure. For most of the data points beyond this margin 'broken waves' were observed only. Therefore, the parameter map can be extended in this region.

In Fig. 10 the same plot is shown for random waves. Again, most data points fall in the region of the parameter map in Fig. 1 where a further distinction by the relative berm width $B_{eq}$ is required. All other data seem to support the branches of the parameter map in the same way than for regular waves. Additionally, the gap in between 'small waves' and 'large waves' is filled by some data points showing mainly 'quasi-standing' waves but some 'slightly breaking' as well. Therefore, an extension of the parameter map for this region is proposed where a further distinction by the relative berm width will be required.

In a second analysis step all data have been plotted for the region where the predicted breaker type is dependent on the relative berm width. In Fig. 11 the relative wave height is plotted versus the relative berm width $B_{eq}$. Again, all boxes indicate the region of the parameter map which are labelled according to the respective breaker type the parameter map predicts. It should be noted that only data are plotted which fall in the region of the map with a relative berm height of $h_b^* = 0.6 \div 0.9$. All other data were removed from the plot.

From Fig. 11 it can be seen that there are almost no data to support the regions of narrow and wide berms so that most of the data points are within the
Figure 10. $H_s^* \text{ vs } h_b^*$ for Random Wave Tests (All Data Sets)

Figure 11. $H_s^* \text{ vs } B_{eq}^*$ for Regular Wave Tests ($h_b^* = 0.6 \div 0.9$, All Data Sets)

box of 'impact breakers' and above. Within this box no further distinction between breaker types can be made, i.e. that all breaker types are more or less spread all over this area. Therefore, more data would be useful testing the influence of narrow and wide berms, and further analysis is needed to find a criterion for further
discrimination of the breaker types. For practical use, however, all data falling in the aforementioned region of 'large waves' and 'moderate berm widths' should be handled as 'impact breakers' and designers have to realise that impacts could occur at the wall.

Together with the amendments of the map already discussed in this paper the following revised parameter map is proposed for the prediction of the most probable loading cases in front of vertical structures (Fig. 12).

The updated map comprises the following modifications and extensions:

- verification of 'broken waves' for 'crown wall' type breakwaters with a relative berm height $h_b^* > 0.9$;
- extension of the map for high mound composite type breakwaters (HMCB) for $h_b^* = 0.9$ to 1.0;
- extension of the parameter map for regions of relative wave heights $H_s^* > 0.6$ ('very large waves');
- modification of range of relative wave heights $H_s^* = 0.20$ to 0.60 for 'large waves'.

6. Concluding Remarks and Future Work

A 'parameter map' has been developed under PROVERBS (Probabilistic Design Tools for Vertical Breakwaters) in the frame of an ongoing MAST III programme of the European Union (under contract no. MAS3-CT95-0041) to classify the wave loading on monolithic coastal structures and to identify which breaker type leads to impact loading.

Data from four different model tests have been used to verify and extend the parameter map so that an updated version (Fig. 12) is proposed for further design purposes.

However, due to some limitation in the data sets the following future work remains to be done:

- All data sets were based on a foreshore slope of 1:50. It is therefore questionable whether the behaviour of waves approaching the structure over steeper slopes is predictable by the present parameter map. More data are therefore needed to extend the parameter map in this respect.
- Almost no data are yet available for very narrow and very wide berms so that the respective regions of the map are based on very few data only. Further model tests or prototype experience are also needed to verify the map in these regions.
- The boundary between high mound breakwater (HMB) and high mound composite breakwater (HMCB) was set to $h_b^* = 0.9$. More data analysis is needed to specify this boundary.
Figure 12. Updated Parameter Map to Identify Loading Cases

with $h_b^* = \frac{h_b}{h_s}$; $H_s^* = \frac{H_s}{h_s}$; $B^* = \frac{B_{eq}}{L}$; $F_h^* = \frac{F_h}{\rho g H_b^*}$
Acknowledgements

The hydraulic model tests in the GWK on the high mound composite type breakwater were funded by Port and Harbour Research Institute, Japan (PHRI) and Coastal Engineering Research Institute, Japan (CERI). Further analysis of these data with respect to breaking wave aspects were funded by the European Union under contract MAS3-CT95-0041 (PROVERBS). Additional support was given by the German Research Council (DFG) within the basic research project 'Design Wave Parameters in Front of Structures With Different Reflection Properties' (OU 1/3-1). Those supports are gratefully acknowledged.

The use of various data sets for the parameter map was only possible due to the kind support by researchers from HR Wallingford (Prof. William Allsop and Kirsty McConnell), PHRI and CERI, Japan. In particular, special thanks are due to the kind support by Dr. S. Takahashi (PHRI) and Dr. K. Kimura (CERI) who collaborated with LWI in two joint research projects in 1996 and 1998, respectively.

LAGRANGIAN MEASUREMENTS OF ACCELERATIONS IN THE CRESTS OF BREAKING AND BROKEN WAVES.

Abstract.

The present investigation reports synoptic measurements and analysis of particle accelerations and kinematics of plunging crests in deep water wave groups. The unexpected occurrence of unusually large waves has been documented on numerous occasions. While little is known about the statistics of these waves, even less is known of the dynamical conditions under which they occur. Nonlinear interactions among individual waves travelling within a group on an opposing current have been identified as an important mechanism in the formation of giant waves in deep waters in the ocean. In this study, the non-linear packet-focusing technique is used to generate steep, deep water plunging waves in two laboratory flumes. In one of these flumes the plunging breakers were generated on opposing currents. The kinematics of these waves are measured just up-wave of the onset of plunging, and these results are compared to those of a superposition model, a modified stretching model, and a model based on Stokes 3rd order theory combined with a linear wave spectrum for an irregular sea on an opposing current, developed for the present study. The present model represents the velocity beneath the plunging breakers significantly better than the two other models.

1. Introduction.

Breaking waves play an essential role in air-sea interactions, and in assessment of impact loads on both fixed and floating coastal structures, platforms and ships see ( Kjeldsen, 1997). Further breaking waves are very important for mixing and spreading of oil pollution in the upper surface layers of the sea. The dynamic action of the crest of a plunging breaker thus becomes particularly important. Even now when theoretical and numerical treatments of the breaking problem have progressed, controlled experimental measurements for development and calibration of numerical ocean basins are needed. The present investigation reports synoptic measurements and analysis of particle accelerations and kinematics of plunging crests. Furthermore a third order simulation technique is developed in order to predict wave kinematics in extreme waves occurring in irregular seas containing coalescing wave groups.

2. Experiments.

One series of experiments were performed in the large (40 m long) Air-Sea Interaction Simulation Facility of the I.O.A. laboratory of the I.R.P.H.E. Institute, located in Marseille. The wave generation technique developed by (Kjeldsen 1982) was used for production of plunging breaking crests in deep water wave groups. A visualization technique (Bonmarin 1989) makes the wave profile visible and an associated image analysis process allows measurements of both the water surface geometry, crest front steepness and asymmetry (Kjeldsen & Myrhaug 1978), (IAHR/PIANC 1986), as well as detailed measurements of accelerations of tracer particles dragged away by breaking and broken waves. Ten experiments designated by the reference of A11 to A21 were performed.

Another series of experiments were performed in the large wave tank at the Canada Centre for Inland Waters. The tank dimensions are 100 m in length, 4.5 m in width and the water depth for all runs were 1 m. The water surface elevations were measured using four capacitance type water surface piercing wave staffs; two were fixed in the tank and two were on a movable carriage. The velocity was measured with an acoustic Doppler current meter (Sontek ADV-1) mounted on the carriage. The surface elevation data and the velocity data for each run were logged on the current meter computer at 25 Hz. A mean flow in the tank, in the opposite direction to the wave travel, was generated with a pump. The flow entered the tank through a diffuser in the floor about 36 m downwave from the measuring station, and left the tank immediately in front of the wave board, also through a floor diffuser. Mean flows (U_M) of 0.04 and 0.095 m/sec were used for the experiments.

3. Results.

A Lagrangian measurement technique is needed in order to measure particle accelerations accurately in non-linear waves, see (Longuet-Higgins 1986.) In order to develop such a technique the wave-following properties of the tracer particles were mapped. A calibration experiment was performed with a symmetric regular wave with steepness a_k = 0.31. Fig 1 shows the measured trajectory, and a theoretical trajectory predicted by second order wave theory. A significant Stokes drift in agreement with the theory was obtained. This relative good agreement between experiment and theory validates the choice of the floating particles. In the breaking waves the different steps of the measurements were i) the reconstruction of the trajectory of the floating particles, ii) measurements of their celerity, and iii) the measurement of their acceleration, these two last measurements being deduced from the trajectory. Fig. 2 shows an example of surface elevation and location of tracer particles in a plunging breaker developing in deep water. Fig. 3 shows the reconstruction of the trajectories of floating particles, one of them colliding with a breaking crest. Fig 4 shows an example of measured horizontal velocities of two particles P2 and P3, shown in the experiment A15, as it develops in Fig. 2. The horizontal velocities are normalized with the wave phase velocity c. Particle P3 reaches a horizontal velocity equal to the wave phase velocity, as can be seen.
Fig. 1. Comparison of trajectories of a floating particle moving on a quasi symmetrical crest ( ak=0.31), and second order Stokes wave theory.

Fig 5 then shows measured horizontal accelerations of the particles P2 and P3, normalized with the gravity acceleration. The horizontal acceleration of particle P3 reaches a value of 1.35 times the gravity acceleration.

Particle P3 reaches a vertical acceleration 0.78 times the gravity acceleration. Fig 6 shows the total acceleration of this particle. The acceleration of the floating particles increases rapidly in the non-breaking region and reaches a maximum value at the time when the overturning part of the crest collides with them. Total acceleration vectors up to 1.55 g were measured at the free surface. Maximum acceleration and maximum velocity are nearly in phase in these breaking waves, leading to large wave forces, and a significant capsizing potential if encounter happens with small floating objects (small boats, rescue floats or wave buoys).

If wave forces are computed on structural elements of a steel jacket or a tension leg platform then both the particle velocity and the acceleration must be known, and data from the established data bank are used for calibration of the 3-order kinematic model developed in this study for extreme waves in irregular seas with or without currents.

Wave particle accelerations in non-linear waves can not easily be deduced from Eulerian measurements. The wave crests show an asymmetrical shape at the breaking onset (Kjeldsen 1997), and work is in progress to establish a correlation between surface particle accelerations and wave asymmetry, see (Kjeldsen, Bonmarin & Duchemin 1998).

Fig. 6. Total acceleration of floating particle. Experiment A15.

In the offshore industry a stretching theory developed by (Wheeler 1970) has traditionally been used for prediction of kinematics of irregular sea states. In this study, we use a modified stretching model (Lo and Dean 1986) as representative of this class of model. (Donelan et al. 1992) report that it produces velocities very similar to the Wheeler method. We also used the superposition method proposed by (Donelan et al. 1992), based on the linear superposition of a sum of freely propagating wave trains. Even when adapted to account for a possible mean flow, these linear models do not adequately represent the velocity beneath the coalescing wave group.

In the present study we therefore developed a third order simulation of the kinematics in steep wave crests, see (Skafel, Drennan and Kjeldsen 1997). This third order simulation technique is based on a combination of two earlier models. The first of these was developed by (Kishida and Sobey 1988) and simulates a Stokes third order wave train on a current with a linear profile.

This model is then used both for cases where non-linear waves propagate on opposing currents, and for cases without currents. However this model does not give a complete description of the wave spectrum developed by the command signal in the wave flume. Therefore the superposition model developed by (Donelan et al. 1992) is also used. The procedure for computation then becomes:
- 1. A third order wave train interacting with a current with a constant vorticity is computed.
- 2. The third order wave train is subtracted from the experimentally obtained surface elevation.
- 3. The kinematics of the remaining wave signal is analysed using the superposition model of (Donelan et al. 1992).
- 4. Finally the solutions obtained in steps 1) and 3) above are added, using the surface of the non-linear wave as mean water level for the additional wave components, in agreement with the concept behind the development of (Donelan et al. 1992).

5. Model Comparison.

Fig 7 shows an example from CCIW experiments of internal maximum horizontal velocities measured below extreme wave crests. The mean predicted velocity profiles beneath the crests using the modified stretching model, the superposition model, and the present third order model are shown in Fig. 8 along with the experimental laboratory profiles. All the kinematic models were run for the surface elevation time series of all the laboratory runs (26 experiments with the same condition). The resulting mean profiles, along with twice the standard deviations about the means are plotted. The narrowness of the spread of the standard deviations presented in Fig. 8 serves as an indication of the excellent reproducability of the wave trains. Fourier analysis of each surface profile was used to find the peak frequency, and hence the peak wave number \( k_0 \). The mean peak wave number for all 26 runs, in this case \( k_0 = 1.38 \text{ m}^{-1} \) was used for normalisation. It can be seen here that the modified stretching model underpredicts the velocity significantly throughout the profile. The superposition model more nearly represents the data. The new third order model developed here best reproduces the data. It slightly underestimates the velocity, lying just outside the two standard deviation range. A further development of the new model is in progress. (Kjeldsen, Skafel, Drennan 1998).
Fig. 7. Panel a shows the time series of the water surface elevation, just upwave of breaking, normalized by the peak wave number \( k_0 = 1.38 \), and frequency \( \omega_0 \). \( U_M \) is the mean current velocity of opposing current.

- : \( U_M = 0 \) cm/sec.  --- : \( U_M = 4 \) cm/sec.  ------: \( U_M = 9.5 \) cm/sec.

Panel b shows the corresponding normalized horizontal orbital velocity \( u \) for \( U_M = 9.5 \) cm/sec.

--- : 4 cm above the still water level.  --- : 20 cm below the still water level.
Fig. 8. Maximum horizontal orbital velocities \( (u) \) beneath the crest just upwave of breaking, normalized by \( k_0 \) and \( \omega_0 \), versus elevation \( (z) \) normalized by \( k_0 \).

*: measured values. — — — : mean of linear superposition model.
— * — : mean of modified stretching model. — — : present model.
The horizontal bar on the data point at the elevation of 0.05 represents two standard deviations about the mean. The shaded areas around the model lines enclose twice the standard deviations.
6. Conclusions.

1. A new third order kinematic model simulating the velocity beneath extreme waves has been developed; it represents the velocity beneath extreme waves occurring in irregular seas with or without current better than the modified Wheeler stretching model and the linear superposition model.

2. The new third order kinematic model can easily be adopted to take into account the directional spreading in a non-linear directional sea state interacting with a current.

3. A Lagrangian measurement technique is needed in order to measure particle accelerations in non-linear waves. By means of a visualisation technique it was possible to measure both the Lagrangian particle accelerations in breaking wave crests, and Stokes drift in steep waves as well as particle drift caused by breaking wave crests.

4. Both horizontal and vertical accelerations were measured not so far from the ones predicted by the numerical model developed by (Vinje & Brevig 1980). Total particle accelerations up to 1.55 g were measured in plunging breakers occurring in deep water.

5. The behaviour of the tracer particles is similar to the one of free floating oceanographic buoys (operated at sea without moorings as in parts of the LEWEX experiment, see (Beal 1989)). If buoys are moored it is well known that they follow a more linear mode. Moored buoys will therefore not measure particle accelerations in non-linear breaking waves correctly.

6. The behaviour of the tracer particles is also similar to the one of rescue floats deployed after a ship accident in a swell. Drift of rescue floats at sea is also depending on wind, and drag coefficients related to float design. Accurate modelling of surface drift of smaller objects is very important for management of search and rescue operations at sea.

7. The wave generation technique of (Kjeldsen 1982), modified for opposing currents, was able to generate unusually large plunging breakers with crest front steepnesses in the range 0.25 - 0.41, similar to observations on the Norwegian Continental Shelf.

7. Further Work.

1. Results are also obtained for spilling and plunging breakers on beaches. These will be dealt with in a separate report.

2. A further development of experimental technique using smaller particles and a high speed camera is considered.

3. A further development of the new kinematic model incorporating an overturning jet on the steep irregular wave is considered, in order to simulate capsizing of smaller objects in a numerical ocean basin.
8. Acknowledgement.

Abstract

In this paper, the VOF method for free surface flow is applied to simulate breaking waves incident on a submerged reef. An efficient numerical wave channel with two absorbing boundaries is developed. Corresponding boundary conditions are prescribed. Smagorinsky's sub-grid scale model is incorporated to account for the sub-grid scale turbulence. Numerical results are compared with laboratory measurements.

Introduction

Owing to the extremely complicated wave manner caused by the wave nonlinearity and breaking, a complete satisfactory theory for wave deformation on uneven topographies seems to be not attainable so far. Small-scale model tests and field observations are still dominant in the traditional study. Nevertheless, small-scale model tests suffer from the scale effects, while large-scale model tests are too expensive.

The booming progress in computer technology in the past decade witnesses the continuous improvements in computational fluid dynamics. With today's personal computer, it is possible to solve the Naiver-Stokes equations for coastal engineering problems.

The VOF method developed by Hirt and Nichols (1981) is among the best candidates for solving free surface flow problems due to its clearness and simplicity of

2Professor, ditto. Tel/Fax: +81-48-858-3561, E-mail: tanimoto@envi.env.civil.saitama-u.ac.jp
tracing free surface. Besides, this method is especially useful for calculating breaking waves, since the free surface is not necessarily required to be single. Several studies based on the VOF method to simulate breaking waves have been reported recently (van der Meer et al., 1992; Lemos, 1992; Petit et al., 1994; van Gent et al., 1994; Sabeur et al., 1996; Kawasaki and Iwata, 1997; Lin and Liu, 1998; etc.).

However, most of these studies either ignore the sub-grid scale turbulence totally, which implies that the sub-grid scale energy dissipation purely relies on the numerical viscosity appeared in the finite difference schemes; or use a constant eddy viscosity of the same order as that of Reynolds Averaged Navier-Stokes (RANS) equations.

Lemos (1992), Lin and Liu (1998) demonstrate two-dimensional breaking wave models based on the Reynolds Averaged Navier-Stokes equations separately. Both of them used the $k-\varepsilon$ model with standard coefficients. Lemos used a linear closure for the Reynolds stress terms, while Lin and Liu used a nonlinear closure to account for the anisotropic turbulence. Nevertheless, Lemos’ results were not compared with experimental measurements directly. Lin and Liu’s results showed that their model could give generally good agreement at the inner surf zone. Near the breaking point, however, the $k-\varepsilon$ model always overestimates the eddy viscosity, and thus leads to an underestimation of surface elevation. If we consider the breaking point is the transition point from laminar flow to turbulent flow, this in one way suggests the limitation of the $k-\varepsilon$ model in predicting the flow transition. Besides, there are too many coefficients in the $k-\varepsilon$ model, and this makes it difficult for calibration.

In the present paper, therefore, we are trying to use a space filter to account for the sub-grid scale turbulence. It is expected that the sub-grid scale turbulence is more isotropic and less flow dependent, therefore, the closure model can be simpler and less sensitive to the parameterization. However, due to the very high Reynolds number and limited computer resources, we restrict the present study to two-dimensional problem.

**Numerical Formulation**

The governing equations are the mass conservation equation for incompressible flows:

$$\frac{\partial u_i}{\partial x_j} = 0$$

and the Navier-Stokes equations:

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{1}{\rho} \frac{\partial p}{\partial x_i} + \nu \frac{\partial}{\partial x_j}[\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}] + g_i$$

in which $\rho$ and $\nu$ are the fluid density and kinematic viscosity, respectively. $g_i$ is the gravitational acceleration at the $i$th direction, $u_i$ is the velocity component, and $p$ is the pressure. Here $i = 1, 2$ correspond to horizontal ($x$) and vertical ($z$) directions, respectively, $j$ is dummy.
Assuming that the sub-grid scale turbulence is isotropic, the filtered Navier-Stokes equations and the continuity equation read:

\[
\frac{\partial \bar{u}_i}{\partial x_j} = 0
\]

\[
\frac{\partial \bar{u}_i}{\partial t} + \bar{u}_j \frac{\partial \bar{u}_i}{\partial x_j} = -\frac{1}{\rho} \frac{\partial p}{\partial x_i} + \nu \left( \frac{\partial^2 \bar{u}_i}{\partial x_j \partial x_j} + \frac{\partial^2 \bar{u}_i}{\partial x_i \partial x_i} \right) - \frac{\partial}{\partial x_j} (\bar{u}_i \bar{u}_j - \bar{u}_i \bar{u}_j) + g_i
\]

The top-hat filter (cell volume) is applied in the above equations, and the over-bars denote the resolvable scale quantities (for example \(\bar{u}_i\)):

\[
\bar{u}_i(x, z, t) = \frac{1}{\Delta x \Delta z} \int_{x-\frac{1}{2} \Delta x}^{x+\frac{1}{2} \Delta x} \int_{z-\frac{1}{2} \Delta z}^{z+\frac{1}{2} \Delta z} u_i(\zeta, \eta, t) d\zeta d\eta
\]

where \(\Delta x\) and \(\Delta z\) are the mesh sizes of the finite-difference equations in \(x\) and \(z\) directions, respectively. The \(\bar{u}_i\) is the filtered velocity component; \(\bar{p}\) is the filtered pressure. The new terms appeared in the filtered equations are:

\[
(\bar{u}_i \bar{u}_j - \bar{u}_i \bar{u}_j) = L_{ij} + C_{ij} + R_{ij}
\]

with \(L_{ij}\), \(C_{ij}\), \(R_{ij}\) referred as the Leonard term, the cross term and the sub-grid scale (SGS) Reynolds term, respectively:

\[
L_{ij} = \bar{u}_i \bar{u}_j - \bar{u}_i \bar{u}_j
\]

\[
C_{ij} = \bar{u}_i \bar{u}_j + \bar{u}_i \bar{u}_j
\]

\[
R_{ij} = \bar{u}_i \bar{u}_j
\]

The prime denotes a SGS quantity. Notice that the sum of the Leonard term and the cross term \((L_{ij} + C_{ij})\) is small comparing with the SGS Reynolds stress (Dear-dorff, 1970), and thus can be neglected. Therefore, we finally obtain the filtered Navier-Stokes equations in which the SGS Reynolds stress need to be modeled.

Applying Boussinesq's eddy-viscosity hypothesis, the SGS Reynolds stress is given by:

\[
R_{ij} = -2\nu_T S_{ij}
\]

where

\[
S_{ij} = \frac{1}{2} \left( \frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right)
\]

is the strain rate tensor of the resolved scales. Smagorinsky's model gives:

\[
\nu_T = (C_s \Delta)^2 |S|
\]

\[
\Delta = (\Delta x \Delta z)^{\frac{1}{2}}
\]

in which \(\nu_T\) is SGS eddy viscosity, \(\Delta\) is SGS length scale for two-dimensional problems, and \(C_s = 0.10\).
Equation (12) is used otherwise of the fluid except at the solid boundary, where the van Driest damping function is applied to the SGS length scale. At free surface, the closure for the SGS Reynolds stress is less certain, we apply Smagorinsky's model at the present stage.

Besides the above equations, a volume of fluid function \( F \) is used to define the fluid region in the VOF method. A unit value of \( F \) corresponds to a cell full of fluid, while a zero value indicates that cell contains no fluid. Cells with \( F \) values between zero and one represent the water-air interface. The governing equation of \( F \) function is given by:

\[
\frac{\partial F}{\partial t} + u_j \frac{\partial F}{\partial x_j} = 0
\]  

(14)

Numerical Methods

The governing equations are discretized using a staggered grid where the velocities are located at the cell faces, the pressures and the \( F \) functions are settled at each cell center. The time increment is achieved by the Euler scheme and the convective terms are approximated by the third-order difference scheme due to stability consideration.

In order to obtain accurate result, boundary conditions must be treated very carefully. In the present study, the boundary conditions for resolved field have been summarized into three kinds, namely, the lateral boundary conditions, the free surface boundary conditions and the solid boundary conditions.

The lateral boundary conditions include the inflow boundary and the outflow boundary (open boundary). At the inflow boundary, we choose to generate the incident wave by simulating a piston-type wave-maker. The wave paddle is driven by the second order Stokes wave theory (Hughes, 1993), and an absorbing wave-maker system (Zhao, 1998) which is essentially same as that in the physical experiment. This method is particularly effective for our case, where waves are generated at deeper water region and encounter a reflective structure (submerged reef with a steep reef face). The secondary wave for this case is very small according to our study. The example of second order Stokes waves incident on a vertical wall is shown in Fig. 1, where \( T \) is the wave period, \( h \) is the still water depth, \( H_i \) denotes the incident wave height, \( L \) is the incident wavelength calculated by linear wave theory, and \( \eta \) is the water surface relative to the still water level.

At the open boundary, an artificial boundary condition has to be given to truncate the computational domain from the infinite physical domain, but without rendering disturbances to the inside area. For wave problems, this is normally fulfilled by the well-known Sommerfeld radiation boundary condition. However, the wave dispersion induced by wave nonlinearity and breaking makes it difficult to use one wave celerity to represent the whole wave field. Hence, a damping zone (Arai, 1993) and the Sommerfeld radiation condition are combined at the open boundary.

Fig. 2 Examples of surface cells partially open to the air
The solid arrows denote the velocities normally calculated;
the dash arrows denote the velocities obtained by extrapolation
The free surface boundary conditions include the dynamic and the kinematic boundary conditions. The dynamic boundary condition is satisfied by $\bar{p} = 0$ at the free surface. The pressures at the surface cells are calculated by linear extrapolation from the cells inside the fluid domain. The kinematic boundary condition is automatically satisfied by Eq. (14). However, special care must be paid to the treatment of velocities at surface cells. The examples are shown in Fig. 2, where parts of the cell faces are exposed to the air. For these cases, the momentum equations for water can not be used. The determination of these values is quite arbitrary. In the original VOF method (Hirt and Nichols, 1981) and some other methods related to the VOF method (ex. Ashgrizon and Poo, 1991), these velocities are obtained by the continuity equation. In the calculation of solitary
wave, Chan and Street (1970) used vertical extrapolation to obtain these velocities, therefore, the continuity equation is not forced at the surface cells. Actually, the approximation of the former method is acceptable provide the flow in nonperiodic. But it brings considerably errors for periodic problem. Figure 3 shows the calculated results by the original VOF method at different vertical positions.

It is seen that the influence of the free surface boundary increases considerably as the vertical position approaches to the surface. And this effect is more pronounced for the horizontal velocities than the vertical velocities. Accordingly, in our calculation, we used the extrapolation to obtain the horizontal velocities. For example, \( u(i + \frac{1}{2}, j) \) in Fig. 2 can be approximated as:

\[
\begin{align*}
&u_{i+\frac{1}{2}, j} = [u_{i-\frac{1}{2}, j} \cdot 0.5 \cdot (\Delta z_j + \Delta z_{j-1}) + u_{i+\frac{1}{2}, j-1} \cdot \Delta x_i]/[\Delta x_i \cdot 0.5 \cdot (\Delta z_j + \Delta z_{j-1})] \quad (15)
\end{align*}
\]

In case the vertical velocity is also exposed to the air (Fig. 2(b)), the vertical velocity can be obtained by the continuity equation. As for the case shown in Fig. 2(a), there is no way to satisfy the continuity equation in the surface cells. The results of the modified calculation are shown in Fig. 4.

In the numerical simulation, still water level is given at time \( t = 0 \). No initial superimposed condition has been introduced to the sub-grid scale variables.

Fig. 4 Examples of orbital velocities calculated by the present calculation: at the trough level \( (z/h = -0.07) \); above the still water level \( (z/h = 0.04) \)
Verification with Experimental Measurements

1. Experimental Setup

Finally, breaking waves propagating on a submerged reef are numerically calculated and verified with previous experimental data (Nakamura 1995).

Figure 5 shows the experimental setup and coordinates layout. The wave channel is 17.0 meters long. The model reef is fully impervious and 32.5 cm high with a seaward reef face of 1:2. Regular waves were generated by a computer-controlled piston type wave-maker. Water surface elevations were measured by capacitance-type wave gauges. In the experiment, only six wave gauges were available. The first two gauges (from the wave paddle) were served as reference gauges for incident waves. The other 15 locations of water surfaces were obtained by moving the remained four wave gauges prior to each run. In each run, data were recorded simultaneously from 6 channels at sampling time interval of 50 ms. Velocities and pressures were measured at three locations (I, II and III) on the slope of the reef for case A. The \( \frac{L}{A} \) in the figure denotes a quarter of incident wavelength calculated by linear wave theory. The incident wave characters are given in Table 1 in which \( x_b \) is the measured position nearest to the breaking point.

In the calculation, incident waves are generated at the left boundary. In order to avoid the pressure divergence at the initial stage, incident wave heights were slowly increased to \( H_{in} \), where \( H_{in} \) is the incident wave height obtained by comparing the surface elevations at reference gauge with the physical experiments. The calculated surface elevations were obtained by integration of the \( F \) function from the bottom of the channel to the water surface. In the position where air entrainment appears inside the fluid domain, the \( F \) function was set to 1 to keep consistency in the experimental measurements. In order to limit effects of wave reflection from the end of the wave channel, the analysis of the experimental data was restricted to the first fully grown-up four or five waves in a record.
2. Calculation Results

Figure 6 shows the normalized vertical distribution of velocities, phase difference and dynamic pressures of case A in which $H$ is the local wave height. To be succinct, only the results of position III are presented here. Besides the experimental results and the numerical simulation, the first order Biesel theory with slight modification (Zhao et al., 1996) is also presented. The general agreements among the analytical solution, the numerical simulation and the experimental results are good. The numerical simulation and the experimental measurement show the same trend of skewness in the vertical velocity and phase difference.

![Graphs showing vertical distribution of velocities, phase differences, and dynamic pressures](image)

Fig. 6 Vertical distribution of maximum and minimum orbital velocities, phase differences and dynamic pressures

- Measured
- Biesel theory
- Present calculation

Figure 7 shows the simulated time series of surface elevations together with experimental measurements. Both the measured and calculated surface elevations include the reflective waves from the submerged reef.
Fig. 7 Comparison of surface elevations (Case B) at positions:
before wave breaking (a, b); near the breaking point (c);
after wave breaking (d, e, f)

○ Measured  ——— Calculated

Fig. 8 Comparison of wave height and mean water level distribution
The wave height distribution and mean water level changes are presented in Fig. 8. It is seen that the numerical simulation can give very good results of breaking waves incident on a submerged reef at the reflection side, near the breaking point, and at the transmission region. However, the calculation intends to underestimate the mean water level changes.

Figure 9 shows the filtered vorticity distribution of case B where BP denotes the position of measured breaking point. According to the calculation, the vortices in the figures are generated by two mechanisms, one is by the breaker, and the other one is by the presence of the submerged reef.

![Fig. 9 Vorticity distribution at different phases: approaching the breaking point (a); after wave breaking (b,c)](image)

The figure indicates that the vortex generated by the breaker is initiated at the toe of the wave front. This vortex is further convected and diffused to almost the whole wave crest.

The other kind of vortices is due to the appearance of the submerged reef. Clockwise and counter-clockwise vortices are generated alternatively depending on the phase of the wave motion. These vortices are not as strong as the one generated by the breaker. They are also convected by the wave.
The figure also shows that for the present condition, the vortex generated by
the breaker is confined above the trough level.

It should be noticed that the present model, as well as other two-dimensional
models, lacks the three-dimensional vortex stretching mechanism. However, two-
dimensional vortex stretching is enabled due to the numerical viscosity.

In Fig.10 we show the spatial distribution of the sub-grid scale eddy viscosity
normalized by kinematic viscosity. The calculation shows that the highest eddy
viscosity, about 120 times of the kinematic viscosity, is appeared slightly after the
measured breaking point. The SGS eddy viscosity is smaller than those calculated
from Reynolds-averaged equations. This is because that in the present method,
only parts of the turbulence whose length scales are smaller than the mesh sizes
are modeled. In the RANS models, all fluctuations are modeled. However, it
seems premature to say at this stage that the fluctuations appeared in our cal-
culation are turbulence. The fact that \( F \) is a step function and the air bubbles
which occasionally appeared in the fluid may also contribute to these fluctuations.
Further study is necessary. At the present stage, our model can only capture the
major flow.

Conclusions and Further Improvements

In this paper, the VOF method is applied to simulate breaking waves incident
on a submerged reef. In the calculation, an absorbing wave-maker is adopted to
handle the wave reflection from the structure. In order to account for the sub-grid
scale turbulence, a space filter is applied. The closure is given by Smagorinsky’s
model. The comparison between the simulation and experimental measurements
showed satisfactory agreements. Future work would use a modified SGS model
instead of Smagorinsky’s SGS model, or develop 3D models to scrutinize the tur-
bulent flow more carefully. The studies of air-water mixing and non-negligible
density variations are also necessary.
Acknowledgements

The work presented here is part of the Ph.D. study of the first author. She is grateful to the Japanese Government and the Japan Society of Promotion of Science for granting her the Monbusho Scholarship and the JSPS fellowship to make this study and the presentation possible. The invaluable suggestions from Prof. Kiyoshi Horikawa, Emeritus of the University of Tokyo, and Dr. Vu Thanh Ca, Saitama University, are gratefully acknowledged.

INFLUENCE OF STEEP SEABED SLOPES ON BREAKING WAVES FOR STRUCTURE DESIGN

N.W.H. Allsop¹, N. Durand² & D.P. Hurdle³

ABSTRACT

Prediction of limiting wave heights in conditions of depth-induced breaking is subject to considerable uncertainties, yet the (local) wave height is probably the most important input variable in design of coastal, harbour or shoreline structures subject to wave action.

This paper presents selected results from laboratory experiments to measure depth-limited wave breaking over steep bed slopes (1:50, 30, 20, and 1:10) in fully random wave conditions. Experimental measurements are compared with predictions for $H_{rms}$, $H_s$ and $H_{max}$ under shoaling and breaking. The effects of shoaling and breaking on the wave height distributions are explored. An alternative empirical method to predict $H_{1/3}$ and $H_{max}$ is suggested.

1. INTRODUCTION

1.1 Is there a problem?

Many coastal structures and some harbour breakwaters are constructed in relatively shallow water depths where the larger wave heights that constitute the primary input parameters in structure design are significantly influenced by depth-limited breaking. Prediction methods to calculate hydraulic or stability responses of these structures generally use the incident significant wave height ($H_s$) as primary input variable, often defined in the water depth at the seaward toe of the structure, $h_s$. Where wave breaking has significant influence on design wave heights, this approach therefore requires that prediction methods for depth-limiting must be robust and reliable.

Design methods for wave overtopping, armour movement and related responses require values of the incident significant wave height, $H_{1/3}$. In contrast, calculations of wave forces using Goda's method often use an upper limit estimate of $H_{\text{max}}$ such as $H_{1/250}$. Neither of these values are reliably derived from wave breaking prediction methods which use spectral measures.

A few design methods use offshore wave heights in deeper water, say $H_{so}$, and use empirical methods to predict the response directly, calibrated for a range of simple bed slopes. The best-known examples are methods developed by Goda (1975, 1985) to predict overtopping or forces on vertical walls which use a single equivalent sea bed slope. Such methods assume that each approach bathymetry may be represented by a simple bed slope, and that the empirical prediction methods fully represent the effects of different wave transformations on the response of interest.

Most experimental studies on wave breaking have been on bed slopes shallower than 1:30, typically 1:50 or 1:100. On these slopes, wave shoaling is relatively mild, and wave breaking reasonably well understood, but there is growing evidence that steep bed slopes transform waves differently and give more severe hydraulic and structure responses. Jones & Allsop (1994), Southgate & Stripling (1996), Hamm & Peronnard (1997), Nelson (1997) and McConnell & Allsop (1998) demonstrate not only that many methods to predict wave conditions under breaking suffer from significant limitations, but that some responses seem to be particularly influenced by local sea bed slopes, in some instances to an extent not covered by using local wave heights in the calculations. These seem to be especially noticeable for slopes steeper than 1:50.

### 1.2 Research studies

New or improved methods to predict wave behaviour and breaker heights are needed to improve safety of structures constructed in the surf zone. In the first instance, a series of hydraulic model studies were completed by HR Wallingford for the Flood & Coast Defence division of the Ministry of Agriculture, Fisheries and Food (MAFF) to provide more information on wave breaking behaviour. Co-operation with Alkyon Consultancy & Research and TUDelft in the Netherlands to share laboratory and field data on wave breaking is intended to ensure as large and reliable a dataset as possible. It should however be noted that the results presented in this particular paper represent only part of the data, and relatively simple levels of analysis.

Other studies on wave breaking at vertical or composite breakwaters have been conducted as part of the EU PROVERBS project, see particularly Calabrese & Allsop (1998). Those studies have concentrated on whether wave conditions, depth and geometry will cause wave impacts on the wall, and are not intended to predict breaking/broken wave heights, so will not be addressed further here.

### 2. PREDICTION METHODS FOR WAVE BREAKING

This paper does not attempt to give an overall review of prediction methods for wave breaking, but draws on the review by Southgate (1995). Additional papers or reports are cited where they amplify or up-date that review. It may be noted that many of the methods cited by Southgate give information only at a single point, but in design of realistic structures, it is important that predictions be valid over a wide range of
relative depths / breaking regions. Predictions of wave breaking are tested here against measurements from the onset of breaking onwards.

The primary cause for wave breaking in deep water is that the wave steepness exceeds the fundamental limit given for individual waves by:

$$\frac{H}{L}_{\text{max}} = 0.142$$  \hspace{1cm} (1)

In shallow water, the main processes of interest in wave breaking may be divided into two. The first processes are those of wave transformations up to, but not beyond, the point of breaking. These include refraction and diffraction (neither discussed further here), and shoaling (here of considerable interest). These processes involve no significant loss of energy and are essentially reversible. The second set of processes are those which occur from breaking onwards. These processes involve significant loss of energy and are not reversible. It is noted that in some analysis, effects of shoaling and then breaking have been somewhat confused. Confusions may also have arisen from differences between regular waves (where all waves behave the same) and random waves (in which breaking positions and other features vary with period and height of each wave). These differences are particularly evident where methods to predict wave breaking have been developed using regular waves only, but are then applied to "real sea" cases where waves are random.

A final source of confusion is the use of significant wave height $H_s$ in design methods, and numerical models to predict wave conditions, without more careful definition of its derivation, be it spectral ($H_s = H_{m0}$) or statistical ($H_s = H_{1/3}$). Differences between $H_{1/3}$ and $H_{m0}$ were first highlighted by Thompson & Vincent (1984) and described more recently by Hamm & Peronnard (1997). The main problem arises where one method has been used to define wave conditions in model testing used to derive empirical design methods, and then a different method is used to derive design wave conditions. Comparisons in this study have shown that differences between $H_{4/3}$ and $H_{m0}$ are greatest for low wave steepnesses when non-linear shoaling is pronounced.

2.1 Flat bed slopes
For very shallow bed slopes, usually taken as flatter than 1:100, it is often assumed that a simple limit to the individual wave height relative to local water depth may be given by:

$$\frac{H_{\text{max}}}{h} = 0.78$$ \hspace{1cm} (2a)

Later researchers showed that this limit, suggested by McCowan based on solitary wave theory (see Southgate, 1995), might be increased to $H_{\text{max}}/h = 0.83$. Perversely, Le Mehaute appears to give a much lower limit of individual wave height relative to local water depth:

$$\frac{H_{\text{max}}}{h} = 0.55$$ \hspace{1cm} (2b)

2.2 Sloping seabeds
The methods most frequently used in practical design calculations for structures are those by Weggel (1972), Goda (1975) and Owen (1980). Weggel used regular wave test data to derive simple empirical expressions to predict maximum wave heights in depth $h_s$:

$$\frac{H_{\text{max}}}{h_s} = \frac{b}{(1 + a h_s/(g T^2))}$$ \hspace{1cm} (3a)
where coefficients a and b are defined in terms of the seabed slope m:
\[
a = 43.75 \left(1 - \exp(-19m)\right) \\
b = 1.56 / \left(1 + \exp(-19.5m)\right)
\]

Goda (1975) developed a prediction method for irregular wave breaking, even suggesting a method to transform the wave height distribution under breaking conditions. For shoaling, Goda used Shuto’s method instead of simple linear wave methods to give the shoaling coefficient \( K_s \).

For wave breaking where \( h/L_{po} \geq 0.2 \):
\[
H_{1/250} = 1.8 K_s H_{so}
\]

For \( h/L_{po} < 0.2 \):
\[
H_{1/250} = \min \{ \beta_0 * H_{so} + \beta_1 * h, \beta_{max} * H_{so}, 1.8 K_s H_{so} \}
\]

where:
\[
\beta_0 = 0.052 \left(\frac{H_{so}}{L_{po}}\right)^{-0.38} \exp(20m^{1.5}) \\
\beta_1 = 0.63 \exp(3.8m) \\
\beta_{max} = \max \{ 1.65, 0.53 \left(\frac{H_{so}}{L_{po}}\right)^{-0.29} \exp(2.4m) \}
\]

Where \( H_{1/3} \) is needed in design, Goda suggested a similar method for \( H_{1/3} \).

For \( h/L_{po} \geq 0.2 \):
\[
H_{1/3} = K_s H_{so}
\]

For \( h/L_{po} < 0.2 \):
\[
H_{1/3} = \min \{ \beta_0 H_{so} + \beta_1 h, \beta_{max} H_{so}, K_s H_{so} \}
\]

where:
\[
\beta_0 = 0.028 \left(\frac{H_{so}}{L_{po}}\right)^{-0.38} \exp(20m^{1.5}) \\
\beta_1 = 0.52 \exp(4.2m) \\
\beta_{max} = \max \{ 0.92, 0.32 \left(\frac{H_{so}}{L_{po}}\right)^{-0.29} \exp(2.4m) \}
\]

Noting that for steep bed slopes, waves may shoal substantially before breaking starts, Owen (1980) developed a simple method to provide first-estimates of the upper limit to the (significant) wave height \( H_{sb} \) in any water depth \( h_s \) for each of five bed slopes. The method was derived as a part-way point in predicting wave overtopping of seawalls, and was not itself validated against any data on breaking wave heights. Owen's simple curves were derived graphically, see Figure 1, but were later described by empirical equations relating breaker index \( H_{sb}/h_s \) to relative depth \( h_s/gT_m^2 \):

![Figure 1](image-url)
In analysing laboratory and field data for slopes up to 1:20, Battjes & Stive (1984) did not detect any systematic dependence of wave conditions on slope, but did find an influence of wave steepness. They developed an expression for a breaking coefficient, taken by Southgate (1995) to give the limiting r.m.s. wave height:

\[ \frac{H_{rms}}{h} = 0.5 + 0.4 \tanh \left( \frac{33 H_{rms}}{L_{po}} \right) \]  

(6)

The literature gives relatively little advice on changes to wave height distributions with breaking, but Simm (1991) cites equations for extreme wave heights \( H_{0.1\%} \) and \( H_{1\%} \) probably originating from Klopman & Stive (1989):

\[ H_{1\%} = 1.517 \frac{H_s}{1+\left(\frac{H_s}{h_s}\right)^{1/3}} \]  

(7a)

\[ H_{0.1\%} = 1.859 \frac{H_s}{1+\left(\frac{H_s}{h_s}\right)^{1/2}} \]  

(7b)

2.3 Numerical models

During this study, many of the wave measurements were also compared with two numerical models: WENDIS and COSMOS2D. WENDIS is a Wave ENergy DISSipation model, designed to estimate near-shore wave conditions at coastal structures where shoaling (linear shoaling theory), bed friction (Hunt and Bretschneider & Reid), and wave breaking (Weggel) may be significant. COSMOS2D is a numerical model of near-shore hydrodynamics, sediment transport and morphological changes which includes wave transformation by refraction, shoaling (linear wave theory), bed friction and wave breaking (Battjes & Stive and Weggel). Some of these comparisons were discussed by Durand & Allsop (1997).

3. EXPERIMENTAL STUDY

Wave conditions were measured using statistical (and later spectral) methods for 2 or 3 water levels over five different bed slopes:

- 1:50, indicative of shallow sand beach slopes;
- 1:30 and 20, indicative of steeper sand beaches;
- 1:10 and 1:7, indicative of rock coasts and shingle beaches.

The results discussed in this paper were mostly derived from supplementary tests conducted by the visiting researcher on a 1:30 slope, with some comparisons with data from the main series of tests on bed slopes of 1:50, 1:20 and 1:10. Additional data for a 1:10 slope by Allsop (1990) and on a 1:20 slope by Southgate & Stripling (1996) has not yet been included in these analyses.

3.1 Outline of experiments

The main tests used uni-modal or bi-modal seas, 30 wave conditions divided into six sequences of five tests, described by Hawkes et al (1998) and Coates et al (1998):

a) Wind-sea only
b) More wind-sea (80%) than swell (20%)
c) Equal wind-sea and swell
d) More swell (80%) than wind-sea (20%)
e) Swell only

Swell and wind sea conditions used standard JONSWAP spectra ($\gamma=3.3$) defined by $H_s$ and $T_p$. Bi-modal conditions combined two JONSWAP spectra, each defined by $H_s$ and $T_p$. Supplementary tests of wave breaking included a few regular wave conditions; some modified spectra of different spectral peakedness ($\gamma=1$ to 7), and a few rectangular spectra. Other measurements in tests reported by Hawkes et al (1998) and McConnell & Allsop (1998) included wave overtopping discharges, rock armour stability, and wave pressures / forces on vertical walls.

![Figure 2](image.png)

**Figure 2** Configuration for supplementary tests on 1:30 bed slope

Most of the tests on wave breaking used the Absorbing Flume at Wallingford with a working length of 36m, and equipped with a random wave generator with computer-controlled absorption system. In each instance, the sea bed slope was terminated in a horizontal section below water, behind which was a gravel beach to absorb remaining wave energy. The supplementary tests on 1:30 slope used a 6m wide flume within a wave basin with two mobile piston paddles, and the 1:30 slope itself was slightly unusual as it featured a short steep (1:10) approach ramp at the toe, Figure 2.

Up to 16 wave probes were placed along the test sections, usually 1 or 2 probes in deep water near the wave paddle, 3 or 4 being placed along the horizontal section at the top of the slope, and the remaining probes up the slope. Each test was run for 500 waves or longer, sampled at 20 Hz (model) giving an average of 20-60 points per wave. In general, wave measurements were analysed statistically using a zero down-crossing definition for each wave. Selected data files were later also analysed spectrally, and some of the results of this analysis are discussed by Hurdle et al (1998) in an accompanying paper.

4. **RESULTS**

4.1 **Parameters derived**

Most wave measurements discussed here are presented as significant wave heights, $H_{1/3}$. Both spectral and statistical methods have been used to derive wave heights during these studies, but most weight in this paper will be given to statistical measures of wave height, particularly $H_s = H_{1/3}$. This should avoid problems of confusion.
between $H_{m0}$ and $H_{1/3}$ highlighted originally by Thompson & Vincent (1984), and most recently by Hamm & Peronnard (1997).

Two other measures of wave heights may be used. The maximum wave height $H_{\text{max}}$ will depend on sample size, and is itself relatively unstable. In this study, $H_{\text{max}}$ is generally given by $H_{99.8\%}$ or $H_{99.9\%}$. A more stable measure of wave height favoured by morpho-dynamic researchers is root mean square wave height, $H_{\text{rms}}$, defined spectrally as $H_{\text{rms}} = H_{m0}/\sqrt{2}$.

The main measures of wave period used here are the spectral peak period, $T_p$, or mean period $T_m$. The peak period is more stable than the mean period measured either spectrally or statistically, and is less susceptible to distortion by measurement or calculation errors. Sea states have been categorised by the (fictional) steepness, $s_p = H_s/L_p$, where $L_p = gT_p^2/2\pi$, or the equivalent using the mean period, $s_m = H_m/L_m$.

### 4.2 General shoaling and breaking

The complex nature of breaking under random waves precludes any presentation of all features in a single graph. The initial form of presentation by Durand & Allsop (1997) is used here for the first few examples with measurements of local significant wave height against distance along the test flume, see Figure 3.

This presentation allows the effect of shoaling to be identified as waves react to the rising seabed. The onset of breaking occurs at the peak of the wave height, although in some tests this onset was quite difficult to assess. Breaking continues as the waves move into shallower water or, for some tests, over the
horizontal bed at the top of the slope, even if at a slower rate. For most of these tests, rates of breaking appear to be relatively constant for a particular bed slope, but breaking starts at different points along the slope and at different depths, depending upon offshore conditions.

The lowest steepness waves in Figure 4, \( s_{m0} = 0.009 \), shoal more than low steepness waves, \( s_{m0} = 0.024 \), or than the moderate steepness waves, \( s_{m0} = 0.045 \). The conditions shown in Figure 4 show little increase in wave height due to shoaling for wave steepnesses of \( s_{m0} \geq 0.045 \), but breaking starts quite far up the approach slope. Lower wave steepnesses show more shoaling, reach a greater wave height and breaking starts earlier.

Durand & Allsop (1997) compared transformations of the same (offshore) wave condition for bed slopes of 1:10, 1:20, and 1:30. Wave breaking on the 1:10 and 1:20 slopes was delayed compared with the 1:30 slope, as might be expected, but the breaking appeared to occur in similar water depths. Over the steeper slopes, the process of breaking and energy dissipation was compressed into rather shorter distances.

**Figure 5** Individual wave heights, \( s_{po} = 0.054 \), 1:30 slope

In deep water, individual wave heights, \( H_j \), generally conform to a Rayleigh distribution. Such distributions plot as straight lines in the format used in Figures 5-8, where individual wave heights are presented as \( (H_j/H_{so})^2 \), and non-exceedance probabilities as \( -\ln(1-P) \). On these scales, \( -\ln(1-P) = 2.0 \) corresponds to \( H_{1/3} \) for a true Rayleigh distribution, \( H_{98\%} \) is given by \( -\ln(1-P) = 3.91 \), \( H_{99\%} \) is given by \( -\ln(1-P) = 4.61 \), and \( H_{99.6\%} \) by \( -\ln(1-P) = 5.52 \).

In Figures 5-8, wave probe 14 is in deepest water, probe 12 is about 2m (model) up the 1:30 slope, probes 8 and 5 are over the slope, and probe 3 is at the top of the slope.

Under breaking, the largest waves in the distribution break first, reducing towards the breaking limit. After some breaking, it is likely that a proportion of the energy will be re-distributed, perhaps combining with waves that have shoaled further. In still
shallower depths, further breaking will then apply over a greater part of the wave height distribution.

Some of these processes are illustrated for a typically steep storm sea state ($s_{po} = 0.054$) in Figure 5. These results do not support the suggestion that individual waves above the breaking limit ($H_s > H_b$) will fall to that limit whilst waves smaller than the breaking limit are unaffected.

Even in the relatively shallow water in these test facilities, wave heights at the gauge in deepest water (probe 14) give only a slight curve away from the theoretical Rayleigh distribution. The effect of breaking for this sea state is relatively uniform, shown by the steady decrease of wave heights at each successive probe from that in deepest water (probe 14) to the shallowest (probe 3).

Retaining the same offshore significant wave height, but further reducing the wave steepness to $s_{po} = 0.018$ in Figure 7, and $s_{po} = 0.007$ in Figure 8 gives more surprising
results, although some of these effects might have been anticipated from the shoaling behaviour shown by some of the results examined by Durand & Allsop (1997).

In Figure 7, the largest waves occur over the start of the approach slope (probes 12 and 8), particularly noticeable for wave heights above $H_{1/3}$. For very low steepnesses in Figure 8, wave heights at $H_{1/3}$ and higher non-exceedance levels increase markedly from the seaward point (probe 14) up the early part of the approach slope (probes 12 and 8). At this last position (probe 8), breaking only reduces individual wave heights below their offshore value above about 98% non-exceedance. Breaking only starts to reduce $H_{1/3}$ by probe 5, well up the approach slope.

4.4 Comparison with prediction methods

As discussed above, random waves do not give a single breaking point, so the identification of onset of breaking under random waves is difficult and may give inaccurate results. For simple prediction methods, more useful comparisons are with wave heights measured after the onset of breaking. These comparisons are however complicated by different definitions of wave height given by the different prediction methods. Weggel's and Goda's methods give estimates of wave heights close to the maximum, $H_{\text{max}}$ and $H_{1/250}$. Owen's simple method gives estimates of $H_{\text{sb}}$.

Considering first maximum wave heights, measurements of $H_{\text{max}}$ shown relative to the local water depth as $H_{\text{max}}/h$ are compared with predictions using Weggel's method for a bed slope of 1:10 in Figure 9, for a slope of 1:30 in Figure 10, and for a slope of 1:50 in Figure 11. The results have been taken from the point of breaking (indicated by the first
reduction of \( H_s \), see for example Figures 3 & 4). Weggel's method does not predict shoaling, so no comparison is made for positions seaward of the breaking point.

For the 1:10 slope in Figure 9, Weggel's prediction gives relative breaking heights \( H_{\text{max}}/H_s \) up to 1.4 at the lowest values of relative depth. Measured maximum wave heights significantly exceed the predicted values for \( h/gT_p^2 < 0.005 \), suggesting that the prediction method may give unsafe results in this region. Safer predictions for the 1:10 slope are given for \( 0.005 < h/gT_p^2 < 0.015 \).

For the 1:30 slope in Figure 10, Weggel’s prediction gives relative breaking heights \( H_{\text{max}}/H_s \) up to about 1.0 at the lowest values of relative depth. Measured maximum wave heights significantly exceed predicted values for \( h/gT_p^2 < 0.002 \), suggesting that the prediction method may give unsafe results in this region. Safer predictions for the 1:30 slope are given for \( 0.002 < h/gT_p^2 < 0.02 \), but the prediction method does still not seem to reproduce well the general effect of increasing breaker index with decreasing relative depth \( h/gT_p^2 \).

For the 1:50 slope in Figure 11, Weggel's prediction gives relative breaking heights \( H_{\text{max}}/H_s \) up to about 0.9 at the lowest values of relative depth measured here. Maximum wave heights however significantly exceed predicted values for \( h/gT_p^2 < 0.007 \), suggesting that Weggel's method may give unsafe results in this region. Safer predictions for the 1:50 slope are given for \( 0.007 < h/gT_p^2 < 0.02 \), but the prediction method does still not seem to reproduce well the general effect of increasing breaker index with decreasing relative depth \( h/gT_p^2 \).

Measurements of \( H_{\text{max}} \) from tests on the 1:30 slope were compared with predictions by Weggel's and Goda's methods by Durand & Allsop (1997). It was noted that only
An alternative approach was therefore sought in which a revised empirical method was fitted to results for bed slopes of 1:10, 1:30 and 1:50, see figures 12-14. In deriving the new empirical method, it was important that the new method will:

a) reproduce the general form of breaking with respect to \( h/gT_p^2 \);

b) reproduce reliably the asymptote at high relative depths;

c) give better description of the breaking limits at low values of \( h/gT_p^2 \);

d) describe limits for \( H_s \) and \( H_{max} \) using equations of the same form.

It was also intended that the new method would be simple to apply in desk study calculations.

A form of equation relating both \( H_s/h_s \) and \( H_{max}/h_s \) to relative depth \( h/gT_p^2 \) was sought. Each potential method was tested against data from these studies for \( H_s \) and \( H_{max} \), and for bed slopes of 1:10, 1:30 and 1:50. The equation was:

\[
y = y_\infty + (y_0 - y_\infty) e^{cx}
\]

where \( y = H_{max}/h_s \) or \( H_s/1/3 \)

\( x = h_s/gT_p^2 \)

and \( c = -b_n^{0.78} \).

Values of the coefficients were derived by minimising total errors in the fit to measured wave heights from these studies, and are summarised in Table 1:

Figure 14  New prediction, 1:50 slope

Shuto's to give the full increase of wave height over steep bed slopes.

Weggel's method is widely used to represent wave breaking in many numerical methods, but under-predicts breaking for low relative depths. A new set of equations / coefficients have been developed and are suggested here. Whilst still requiring further checking, the new methods seem relatively robust.

5. CONCLUSIONS

These studies have demonstrated that present methods to predict inshore wave conditions on steep bed slopes for structure design suffer some important limitations.

Wave shoaling is particularly important in increasing wave heights on steep bed slopes, but requires the use of non-linear methods such as

INFLUENCE OF FALSE WAVES ON WAVE RECORDS STATISTICS

Marcos H. Giménez1, Carlos R. Sánchez-Carratalá2, and Josep R. Medina3, Member ASCE

ABSTRACT

Wave discretization is a usual procedure in ocean engineering for the statistical analysis of wave records. Different criteria can be used for performing that discretization. The orbital criterion presents important advantages with respect to the zero-up-crossing criterion, more commonly used. These criteria provide significantly different statistical results, as shown when applied to wave records from the scalar Waverider buoy of Valencia, off the Mediterranean Spanish coast.

INTRODUCTION

Statistical parameters, as the significant wave height and the mean wave period, are commonly used in coastal and maritime engineering applications. However, wave statistics depend on the criterion used for discretizing waves in a wave record. The zero-up-crossing (ZUC) criterion is the most widely used up to now. Recently, Giménez et al. (1994a) have proposed a new criterion for discretizing waves that is based in the analysis of the combined vertical and horizontal movement of a particle in the sea surface, and not only of its vertical movement as done by the other available criteria. The so-called orbital criterion has been shown to be more consistent and robust, and to have less variability than the ZUC criterion.

This paper presents the different results obtained when applying the ZUC and orbital criteria for the statistical analysis of wave records from a waverider buoy installed in front of the Valencia harbour in the Spanish coast. The accomplished comparison of both criteria in the time domain clearly shows the superiority of the

orbital criterion for the statistical analysis of wave records, giving results in better accordance with theoretical values.

ORBITAL CRITERION AND FALSE WAVES

In the ZUC criterion, a discrete wave is defined by two consecutive up-crossings of the mean level, that is, a complete cycle of vertical movement. As a consequence, results are very sensitive to the presence of small ripples in the sea surface as well as to the unavoidable noise in the measuring and transmission systems. In the orbital criterion, a discrete wave corresponds to a complete rotation of a surface point around its mean position. This rotation involves a complete cycle of both vertical and horizontal movement. For this reason, there could be ZUC waves that are not orbital waves: they are called false waves, since they lack some important properties that one would like to be fulfilled by progressive waves.

Fig. 1(a) shows a piece of a real wave record with three zero-up-crossings, denoted as A, B, C, and therefore two waves AB and BC according to the ZUC criterion. Fig. 1(b) shows the corresponding orbital representation in the complex plane, making it clear that there is only one complete rotation from A to C. Therefore, there is only one wave according to the orbital criterion, as indicated in Fig. 1(c). The aforementioned can also be applied to the piece of wave record shown in Fig. 2.

ADVANTAGES OF THE ORBITAL CRITERION

The presence of noise in a wave record results in the appearance of small waves that do not actually exist. Giménez et al. (1994a) have shown that most of them are false waves. Since the orbital criterion eliminates false waves, it is less sensitive to noise than the ZUC criterion. For instance, a 5% of noise results in an underestimation of the actual mean wave period of about a 5% -same level as noise- when using the orbital criterion. On the contrary, the error tends to be as high as a 20-25% when using the ZUC criterion. Furthermore, the orbital criterion is physically more consistent and, as proved by Giménez et al. (1994b), the mean period of orbital waves presents less sampling variability than the mean period of ZUC waves. Using ARMA random wave numerical simulations, Sánchez-Carratalá (1995) has pointed out the very good fitting of the sampling variability of many sea state parameters achieved when the orbital criterion for discretizing waves is used.

Advantages of the orbital criterion can be extended to the analysis of directional seas. As proposed by the IAHR Working Group on Wave Generation and Analysis (1989), the mean wave direction is commonly used as the representative direction of a directional sea state. The mean direction was defined by Longuet-Higgins (1957), and corresponds to the direction in which the energy is propagated. Therefore, its determination is essential in the study of many engineering problems, such as evaluation of longshore sediment transport or pollutant propagation and dispersion. Giménez and Sánchez-Carratalá (1997) have shown that the mean direction is the direction that presents the maximum number of orbital waves. Therefore, energy propagation is associated with orbital waves rather than with ZUC waves.
INFLUENCE OF THE DISCRETIZATION CRITERION ON WAVE STATISTICS

As mentioned above, Figs. 1 and 2 show two examples of the presence of false waves in real wave records. However, there is a significant difference between both of them. On the one hand, the false wave in Fig. 1 has its crest before its trough, and henceforth will be named crest-trough or CT-type false wave. On the other hand, the false wave in Fig. 2 has its trough before its crest, and consequently will be named trough-crest or TC-type false wave. It can be noted that the presence of false waves of any type results in one orbital wave whose wave period is the sum of the two corresponding ZUC wave periods. Therefore, the mean orbital wave period $\bar{T}_r$ will always be greater or equal than the mean ZUC wave period $\bar{T}_z$.

As shown by Longuet-Higgins (1958), following Rice (1954), the mean ZUC wave period for Gaussian waves is $T_{02}$. On the other hand, Giménez et al. (1994a) have proved, both mathematically and numerically, that the mean orbital wave period is $T_{01}$. The value of these spectral parameters is given by the following expression:

$$T_{01} = \sqrt[\mu]{\frac{m_i}{m_n}}$$

(1)

where $m_n$ is the $n$th order moment of the variance spectrum $S_n(f)$:

$$m_n = \int_0^{\infty} f^n S_n(f) df$$

(2)

and $f$ is the frequency. It can be mathematically proved that $T_{01} \geq T_{02}$, in accordance with the fact that $\bar{T}_r \geq \bar{T}_z$.

The way in which a false wave affects the wave heights of a wave record depends on its type. On the one hand, a CT-type false wave, as the one shown in Fig. 1, results in a small ZUC wave followed by a higher one; the height of the corresponding orbital wave is the same as the higher ZUC wave. On the other hand, a TC-type false wave, as the one shown in Fig. 2, results in two medium-sized ZUC waves; the height of the corresponding orbital wave is higher than both ZUC waves. As a consequence, the value of any statistical wave height parameter (mean wave height, root mean square wave height, significant wave height) is greater for orbital waves than for ZUC waves. Furthermore, the distribution of orbital wave heights presents less small waves (because of CT-type false waves), less medium-sized waves (because of TC-type false waves) and more high waves (because of TC-type false waves).

The elimination of small ripples observed in real wave records is a usual procedure in ocean engineering. For instance, Rye (1974) and Thompson and Seelig (1984) propose to remove the waves whose height or period do not reach certain threshold values, because these waves are considered of secondary interest for
Figure 1. Example of CT-type false wave in wave record 0900010395V: a) ZUC waves; b) orbital analysis; c) orbital wave.
Figure 2. Example of TC-type false wave in wave record 0100010395V: a) ZUC waves; b) orbital analysis; c) orbital wave.
Table 1. Description of the analyzed wave records.

Engineering applications. These threshold values are obviously arbitrary, and they generally only remove the ripples that are ZUC waves, that is, the CT-type false waves. In this sense, the orbital criterion is more consistent and not arbitrary, and can be effectively used to avoid the effect of noise in wave records as suggested by Kitano and Mase (1998).

Using numerical simulations, Giménez et al. (1994b) have proved that wave statistics are altered by the selection of the wave discretization criterion. Pires-Silva and Medina (1994) have obtained significant differences in the mean periods of wave records from a waverider buoy located off the west coast of Portugal. In the next section, the results of applying the orbital and ZUC criteria to wave records from the scalar buoy of Valencia are analyzed.

WAVE RECORDS STATISTICS

The scalar buoy of Valencia is a Waverider buoy located in front of the Valencia harbour, off the Mediterranean Spanish coast, at 20 m water depth. Table 1

Table 2. Spectral parameters of the analyzed wave records.
indicates the analyzed wave records, that have been taken from a storm with a return period of about 2 years, happened on March 1, 1995. Record length is 5120 points, and sampling interval 0.5 s. Fig. 3 shows the smoothed variance spectra of the analyzed records, with 32 degrees of freedom in each spectral component.

Spectral parameters

Table 2 shows some spectral parameters of the wave records. The parameters $m_0$, $T_{01}$ and $T_{02}$ have been defined in Eqs. (1) and (2), while $(8m_0)^{1/2}$ and $H_{m0} = 4m_0^{1/2}$ are, respectively, the spectral estimations of the root mean square wave height and the significant wave height. The parameter $\pi_f = 1 - T_{02} / T_{01}$, that appears in Table 2 as a percentage, is the spectral estimation of the rate of false waves (see Giménez et al., 1994a). $Q_e$ is the spectral peakedness parameter introduced by Medina and Hudspeth (1987), divided by two for correcting its sampling bias, as indicated by van Vledder (1992) following Elgar et al. (1984). Finally, $\gamma_{Q_e}$ is the peak enhancement factor of the JONSWAP-Goda spectrum (see Goda, 1979) that has the same value of $Q_e$.

Statistical parameters

Table 3 shows the number of orbital waves, $N_r$, and ZUC waves, $N_z$, that result of applying both criteria to the analyzed wave records. The parameter $p_f = 1 - N_r / N_z$, expressed in Table 3 as a percentage, is the rate of ZUC waves that are false waves. As it can be observed, its value is about a 10% for the storm under consideration.

Table 4 presents a set of wave height and period statistical parameters. The parameters $\bar{T}$, $H_{rms}$ and $H_{1/3}$ are, respectively, the mean wave period, root mean square wave height and significant wave height. The subscripts $r$ or $z$ are used to indicate whether the orbital or the ZUC criterion has been applied. The relations between the values corresponding to both criteria are also given. As predicted by the theory, the mean orbital wave period is greater than the corresponding ZUC value, about a 10% for the analyzed wave records. The same can be stated for the characteristic orbital wave heights, that are greater, about a 5-7% in the case of $H_{rms}$ and a 2-4% in the case of $H_{1/3}$, than the corresponding characteristic ZUC wave heights.

Figs. 4 and 5 show, respectively, the distributions of normalized wave heights and wave periods of the analyzed wave records. According to the theory, the use of

Table 5. Covariance coefficients of the analyzed wave records
where $\bar{H}$ and $\sigma_H$ are, respectively, the mean and standard deviation of wave heights. Table 5 also includes the values of the covariance coefficient between wave height and wave period

$$c_{HT}(0) = \frac{1}{\sigma_H \sigma_T} \sum_{i=1}^{N} (H_i - \bar{H})(T_i - \bar{T})$$

(4)

where $\bar{T}$ and $\sigma_T$ are, respectively, the mean and standard deviation of wave periods.

As shown in Table 5, $c_{HH}(1)$ for orbital waves is up to a 16% greater than the corresponding value for ZUC waves. This difference is a consequence of the elimination of small ripples in the sea surface that can significantly distort the length of run of wave groups (see Giménez et al., 1999). On the contrary, $c_{HT}(0)$ has a smaller value, about a 15-20%, when applying the orbital criterion. In fact, most of the false waves that can be found in a wave record have both small height and small period, and therefore they contribute to a greater value of $c_{HT}(0)$ when the ZUC criterion—-that does not eliminate those false waves— is used.

Relations between statistical and spectral parameters

Table 6 presents the relations between statistical parameters and their corresponding spectral estimations observed in the analyzed wave records. The following results can be remarked: both the mean orbital wave period $T_o$ and mean ZUC wave period $T_{z}$ are close to their respective theoretical values, $T_{01}$ and $T_{02}$, the root mean square orbital wave height is almost equal to its spectral estimation, while the corresponding results with ZUC waves differ about a 5%, the significant orbital wave height differs about a 2% with respect to its spectral estimation, while this

Table 6. Relations between statistical and spectral parameters of the analyzed wave records.
difference increases to about a 5% in the case of ZUC waves; the false waves rate can oscillate over an interval of \( \pm 20\% \) around its spectral estimation.

**CONCLUSIONS**

The results obtained with the application of the zero-up-crossing criterion for the analysis of real wave records are very sensitive to the presence of small ripples of secondary interest in ocean engineering, as well as to the unavoidable noise in the measuring and transmission systems. On the contrary, the orbital criterion is more consistent and robust, and avoids the arbitrary selection of threshold levels for removing small ripples in the statistical analysis.

The accomplished analysis of wave records from the scalar buoy of Valencia makes clear the influence of the selected discretization criterion on wave records statistics. The orbital wave heights and periods are, on the average, greater than the corresponding ZUC values, and show a better accordance with their corresponding spectral estimations.

Changing of local wave climate
due to ebb delta migration

Ralf Kaiser$^1$ & Hanz D. Niemeyer$^1$

Abstract:

Field measurements highlighted enormous changes in the attenuation of waves propagating from offshore across the ebb delta on the shore face of the East Frisian island of Norderney. The application of mathematical wave model SWAN made evident that the migration of the ebb delta is the cause of these changes. The results are very important for coastal protection measures.

Introduction

The fate of a combined shore face and beach nourishment on the East Frisian island of Norderney (fig. 1) was evaluated. This study was part of the NOURTEC project (Innovative Nourishment Technologies) [Niemeyer et al. 1995] in the framework of the MAST II - Program of the Commission of the European Communities and commissioned to Danish, Dutch and German institutions. Necessarily investigations on local wave climate were incorporated basing as well on field measurements as on mathematical wave models [Niemeyer et al. 1997].

$^1$ Coastal Research Station of the Lower Saxonian Central State Board for Ecology, P.O. Box 1221, 26534 Norderney/East Fris, Germany
Field measurements were carried out by directional wave riders (fig. 1); both the well-established second generation model HISWA [Holthuijsen & Booij 1987; Booij & Holthuijsen 1992] and the newly developed third generation model SWAN [Ris 1997; Holthuijsen et al 1997] have been applied, where the latter is referred to in this paper. The joint application of field measurements and mathematical modeling is regarded as an effective approach for gaining as well reliable data as spatial information on local wave climate.

Field measurements in the offshore area and on the shore face of the island of Norderney highlighted enormous changes in wave damping on the ebb delta of the tidal inlet. In comparison to results from earlier investigations [Niemeyer 1987] waves propagating across the ebb delta are significantly lesser attenuated than before. Even for conditions with no remarkable set-up above mean high tide the shelter effect of the ebb delta for the northwestern shoreface of the island was remarkably reduced.

This change in the shoreface wave climate is a result of the changes of the ebb delta morphology of the Norderneyer Seegat in the last 35 years (fig. 2). Whereas the southwestern part of the system has not changed decisively, the central section has suffered substantial erosion particularly in the upper part. Even the -5m line (with respect to German Datum, which is about mean sea level) which is regarded as the base line of the ebb delta system has two openings, allowing the penetration of higher waves on the shoreface.

In order to get a deeper and more systematic insight into background of these processes runs with the mathematical wave model SWAN [RIS et al. 1995] have been carried out for four distinct morphological situations of the area seaward of the tidal inlet and the northwestern shore of the island of Norderney: the bathymetries of 1960, 1975, 1990 and 1995 were used as a basis for model topography.
Verification and Sensitivity study

The verification was carried out for several distinct water levels and offshore wave boundary conditions. The results for Pos. 19 are generally good and sometimes excellent (fig. 3). It became apparent that the fitting of model results and measurements on the northwestern shoreface of Norderney improves, if the TRIAD option in SWAN is switched off. With this setting SWAN generally gives a good representation of the spectrum with a slight underprediction of the significant wave height and slight overprediction of the mean wave period at Pos. 19. For other positions in the inner part of the inlet the incorporation of the TRIAD interaction gives the better results. Since the major interest of this study is focused in wave climate on the shoreface of the northwestern beach, in all runs discussed for this case the TRIAD interaction have been switched off.

Ebb Delta
Norderney

Fig. 3: Comparison of the measured and calculated energy spectrum at Pos. 19

Fig. 4: Increase of significant wave heights due to uniform local wind; boundary conditions: Water level: MSL+1.58m; Hs=3.51m, Tm=7.1s; Wind: 7.7 m/s, 30°
Checking the necessity of a local varying wind field a crude estimation can be done in comparing model results with a uniform wind field to a run with out any wind (fig. 4). The difference between wave heights for situations with no wind and uniform wind are smaller than 2% on the shoreface. Therefore it is not necessary to imply here a local varying wind field. Further inwards in the inlet and especially behind the island the influence of the local wind becomes substantial, so that there might be the demand for a local varying wind field.

It became also significantly evident that the application of the third generation model SWAN delivers results matching much better the prototype data than with the second generation model HISWA achievable (Niemeyer & Kaiser 1998). Furthermore SWAN delivers full spectral information.

Morphological changes of the ebb delta

The comparison of the topography for the distinct four situations makes significant morphological changes evident (fig. 5): Whereas the ebb delta is becoming even more pronounced after 1960 with a climax in 1975 the later surveys in 1990 and 1995 highlight a reduction of the shallows with heights above German datum NN - 5 m accompanied by a migration and seaward directed deepening of the main inlet channel between 1990 and 1995: Both morphological changes enhance onshore wave penetration in direction of the island’s northwestern shores.

Fig. 5: Bathymetry of the seaward area of the western part of the island of Norderney with the ebb delta in 1960, 1975, 1990 and 1995 (depths related to German datum NN= MSL)
The models have been run for distinct water levels and offshore wave parameters as seaward boundary conditions. Exemplary for an ordinary tide the results of a run with the following boundary conditions are highlighted here which have been gained from field measurements: Set-up of about 0.3 m above MHWL (in sum equivalent to a water level of NN +1.42 m) and an offshore wave field (fig. 6) with a significant wave height $H_s = 2.98$ m and a peak period $T_p = 6.4$ s. Wind comes from 344° with a velocity of 8.2 m/s. The model runs with SWAN confirm the impression already gained from field measurements with respect to the penetration of

![Graph of model results for ordinary tide](image)

**Fig. 6:** Measured spectrum at the seeaward boundary at 17.11.95, 04:58

![Significant wave heights in the offshore area](image)

**Fig. 7:** Significant wave heights in the offshore area, in the tidal inlet Norderneyer Seegat and on the northwestern shoreface of the island of Norderney in 1960, 1975, 1990 and 1995. Boundary conditions: Water level: MSL+1.42m; Wind: 8.2m/s, 344°
higher waves onto the northwestern shoreface of the island of Norderney (fig. 7): For the situations of 1960 and 1975 no significant changes occur. But already for the topography of 1990 higher waves with $1.75 \text{ m} < H_s < 2.00 \text{ m}$ propagate across the ebb delta though not appearing nearshore.

For the topography of 1995 waves with heights with this order of magnitude occur on a large part of the shoreface. This increase in nearshore wave energy has the same trend as prototype data; the measured wave heights on the shoreface are even slightly higher than those being computed with the model for the same offshore conditions.

The comparison between the portion of breaking waves for the topography of 1960 and 1995 highlights the change in wave transformation over the bars of the ebb delta (fig. 8). In 1960 there is a broad breaker zone at the offshore edge of the eastern ebb delta and two successive breaker systems in the western part. In 1995 there is much lesser wave breaking on the shoals of the ebb delta in its central and eastern part. Also the formerly existing two breaker zones in the western part have changed into a more pronounced single one due to the higher shoals of 1995 in that area.

In order to make the effect of this change in local wave climate more evident for the dynamics on the northwestern shoreface and beaches of the island of Norderney the computed significant wave heights for all four morphological situations are compared at 17 selected points at the edge of shoreface and beach parallel to the island’s northwestern shore (fig. 9). For the situations of 1960 and 1975 there are no remarkable changes in wave climate. The significant wave heights are of the same order of magnitude on the whole stretch of the northwestern shoreface. In 1990 there is an increase of wave heights up to 40%, particularly in the stretch between the reference points 3 and 5 but they decrease further downdrift and become even smaller in the eastern part of the study area. In 1995 wave height have additionally increased in all places downdrift of point 4 (fig. 9).
The difference between the four morphological situations absolutely has to be considered in comparing the effectiveness of different beach nourishments in the last 35 years. The unfavorable boundary conditions of 1995 compared to the previous situations are another indication for the superior effectiveness of the combined nourishment executed in the framework of NOURTEC project.

Explanatory for wave conditions during a storm are the results of a run with the following boundary conditions which have been gained from field measurements in January 1995: Set-up of about 2.3m above MHWL (in sum equivalent to a water level of NN + 3.46 m) and an offshore wave field (fig. 10) with a

---

**Fig. 9:** Significant wave heights at the edge of shoreface and beach parallel to the northwestern shore of the island of Norderney according to the bathymetry in 1960, 1975, 1990 and 1995 (computed with SWAN)

**Fig. 10:** Measured spectrum at the seaward boundary at 10.011.95, 04:56
significant wave height $H_s = 6.41$ m and a peak period $T_p = 11.1$ s. Wind direction is $295^\circ$ with a velocity of $22$ m/s. As well as for the results for the ordinary tidal conditions here occur also only small differences between the local wave heights calculated for the morphologies of 1960 and 1975 (fig. 11). Nevertheless, in 1990 higher waves in the order of 2.5 - 2.75 m arrive at the north western shoreface of the island. Also, a penetration of higher waves into the inlet is evident. In 1995 the erosion in the central part of the ebb delta has reduced the effectiveness of the ebb delta remarkably to act like a breakwater. Wave attenuation is there less pronounced leading to higher energy dissipation on the shoreface with a more pronounced breaker zone.

Also for the storm conditions a quantitative comparison has been carried out for the the significant wave heights at 17 selected points at the edge of shoreface and beach parallel to the island’s northwestern shore (fig. 12) on the basis of the results of the mathematical model. As well as for the ordinary tide condition the situations of 1960 and 1975 show no remarkable changes in wave climate for storm conditions. The significant wave heights are of the same order of magnitude on the whole stretch of the northwestern shore face. In 1990 there is an increase of wave heights starting at reference point 2 reaching its maximum at point 9 with about 15%, decreasing further down drift and become even smaller in the eastern part of the study area. In 1995 the wave heights are nearly in the same order of

![Fig. 11: Significant wave heights in the offshore area, in the tidal inlet Norderneyer Seegat and on the northwestern shoreface of the island of Norderney in 1960, 1975, 1990 and 1995. Boundary conditions: Water level: MSL+3.46m; Wind: 22m/s, 295°](image-url)
magnitude as in 1990 up to reference point 6 but then further increasing down drift and remaining on a high level up to the end of the investigation area. The maximum increase in wave height is about 20% between the reference points 8 and 10 comparing the 1960 and 1995-situation.

Conclusively the relation of wave heights on the shoreface and the offshore wave boundary condition has been calculated both for the ordinary tide and the storm situation (fig. 13). On the one hand the results highlight the presently decreased capability of the ebb delta to reduce the offshore wave energy. For ordinary tidal high water levels even waves with a significant height of about 3 m reach the shoreface only reduced by 25% (reference point 7). In the other case the wave heights ($H_s = 6.4m$ at the offshore boundary) during a storm event with a set-up above MHWL of about 2.3m were reduced at least by 50%. These figures are remarkably smaller than for the modified situations of earlier states.

Comparing the morphological states of 1960 and 1995 the consequences of the ebb delta migration can be differentiated for different boundary conditions: For the storm condition there is an increase at the shoreface in the maximum from 40% to 50% of the offshore wave height. This increase starts slowly at the western edge and is then nearly the same downdrift of point 6. For the ordinary tide and the morphology of 1960 the relation of foreshore to offshore wave height starts at nearly the same value as for the storm condition.
increasing further down drift and reaching its maximum in point 9 with about 58%. The situation of 1995 is in contrast to that much faster increasing with a distinctive maximum between the points 4 and 9. As a consequence the foreshore wave height in 1995 is at point 7 about 75% of the offshore wave height compared to only 50% in 1960. This is also reflected in the higher erosion rates in that stretch (Niemeyer et al. 1997).

**Conclusion**

Wave climate studies have been carried out for distinct bathymetries of ebb delta, shoreface and tidal inlet by application of the mathematical wave model SWAN. It has proved to be a suitable tool for the reproduction of the wave climate in an environment with heterogeneous morphological pattern. The results of the verification runs show a good agreement for the wave parameters in the whole study area and the same for the spectrum on the shoreface. It is important to have sufficient areal wave data for the verification in different stages of the transformation of the wave field. The application of the third generation model SWAN leads to an improved fitting of model results and field data in comparison to the earlier used second generation model HISWA.

The changes of the ebb delta morphology of the Norderneyer Seegat within the last 35 years caused a higher impact of waves on the north western shoreface. Consequently both beach erosion and losses of nourished material increase remarkably.
For ordinary tides changes of wave climate on the shoreface are relatively higher than for storm conditions.

Sensitivity of wind wave simulation to coupling with a tide/surge model with application to the Southern North Sea

J. Monbaliu\textsuperscript{*}, C.S. Yu\textsuperscript{1} and P. Osuna\textsuperscript{*}

Abstract

The wave-current interaction process in a one way coupled system for the Southern North Sea region was studied. To this end, a modified version of the third-generation spectral wave model WAM was run in a three level nested grid system, taking into account the hydrodynamic fields (coupled version) computed by a tide/surge model. The resolution in these three grids corresponds roughly to 35 km (coarse), 5 km (local) and 1 km (fine). Hydrodynamic information was only available at the resolution of the local grid. Results are compared with those of the same version without considering the interaction with tide and surges (uncoupled version). The emphasis is on the results from the local grid calculations. The sensitivity to the source of boundary conditions (coupled vs. uncoupled) and to the frequency of information exchange is investigated. Also the spectral evolution is studied.

Numerical results in the local grid are in good agreement with buoy data. The phase and amplitude of the modulations of wave period observed from the buoy data are quite well reproduced by the coupled version. The model results in the local grid did not show much sensitivity to the source of boundary condition information, nor were they very sensitive to the information update frequency of the hydrodynamic fields. The directional spectra computed in the coupled mode show a broader energy distribution and a more rapid growth. The fine grid results only differ marginally from the local grid results due to the limited resolution of the hydrodynamic fields used.

1 Introduction

Wind generated waves can be affected considerably when they interact with currents. When waves propagate on an inhomogeneous and unsteady current field, some particular characteristics of the wave signal are modified, e.g. wavelength, amplitude, frequency, direction, etc. A review of the theoretical aspects concerning the wave–current interaction can be found in Jonsson (1990).

In coastal regions with appreciable tide, the varying water depth as well as the varying currents influence the wave pattern. Besides of the current interaction processes, interaction with the bottom introduce a series of linear and non-linear mechanisms in the spectral transformation (Shemdin et al., 1980). According to Graber and Madsen (1988), in finite-depth waters the shape of the spectrum is to a great extent influenced by the bottom friction term.

By coupling a third generation wave model with a two-dimensional or three-dimensional current model, improved estimates of wave parameters or improved estimates of surge levels can be obtained. Improved parameter estimates for wave conditions are, next to a help for safer navigation and design of coastal structures, of considerable interest for the estimation of sediment movement since wave action can determine to a large extent the resuspension, deposition rate, and transport of sediments (Mei et al., 1997). Coupling can be done at different levels of complexity. Complex coupled systems can have dynamic interactions, where changes in one model also affect the processes in the other model(s) and an iterative numerical procedure might become necessary. The simplest configuration is a loose one way coupling where information from one model is transferred to another model. Considerable work has already been done. Two literature examples are given to illustrate the concept. Mastenbroek et al., (1993) studied the effect of waves on the calculation of storm surges in the North Sea. They reported that taking the dependence of the drag coefficient on the sea state into account, it is possible to improve the storm surge predictions. Tolman (1990) studied the effect of currents on the wave field in applications with a relatively coarse space resolution.

In this work, we explore the dependence of the wave evolution on an inhomogeneous, unsteady current field in finite–depth waters and this at intermediate spatial resolution (O(5 km)). To this end the third-generation WAM model (Günther et al., 1994) was modified (Luo and Sclavo, 1997; Monbaliu et al, 1998) and it was implemented for applications in the North Sea. The hydrodynamic fields were computed by a tide/surge model and transfered off-line to the wave model. The main goal here is to investigate the sensitivity of the results at the local scale to the frequency of information exchange and to the source of boundary conditions in a loose one way coupled system.
2 The numerical models

2.1 The wave model

The wave model used is the third generation WAM Cycle-4 model (Günther et al., 1994). The model solves an energy balance equation for the spectrum \( F(f, \theta) \) as a function of the wave frequency, \( f \), wave direction, \( \theta \), and the geographical position, \( x \), and time, \( t \). The standard version of WAM propagates the energy over a calculational grid in Cartesian coordinates \( x(x, y) \) for small area applications or in spherical coordinates \( x(\phi, \lambda, r) \) for model applications over large areas as to take into account the swell propagation over great circles. For this work the last option is used. The WAM model permits the inclusion of a stationary current background and uses the relative frequency, \( \sigma \), as a coordinate. Under these conditions, the energy transport equations solved in the WAM Cycle-4 model code is equivalent to the action density transport equation. The transport equation for the evolution of the wave spectrum \( F(t, \phi, \lambda, \sigma, \theta) \) then reads

\[
\frac{\partial F}{\partial t} + (\cos \phi)^{-1} \frac{\partial}{\partial \phi} (\phi \cos \phi F) + \frac{\partial}{\partial \lambda} (\lambda F) + \sigma \frac{\partial}{\partial \sigma} \left( \sigma F - \frac{F}{\sigma} \right) + \frac{\partial}{\partial \theta} (\theta F) = S_{\text{tot}},
\]

where the expressions \( \phi, \lambda, \sigma, \) and \( \theta \) represent the rate of change of energy in the space \( (\phi, \lambda, \sigma, \theta) \). At the right hand side of (1), \( S_{\text{tot}} \) is the function representing the source and sink functions, and the conservative non-linear transfer of energy between wave components. In the present application, it includes wind input \( S_{\text{in}} \), non-linear quadruplet wave-wave interactions \( S_{\text{nl}} \), whitecapping dissipation \( S_{\text{diss}} \) and bottom friction dissipation \( S_{\text{bf}} \). Standard values were used for the empirical coefficients in the source terms. The model has been used in a quasi-steady approach, assuming that the current and the water depth vary only slowly. A detailed description of the physics incorporated in WAM Cycle-4 model and its numerical implementation can be found in Komen et al., (1994). Details on the improvements, alterations and additions for application in nearshore regions can be found in Luo and Sclavo (1997) and Monbaliu et al. (1998).

2.2 The tide/surge model

The hydrodynamic \((u, v, \eta)\) fields are computed with a model based on the shallow water equations. The spherical coordinate expressions for this set of equation are (Washington and Parkinson, 1986)

\[
\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial \lambda} + v \frac{\partial u}{\partial \phi} - \frac{u v \tan \phi}{R} - 2 \omega \sin \phi \nu = - \frac{g}{R \cos \phi} \frac{\partial \eta}{\partial \lambda} - \frac{1}{\rho R \cos \phi} \frac{\partial P_a}{\partial \lambda} - \frac{\tau_{h\lambda}}{\rho(h + \eta)} + \frac{\tau_{g\lambda}}{\rho(h + \eta)} + A_h \left[ \nabla^2 u + \frac{u}{R^2} (1 - \tan^2 \phi) - 2 \frac{\tan \phi \partial v}{\cos \phi \partial \lambda} \right],
\]

(2)
\[
\frac{\partial v}{\partial t} + \frac{u}{R \cos \phi} \frac{\partial v}{\partial \lambda} + \frac{v}{R} \frac{\partial v}{\partial \phi} - \frac{u^2 \tan \phi}{R} + 2\omega \sin \phi u = - \frac{g}{R} \frac{\partial \eta}{\partial \phi} + \frac{1}{\rho R} \frac{\partial P_a}{\partial \phi} - \frac{\tau_{\phi \phi}}{\rho (h + \eta)} + \frac{\tau_{\phi \lambda}}{\rho (h + \eta)} + A_h \left[ \nabla^2 v + \frac{v}{R^2} (1 - \tan^2 \phi) + 2 \frac{\tan \phi \partial u}{\cos \phi \partial \lambda} \right],
\]

where \((u, v)\) are the horizontal \((\lambda, \phi)\) components of the velocity, \(\rho\) the sea water density, \(g\) the acceleration due to the gravity, \(\omega\) the angular speed of the earth's rotation, \(\eta\) the water elevation (with respect to mean sea level), \(h\) the mean depth, \(P_a\) the atmospheric pressure, \((\tau_{\phi \phi}, \tau_{\phi \lambda})\) the bottom stress components due to friction, \((\tau_{\phi \phi}, \tau_{\phi \lambda})\) the surface stress components due to wind, \(A_h\) the depth averaged kinematic eddy viscosity, and \(\nabla^2\) denotes the horizontal Laplacian operator in spherical coordinates. Equations (2) and (3) are the vertically integrated momentum equations and equation (4) states the conservation of mass. The information concerning the numerics can be found in Yu (1993).

3 Model implementations

3.1 WAM model implementations

Three nested grid were used: one coarse grid of which the domain extends up to 70N (Figure 1) as to capture the swell generated outside but traveling into the region of interest; a local grid covering part of the Southern North Sea basin (Figure 2); and a high resolution grid which takes into account the most important details of the bathymetry near the Flemish coast (not shown). The emphasis in this study is on the results obtained for the local grid.

The spectrum \(F(f, \theta)\) was discretized using 12 directions and 25 frequencies with the standard logarithmic distribution. Both the coupled and uncoupled versions of the WAM model were run over the same grid and the option for energy propagation in spherical coordinates was used for all runs.

From the time series of wave parameters calculated from buoy data we used the significant wave height,

\[
H_s = 4\sqrt{m_0},
\]

and the zero upcrossing period,

\[
T_{m02} = \sqrt{m_0/m_2},
\]

where

\[
m_i = \int \int F(f, \theta) f^i df d\theta.
\]
Figure 1: Coarse and CSM grid domain. The coarse grid bathymetry is included. Boundary condition for a nested local grid (region indicated by the square) are generated. Depth values are in meters.

Figure 2: Local grid bathymetry with location indication of the WEH and A2B buoys. Boundary condition for a fine grid (region indicated by the square) are generated. Depth values are in meters.
Wind data are six-hourly winds for the North Sea region produced by UKMO (United Kingdom Meteorological Office). The wind data were interpolated onto the coarse grid points. This wind data set was then also used for the two nested grids, where they were interpolated internally in the WAM-model. Time interpolation was not used. Details concerning the different grids and integration time steps used are given in Table 1.

3.2 Surge model implementation

The hydrodynamic fields were obtained from a Continental Shelf Model (CSM) which solved the set of equations (2)–(4) with a spatial coverage and resolution indicated in Table 1. The model was forced at the boundary with eight tidal constituent. No surge effect was taken into account. Current $(u,v)$ and elevation $(\eta)$ fields were generated on a Type-C grid. These fields were linearly interpolated to the local and fine WAM type-A grids. Note that $\eta$ points from the CSM grid correspond to the local grid WAM points. For the coarse grid, the closest values of $(u,v)$ were assigned to each wet point of the WAM grid. For the hydrodynamic data from 63°N to 70°N needed in the WAM coarse grid coupled run, the values at the 63°N points were taken.

4 Results

4.1 Introduction

The performance of coupled and uncoupled versions of the WAM was tested on a one-month period (February 1993) for the coarse and local grid. The fine grid version was run only for a 15-day period due to the high computational effort required.
In what follows, time series at the locations WEH (Westhinder) and A2B from both coupled and uncoupled WAM results are compared with the available buoy data. The sensitivity to ‘coupled’ information in the boundary conditions, and to the frequency of information exchange is addressed for the local grid application. The evolution of 1D–spectra and 2D–spectra in ‘coupled’ and ‘uncoupled’ mode are discussed.

4.2 Time series

Time series calculated by WAM at station WEH (30m depth) show a good agreement with buoy data, especially for significant wave height (Hs) values during high-wave events (see Figure 3). The small modulations visible in the buoy data at WEH seem well reproduced by the coupled version of WAM. However, the presence of some modulations in the uncoupled run results suggests that part of the modulations in the signal must come from wind variability. The bias for Hs in the coupled and uncoupled results is -0.072m and -0.143m, respectively. The intercomparison between results from coupled and uncoupled models show differences (coupled - uncoupled) in Hs smaller than 0.25m, with a mean difference of 0.02m. Modulations of Tm02, corresponding to the dominant semidiurnal tide period, are quite clear in the buoy data (Figure 3). The importance of including the hydrodynamic fields is highlighted qualitatively by the good agreement between buoy data and WAM-coupled results for Tm02. This is not directly reflected in the value for the bias for Tm02, which were 0.032s for the coupled and 0.034s for the uncoupled run, respectively. The model results themselves showed differences up to 1.0s, with a mean difference of -0.15s.

In the more shallow A2B station (11m depth), overestimation of model results with respect to buoy data is observed, both in Hs and in Tm02 (Figure 4). Although it is possible to reduce the observed differences by tuning of the empirical coefficient in the bottom friction term (see Luo and Monbaliu, 1994, Luo et al., 1996), this was not done since it was not considered important for the scope of this work. At this station, the bias was -0.128m and -0.116m for Hs and -0.846s and -0.965s for Tm02 in the coupled and uncoupled mode, respectively. The importance of tidal modulations is again observed at this location and it is qualitatively well reproduced in the coupled run. Differences between coupled and uncoupled model results do not exceed 0.25m in Hs and 1.0s in Tm02, whereas the mean difference in the Hs and Tm02 value was 0.014m and -0.217s, respectively.

4.3 Sensitivity to boundary conditions

In order to explore the necessity to run in coupled mode on a coarse grid in order to supply good boundary conditions for a subsequent nested run, the application on the local grid was run once using boundary conditions from the coupled and once from the uncoupled coarse grid run. In both cases, results showed clearly the tidal modulation effect on Tm02 (Figure 5a). The observed differences are small and most of the time do not exceed 5%, which seem to suggest that running the coarse grid
Figure 3: Time series of significant wave height ($H_s$) and zero upcrossing period ($T_{m02}$) at station WEH of the local grid.

Figure 4: Time series of significant wave height ($H_s$) and zero upcrossing period ($T_{m02}$) at station A2B of the local grid.
application in coupled mode, does not have a dramatic influence on the local grid runs. Tide-induced modulations, at least on the space scales used here, are mainly a local effect.

![Graph](image)

**Figure 5:** Time series showing the sensitivity to: (a) boundary conditions, and (b) information exchange of \( T_m^{02} \) at station WEH.

### 4.4 Sensitivity to frequency of information exchange

In a coupled system, an important factor to define is the frequency of information transfer between model components. In this work, hydrodynamic fields were updated every 20 minutes (standard coupled mode), which seems suitable for the temporal scale of tide variability. In order to investigate the sensitivity of the model results to the frequency of information exchange, the coupled model on the local grid was also run with an update of the hydrodynamic fields every 60 min. The results were compared with those of the standard run. The time series of \( T_m^{02} \) presented in Figure 5b, show differences smaller than 5%. Some details in the modulation are missed. For this spatial scale and with current and depth fields which vary only slowly in time and space, the main variation in the spectral periods are well reproduced by the Doppler shift. As one can observe from the time series, the tidal modulations respond mainly to the semidiurnal tidal constituent M2. Further decrease of the frequency of information exchange will lead to increased loss of information.
4.5 Spectral evolution

In order to clarify the observed differences in the time series, it is appropriate to analyze how the spectral shape evolves in the presence of a current field. In Figure 6 we can observe the history of the 1D-spectra at station WEH as calculated by the coupled and uncoupled version of WAM. The frequency shifting effect is clearly observed as modulation with a period corresponding to the semidiurnal tidal constituent. These modulations are mainly observed at intermediate and low frequencies, where the effect is not masked by the wind variability.

![Figure 6](image)

Figure 6: Evolution of the 1D spectra calculated by WAM coupled and uncoupled at location WEH. A logarithmic distribution of contour labels is used in both cases.

A definitive insight to clarify the differences in time series is the intercomparison of directional spectra. Hubbert and Wolf (1991) and Holthuijsen and Tolman (1991) studied the propagation of a wave spectrum across a current eddy. They found that the interaction with the current produce changes in the shape of the spectra (broadening and bimodality at some parts of the whirl) associated to the current induced refraction. The coupled runs produced slightly broader spectra than the uncoupled version, mainly at small angles between wave and current direction. An illustration of is given in Figure 7. Starting from almost the same spectrum (date: 93022515), it is possible to observe six hours later a fast growth of energy in the spectrum calculated by the coupled version. The fast growth is due to the wind, which remained relatively constant in magnitude and direction during that period. This produced a shifting of the mean wave direction toward the wind direction, almost 90 degrees from the original direction. Note that the WAM-model does not
have a linear ‘Phillips’ term in its wind input source function. It was not investigated in how far this is responsible for the lack of growth in the uncoupled version.

![Figure 7: 2D spectra at station A2B calculated by WAM coupled and uncoupled. Significant wave height (Hs), wind direction (dark line) and date are always indicated. For coupled results, current magnitude (U) and current direction (light line) are indicated. The same contour labels were used in all figures (1, 5, and from 10 to 100% every 10% of 0.1m²/Hz/deg).](image)

4.6 Further work

The fine grid bathymetry for the Flemish Coast is much more complicated than can be anticipated from Figure 2. Many sand banks more or less parallel with the coast are present. Their spatial scale is small such that they disappear from the local grid resolution. A fine grid wave model was nested in the local grid (see section 3.1). For the hydrodynamic fields linear interpolation from the CSM-grid (equal to the local wave model grid) to the fine grid was used. Comparison of time series at A2B from the local and fine grids showed only negligible differences. This is not unexpected since all the variability in the current field induced by the local bathymetry is not represented in the interpolated current field. If the details of the bathymetry are not taken into account in the calculation of the hydrodynamical variables, the directions of the waves and the currents become more and more perpendicular as
one approaches the coast. This produces a negligible effect of the currents on the characteristics of the wave field. The next logical step is therefore to use the same resolution for the hydrodynamic and the wave field calculations.

5 Conclusions

A modified version of the third generation spectral wave model WAM was used in a three level nested grid application to study the interaction of waves with currents. Numerical results from the local grid showed a very good agreement with buoy data. At the shallower station A2B some slight modulations (approximately ±0.1m) of the significant wave height were observed. Tidal effects were better visible as modulations on the wave period. These last effects were larger at the station WEH than at the station A2B.

Local grid results using boundary conditions from a coarse uncoupled run were qualitatively and quantitatively as good as the results considering boundary information from a coupled coarse run. This indicates that the results in the local grid are not sensitive to 'coupled' or 'uncoupled' boundary information. The results also do not seem very sensitive to the update frequency (from 20 to 60min) of the hydrodynamic information. This means that at least for this local grid application, currents and water depths vary slowly and that the doppler shift reproduces to a large extent the hydrodynamic interactions.

Tidal modulations with a period corresponding to the semidiurnal tidal constituent were observed in all the frequency components of the spectra. The directional spectra computed by the coupled version of WAM had a broader energy distribution and a more rapid energy growth was observed in changing wind conditions.

The negligible differences between local and fine grid results were attributed to a lack of spatial resolution in the hydrodynamic field. The next logical step is therefore to use the same spatial resolution for the wave and for the hydrodynamic calculations.

Acknowledgments

The buoy data were provided by AWK of the Ministry of the Flemish Community. This study is carried out with financial support from the PROMISE project under the EC-MAST III PROGRAMME, contract MAS3 CT 9500025.

Abstract

This paper presents probability density functions applicable to peaks, troughs and peak-to-trough excursions of coastal waves with finite water depth in closed form. It is found that for a non-Gaussian waves for which the skewness of the distribution is less than 1.2, the probability density function of peaks (and troughs) can be approximately represented by the Rayleigh distribution with a parameter which is a function of three parameters representing the non-Gaussian waves. The agreement between the probability density functions and the histograms constructed from data obtained by the Coastal Engineering Research Center is satisfactory.

Introduction

It has been known that waves in finite water depth (hereafter defined as coastal waves) are, in general, considered to be a nonlinear, non-Gaussian random process. The profile of wave peaks (positive side) is sharp as contrasted to the round profile of the troughs (negative side) as shown in Figure 1. The degree of difference in the positive and negative sides of the wave profile can be presented mathematically in terms of skewness. It is highly desirable that the statistical properties of peaks and trough amplitudes be presented separately, and then the properties of wave height (peak to trough excursion) may be obtained through the distribution function applicable to the sum of two independent

958
random variables (peaks and troughs). Furthermore, it is requisite that the probability distributions of peaks and troughs be developed from the distribution representing a non-Gaussian wave profile; the same approach as considered for derivation of the Rayleigh probability distribution for Gaussian waves in deep water.

Only a limited number of studies has been carried out on the probability distribution of coastal wave height. It is often assumed in these studies that the wave profile is amplitude modulated and follows the Stokes expansion to the second or third components; Tayfun (1980), Arhan and Plaistad (1981), among others. There is some reservations, however, in applying Stokes theory for shallow water waves unless the expansion includes higher order terms. Furthermore, it is advisable not to assume any preliminary form of the wave profile for derivation of its probability distribution.

Another approach for derivation of the probability distribution of wave amplitudes is to apply the Gram-Charlier series distribution representing coastal wave profiles; Ochi and Wang (1984) for example. The results, however, are not promising since the Gram-Charlier series distribution is not given in closed form and the density function at times becomes negative for large negative displacements.

On the other hand, several empirical probability distributions applicable for coastal wave heights have been developed from analysis of observed data. These include Kuo and Kuo (1975), Goda (1975), Ochi, Malakar and Wang (1982) and Hughes and Borgman (1987), among others.

In the present paper, the probability function applicable to amplitudes of response of a nonlinear mechanical system (Ochi 1998) is applied to coastal waves. That is, the probability density function applicable to peaks and troughs of wave data are presented separately in closed form as a function of three parameters representing non-Gaussian waves. Since these three parameters have been presented as a function of water depth and sea severity (Robillard and Ochi, 1996), the probability density function of wave amplitudes of coastal waves can be evaluated for a specified water depth and sea severity.

**Probability Distribution of Wave Peaks**

For derivation of the probability distribution representing statistical properties of wave peaks, a peak envelope process, denoted by \( \xi(t) \), shown in Figure 2 is considered.

**Figure 2**

Definition of the envelope process of peaks of non-Gaussian wave
The non-Gaussian random waves \( y(t) \) are expressed as a function of normal random process and its square. That is,

\[
y(t) = U(t) + a\{U(t)\}^2
\]  

(1)

where \( a \) is a constant and \( U(t) \) is a Gaussian wave with mean \( \mu_x \) and variance \( \sigma_x^2 \); all of these parameters can be evaluated from data. The parameter \( a \) represents the intensity of non-Gaussian wave characteristics; the larger the \( a \)-value the stronger the nonlinearity. We may consider \( Y \) and \( U \) to be random variables for a given time of \( y(t) \) and \( u(t) \), respectively, and the functional relationship given in Eq.(1) is inversely expressed as follows (Ochi and Ahn 1994):

\[
U = \frac{1}{\gamma a} \left( 1 - e^{-\gamma a Y} \right)
\]  

(2)

where \( \gamma = 1.28 \) for \( y > 0 \), \( 3.00 \) for \( y < 0 \).

It is noted that the random variable \( U \) defined in Eq.(2) is normally distributed with sample space \( (-\infty, 1/\gamma a) \) instead of \( (-\infty, \infty) \) as originally defined. However, this restriction does not affect the distribution of \( U \), in practice, since the value of \( (\mu_x + 3\sigma_x) \) where the density function of the normal variate \( U \) becomes almost zero, is much smaller than \( 1/\gamma a \). Hence, the sample space \( (-\infty, 1/\gamma a) \) is essentially equivalent to \( (-\infty, \infty) \).

For the random variable \( U \) associated with the peak envelope process, the mean value is \( \mu_x \) but the variance is that affiliated with the positive (peak) side only which can be evaluated by

\[
s_1^2 = 2 \int_0^\infty y^2 f(y) dy
\]  

(3)

\[
= \frac{2}{\lambda_1^2} \left\{ \frac{1}{2} \left[ \frac{1}{\sigma_x} \right]^2 + \sqrt{2/\pi} \left( \frac{\lambda_1}{\sigma_x} \right) + \frac{3}{2} \left( \frac{\lambda_1}{\sigma_x} \right)^4 \right\}
\]

where \( \lambda_1 = aY, \gamma = 1.28 \) for the positive \( y \).

The probability density function \( f(y) \) in Eq.(3) represents a non-Gaussian random wave profile and is given by

\[
f(y) = \frac{1}{\sqrt{2\pi}\sigma_x} \exp \left\{ -\frac{1}{2\gamma a^2 \sigma_x^2} \left( 1 - e^{-\gamma a Y} \right)^2 - \gamma a Y \right\}
\]  

(4)
Next, we may define the random variable $V$ by subtracting the mean value $\mu_x$ from the random variable $U$. That is,

$$V = U - \mu_x = \frac{1}{\lambda_1} \left( 1 - e^{-\lambda_1 Y} \right) - \mu_x \tag{5}$$

We may write the cosine and sine components of $V$ as $V_c$ and $V_s$, respectively, and the joint probability density function of $V_c$ and $V_s$ is given by a statistically independent bi-variate normal distribution with zero mean and a common variance $\sigma^2$. That is,

$$f(v_c, v_s) = \frac{1}{2\sigma_1^2} \exp \left\{ -\frac{1}{2\sigma_1^2} (v_c^2 + v_s^2) \right\} \tag{6}$$

By applying the change of random variable technique and by using the relationship given in Eq.(5), the joint probability density function $f(v_c, v_s)$ is transformed to the joint probability density function $f(y_c, y_s)$. Furthermore, we may write $Y_c$ and $Y_s$ as a function of amplitude and phase. That is,

$$Y_c = \xi \cos \tau \tag{7}$$

$$Y_s = \xi \sin \tau$$

where $\xi$ - amplitude (peak), $\tau$ - phase.

Then, we can derive the joint probability density function of $\xi$ and $\tau$ as follows:

$$f(\xi, \tau) = \frac{\xi}{2\sigma_1^2} \exp \left\{ -\frac{1 - \lambda_1 \mu_x}{\lambda_1 \sigma_1} \right\} - \lambda_1 \xi (\cos \tau + \sin \tau)$$

$$\hspace{1cm} + \frac{1 - \lambda_1 \mu_x}{\lambda_1 \sigma_1^2} \left( e^{-\lambda_1 \xi \cos \tau} + e^{-\lambda_1 \xi \sin \tau} \right)$$

$$\hspace{1cm} - \frac{1}{2\lambda_1 \sigma_1^2} \left( e^{-2\lambda_1 \xi \cos \tau} + e^{-2\lambda_1 \xi \sin \tau} \right), \tag{8}$$

$$0 \leq \xi < \infty, \ 0 \leq \tau \leq 2\pi.$$
\[ f(\xi) = \left(1 + \lambda \mu_\star \right) e^{-\frac{\left(\lambda \sigma_1^2 - \mu_\star\right)^2}{\left(1 + \lambda \mu_\star\right)\sigma_1^2}} \left(1 + \frac{\lambda \mu_\star}{2\sigma_1^2} \xi^2\right) I_0 \left(\sqrt{2} \left(\frac{\lambda \sigma_1^2}{\sigma_1^2}\right) \xi\right) \]

\[ 0 \leq \xi < \infty. \quad (9) \]

The detailed description of the derivation of Eq. (9) is given in the reference Ochi (1998).

In the case of Gaussian waves, \( \mu_\star \) as well as \( \lambda \) are both zero, and the variance \( \sigma_1^2 \) reduces to \( \sigma^2 \). Hence, Eq. (9) becomes

\[ f(\xi) = \frac{\xi}{\sigma^2} e^{-\frac{\xi^2}{2\sigma^2}} \quad (10) \]

which is the Rayleigh probability density function applicable for amplitudes of narrow-band Gaussian waves.

In Eq. (9), let us write

\[ \frac{\sigma_1^2}{1 + \lambda \mu_\star} = \sigma_1^2 \]

\[ \frac{\sqrt{2} \left(\lambda \sigma_1^2 - \mu_\star\right)}{1 + \lambda \mu_\star} = c_1 \quad (11) \]

then, we have the probability density function of the positive amplitude as

\[ f(\xi) = \frac{\xi c_1}{\sigma_1^2} \cdot I_0 \left(\frac{c_1 \sigma_1^2}{\sigma_1^2}\right) \quad (12) \]

The above equation is the probability density function applicable for the sum of two statistically independent random processes; one being a narrow-band Gaussian random process with zero mean and variance \( \sigma_1^2 \), the other a sine wave with amplitude \( c_1 \), both having the same frequency (Rice 1945). This implies that the probability density function of the envelope of the positive side of the non-Gaussian waves given in Eq. (9) is equivalent to the probability density function of the envelope of a random process consisting of the sum of a narrow-band Gaussian wave with zero-mean and variance \( \sigma_1^2/(1+\lambda \mu_\star) \) and a sine wave with amplitude \( \sqrt{2} \left(\lambda \sigma_1^2 - \mu_\star\right)/(1+\lambda \mu_\star) \). This result provides insight as to the structure of the probability distribution function of wave height in finite water depth.
It is further possible to simplify Eq. (12) for non-Gaussian waves for which the skewness of the distribution is less than approximately 1.2. That is, we may approximate the modified Bessel Function in Eq. (12) as

\[ I_0(z) \sim \exp \left\{ \frac{z^2}{5} \right\}, \quad \text{where } z < 3.0 \]  

A comparison of the approximate formula and \( I_0(z) \) is shown in Figure 3. By applying the approximation given in Eq. (13), the probability density function given Eq. (12) can be expressed in the following form:

\[ f(\xi) = K \cdot \left( \frac{1}{s_1} \exp \left[ \frac{c_1^2}{2s_1^2} \right] \right) \cdot \xi \exp \left\{ -\frac{1}{2s_1^2} \left( 1 - \frac{2c_1^2}{5s_1^2} \right)^2 \right\} \]  

\[ 0 < \xi < \infty \]  

where \( K \) is a normalization factor determined from the condition that the integration of Eq. (14) in the sample space be unity. Then we have

\[ f(\xi) = \frac{1}{s_1} \left( 1 - \frac{2c_1^2}{5s_1^2} \right)^{\frac{1}{2}} \cdot \exp \left\{ -\frac{1}{2s_1^2} \left( 1 - \frac{2c_1^2}{5s_1^2} \right)^2 \right\} \]  

\[ 0 < \xi < \infty \]  

This is the Rayleigh probability density function. Thus, it is found that amplitudes of the positive part of non-Gaussian waves may be approximately distributed following the Rayleigh probability distribution with the parameter \( (2s_1^2)/(1-(2c_1^2/5s_1^2)) \).

Figure 4 shows a comparison of the exact (Eq. 9) and the approximate (Eq. 15) probability density functions with the histogram constructed from data shown in Figure 1. The data shown in the
figure are obtained at Duck, North Carolina, by the Coastal Engineering Research Center during the ARSLOE Project. As seen, the difference between the exact and approximate density functions is very small and they represent well the histogram of peaks.

**Derivation of Probability Distribution of Wave Troughs**

The probability density function applicable to troughs of non-Gaussian waves, denoted by \( f(\eta) \), has essentially the same form as Eq. (9). The parameter \( \lambda_2 \) and variance \( \sigma_2^2 \) in Eq. (9), however, should be replaced by \( \lambda_z \) and \( \sigma_z^2 \), respectively, which are appropriate for troughs. The variance \( \sigma_z^2 \) for the trough envelope process can be evaluated by subtracting \( \sigma_1^2 \) from twice the data variance \( \sigma^2 \) computed including both positive and negative displacements from the mean value. That is, the probability density function is given by

\[
f(\eta) = \frac{(1 + \frac{\gamma \lambda_2}{\sigma_2^2}) \eta}{\sigma_2^2} e^{-\frac{1}{2}} \left( \frac{\lambda_2 \sigma_2^2 - \lambda_2 \eta}{\sigma_1^2 + \lambda_2 \sigma_2^2 - \lambda_2 \eta} \right) I_0 \left( \sqrt{2} \frac{\lambda_2 - \frac{\lambda_2 \eta}{\sigma_2^2}}{\sigma_2^2} \right)
\]

where

\[
\sigma_2^2 = 2E[y^2] - \sigma_1^2
\]

\[
\lambda_2 = a \gamma \text{ with } \gamma = 3.00
\]

As in the case for the probability distribution of peaks, the probability distribution of envelope of troughs is equivalent to that of a random process consisting of the sum of a narrow-band Gaussian wave with zero-mean and variance \( \sigma_2^2/(1 + \lambda_2 \eta) \) and a sine wave with amplitude \( \sqrt{2} (\lambda_2 \sigma_2^2 - \lambda_2 \eta)/(1 + \lambda_2 \eta) \). These may be denoted by \( s_2^2 \) and \( c_2 \), respectively. Furthermore, the probability density function may be expressed approximately by the following Rayleigh probability distribution:
Figure 5 shows a comparison between the exact (Eq. 16) and approximate (Eq. 17) probability density functions applicable for the troughs of non-Gaussian waves and the histogram constructed from data. As seen, the difference between the exact and approximate density functions is extremely small and the overall agreement between the histogram and density functions is satisfactory.

**Probability Distribution of Wave Height**

Wave height is defined as a peak-to-trough excursion. As stated earlier, peak and trough envelope processes are independently considered for probability distribution of peaks and troughs of non-Gaussian waves. The results of analysis have shown that large peak envelopes and large trough envelopes do not occur simultaneously, in general. Correlation between the two envelopes is rather small; hence, it is assumed that peaks and troughs are statistically independent and thereby the probability density function of peak-to-trough excursions may be obtained as a convolution integral of the two probability density functions, \( f(\xi) \) and \( f(\eta) \). That is

\[
f(\xi) = \int_0^\infty f_\xi(\xi) f_\eta(\xi - \xi) \, d\xi
\]

where \( f_\xi(\cdot) \) and \( f_\eta(\cdot) \) represent the probability density functions given in Eqs. (9) and (16), respectively, for the exact density functions, and Eqs. (15) and (17), respectively, for the approximate density functions.

The integration given in Eq. (18) cannot be analytically carried out for the exact density functions because of the product
of two modified Bessel functions involved. The probability density function of \( \zeta \), therefore, is numerically evaluated. The convolution integral for the two approximate probability density functions given in Eqs.(15) and (17), however, can be analytically carried out. It is the sum of two independent Rayleigh distributions. That is, by writing the parameters of the Rayleigh distributions applicable for the peaks and troughs as

\[
R_1 = \left( \frac{2s_1^2}{1 - \left( \frac{2c_1^2}{5s_1^2} \right)} \right)
\]

\[
R_2 = \left( \frac{2s_2^2}{1 - \left( \frac{2c_2^2}{5s_2^2} \right)} \right)
\]

(19)

the probability density function of the sum of the Rayleigh distribution, denoted by \( f(\zeta) \), becomes

\[
f(\zeta) = \frac{2\sigma}{R_1} \cdot e^{\frac{\zeta^2}{R_1}} \cdot \frac{2(\zeta - \xi)}{R_2} \cdot e^{\frac{-\xi^2}{R_2}} \cdot d\xi
\]

\[
= \frac{2\sigma}{(R_1 + R_2)^2} \left\{ \frac{-\xi^2}{R_1} + \frac{-\xi^2}{R_2} \right\}
\]

\[
+ \frac{2\sqrt{\pi}}{R_1 + R_2} \cdot e^{-\frac{\zeta^2}{R_1 + R_2}} \cdot \left( \frac{2}{R_1 + R_2} \zeta^2 - 1 \right)
\]

\[
\times \left\{ \Phi \left( \frac{2R_1}{\sqrt{R_1(R_1 + R_2)} \zeta} \right) - \Phi \left( \frac{2R_2}{\sqrt{R_2(R_1 + R_2)} \zeta} \right) \right\}, \quad 0 < \zeta < \infty
\]

(20)

where \( \Phi = \) cumulative distribution function of the standardized normal distribution.

Figure 6 shows a comparison between the exact (Eq.18) and approximate (Eq.20) probability density functions for the peak-to-trough excursions and the histogram constructed from the same wave data as used for the histograms of peaks and troughs. The difference between the exact and approximate density functions is negligibly small, and the theoretical density functions agree reasonably well with the histogram. Included also in the figure is the Rayleigh probability density function applicable for Gaussian waves commonly considered for analysis of deep water waves. The probability density function for the Gaussian wave assumption substantially deviates from the histogram.

The cumulative distribution function of the wave height can be evaluated by integrating Eq.(20) with respect to \( \xi \). The derivation of the distribution function, however, may be much easier using the
following approach since the distributions of the peaks and troughs are assumed to be statistically independent. That is

\[ F(\xi) = \int \int f(\xi, \eta) d\xi d\eta = \int \left( \int f(\eta) d\eta \right) f(\xi) d\xi \]  \tag{21}

By applying Eqs. (15) and (17), and with the parameters given in Eq. (19), we have

\[ F(\xi) = 1 - \frac{1}{R_1 + R_2} \left[ -\frac{\xi^2}{R_1} e^{-\frac{\xi^2}{R_1}} + \frac{\xi^2}{R_2} e^{-\frac{\xi^2}{R_2}} \right. \\
+ \left. 2 \sqrt{\frac{\pi R_2}{R_1 + R_2}} e^{-\frac{\xi^2}{R_1 + R_2}} \Phi \left( \sqrt{\frac{2R_1}{R_1 R_2}} \xi \right) - \Phi \left( \sqrt{\frac{2R_2}{R_1 R_2}} \xi \right) \right] \]

\[ 0 < \xi < \infty \]  \tag{22}

It may be of interest to see how the shape of the probability distribution of amplitudes of coastal waves changes when wave energy propagates from deep to shallow water. Figure 7 shows an example of the probability density functions of peaks and troughs along with wave records simultaneously measured at four locations (60 m, 151 m, 456 m and 12 km offshore) during the ARSLOE Project. The waves obtained at the 12 km offshore are considered to be Gaussian at the time of measurement. As seen, the mode of the Rayleigh distribution applicable to non-Gaussian waves shifts to the smaller values as waves approach the shoreline. In particular, the rate of change of the probability density function of troughs is much faster than that
Figure 7  Probability density functions of wave peaks and troughs obtained from data at various locations in the nearshore zone of peaks. This is understandable since wave troughs are much more susceptible to bottom effect.

**Significant Wave Height**

Significant wave height defined as the average of the highest one-third wave heights, denoted by \( H_s \), is most commonly used for representing the severity of random waves. It can be evaluated by

\[
H_s = 3 \int_{\zeta^*}^{\infty} \zeta f(\zeta) d\zeta
\]  

(23)

where \( \zeta^* \) = the value of wave height \( \zeta \) for which \( F(\zeta) = 2/3 \),

\( f(\zeta) \) = probability density of wave height.
Equation (23) yields a very simple result for deep water:

\[ H_s = \sqrt{m_0} \]

where \( m_0 \) is the area under the spectral density function. For non-Gaussian waves, however, the computation of Eq. (23) is rather complicated. After some mathematical manipulations, we can derive

\[
H_s = 3 \left[ \left( \frac{R_1}{R_1 + R_2} \right)^2 \psi^2 \right] e^{-\frac{\psi^2}{2}} + \frac{R_1}{R_1 + R_2} e^{-\frac{\psi^2}{2}} \left[ 1 - \Phi \left( \frac{2}{R_1^* \psi} \right) \right]
\]

Comparisons of significant wave heights computed by Eq. (24) and those evaluated from data obtained at three water depths is shown in Table 1. Included also in the table are those computed by using the formula applicable for deep water. As seen in the table, significant wave heights computed based on non-Gaussian and Gaussian concepts do not differ more than 6 per cent, and the significant wave height obtained from measured data is between the two computed values for a given water depth. As shown in Figure 6, the probability density function of wave height for non-Gaussian waves intersects that of Gaussian waves at a large wave height. This results in the centers of gravity of the highest one-third of these two probability density functions (significant wave heights) may not be too far apart.

In order to supplement the above-mentioned statement, Figure 8 is prepared. The figure shows the cumulative distribution function of wave heights computed at two water depths based on Gaussian and non-Gaussian concepts. As seen, the two cumulative distribution functions slowly approach each other with increase in wave height and intersect at a certain high wave height. The value of the significant wave height is slightly greater than the wave height at

the point of crossing, but much less than the height where the two distribution functions start separating widely. Since the computation of significant wave height based on the Gaussian concept is quite simple, and since computed significant wave height is close to that computed using the formula for non-Gaussian waves, it may be concluded that the formula to evaluate significant wave height in deep water may also be applied approximately to non-Gaussian waves as far as the evaluation of significant wave height is concerned.

Conclusions

Probability density functions applicable to peaks, troughs and peak-to-trough excursions of coastal waves with finite water depth are presented separately in closed form. It is found that the probability density function applicable to peaks (and troughs) consists of the sum of narrow-band Gaussian waves and sine waves having the same frequency. It is also found that for non-Gaussian waves for which the skewness of the distribution is less than 1.2, the probability density function of peaks (and troughs) can be represented approximately by the Rayleigh distribution with a parameter which is a function of three parameters representing the non-Gaussian waves. Since these three parameters have been presented as a function of water depth and sea severity, the probability density function of amplitudes of coastal waves can be evaluated for a specified water depth and sea severity. The
agreement between the probability density functions and the histograms constructed from data obtained by the Coastal Engineering Research Center during the ARSLOE Project is satisfactory.

The significant wave height of non-Gaussian coastal waves is analytically derived. The results of the computations show that computed significant wave height is close to that evaluated by applying the formula for waves in deep water (Gaussian waves). Therefore, since the computations based on the Gaussian concept are quite simple, it may be used for non-Gaussian waves as far as the evaluation of significant wave height is concerned.

Increase of wave height in the North Pacific Ocean

Kozo Okada¹, Yasushi Suzuki², Yoshihiro Utsunomiya³ and Yoshihiro Watanabe⁴

Abstract

We analyze annual variations and the long-term tendency of wave heights along the coast of Japan, based on observed data for more than 10 years. And we analyze the trend of wave heights over the last 10 years in the North Pacific with hindcast data. As a result of the analysis, the wave height has shown an increase trend at most stations along the Pacific coast of Japan. The average increase rate is 0.6 cm/year. The estimated wave height by a wave model also shows an increased trend in the North Pacific Ocean. Since there is a correlation relation between 500hPa height anomaly at specific areas and the wave height anomaly at each station, an increase trend of wave height in the Northern Hemisphere is supposed to be related to the change in an atmospheric planetary wave pattern.

Introduction

In recent years, there has been a growing interest in the climate change represented by the global warming and the influence of the climate change to the world. It is shown by numerical calculations of climate models that if carbon dioxide keeps on being exhausted at the current levels, a surface atmospheric temperature will rise more than 2 °C 100 years later. It is imagined that the global warming makes not only the sea level rise but also causes changes of meteorological and ecological system in the oceans.

Ocean waves are important natural conditions for the design of ships and harbors and for the prevention of coastal disasters. It is important for these purposes to understand the current state of a long-term change in ocean waves, which is believed to be related closely to the climate change.

In this paper we analyze the long-term change of ocean waves along the coast of Japan and in the North Pacific Ocean. We use observational data obtained for more
than 10 years at most stations along the coast of Japan, and 10-year global hindcast data by a wave model. As a result of the analysis, it is shown that the wave height has had the increasing trend over the past 10 to 20 years at most stations along the Pacific coast of Japan and in the North Pacific Ocean.

It is shown that annual variations of ocean wave height at stations are related to the strength of anomaly from the normal monthly mean of 500hPa height of the atmosphere and the strength of Asian monsoon, according to the correlation analysis with a wave height and 500hPa height. It is suggested from these that there is a possibility of the increasing tendency of wave height in the North Pacific to originate in the change of the weather related to an atmospheric circulation in the middle layer.

**Data analysis**

Figure 1 shows major wave observation stations in Japan. Open circle is the Meteorological Agency's station, and closed circle is the Harbor Bureau's. Japan Meteorological Agency has been executing the wave observation at 11 stations along the coast of Japan for about 22 years from 1976 to present, for the purpose of wave watch and wave forecast for the fishery, the safe navigation and marine leisure in coastal areas. Harbors Bureau in Ministry of Transport has been observing coastal waves at about 44 stations for about 26 years from 1972 to present for the harbor design and the maintenance.
Almost all locations of these observation stations are in 1 or 2 kilometers offing from the shore. The depth is about 50m at these stations. Ultrasonic type wave meters are placed at the bottom of the ocean to measure the sea surface level. The observation interval is two hours at the Harbors Bureau's station. It is three hours in the routine observation at Meteorological Agency, but is one hour in the urgent observation like the case of a typhoon. Significant wave height and other parameters are calculated from the record of sea level for 20 minutes. The sampling time is 0.25sec or 0.5sec.

We chose the data from the stations where observations have been continued for a long period without a displacement of the position or an interruption of the observation. Table 1 shows the stations and the period of data chosen for analysis along the Pacific coast. Table 2 is those along the Sea of Japan coast. We use a monthly mean significant wave height, as an index to represent a long-term tendency of ocean waves. Hereafter we use the word the monthly mean wave height to mean the monthly mean significant wave height. A monthly mean wave height is not calculated if the data are not available for more than 80 percents of the time in a month.

Figure 2 shows a seasonal change of the monthly mean wave height and the 12 months running mean at the coast of Japan Sea (the top figure) and the coast of Pacific Ocean (the bottom figure). As can be seen, the monthly mean wave height at the coast of Japan Sea exhibits seasonal variations, low in summer and high in winter. High waves are caused by a strong wind in the northwest of the Asian monsoon in the Sea of Japan in winter.

On the other hand, the monthly mean wave height at the Pacific coast generally fluctuates over a period of about six months. The wave height is larger in both spring and autumn and is lower in both winter and summer at the Pacific coast. For this weather factor, it is thought that although monsoonal wind blows in the northwest in winter, waves don't greatly develop at the Pacific coast, because the Fetch is short in this direction. Waves develop in spring and autumn at the Pacific coast, because depressions occur with the period of a few days in the Sea of Japan or the East China Sea and move from the southwest toward northeast through Japan while developing in these seasons. Moreover, swells and wind waves develop under the influence of typhoons in autumn.

The thick solid line shows the variation with a several years period both at the Sea of Japan and the Pacific coast. When we pay attention to the coast of Japan Sea, we can see the annual variation of wave height has an increasing wave height in 1981, 1984, 1986, and 1988. In these years, the wave height develops in winter (figure 3). Therefore, the annual mean wave height is chiefly controlled by the mean wave height in winter at the coast of Japan Sea.

![Figure 2: Annual variation of monthly mean wave height (thin line) and 12 months running mean (thick line). (top figure; the Japan Sea coast, bottom figure; the Pacific coast)]
On the other hand, it is shown that the seasonal mean wave height at the Sea of Japan coast in winter has a correlation with the seasonal mean temperature at 500hPa height over the Sea of Japan (Figure 3). The solid line with open circles is the seasonal mean temperature in winter at 500hPa height over the Sea of Japan. The dashed line with closed triangles is a seasonal mean wave height in winter at the coast of Japan Sea. These time series show peaks at the same years. For example, in 1981, 84 and 86. It is known that the temperature at 500hPa over the Sea of Japan is related to the intensity of cold air mass on the Asian continent in winter. When the temperature is lower, the intensity of cold air mass is strong and the northwest monsoon wind is strong. It is thought that such a weather condition develops wave heights more than a usual year in the Sea of Japan. After all, it is suggested that the variation of wave heights with a several years period in the Sea of Japan depend on a change in the intensity of Asian monsoon in winter.

![Fig.3](image)

**Fig.3** Time series of mean wave height in winter at Kyogamisaki and mean temperature in winter at 500hpa height over the Japan Sea.

We determined the long-term tendency of the monthly mean wave height by a least square method at observation stations, where data has existed for more than 10 years from a year before 1985 to 1994 (Table 1, 2). Figure 4 gives the examples of the time series of the monthly mean wave height and the linear trend at the Pacific coast (the top figure) and the Japan Sea coast (the bottom figure). The wave heights show the increasing trend at these stations.
Fig. 4 Time series of monthly mean wave height and the linear trend.
(top figure: the Pacific coast, bottom figure: the Japan Sea coast)

The trend of wave heights was gotten in a nationwide coast. Figure 5 shows the rate of change of wave heights per year at each station along the coast of Japan. According to this result, the long-term tendency of wave height at the coast of the Sea of Japan differs from one station to another (the bottom figure). The tendency is not uniform along the coast of the Sea of Japan. On the other hand, the monthly mean wave height at the Pacific Ocean coast shows the increasing tendency in most observation stations. The average rate of the increasing tendency is about 0.6 cm/year along the coast of the Pacific Ocean (the top figure).

Figure 6 shows the long-term tendency in each season. In spring from March to May (the top of left side figure), the decreasing tendency is shown at many stations along the Pacific Ocean coast, and the increasing tendency is shown at many stations along the Sea of Japan coast. In summer from June to August, the increasing tendency is shown at most stations along the Sea of Japan coast, but the tendencies are not uniform along the Pacific Ocean coast. In autumn and winter a remarkable wave height increasing is shown at most observation stations along the Pacific Ocean coast. It is found from these that the increase of wave height at the Pacific Ocean coast has occurred in autumn and winter.
Fig. 5 Long-term change rate (cm/year) of the significant wave height.
(top figure: the Pacific coast, bottom figure: the Japan Sea coast)
Fig. 6 Long-term change rate (cm/year) of SWH in seasons.
Result of wave model

We analyzed the long-term variation of wave heights in the North Pacific Ocean by the wave model, that was developed by Suzuki and Isozaki (1994). This model is classified as the third generation model, which is based on the energy balance equation and considers a non-linear effect among wave components. The source functions of this model consist of the empirical formula of Mitsuyasu-Honda (1982) connected to Hsiao and Shemdin (1983) for the input energy by wind, the empirical formula obtained by dimension analysis for dissipation by whitecapping, and the effective calculation of wave components for nonlinear interaction between waves, respectively. This model uses the hybrid upstream difference scheme for the advection calculation of energy. As for the calculation accuracy of this wave model, the root mean square error of wave height is less than 1m, and the accuracy is very high for practical wave forecasts (Figure 7).

The global wave variation in the last ten years has been analyzed by using this model and the wind data of the European Centre for Medium-range Weather Forecasts. An analyzed wind of ECMWF was converted to 10m-wind above a sea surface by using an observed wind at NOAA and JMA buoys and used. The analysis period is 10 years from 1985 to 1994. During this period, the ECMWF model was modified and the accuracy was improved.
Figure 8 shows a global distribution of the trend in wave height for 10 years from 1985 to 1994. The contour interval is 20 cm. According to this, one of the largest increasing trends of wave height is shown in the center of the North Pacific Ocean. The maximum value is about 60 cm in the last ten years. The increase of wave height is about 20 cm at the Pacific coast of Japan over ten years. This magnitude is nearly the same as that of the rate of the increase obtained from the observation data along the coast. It is interesting that both the calculated wave height and the observed one show the increasing tendency with the same magnitude along the Pacific coast of Japan.

The wave height in the middle latitude area of the North Atlantic Ocean shows an increasing tendency, as it does in the North Pacific Ocean. On the other hand, the decreasing tendency of wave height is shown in the high latitude area of the Southern Hemisphere. This reason is not clear yet.

Wave Height Rising (1985–94)

Fig. 8 Increase of wave height during 10 years from 1985 to 1994. Contour lines show the total increase of wave height. Solid lines indicate positive values (increase) and dashed lines indicate negative values (decrease). The increase was obtained by fitting a linear regression curve to the monthly mean wave height.

Discussion

As shown above, the wave height shows the tendency of increase at most of the observation stations along the Pacific coast of Japan. The increasing tendency is shown in all seasons except spring (Figure 6). It is also shown that the increasing tendency is especially dominant in autumn and winter. As the primary weather factor causing the wave height increase, it is thought that the number of typhoon approaching to and hitting Japan has been increasing recently, and that atmospheric depressions develop more frequently in winter around Japan, since Asian Monsoon
tends to be weak in recent winters.

According to the numerical simulation by a wave model, the trend of wave height over the recent 10 years shows a tendency of increase in the North Pacific Ocean with a maximum of 6cm/year (Figure 8). A long-term tendency in the mid latitude area of the North Atlantic Ocean is also an increase, with the rate of approximately 2cm/year according to the hindcast data. The order of magnitude of this rate is equal to the result of the analysis of E.Bouws et al (1996) from the wave chart for 27 years from 1961 to 1987, though both these analysis periods are different. It is also interesting that the wave height shows an increasing tendency in both the North Pacific and the North Atlantic Oceans.

As one of the primary factors of a long-term change of ocean waves, there is a possibility that the change of atmospheric circulation in the upper layers is related to this. Figure 9 shows a correlation relation between an anomaly of monthly mean wave height at Sendai and 500hPa height at latitude 45°N longitude 155°E in winter.

Figure 10 shows the distribution of correlation coefficient between an anomaly of monthly mean wave height from a climatic value at Sendai and an anomaly of monthly mean 500hPa height in the Northern Hemisphere. It is shown that there are three places with evident correlation relation between anomaly of ocean wave height and 500hPa height in this figure. The correlation relation between the anomaly of 500hPa height and wave height is shown to exist also at other wave observation stations. This means that when atmospheric circulation fields in the upper layer
change compared with ordinary states, a weather system at the ground surface tied to these circulation changes too, and as a result, wave statistics values change. Therefore, wave height showing the increase tendency in the North Pacific Ocean suggests the possibility that the weather system at the ground surface is changing.

Fig. 10 Correlation coefficients between anomaly of monthly mean wave height at Sendai and anomaly of monthly mean 500hPa height in the northern Hemisphere in winter. Thick contour lines indicate plus correlation and thin lines indicate minus correlation.

Conclusion

A long-term tendency of monthly mean wave height has shown the tendency of increase at most observation stations along the Pacific coast of Japan. The increasing tendency of wave height based on the observation data does not contradict with the numerical calculation result. Therefore, there is a possibility that wave height has increased over the recent ten years in the North Pacific Ocean.

The following is thought as this factor. It has been shown that the anomaly of monthly mean wave height at each wave observation station has a high correlation with the anomaly of 500hPa height in a specific area. This suggests that the change in the planetary wave pattern in the upper layer of atmosphere generate the changes of wave climate. For instance, in the winter when the planetary wave moves to the north and locates in a higher latitude area than a usual year, it tends to cause a warm winter in Japan. At that time the monthly mean wave height tends to be larger than usual
along the Pacific coast of Japan, since synoptic-scale weather disturbances are frequently generated in such a warm winter.

The long-term change in weather systems related to a planetary wave is thought to be one of the factors controlling the wave height increase tendency in the North Pacific. However, the evidence or the mechanism of the change in the weather disturbance has not been clarified yet. It is indeed necessary to investigate the change in the weather disturbance activity.

The present study was carried out as part of the Improvement of Precision of Wave Information Program, which has been supported by the Nippon Foundation. The authors gratefully acknowledge Japan Meteorological Agency and Harbors Bureau in Ministry of Transport for providing wave observation data. The authors are also grateful to Prof. Y. Ogura for his fruitful advice.
ANALYSIS OF WAVE DATA AT SINES

Carlos Pita (1) and Fernando Abecasis (2)

Abstract

The aim of this paper is to summarise the main results obtained from wave data collected in the Portuguese west coast near Sines Harbour. In spite of special attention given to wave characteristics during storm occurrences, some considerations about mean wave regimen will be done.

Introduction

Sines Harbour is located in the South part of Portuguese west coast (fig. 1).

Acquisition of wave data is made in a regular basis at Sines since 1973, with some interruptions for maintenance of recorder devices or caused by buoys mooring problems. Unfortunately only after 1981 data processing is carried out systematically. So, at this moment, available data cover a period of 18 years, period of time still insufficient for a good definition of extreme values, but interesting to provide information about the tendencies of these extreme values, specially when compared with design conditions.

Two Datawell directional wave buoys are installed at depths of -100 m CD and -50 m CD. In spite of some small variations in the positions of these buoys, after their removal for maintenance needs, it may be assumed (taking into account mathematical model results) that, for wave regimen characterisation, data from each depth may be considered as recorded at the same point.

Wave Data

Wave data is nowadays obtained in a continuous form. Records are segmented in parts with a duration of about 20 minutes, which are subjected to an on-line computation at Administração do Porto de Sines (APS) facilities. This analysis allows the computation, for each record, of maximum individual wave height, $H_{\text{max}}$, significant wave height, $H_s$, mean period, $T_z$ and main direction.

These 20 minutes records are also digitally registered. In a subsequent treatment, done by the Portuguese hydrographic service, Instituto Hidrográfico (IH), parameters like peak period or wave height and wave period distributions are also computed.

In present paper most of used results where obtained from APS on-line computations, complemented in some cases by the evaluation of wave parameters done at IH. The results of some studies performed by Laboratório Nacional de Engenharia Civil (LNEC) and by IH are also used.

Storm Waves

It was assumed by the Portuguese coastal engineers, taking into account their experience about wave conditions in the Portuguese west coast, that a “storm” occurs when there is one exceedance of a significant wave height of 5.0 meters. In the case of Sines there is a “storm” if the significant wave height of 5.0 meters is exceeded at least in one of the two wave buoys.

Considering this definition, a total of 57 storms happened since the beginning of 1981 until February 1998.

In table I the main characteristics of these storms, namely maximum values of $H_s$, $H_{\text{max}}$ and associated main direction are presented for the two wave buoys. The total time of exceedance of $H_s = 5.0$ meters is also presented, with a maximum error in each storm of $\pm 1$ hour.

According to this table, since 1981 storm total duration is around 1,000 hours (aprox. 42 days) with maximum yearly duration in 1989 (about 200 hours) and 1996 (222 hours) - fig. 2.

Wave conditions are in general more severe at the depth of -100 m CD than at -50 m CD (as it was expected) - figures 3 and 4, with maximum values of:

- Depth -100 m CD: $H_s = 9.6$ m
- Depth -50 m CD: $H_s = 9.0$ m

Anyway, largest $H_{\text{max}}$ had occurred at buoy at -50 m CD, with a value of 16.1 m, against a value of $H_{\text{max}} = 14.7$ m at -100 m CD.

**Notes:**

1. Identified as a "storm" due to the occurrence of Hs > 5.0 meters in other points of Portuguese coast. As there is no data from the buoy positioned at -100 m CD, it was impossible to confirm deep water conditions.
2. Due to a problem with the measurement devices, records do not cover all the storm. Storm duration could not be properly evaluated.

More frequent values of Hmax and Hs are:

- **Depth -100 m CD:** Hmax between 10.3 and 10.7 m
  Hs between 5.3 and 5.7 m
- **Depth -50 m CD:** Hmax between 7.3 and 7.7 m
  Hs between 4.8 and 5.2 m
Wave directions during storms at a depth of -100 m CD are dominant in the sector 270° - 320°, with a few occurrences from 225° (SW). At -50 m CD existing data are not enough to get good conclusions, but a concentration between 280° and 300° seems to occur, as it was expected, if refraction effects are taken into account (Fig. 5).

Wave Parameters

Wave Heights Distribution

Theoretically, assuming a Rayleigh distribution for individual wave heights during any record of each storm, the parameters $H_{\text{max}}$ (maximum individual wave height of each record), $H_1$ (average of 1% higher wave heights of the record), $H_{10}$ (average of the
10% higher wave heights of the record) are related with Hs (average of 33.3% highest wave heights of the record) by the following relationships:

\[ H_{\text{NA}}^{\text{max}} = \sqrt{\frac{\ln \text{NA}}{2}} H_s \]  \hspace{1cm} (1)

in which NA is the number of waves of the record and \( H_{\text{NA}}^{\text{max}} \) is the average maximum wave height expected in a record with a number of waves Na and a significant wave height, Hs,

\[ H_1 = 1.668 H_s \]  \hspace{1cm} (2)
\[ H_{10} = 1.273 H_s \]  \hspace{1cm} (3)

To evaluate the validity of these relations, individual records from the buoy positioned at a depth of -100 m CD obtained during storm conditions were analysed. Results are presented at figures 6 to 8.

These results suggest the following comments and conclusions:

a) As each record contains less than 150 waves, the parameter H1 has no statistical meaning. The group of the 1% higher waves is composed by one single wave, and, in consequence, \( H_1 = H_{\text{max}} \). No conclusion can be obtained about the correctness of the relation \( H_1 = 1.668 H_s \). Anyway, the tendency of the results is that values evaluated by theoretical relationship are higher than observed values - Fig. 6.
b) Average values of the relation \( H_{10}/H_s \) are around 1.23 and 1.27, in the range of 0 to -2% around theoretical value. At the peak of the storm, these oscillations are larger, varying between +0.5% and -7.3%. Maximum and minimum values of this relation oscillate around +5% and -9% of theoretical value.

These oscillations are small enough to conclude that theoretical values are very close to the real ones and can be used to evaluate \( H_{10} \) in the absence of computed values - Fig. 7.

c) Relations between \( H_{\text{max}} \) and \( H_s \) have average values of 1.5 to 1.6, as expected from theoretical results. Anyway, the results show a large scatter and, at the peak of the storm, these relations can oscillate ±20% around theoretical value - Fig. 8.
Relationships between Wave Heights, Directions and Peak Periods

In figure 9 is done a presentation of the value of $T_p$ associated to the maximum $H_s$ in each storm. This presentation illustrates that parameter $T_p$ has a large scatter in recorded wave storms at Sines. The same conclusion can be obtained considering maximum $T_p$ at each storm and associated values of wave directions (fig. 10) and $H_s$ at the same record (fig. 11).

Anyway, it must be noticed that large values of $T_p$ can occur at Sines, as, during more than 50% of the storms, $T_p$ values higher than 15 seconds were computed at both wave buoys (Table VI). It is also interesting to recognize that records done at the same hour in both wave buoys do not show the same value of $T_p$, with differences that can reach 2 seconds (Table VII). Anyway, in both positions most frequent values occur for $H_s$ between 4 and 6 meters and $T_p$ from 15 to 18 seconds (Table VI).

These conclusions were checked in a study conducted by IH and LNEC (ref. [1]), where it was stated that:

a) Significant Wave Heights:
A strong correlation between significant wave heights was found (91%). According to linear model and from a general way significant wave heights at -50 m CD are about 80 - 90% of significant wave heights at -100 m CD.

b) Peak Periods
Correlation coefficient between records obtained at the two points is about 76 to 77%.

Wave Propagation

The importance of previous results is due to a large discussion, which took place after west breakwater accident in 1978, about the possibility of occurrence of energy concentrations on the breakwater.

In fact, a lot of refraction studies were carried out at different institutions after 1978 accident at Sines west breakwater, with very different conclusions, some of them pointing out the possibility of occurrence of wave concentrations on the breakwater.

Mathematical studies or physical model tests with regular waves carried out either at LNEC (Portugal) and LCHF (France) concluded by the possibility of occurrence of refraction coefficients up to 1.5 or even higher.

On the other hand, tests in a physical model with irregular waves performed at DHL (Netherlands) lead to the conclusion that do not occur refraction coefficients higher than 1.1. Besides, the reaches of the breakwater in which the occurrence of energy concentrations could be expected were not the same in the different studies.

The differences in the conclusions of different studies can be explained by the use of different techniques (traditional refraction diagrams with different bottom digitalisation, model studies with regular waves or with random waves).
At figure 12 relations between existing wave data collected with directional wave buoys at depths of -100 m CD and -50 m CD are presented. In spite of an important dispersion, these results seem to show that:

- For wave directions at depth -100 m CD below 300 degrees, a relation between significant wave heights of 0.9 to 1.0 may be expected, with a variation of directions lower than 10° towards the perpendicular to the breakwater (the direction of which is 270°);
- For wave directions at deep water between 300 and 310°, relations between wave heights at depths of -50 m CD and -100 m CD of 0.6 to 0.9 can occur, with variations on the direction of 14 to 22°;
- For wave directions higher than 310°, relations lower than 0.8 between significant wave heights can be expected;
- No influence of peak period was found in these relations.
- Anyway in the referred study conducted by IH and LNEC, it was found for the Mean Direction of Peak Period a small correlation coefficient (0.88). The direction in the deeper water location shows a rotation of about 12° North with reference to lower water depths.

Fig. 12 - Relations between Significant Wave Heights, Wave Directions and Peak Periods at -100 m CD and -50 m CD

It must be stated that these results are preliminary, additional analysis and a physical explanation for them being required (for instance, to evaluate how much they were affected by local winds or by reflections in the breakwater).

Wave regimen - Extreme Values

During initial studies of Sines West Breakwater a wave climate was defined, conducting to the extreme values presented in Table VIII.

After 1978 accident, during the studies about the rehabilitation of the breakwater, PRC Harris defined, mainly based in hindcast studies performed by WES, a new deep water wave climate, supported in a Gumbel distribution. This climate was
used, taking into account refraction and diffraction effects, in the design of all the breakwaters existing at Sines harbour. Extreme values of this climate are also presented in Table VIII.

Since 1981 a lot of additional storm data were collected, as indicated at Table I. In general, maximum waves occur during the winter, which in Portugal is, in what sea conditions is concerned, between October and March. It is the author's opinion that a "maritime year" is extended from October until October of next year (like the hydrologic year).

Yearly maximum individual and significant wave data according to the previous definition are the following in the period from 1980/1 until 1997/8:

<table>
<thead>
<tr>

Using Gumbel and Log-Normal Distributions the Extreme Values of Hs and Hmax associated to different Return Periods were computed. They are presented at Table X.

Presented values for -50 m CD depth were computed using a very small time series (10 values) and should be considered with additional caution, specially because a sample of 17 values was available for the depth of -100 m CD.

Obtained values are between adopted design values after west breakwater accident and those established initially. In spite of, once again, the importance of being very careful about these conclusions, it is important to the owner of the harbour and to its users to be confident that wave action influence on the structures have a high probability of being from safe side.

Wave regimen - Mean Values

Measured mean wave conditions are clearly in accordance with values defined by Frederick R. Harris in their studies. Main results are summarised in figure 13.

These results show that, as expected, predominant wave directions are in the reach WNW to W and that only in 10% of the time (38 days per year) Hs exceeds 3.0 meters.

Conclusions

- A total of 57 wave storms occurred at Sines since 1981, with a total duration of about 1,000 hours with Hs ≥ 5.0 meters.

- Maximum recorded values of wave heights were:
  - at a depth of -100 m CD: Hs =  9.6 m
    Hmax = 14.7 m
  - at a depth of -50 m CD: Hs =  9.0 m
    Hmax = 16.1 m
- Using existing data and assuming that statistical distributions of yearly maximum values of $H_s$ and $H_{\text{max}}$ are Gumbel or Log-normal, the following extreme values of $H_s$ and $H_{\text{max}}$ were obtained for a depth of -100 m CD:

  - With a return period of 10 years:
    - $H_s$ from 8.9 to 9.0 meters
    - $H_{\text{max}}$ from 14.1 to 15.0 meters
  
  - With a return period of 50 years:
    - $H_s$ from 10.7 to 11.0 meters
    - $H_{\text{max}}$ from 16.6 to 17.2 meters
  
  - With a return period of 100 years:
    - $H_s$ from 11.4 to 11.9 meters
    - $H_{\text{max}}$ from 17.8 to 19.1 meters

**BIBLIOGRAPHY:**

ON THE STATISTICAL VARIABILITY
OF WAVE HEIGHT AND PERIOD PARAMETERS

Carlos R. Sánchez-Carratalá
and Marcos H. Giménez

ABSTRACT

A new method for the determination of short-term variability of some commonly used wave height and period parameters is presented. The new TFD method combines some previously available time and frequency domain approaches, optimizing their application and giving greater accuracy with easy implementation. Short-term variability predicted by the new TFD method is consistently higher than the one obtained with theoretical frequency domain expressions, and proves to be in very good agreement with sampling variability observed in Gaussian, non-periodic and non-deterministic random wave records generated with stable ARMA numerical simulators.

INTRODUCTION

Random nature of ocean waves and their modelling as a stochastic process are basic assumptions commonly used in engineering problems. Although a great deal of effort has been dedicated to describe the statistical behaviour of some important sea state parameters, many problems related to their short-term variability still remain unsolved. Short-term variability can be defined as the statistical sampling variability of any time or frequency domain parameter when it is calculated from a finite length wave record that is supposed to be taken from a theoretically infinite length realization of the underlying stochastic process. Knowledge of short-term variability is important in many practical applications, such as: assessment of wave climate uncertainty; risk-based design and economic analysis of offshore and coastal structures; estimation of maintenance and insurance costs of maritime works; and design of physical or numerical experiments.

Although continuous measurement of the sea surface movement is no problem with most modern wave recorders -like scalar and directional bouys or coastal and satellite radars-, wave climate non-stationarity makes necessary to divide long wave records into finite length time (space) intervals, if the commonly assumed stationarity (homogeneity) hypothesis is to be fulfilled, at least in a wide sense. Furthermore, many ongoing measurements are being made over short intervals and much existing data are in this form. Sampling variability can be reduced at the expense of a lost of resolution in the time or frequency domain by averaging over time intervals or frequency bands, but it can still be important for some purposes. This means that, even assuming ergodicity, we are forced to face up to sampling variability in practical applications.

One of the main difficulties found in theoretical developments for estimating short-term variability has its origin in the use of a specific wave discretization criterion for the analysis of wave records in the time domain (zero-up-crossing, zero-down-crossing, orbital, etc.). Two basic approaches have been proposed in the last decades to overcome this problem: (1) a numerical approach in the time domain (TD approach) that is based in the numerical simulation of random wave records (e.g., Goda, 1977, 1987); and (2) an analytical approach in the frequency domain (FD approach) that takes advantage of some relations between time domain and frequency domain parameters (e.g., Tucker, 1957; Cavanié, 1979; Giménez et al., 1994b). Some interesting contributions to the theoretical and experimental study of sampling variability of spectral estimates and spectral integrals are discussed in Donelan and Pierson (1983), Young (1986), Elgar (1987) and Forristall et al. (1996), among others.

This paper presents a new method for the determination of short-term variability of some widely used wave height and period parameters. The new combined time and frequency domains method (TFD method) integrates the two aforementioned approaches, optimizing their application and giving greater accuracy with easy implementation.

VARIABILITY OF WAVE HEIGHT PARAMETERS

Henceforth, we will use the subscript $R$ -in connexion with a time or frequency domain parameter- to point out that it has been calculated from a wave record of duration $T_R$. Additionally, we will use the subscript $r$ -in connexion with a time domain parameter- to indicate that the orbital criterion for discretizing waves has been applied for the statistical analysis of a wave record. In the orbital criterion a discrete wave is defined by a complete rotation of a sea surface particle around its mean position. The orbital criterion has proved to be more consistent and robust (see Giménez et al., 1994a) and to present less sampling variability (see Giménez et al., 1994b) than the commonly used zero-up-crossing criterion. Furthermore, as shown by Giménez and Sánchez-Carratalá (1997), energy propagation in directional seas is closely related with orbital waves.

Making use of the approximate expression (A.13) obtained in Appendix A for the coefficient of variation of the product of two random variables $x$ and $y$, we have that when:
the coefficient of variation of \( H_{1/p,R,R} \) is approximately given by:

\[
v[H_{1/p,R,R}] = \sqrt{v^2[H_{1/p,R,R}]} + \sqrt{v^2[H_{1/p,R,R}]/m_{0,R}}
\]  

(2)

where \( v[\cdot] \) is an operator denoting the population coefficient of variation of the random variable considered as argument; \( H_{1/p,R,R} \) is the mean orbital wave height of the \( 1/p \) highest waves in a wave record of duration \( T_R \) (specifically, when \( p=1 \) we obtain the mean wave height, \( H_{1/1,R,R} = H_{R,R} \); and when \( p=3 \) we obtain the significant wave height, \( H_{1/3,R,R} \)); and \( m_{n,R} \) is the \( n \)th order spectral moment of a wave record of duration \( T_R \).

On the one hand, the value of \( v[\sqrt{m_{0,R}}] \) in Eq. (2) can be calculated analytically in the frequency domain using the following approximate expression derived by Cavanie (1979):

\[
v[\sqrt{m_{0,R}}] = \sqrt{\frac{1}{4T_R m_0}} \int_0^{\infty} S_n(f) df
\]  

(3)

where \( f \) is the cyclic frequency; \( S_n(f) \) is the variance spectrum of the process; and \( m_n \) is the \( n \)th order spectral moment of the process. Eq. (3) can be reformulated using the well-known spectral peakedness parameter \( Q_e \) proposed by Medina and Hudspeth (1987), so that:

\[
v[\sqrt{m_{0,R}}] = \sqrt{\frac{Q_e}{8N_{w,r,R}}}
\]  

(4)

where \( N_{w,r,R} = T_R/T_{01} \) is the spectral estimation of the number of orbital waves in a wave record of duration \( T_R \); and \( T_{01} = m_0/m_1 \) is the spectral estimation of the mean orbital wave period of the process, as shown by Giménez et al. (1994a).

On the other hand, the value of \( v[H_{1/p,R,R}/\sqrt{m_{0,R}}] \) in Eq. (2) should be calculated numerically in the time domain using a harmonic DSA random wave numerical simulator (see Tuah and Hudspeth, 1982), as suggested by Sánchez-Carratalá (1995). This kind of simulator has no variability in the frequency domain for a record duration equal to its recycling period, and thus:
\[ \nu[H_{1/p,R}/\sqrt{m_{0,R}}] = \nu[H_{-DSA}[H_{1/p,R}]] = n_{H-DSA}[H_{1/p,R}] \tag{5} \]

where \( n[\cdot] \) is an operator denoting the sample coefficient of variation of the random variable considered as argument.

The value of \( n_{H-DSA}[H_{1/p,R}] \) has been calculated for different wave height parameters \((p=1,3,10)\), different record durations \((T_R=2^k \Delta t, k=6,7,13, \Delta t=1 \text{ s})\), and different peak enhancement factors of a JONSWAP-type spectrum \((\gamma=1,3,7)\), using samples of 200 wave records generated with an H-DSA\((2^k)\)-FFT numerical simulator, that is, a harmonic wave superposition simulator with \(2^k\) one-sided DSA frequency components, implemented with an FFT algorithm. According to theoretical and numerical evidence (see, e.g., Goda, 1987), the results obtained have been fitted with a least squares technique to a function of the following type:

\[ n_{H-DSA}[H_{1/p,R}] = k T_R^{-n} \tag{6} \]

Table 1 gives the coefficients \( k=k(p,\gamma) \) and \( n=n(p,\gamma) \) in Eq (6), obtained for each wave height parameter \((p=1,3,10)\) and each peak enhancement factor \((\gamma=1,3,7)\), with \( T_R \) in seconds.

**TABLE 1** Coefficients \( k \) and \( n \) in Eqs (6) and (11) for different sea state parameters \((T_R \text{ in seconds})\).

**VARIABILITY OF WAVE PERIOD PARAMETERS**

Making use of the approximate expression (A 13) obtained in Appendix A for the coefficient of variation of the product of two random variables \( x \) and \( y \), we have that when
the coefficient of variation of $T_{r,R}$ is approximately given by:

$$v^2 = \sqrt{\frac{1}{T_R} \int_0^{T_R} (T_{01,R} - 1)^2 S_n^2(f) df}$$  

$$v^2 = \sqrt{\frac{1}{T_R} \int_0^{T_R} (T_{01,R} - 1)^2 S_n^2(f) df}$$  

(9)

On the other hand, the value of $v[T_{01,R}]$ in Eq. (8) should be calculated numerically in the time domain using a harmonic DSA random wave numerical simulator, as suggested by Sánchez-Carratalá (1995). This kind of simulator has no variability in the frequency domain for a record duration equal to its recycling period, and thus:

$$v^2 = \sqrt{\frac{1}{T_R} \int_0^{T_R} (T_{01,R} - 1)^2 S_n^2(f) df}$$  

(10)

The value of $n_{H-DSA}[\bar{T}_{r,R}]$ has been calculated for different record durations ($T_R=2^k \Delta t$, $k=6,7,\ldots,13$; $\Delta t=1$ s), and different peak enhancement factors of a JONSWAP-type spectrum ($\gamma=1,3.3,7$), using samples of 200 wave records generated with an H-DSA$(2^{k+1})$-FFT numerical simulator. According to theoretical and numerical evidence (see, e.g., Goda, 1987), the results obtained have been fitted with a least squares technique to a function of the following type:

$$n_{H-DSA}[\bar{T}_{r,R}] = k T_R^{-n}$$  

(11)

Table 1 gives the coefficients $k=k(\gamma)$ and $n=n(\gamma)$ in Eq. (11), obtained for each peak enhancement factor ($\gamma=1,3.3,7$), with $T_R$ in seconds.

Table 2 gives a comparison between short-term variability predicted by the FD approach and the new TFD method, for each peak enhancement factor ($\gamma=1,3.3,7$), and for a record duration of about 100 waves. According to these results, sampling
variability of wave height and period parameters included in this study, is systematically underestimated by the presently available frequency domain expressions.

**TABLE 2** Comparison between short-term variability predicted by the FD approach and the new TFD method for different sea state parameters ($T_r$ in seconds) ($N_{w,r,R}=100$)

**CONTRAST WITH NUMERICAL SIMULATIONS**

The new TFD method herein presented has been compared with sampling variability estimates obtained by numerical simulation, in order to test its performance. Samples of 100 wave records with about 1000 waves each one ($N=8192, \Delta t=1$ s), corresponding to different sea states characterized by a JONSWAP-type spectrum ($\gamma=1, 3, 7$), have been generated using an AR(100)-RT(0.05) numerical simulator, that is, a digital linear filter with 100 autoregressive parameters, fitted with the robust technique proposed by Medina and Sánchez-Carratalá (1991), with only a 0.05% of white noise in the target spectrum. Digital filters obtained with the robust technique are always stable, and present extremely low fitting errors according to the hierarchic criteria introduced by Medina and Sánchez-Carratalá (1988) for qualifying ARMA representations of ocean wave spectra.

Figs 1, 2, 3 and 4 show the evolution of the coefficient of variation of $H_{r,R}$, $H_{1/3,r,R}$, $H_{1/10,r,R}$, and $T_{r,R}$, respectively, as a function of the number of waves $N_{w,r,R}$, for different peak enhancement factors ($\gamma=1, 3, 7$). The continuous thin line represents the sampling variability predicted by the new TFD method according to Eqs (2) or (8), while the dashed thin lines are an estimation of the corresponding 95% confidence intervals. The thick line represents the sampling variability obtained from a sample of numerically simulated wave records, showing the overall good performance of the new TFD method for predicting sampling variability of wave height and period parameters in random Gaussian seas.

(a) $\gamma=1$; (b) $\gamma=3.3$; (c) $\gamma=7$. 
CONCLUSIONS

A new method for the determination of short-term variability of some commonly used wave height and period parameters has been developed as a combination of some previous time and frequency domain approaches. Short-term variability predicted by the new time and frequency domains method (TFD method) is consistently higher than the one obtained with theoretical frequency domain expressions. The difference is specially notorious for $H_{1/10, r, R}$ (17\textendash29\%) and $T_{r, R}$ (54\textendash57\%).

Results obtained with the new TFD method have proved to be in very good agreement with sampling variability observed in Gaussian, non-periodic and non-deterministic random wave records generated with stable ARMA numerical simulators, thus constituting a straightforward and reliable alternative for the prediction of short-term variability of many time domain parameters.

APPENDIX A. Coefficient of variation of the product of two random variables

Let $x$ and $y$ be two random variables distributed in the interval $[0, +\infty]$ with a joint probability density function $p(x, y)$. The aim of this Appendix is to obtain an approximate expression for the coefficient of variation of the product $xy$.

Let $a$ be a random variable defined as the following function of $x$ and $y$:

$$a = a(x, y) = xy$$

(A.1)

The first and second order partial derivatives of $a$ with respect to $x$ and $y$ are:

$$\begin{align*}
\frac{\partial a}{\partial x} &= y; \quad \frac{\partial a}{\partial y} = x \\
\frac{\partial^2 a}{\partial x^2} &= 0; \quad \frac{\partial^2 a}{\partial y^2} = 0; \quad \frac{\partial^2 a}{\partial x \partial y} = 1
\end{align*}$$

(A.2)

A Taylor series expansion of $a$ around the point $(x_0, y_0)$ gives:

$$a = (a) + \frac{1}{1!} \left( \frac{\partial a}{\partial x} \right)_0 (x-x_0) + \frac{1}{1!} \left( \frac{\partial a}{\partial y} \right)_0 (y-y_0) +$$

$$+ \frac{1}{2!} \left( \frac{\partial^2 a}{\partial x^2} \right)_0 (x-x_0)^2 + \frac{1}{2!} \left( \frac{\partial^2 a}{\partial y^2} \right)_0 (y-y_0)^2 + \frac{1}{1!1!} \left( \frac{\partial^2 a}{\partial x \partial y} \right)_0 (x-x_0)(y-y_0) + ...$$

(A.3)

On substituting (A.2) in (A.3) for $x_0 = E[x]$ and $y_0 = E[y]$, we obtain the following exact expression for $a$:
\[ a = E[x] E[y] + E[y] (x - E[x]) + E[x] (y - E[y]) + (x - E[x]) (y - E[y]) = \]
\[ = E[x] E[y] \left[ 1 + \frac{(x - E[x])}{E[x]} + \frac{(y - E[y])}{E[y]} + \frac{(x - E[x]) (y - E[y])}{E[x] E[y]} \right] \quad (A.4) \]

where \( E[x] \) is the expected value of the random variable \( x \).

Hence, the mean value of \( a \) is:

\[ E[a] = \int_0^\infty \int_0^\infty a p(x,y) \, dx \, dy = \]
\[ = E[x] E[y] \left( 1 + \frac{C[x,y]}{E[x] E[y]} \right) = E[x] E[y] \left( 1 + c[x,y] \frac{\sigma[x]}{E[x]} \right) \quad (A.5) \]

where \( C[x,y] \) and \( c[x,y] \) are, respectively, the covariance and the normalized covariance of the random variables \( x \) and \( y \); and \( v[x] \) is the coefficient of variation of the random variable \( x \), given by:

\[ v[x] = \frac{\sigma[x]}{E[x]} \quad (A.6) \]

where \( \sigma[x] \) is the standard deviation of the random variable \( x \).

Let \( b \) be a random variable defined as the following function of \( x \) and \( y \):

\[ b = b(x,y) = x^2 y^2 \quad (A.7) \]

that is, \( b = a^2 \).

The first and second order partial derivatives of \( b \) with respect to \( x \) and \( y \) are:

\[
\begin{align*}
\frac{\partial b}{\partial x} &= 2xy^2 ; \quad \frac{\partial b}{\partial y} = 2x^2 y \\
\frac{\partial^2 b}{\partial x^2} &= 2y^2 ; \quad \frac{\partial^2 b}{\partial y^2} = 2x^2 ; \quad \frac{\partial^2 b}{\partial x \partial y} = 4xy
\end{align*}
\quad (A.8)
\]

A Taylor series expansion of \( b \) around the point \( (x_0, y_0) \) gives:
\[ b = (b_0 + \frac{1}{11!} \left( \frac{\partial b}{\partial x} \right) (x-x_0) + \frac{1}{11!} \left( \frac{\partial b}{\partial y} \right) (y-y_0) + \]
\[ + \frac{1}{2!} \left( \frac{\partial^2 b}{\partial x^2} \right) (x-x_0)^2 + \frac{1}{2!} \left( \frac{\partial^2 b}{\partial y^2} \right) (y-y_0)^2 + \frac{1}{11!} \left( \frac{\partial^2 b}{\partial x \partial y} \right) (x-x_0) (y-y_0) + \ldots \]  

(A.9)

On substituting (A.8) in (A.9) for \( x_0 = E[x] \) and \( y_0 = E[y] \), we obtain the following approximate expression:

\[ b = E^2[x] E^2[y] + 2 E[x] E^2[y] (x - E[x]) + 2 E^2[x] E[y] (y - E[y]) + \]
\[ + E^2[y] (x - E[x])^2 + E^2[x] (y - E[y]) + 4 E[x] E[y] (x - E[x]) (y - E[y]) = \]
\[ + \frac{(x - E[x])^2}{E^2[x]} + \frac{(y - E[y])^2}{E^2[y]} + 4 \frac{(x - E[x]) (y - E[y])}{E[x] E[y]} \]  

(A.10)

Hence, the mean value of \( b \) is:

\[ E[b] = \int_0^\infty \int_0^\infty b \cdot p(x,y) \, dx \, dy = \]
\[ = E^2[x] E^2[y] \left( 1 + \frac{\sigma^2[x]}{E^2[x]} + \frac{\sigma^2[y]}{E^2[y]} + 4 \frac{C[x,y]}{E[x] E[y]} \right) = \]
\[ = E^2[x] E^2[y] \left( 1 + \nu^2[x] + \nu^2[y] + 4 c[x,y] \nu[x] \nu[y] \right) \]  

(A.11)

Now from (A.5) and (A.11) we find that the square of the coefficient of variation of \( a \) is given by:

\[ \nu^2[a] = \frac{\sigma^2[a]}{E^2[a]} = \frac{E[b] - E^2[a]}{E^2[a]} = \]
\[ \frac{E^2[x] E^2[y] \left[ \nu^2[x] + \nu^2[y] + 2 c[x,y] \nu[x] \nu[y] - c^2[x,y] \nu^2[x] \nu^2[y] \right]}{E^2[x] E^2[y] \left( 1 + 2 c[x,y] \nu[x] \nu[y] + c^2[x,y] \nu^2[x] \nu^2[y] \right)} \]  

(A.12)

Assuming that \( \nu[x] < 1 \), \( \nu[y] < 1 \) and \( c[x,y] < 1 \), we obtain the following approximate expression for the coefficient of variation of the product \( xy \):

\[ \nu[xy] = \sqrt{\nu^2[x] + \nu^2[y]} \]  

(A.13)
REFERENCES

Duration in Wave Climate Analysis

Rodney J. Sobey* and Leah S. Orloff†

Abstract
The relationship between sea state intensity, sea state duration and frequency is pursued in the context of wave data from five sites in U.S. waters. A rational methodology is presented for the interpolation and extrapolation of measured trends, based on extreme value series for intensity, given duration. The inevitable short duration data base problem is addressed by routine application of the triple annual maximum methodology. A format is suggested for IDF data preparation and presentation. Examples are given for wave climate data on the Pacific and Atlantic coasts of the United States.

Introduction
The long term history of wave conditions at a particular site exhibits similar variability to other climate variables such as atmospheric pressure, precipitation, stream flow, temperature and wind speed. Wave measurement programs have only recently become commonplace. Apart from the relatively short duration of available data sets, analysis techniques in wave climate have followed, where appropriate, the established practices for other climate variables.

Though by no means universal, a common trend in wave measurement practice is a twenty minute burst sample every hour. This is the practice, for example, of the National Data Buoy Center (NDBC), for the numerous surface buoys in its network throughout U.S. waters. Each burst sample provides a single wave climate intensity estimate, typically the significant wave height $H_s$.

Wave climate attention has often focused on frequency analyses of the intensity alone. Extreme value analyses, leading to intensity-frequency summaries, are relatively routine, except for extrapolation uncertainties that are a direct consequence of the short duration of existing wave data series.

*Professor, Department of Civil and Environmental Engineering, University of California, Berkeley, CA 94720, U.S.A.
†Graduate Student, Department of Civil and Environmental Engineering, University of California, Berkeley, CA 94720, U.S.A.
But there is also a time scale to an historical record of a local wave climate; Figure 1, for example, shows a month of data from the NDBC buoy 46026 off San Francisco, California. The intensity is the significant wave height estimate from hourly burst samples. There is considerable interest in the duration or persistence of the sea state intensity, in applications ranging from the planning of engineering operations at sea to the closure of tidal inlets into coastal wetlands.

In a wave climate, both the intensity or wave height $H$ and the duration $D$ of sea state exceedance of this intensity are random variables. In most wave monitoring programs, burst-sample-averaged intensity is routinely characterized by the significant wave height; $H$ throughout is identified as the significant wave height. Intensity-duration-frequency curves are an interpreted presentation of the joint distribution
of intensity and duration, with CDF $F_{H,D}(h,d)$ and PDF $f_{H,D}(h,d)$. $h$ and $d$ are realizations of the random variables $H$ and $D$ respectively.

In surface water hydrology, it is a common practice to summarize precipitation records as IDF (intensity-duration-frequency) curves, and not just as intensity-frequency curves. An IDF-style presentation can be equally useful in wave climate characterization. In this paper, the relationship between sea state intensity, sea state duration and frequency will be pursued. Initial attention will be directed to the trends suggested by measured data. This leads to a rational methodology for the interpolation and extrapolation of measured trends and a suggested format for IDF data preparation and presentation.

**Observational Data**

Field data suitable for the extraction of coupled intensity-duration information must be able to resolve sea state durations. At a minimum, hourly observations of $H$ seem necessary. Some historical data sets with 3 or 6 hours between burst samples cannot adequately resolve the expected range of sea state duration.

Given that the historical record has adequate time resolution, intensity and duration data may be extracted from the record in three different ways, as

(a). joint intensity-duration observations,

(b). duration, given intensity, observations, and

(c). intensity, given duration, observations.

Each of these approaches has intrinsic value. There is potentially useful information in a focus on both population and extreme value events. In particular, an extreme value analysis of data sets (b) or (c) is a basis of the IDF-style presentations.

The measured wave climate records used in the present study have been taken from the NOAA Marine Environmental Buoy Database (National Oceanic and Atmospheric Administration (1992) and supplements), available on CDROM. Details of the two sites on which attention has been focussed are listed in Table 1. Data gaps of one or two hours in these records were filled by linear interpolation. Exceedance intervals interrupted by longer gaps have been ignored.

Annual maximum series for duration given intensity that are extracted from this data often have no entries in some years for the higher intensities. Unfortunately, this identifies a major weakness of efforts to extrapolate the duration given intensity data to extreme events, like the 100 year event, that are well beyond the overall duration of the data record. Fortunately, the alternative extreme value presentation of this same data, as intensity given duration, largely circumvents this difficulty.

Table 1: Wave Data Base

Intensity, given Duration, Observations

Extreme value analyses is based on direct extraction of sea state intensity at a given duration. A moving window search has been adopted to identify the largest intensity $h$ that is continuously exceeded over the target duration. The search may be applied over any period that is sufficiently long to include several storm hydrographs; a week would generally be sufficient, a month would certainly be. The width of the moving window is the target duration $d$; values of 1, 2, 3, ... 12, 15, 18, ... 36, 42, 48, ... 72, 84, 90, ... 144 hours have routinely been adopted.

In the expectation of using either annual maximum series (AMS) and triple annual maximum series (TAMS), the moving window search has been applied over all periods of one calendar month in the historical record. For each target duration, this provides a data series of monthly maximum intensities that are maintained in the record for the target duration. These monthly maximum series are then organized into climate years and ranked in descending order of magnitude to define the TAMS series, which includes $H_1$, the series of annual maximum intensity, $H_2$, the series of the annual second largest monthly maximum intensity, and $H_3$, the series of the annual third largest monthly maximum intensity. Extreme value analyses may be based on these data series.

An immediately apparent feature of these observations is the sparsity of the data. The longer records in the entire NOAA data base have twelve to sixteen climate years. Reliable information is concentrated at average recurrence intervals of less than 5 years. Yet extrapolation to 100 year events is routinely expected.

The present study adopts a generic and very direct approach. There is no insistence on a single probability distribution and there is a direct focus on the inevitable interest in the longer recurrence intervals, extending to 100 years. Attention is directed to extreme value series and extreme value distributions.
Intensity, given Duration - Interpolation and Extrapolation of Extreme Value Series

While the existing wave climate literature has mostly focused on the conditional distribution for duration given intensity, an equally appropriate representation of intensity-duration-frequency curves is available from the conditional distribution for intensity given duration, with CDF $F_H(h \mid d)$ and PDF $f_H(h \mid d)$. The NOAA observational data appears to be more sympathetic to this approach. It also retains the familiarity of intensity-frequency analyses.

Following the adoption of a specific distribution to aid interpolation and extrapolation, the distribution CDF and PDF become $F_{H}(h \mid d; p_1, p_2, \ldots)$ and $f_{H}(h \mid d; p_1, p_2, \ldots)$ respectively. The distribution parameters $p_1(d), p_2(d), \ldots$ are dependent on the given intensity $d$. Once the distribution is established, intensity ($h$), duration ($d$) and frequency (the return period or average recurrence interval $T_R$) are related as

$$1 - \frac{\Delta t}{T_R} = F_{H}(h \mid d; p_1, p_2, \ldots)$$

in which $\Delta t$ is the time interval of the observational data series to which $F_{H}(h \mid d; p_1, p_2, \ldots)$ or $f_{H}(h \mid d; p_1, p_2, \ldots)$ has been fitted. For AMS data, $\Delta t$ is $1$ year. An IDF-style presentation might have duration as the abscissa, intensity as the ordinate and frequency as the parameter of a family of curves. The PDF, CDF, mean and variance for a range of candidate two-parameter distributions have been listed in Table 2.

The classical approach would separately address the intensity data at each duration. Given an AMS series for intensity at that duration and the choice of the extreme value distribution (say from Table 2) to aid interpolation and extrapolation, the probability model would be fitted to the AMS data by probability plotting, by the method of moments, by the least squares method or by the method of maximum likelihood. Knowing the parameters of the distribution, the CDF is completely defined together with the preferred interpolation within the range of the data. The preferred extrapolation beyond the range of the data is also defined. Confidence bands on the extrapolation would finally be estimated, often following the Central Limit theorem or the Kite (1975) method of moments.

This classical approach however does not take full advantage of the data. The data sets are very short and AMS series can be supplemented through controlled recognition of marginally less extreme events. Partial duration series (the peak-over-threshold method) or triple annual maximum (TAMS) series have both been used to advantage in this context. The classical approach also does not acknowledge that data at different durations remain samples from the same wave climate. Using all the

extreme value data together has the potential to provide a superior prediction of the IDF curves. The TAMS approach has been extended to this purpose.

### A TAMS Methodology for Wave Climate IDF

Typical record durations from the NOAA data base identify a very familiar problem in wave climate analysis. The record duration, a decade or so, must be significantly extrapolated to provide estimates of the 50 and 100 year events that are expected from frequency analyses. For the NOAA data in Table 1, the AMS series have twelve or thirteen data points, sufficient for a reliable estimate of perhaps a 25 year event. And these are the long established stations in the data base.
The extrapolation uncertainty can be mitigated by using additional data from the complete duration series, using either a partial duration series or a triple annual maximum series (Sobey and Orloff 1995). The latter approach has been adopted as the basis for the present analysis.

The results of an initial exploratory analysis, using the Sobey and Orloff algorithm on the TAMS data for each duration for the data at Portland, Maine, is shown as the markers in Figure 2. Each of the four Table 2 extreme value distributions has been TAMS-fitted to the data. The TAMS series extracted from the data at the different durations are not unrelated, being extracted from the same historical record. It is not surprising that some of the distribution parameters, such as $u$ and $v$ for Extreme Value I, follow a very consistent trend. Some data scatter is expected, and is an endemic problem of geophysical field data, especially from a relatively short duration record. Nevertheless, the declining probability levels of the longer duration events anticipates smoothly-evolving trends in the distribution parameters. For example, smoothed estimates of both $u$ and $v$ are monotonically decreasing with $D$ in Figure 2a.

Figures 2a through d provide some visual measure of the relative acceptability of each of the four extreme value distributions. The Extreme Value I results (Figures a) look very plausible, the trends being monotonic and the data scatter relatively minor. The Extreme Value II results (Figures b) do not appear acceptable; the $u$ trends is plausible but the jumps in the $\alpha$ response would seem to preclude this distribution as a candidate for data interpolation and extrapolation. The results for Extreme Value III (Figures c) are relatively smooth, except for the $\alpha$ response at large $D$, where also the response seems no longer monotonic. There is a suggestion that this distribution is also unacceptable. The Log Normal (Figures d) results are relatively encouraging. Both $\alpha$ and $\beta$ are monotonically evolving, though the data scatter for $\beta$ is moderately coarse. This result is perhaps acceptable, but seemingly less so than Extreme Value I for this data set.

The trends exhibited by both Table 1 data sets were roughly similar. On a visual basis, the Extreme Value II and III distributions were rejected as suitable candidates for interpolation and extrapolation. The Extreme Value I trends were relatively smooth and monotonic. The Log Normal $\beta$ parameter trends were less smooth and not always monotonic. On this visual measure, the Extreme Value I distribution is preferred for these data sets. But selecting the appropriate distribution for data interpolation and extrapolation is a subjective process. It must be guided by the trends of the particular data set and also by measures of analysis acceptability in addition to a purely heuristic interpretation. Data sets from other geographical sites may be very different.

Similar analyses for all Table 1 data sites were completed. Collectively, such figures and tables provide the information upon which a selection of an extreme value

Units of \( a_i \), \( b_i \) and \( c_i \) assume \( D \) in hours; \( u \) and \( v \) in m; \( \alpha \) and \( \beta \) are dimensionless.

Table 3: Parameters of Equation 2 curve fits to Extreme Value I and Log Normal distribution parameters.

distribution must be based. As with most extreme value analyses in the natural environment, this choice remains somewhat subjective.

**IDF Summaries for US Waters**

Given a choice of extreme value distribution, intensity-duration-frequency curves can be constructed.

Interpolation and extrapolation of results such as Figure 2 may be facilitated by smoothing the trends to the empirical curve

\[
p_i(d) = \exp \left[ a_i + b_i d + c_i d^2 \right]
\]

(2)

where \( p_i (i = 1,2) \) are the distribution parameters. There is no fundamental basis for such a relationship, except that it does reasonably follow the \( p_i(d) \) trends. Least squares curve fits of Equation 2 to the data in Figure 2 and similar for other sites define the parameters \( a_i \), \( b_i \) and \( c_i \). These curve fits for all four of the Table 2 distributions are included as the solid lines on Figure 2 for the Portland, Maine site. Parameters for Extreme Value I and Log Normal at all the Table 1 sites are listed on Table 3. These distributions seem to be the most plausible for these sites, though this may not be the case for other sites.

Given an extreme value distribution and the \( p_i \) parameters as a smooth function of duration \( D \), an IDF curve can be constructed for a given average recurrence interval \( T_R \) from solutions to Equation 1.

\[
1 - \frac{\Delta t}{T_R} = F_H(h|d;p_1(d),p_2(d))
\]

(3)
This is an implicit algebraic equation in $h(d; T_R)$, which can be solved for each duration by standard numerical algorithms such as Newton-Raphson, regula falsi or the secant method. As a result of the smoothing implicit in the Equation 2 curve fits, these solutions will also be smoothly varying. Completing these solutions for a range of appropriate average recurrence intervals, typically 2, 5, 10, 20, 50 and 100 years provides the classical IDF presentation.

IDF predictions from the Extreme Value I and Log Normal distributions for the San Francisco, California and Portland, Maine sites are shown as Figures 3 through 6. These predictions show excellent trend agreement but only moderate magnitude agreement. More can not be expected, these figures once again demonstrating the fragility of extreme value analyses from short duration data.
Conclusions

The relationship between sea state intensity, sea state duration and frequency is pursued in the context of wave data from the NOAA Marine Environmental Buoy Database at two sites in U.S. waters.

Detailed attention has been given to extreme events, where the popular approach has been a focus on duration, given intensity. Existing studies have mostly utilized wave data from the European and Japanese waters. Analyses have mostly been based on an assumption that the conditional distribution of the population of duration, given intensity, follows the Weibull distribution. This distribution does not seem especially appropriate in U.S. waters.

The present approach is a direct focus on extreme events, through extreme value data extracted from observational records. IDF (intensity-duration-frequency) summaries may originate from the conditional extreme value distribution for duration,
given intensity, or from the conditional extreme value distribution for intensity, given duration. Extracting the data as duration, given intensity, results in significant data gaps for the more extreme intensities. Intensity, given duration, data appears to be much less problematic.

A rational methodology is presented for the interpolation and extrapolation of measured trends, based on extreme value series for intensity, given duration. The inevitable short duration data base problem is addressed by routine application of the triple annual maximum methodology.

A format is suggested for IDF data preparation and presentation. Examples are given for wave climate data on the Pacific and Atlantic coasts of the United States.

Encounter Probability of Individual Wave Height

Zhou Liu¹ and Hans F. Burcharth ²

Abstract
Some coastal and offshore structures, e.g. offshore platforms and vertical wall breakwaters in deep water, are often designed according to a design individual wave height.

The conventional method for the determination of the design individual wave height is first to obtain the design significant wave height corresponding to a certain exceedence probability within a structure lifetime (encounter probability), based on the statistical analysis of long-term extreme significant wave height. Then the design individual wave height is calculated as the expected maximum individual wave height associated with the design significant wave height, with the assumption that the individual wave heights follow the Rayleigh distribution.

However, the exceedence probability of such a design individual wave height within the structure lifetime is unknown.

The paper presents a method for the determination of the design individual wave height corresponding to an exceedence probability within the structure lifetime, given the long-term extreme significant wave height. The method can also be applied for estimation of the number of relatively large waves for fatigue analysis of constructions.

1. Introduction
Some coastal and offshore structures, e.g. offshore platforms and vertical wall breakwaters in deep water, are often designed according to a design individual wave height.

The determination of the design individual wave height is based on a long-term wave measurement or hindcast. Most often the data set consist of maximum

¹Assistant Professor, Ph.D.
²Professor, dr.techn., Department of Civil Engineering, Aalborg University, Denmark
significant wave heights for the most severe storms within a number of years. An extreme significant wave height is the peak value of the significant wave height in a storm which exceeds a predefined threshold.

The conventional method for the determination of the design individual wave height is first to obtain the design significant wave height corresponding to a certain exceedence probability within a structure lifetime (encounter probability), based on the statistical analysis of the extreme data set. Then the design individual wave height is calculated as the expected maximum individual wave height associated with the design significant wave height (sea state), with the assumption that the individual wave heights follow the Rayleigh distribution.

For example, if the design level for the design significant wave height is a return period of 100 years ($T=100$ years), then by extreme analysis we find out that $H_{s}^{100 \text{ years}} = 10.2$ m. With the assumption that the individual wave heights follow the Rayleigh distribution, the expected maximum individual wave height associated with the design significant wave height is

\[
(H_{\text{max}})_{\text{mean}} \approx \left( \sqrt{\frac{\ln N}{2}} + \frac{0.577}{\sqrt{8 \ln N}} \right) H_{s}^{100 \text{ years}}
\]

where $N$ is the number of individual waves related to $H_{s}^{100 \text{ years}}$. In engineering practice it is normally assumed that $N$ is in the order of 1000 for the stationary peak of the storm, which corresponds to $(H_{\text{max}})_{\text{mean}} = 19.7$ m.

However, the return period of such design individual wave height remains unknown.

The paper presents a method for determination of the return period of a design individual wave height. The encounter probability of the design individual wave height, i.e. exceedence probability within structure lifetime $L$, is

\[
p = 1 - \exp \left( \frac{L}{T} \right)
\]

The only input of the method is an extreme data set (minimum input). The accuracy of the result can be improved if more information are available, e.g. the duration of the storms, joint distribution of wave height and period etc.

The method can also be applied for estimation of the number of relatively large waves for fatigue analysis of constructions.
2. Distribution of individual wave height in a storm: \( F_s(H) \)

Because the structures are located in deep water, it is assumed that, with a given significant wave height \( H_s \), the individual wave height \( H \) follows the Rayleigh distribution:

\[
F_R(H) = 1 - \exp \left( -2 \left( \frac{H}{H_s} \right)^2 \right)
\]  

However, the significant wave height is varying throughout a storm. Based on some prototype records it is assumed that \( H_s \) grows and decays linearly between the threshold of significant wave height, \( H_{s,t} \), and the peak significant wave height \( H_{s,p} \). For the convenience, an equivalent storm history is used, cf. Fig. 1.

![Realistic storm history and the equivalent storm history](image)

Fig. 1. Realistic storm history and the equivalent storm history (Burcharth et al. 1992).

If it is further assumed that the average wave period within a storm is constant and independent of \( H_s \), then the distribution of individual wave height in a storm is

\[
F_s(H) = \int_{H_{s,t}}^{H_{s,p}} F_R(H) \frac{1}{H_{s,p} - H_{s,t}} \, dH_s \\
= 1 - \frac{1}{H_{s,p} - H_{s,t}} \int_{H_{s,t}}^{H_{s,p}} \exp \left( -2 \left( \frac{H}{H_s} \right)^2 \right) \, dH_s
\]  

Note that \( F_s(H) \) is independent of storm duration.

Fig. 2. shows an example of the difference between the individual wave height distribution in a storm and the Rayleigh distributions corresponding to \( H_{s,t} \) and \( H_{s,p} \), respectively.
Fig. 2. Example of individual wave height distribution in a storm.
3. Long-term distribution of significant wave height: $F(H_s)$

The long-term distribution of significant wave height is obtained by the statistical analysis of the extreme data set. The general procedure is:

1) Choice of the extreme data set based on long-term wave height measurement/hindcast
2) Choice of several theoretical distributions as the candidates for the extreme wave height distribution
3) Fitting of the extreme wave heights to the candidates by a fitting method.
4) Choice of the distribution based on the comparison of the fitting goodness among the candidates

For more details please refer to Burcharth et al. (1994). The obtained long-term distribution of $H_s$ gives information on the occurrence probability of storms over the threshold $H_{s,t}$ (which can be converted to the number of the storms in the structure lifetime), and the corresponding peak value $H_{s,p}$ in the storms.

4. Long-term distribution of individual wave height: $F_L(H)$

If we keep the assumption that the average wave period is constant and independent of the significant wave height, the long-term distribution of individual wave height can be expressed as (cf. Fig. 3)

$$F_L(H) = \int_{H_{s,t}}^{\infty} F_S(H) f(H_s) \, dH_s$$  \hspace{1cm} (5)

where $f(H_s)$ is the density function of the long-term significant wave height distribution, obtained by the extreme analysis, and $F_S(H)$ is the distribution of individual wave height in a storm.

\textit{Density function}

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{density_function.png}
\caption{Illustration of the integral in eq (5).}
\end{figure}
5. Return period and encounter probability of design individual wave height

According to the definition of return period, the return period of the individual wave height $H$ is

$$T = \frac{1}{\lambda'(1 - F_L(H))}$$

where $\lambda'$ is the number of individual waves related to extreme storm, i.e. all $H_s$ in the storm $\geq H_{s,t}$, and $F_L(H)$ is the long-term distribution of individual wave height.

The only unknown in eq (6) is $\lambda'$. Obviously the value of $\lambda'$ depends on the threshold level $H_{s,t}$. The lower $H_{s,t}$, the larger $\lambda'$.

Smith (1988) investigated by field measure the relation between $H_{s,t}$ and $P$, occurrence probability of the event $H_s \geq H_{s,t}$. The threshold $H_{s,t}$ is represented by the number of extreme storms per year, $\lambda$. The definition of $\lambda$ and $P$ is illustrated by Fig. 4.

![Figure 4: Illustration of definition of $\lambda$ and $P$.](image)

The locations of the field measurement are given in Table 1. They represent a wide geographical spread and variety of wave conditions. Each location includes 58,440 significant wave heights by hindcast study three hours apart from January 1, 1956 to December 31, 1975 (20 years).

Long-term distribution of significant wave height

The number of extreme storm per year is $\lambda = 15/20$. By fitting the peak significant wave height to the Weibull distribution

$$F(H_s) = 1 - \exp \left[ -\left( \frac{H_s - H_{s,t}}{A} \right)^k \right]$$

(8)

where $H_{s,t} = 3 \text{ m}$, we obtain the Weibull distribution parameters $A = 3.24$ and $k = 1.83$.  

By inserting the definition of return period $T$

$$T = \frac{1}{\lambda \left(1 - F(H_s)\right)}$$  \hspace{1cm} (9)

into eq (8), we obtain

$$H_s = A \left(-ln\left(\frac{1}{\lambda T}\right)\right)^\frac{1}{\lambda} + H_{s,t}$$  \hspace{1cm} (10)

The fitting is depicted in Fig. 5.

**Fig. 5. Fitting of extreme data set to Weibull distribution.**

If the design level for the design significant wave height is a return period of 100 years ($T=100$ years), we get $H_s^{100 \text{ years}} = 10.2 \text{ m}$.

By eq (1) with $N = 1000$, the expected maximum individual wave height associated with the design significant wave height is $(H_{\text{max}})^{\text{mean}} = 19.7 \text{ m}$. In the following we will try to obtain the return period and encounter probability of $(H_{\text{max}})^{\text{mean}}$.

**Long-term distribution of individual wave height: $F_s(H)$**

The long-term distribution of individual wave height is calculated by eq (5) and shown in Fig. 6.
Return period and encounter probability of individual wave height

By eq (7) we get the occurrence probability of the event \((H_s \geq H_{s,t})\)

\[ P = 0.003\lambda = 0.0025 \]

If we assume that the average wave period is \(\bar{T} = 12 \text{ s}\) (average wave period in Table 2), the number of individual waves per year is

\[ 365 \times 24 \times 60 \times 60 / \bar{T} = 2,628,000 \]

and the number of individual waves related to the extreme storm is

\[ \lambda' = 2,628,000 \times P = 6750 \]

The return period of individual wave height is calculated by eq (6) and shown in Fig. 7.
It can be seen from Fig. 8 that the return period of $H_{\text{max}} \text{mean} = 19.7 \, \text{m}$ is 38 years. By Fig. 8 we can also choose a design individual wave height corresponding to a certain return period, e.g. $H_{100 \, \text{years}} = 21.4 \, \text{m}$.

Fig. 8 gives the encounter probability of individual wave height within a structure lifetime of 25 years.
7. Conclusions

- A method for estimation of return period and encounter probability of individual wave height has been developed. The method is based on extremely limited wave information (extreme data set). Improvement of the estimate can be expected if more information, e.g. the storm duration, is available.

- The method can also be applied for estimation of the number of relatively large waves for fatigue analysis of constructions.

WAVE RUN-UP AND OVERTOPPING: 
PROTOTYPE VERSUS SCALE MODELS

Julien DE ROUCK¹, Raf VERDONCK¹, Peter TROCH¹,
Luc VAN DAMME², Flemming SCHLÜTTER³, John DE RONDE⁴

ABSTRACT

The determination of the crest level is one of the most important points in the design of sloping coastal structures. The crest level of sloping coastal structures is governed by wave run-up and overtopping. Recent measurement results of run-up on prototype have indicated that wave run-up may be underpredicted by scale model tests. So full scale measurements of wave run-up is necessary. At the same time the overtopping discharge on a prototype breakwater will be measured. Within the MAST III - OPTICREST project, these measurements will be carried out at coastal structures at two locations: Zeebrugge (Belgium) and Petten (The Netherlands). The results obtained from these prototype measurements will be compared with those from scale model tests and will be used to calibrate numerical models. This paper also presents the contents of the OPTICREST project.

1 INTRODUCTION

In the past few decades, the dimensions of seagoing vessels have increased strongly. As a result, many harbours have been constructed in open sea. Harbours need to facilitate smooth and unhindered transfer of passengers and cargo between vessels and land. In order to prevent storms from impeding these harbour activities, the harbour area has to be sheltered.

Sloping structures, such as rubble mound breakwaters are often used for such harbour sheltering purposes. Yet some aspects of their design still remain unsolved. One of these aspects is the crest level. The level to which breakwaters should be built is governed by the phenomena of wave run-up and overtopping. A wave run-up level is

1039
defined as the vertical distance between the Still Water Level (SWL) and the highest point reached by the wave up-rush on the slope.

Recent research (De Rouck et al., 1996; Troch et al., 1996b) showed that wave run-up may be underpredicted by model tests. Since the design of the crest level of sloping coastal structures is based on such tests, or on formulae derived from such tests, this has serious implications.

In order to establish better design rules for the crest level of sloping coastal structures, prototype measurements of wave run-up and overtopping are essential. Section 2 describes the discrepancies that have been observed between prototype and scale model measurements of wave run-up.

Section 3 provides a theoretical background on the subjects of run-up and overtopping.

Section 4 describes prototype wave run-up and overtopping measurements on a rubble mound breakwater and prototype measurements of run-up on a sea dike.

Finally section 5 presents a project description of OPTICREST.

2 DISCREPANCIES BETWEEN PROTOTYPE AND SCALE MODEL WAVE RUN-UP

During the MAST II project 'Full scale dynamic load monitoring of rubble mound breakwaters' (MAS2-CT92-0023), wave run-up was measured on the NW breakwater of the Zeebrugge harbour (Belgium). The prototype measurements were compared with run-up levels obtained from scale model tests. The breakwater was modelled in three different laboratories: Aalborg University, Denmark; Flanders Hydraulics, Belgium; University College Cork, Ireland. The run-up levels observed in the scale model tests fit well with experimental design curves. However, as shown in figure 1 the prototype measurements, were approximately 50% higher (De Rouck et al., 1996). This difference confirms the experience in many harbours that wave overtopping is much higher during exploitation, than was expected during design.

![Figure 1. Wave run-up levels with 2% exceedance probability, obtained from prototype and scale model measurements.](image-url)
All prototype results were obtained during one storm event. Due to the observed wave characteristics and the breakwater geometry, all data are concentrated in an area of Iribarren numbers around 3. Future measurements in a wider range of Iribarren numbers are necessary to confirm this trend for higher full scale run-up levels.

Nowadays, the design of the crest level of sloping coastal structures is based on scale model tests, or on design rules based on such tests. So the aforementioned discrepancy between prototype and scale model run-up levels has very serious consequences: 'the discharge outside will be higher than expected for a given crest level' or 'to limit the discharge to a given value, the crest has to be built higher'. Therefore, further research is necessary.

3 THEORETICAL BACKGROUND

To get a better insight in the problem first a short theoretical background both on wave run-up and wave overtopping is given. So the reader easily can find out which parameters are important with regard to run-up and overtopping.

3.1 Wave run-up

Extensive laboratory testing on wave run-up has been performed by Losada, Van der Meer and others, leading to design rules used today.

Losada and Giminez - Curto (1981) present a formula to calculate run-up on rough slopes:

\[ \frac{R_u}{H} = A \left( 1 - \exp (-B \cdot \xi) \right) \]  

where \( R_u \) = run-up level (m), \( H \) = wave height (m), \( \xi \) = Iribarren number (-), \( A \) and \( B \) = experimental coefficients (-) (\( A = 1.322 \); \( B = -0.966 \)).

This formula is based on tests using regular waves. The slopes that were tested, were rip-rap slopes.

The formula for wave run-up on rough slopes, proposed by Van der Meer and Stam (1992), takes the form:

\[ \frac{R_{ux\%}}{H_s} = a \cdot \xi_{sm} \quad \text{for} \quad \xi_{sm} \leq 1.5 \]  
\[ \frac{R_{ux\%}}{H_s} = b \cdot \xi_{sm}^c \quad \text{for} \quad \xi_{sm} \leq 1.5 \]  
\[ \frac{R_{ux\%}}{H_s} \leq d \quad \text{for permeable structures} \]

where: \( R_{ux\%} \) = the run-up level (m) with an exceedance probability of \( x\% \), \( H_s \) = the significant wave height (m), \( \xi_{sm} \) = the surf similarity parameter or Iribarren number (-), based on the mean period, \( a \), \( b \), \( c \) and \( d \) = experimental coefficients (-) depending on the exceedance probability \( x \).

The coefficients for different probabilities of exceedance are given in table 1.
The formula by Van der Meer is based on tests using irregular waves. The slopes that were tested, were rip-rap slopes, ranging from 1:2 to 1:6. Wave steepness ranged from 0.004 to 0.06.

Recently a general expression of wave run-up for irregular waves has been published (Burcharth, 1998; Van der Meer et al., 1998).

\[
\frac{R_{ux%}}{H_s} = (A\xi + C)\gamma_r \gamma_b \gamma_h \gamma_\beta
\]

(5)

where

- \( R_{ux%} \) run-up level exceeded by x% of the incident waves
- \( \xi \) surf similarity parameter, e.g. \( \xi_{op} \)
- \( A, C \) coefficients dependent on \( \xi \) and x but related to the reference case of a smooth, straight impermeable slope, long-crested head-on waves and Rayleigh distributed wave heights
- \( \gamma_r \) reduction factor for influence of surface roughness; \( \gamma_r = 1 \) for smooth slopes
- \( \gamma_b \) reduction factor for influence of a berm; \( \gamma_b = 1 \) for non-bermed profiles
- \( \gamma_h \) reduction factor for influence of shallow water conditions where the wave height distribution deviates from the Rayleigh distribution; \( \gamma_h = 1 \) for Rayleigh distributed waves
- \( \gamma_\beta \) factor for influence of angle of incidence \( \beta \) of the waves; \( \gamma_\beta = 1 \) for head on long-crested waves, i.e. \( \beta = 0^\circ \). The influence of directional spreading in short-crested waves is included in \( \gamma_\beta \) as well.

The coefficients A and C, together with estimates of the coefficient of variations for \( R_u \), are given in Table 2. The symbol \( R_{ux} \) means the significant \( R_u \).
Table 2. Coefficients in eq (5) for run-up of long-crested irregular waves on smooth impermeable slopes (Burchart, 1998).

Within the MASTIII-project MAS3-CT97-0116 'The optimisation of crest level design of sloping coastal structures through prototype monitoring and modelling' (OPTICREST) measurements on site will be carried out on the NW rubble mound breakwater in Zeebrugge (rough permeable) and the sea dike in Petten (smooth impermeable). The main difference is the roughness and the void ratio of the armour layer. So only $\gamma_r$ will be discussed in more detail here. For variations of $\gamma_b$, $\gamma_h$ and $\gamma_p$ reference is made to De Waal and Van der Meer (1992) and Van der Meer et al. (1998).

The original factor $\gamma_r$ given in TAW (1974) and in the SPM (1984) has been updated based on experiments including large scale tests with random waves. The new $\gamma_r$ values taken from de Waal and Van der Meer (1992) are valid for $1 < \xi_{op} < 3.4$. For larger $\xi_{op}$ values the $\gamma_r$ factor will slowly increase to 1.

Table 3. Surface roughness reduction factor $\gamma_r$ in eq. (5), valid for $1 < \xi_{op} < 3.4$. (de Waal and van der Meer, 1992)

3.2 Overtopping

The experimental study of overtopping also has led to a number of empirical formulae. Several formulae which relate a dimensionless average discharge to a dimensionless freeboard have been published. The freeboard of a structure is defined as the vertical distance between the Still Water Level (SWL) and the crest of the structure. This type of formulae are called 'simple regression models'.

Another approach to calculate overtopping discharges is the use of 'weir models'. These models are based on a theoretical derivation which considers the crest of a structure to be a weir.

It has to be emphasised that the formulae give average overtopping discharges. These values should be used very carefully when thinking about admissible overtopping discharges. The intensity of water hitting a specific location is very much dependent on
the geometry of the structure and the distance from the front of the structure. The maximum intensities might locally be up to two orders of magnitude larger than the average discharge.

Moreover, what is regarded as acceptable conditions is to a large extent a matter of local traditions and individual opinions.

Some background on both models for calculating the average discharge are presented.

### 3.2.1 Simple regression models

The advantage of simple regression models over weir models is that they are very easy to use. The disadvantage is that they do not fulfil the boundary conditions:

- When the crest becomes very high, the overtopping discharge should be zero.
- When the freeboard is zero, the overtopping discharge should remain finite.

Owen (1980) relates a dimensionless freeboard to a dimensionless discharge by an exponential relationship:

\[
Q^* = A \cdot \exp\left(\frac{-B \cdot R^*}{r}\right)
\]  

The dimensionless variables are defined as:

\[
Q^* = \frac{Q}{T_m g H_s} = \frac{Q}{\sqrt{g H_s^3}} \cdot \frac{s}{2\pi}
\]

and

\[
R^* = \frac{R_c}{T_m g H_s} = \frac{R_c}{H_s} \cdot \frac{s}{2\pi}
\]

where: \(A\) and \(B\) = experimental coefficients (-), \(r\) = coefficient (-) ranging from 0 to 1 to account for the roughness of the slope, \(Q\) = mean overtopping discharge per meter crest length (m³/s.m), \(T_m\) = mean wave period (s), \(g\) = gravitational acceleration (m/s²), \(s\) = wave steepness (-), \(R_c\) = freeboard (m).

The parameter ranges tested by Owen were: \(R^*\) ranging from 0.05 to 0.30, \(Q^*\) ranging from \(10^{-6}\) to \(10^{-2}\), slope ranging from 1:1 to 1:4, \(d/H_s\) (where \(d\) = water depth (m)) ranging from 1.5 to 5.5 and \(H_s/L_{o,mean}\) (where \(L_{o,mean}\) = mean deepwater wave length) ranging from 0.035 to 0.055.

Allsop & Bradbury (1988) propose a different relationship between a dimensionless freeboard and a dimensionless discharge:

\[
Q^* = A \cdot F^* - B
\]

The dimensionless variables are defined as:

\[
Q^* = \frac{Q}{T_m g H_s} = \frac{Q}{\sqrt{g H_s^3}} \cdot \frac{s}{2\pi}
\]
and

\[ F_* = \frac{R_c}{H_s} \cdot \frac{R_c}{T_m \sqrt{gH_s}} = \frac{R_c^2}{H_s^2} \frac{s}{2\pi} \]  \hspace{1cm} (11) \]

where A and B = experimental coefficients (-).

Other formulae are discussed by Burcharth (1998).

A more recent regression model is given by Van der Meer et al. (1998):

\[ q = 0.06 \cdot \tan \alpha \cdot \xi_{op} \cdot \exp \left( -4.7 \cdot \frac{R_c}{H_s} \cdot \frac{1}{\xi_{op} \cdot \gamma_f \gamma_f \gamma_f \gamma_f} \right) \]  \hspace{1cm} (12) \]

With as a maximum:

\[ q \leq 0.2 \cdot \exp \left( -2.3 \cdot \frac{R_c}{H_s} \cdot \frac{1}{\gamma_f \gamma_f \gamma_f} \right) \]  \hspace{1cm} (13) \]

where: \( q = \) mean overtopping discharge per meter crest length (m³/s.m), \( \alpha = \) slope angle (rad), \( \xi_{op} = \) the Iribarren number (-) calculated with the peak period and the deepwater wave length, \( \gamma_f = \) a reduction factor (-) to account for the effect of a berm, \( \gamma_f = \) a reduction factor (-) to account for the roughness of the slope, \( \gamma_f = \) a reduction factor (-) to account for the effect of oblique wave attack, \( \gamma_f = \) a reduction factor (-) to account for the effect of a vertical wall.

Full discussion of the influence of a berm, roughness, oblique wave attack, etc... can be found in van der Meer et al. (1998).

### 3.2.2 Weir models

As an example the first weir model, developed by Kikkawa et al. (1968) is presented. Based on theoretical considerations, the following formula is derived:

\[ \frac{Q}{\sqrt{2g \cdot H_0^{3/2}}} = \frac{2}{15} \cdot M \cdot (1 - K_0)^{3/2} \]  \hspace{1cm} (14) \]

Where: \( H_0 = \) deep water wave height (m), \( K_0 = \) a dimensionless freeboard (-), \( M = \) experimental coefficient (-).

The left hand side of equation (14) can be considered as a dimensionless discharge. Thus this equation gives a relationship between a dimensionless discharge and a dimensionless freeboard. It holds the advantage over a simple regression model that it contains more physics and satisfies both boundary conditions:

- When the freeboard equals the highest run-up level, \( K_0 \) becomes 1 and the discharge becomes 0.
- When the freeboard is zero, \( K_0 \) becomes zero and the discharge remains finite.
4 PROTOTYPE MEASUREMENTS OF RUN-UP AND OVERTOPPING

In order to investigate whether there are systematic differences between run-up levels and overtopping discharges measured in (small) scale models and on full scale, in-situ measurements in Zeebrugge will proceed within OPTICREST. Also in-situ measurements of run-up will be carried out on a smooth sea dike in Petten (The Netherlands). At both locations tide and wind data are available through a nationally funded project.

The main objectives of OPTICREST are:
- Provide designer with improved design rules for the crest level design of sloping coastal structures
- Verify and calibrate scale models for run-up with full scale data
- Calibrate numerical models with full scale data and model test data

The partners of the OPTICREST project are:
- University of Gent (Coordinator)
- Flemish Community (Coastal Division; Flanders Hydraulics)
- Aalborg University
- Leichtweiss Institut für Wasserbau
- University College Cork
- Delft Hydraulics
- Rijksinstituut voor Kust en Zeeën
- Universidad Politecnica de Valencia
- Instituto Hidrografico

The project runs from 1 March 1998 till 28 February 2001.

4.1 Zeebrugge (Belgium)
The port of Zeebrugge is situated on the eastern part of the Belgian coastline and is protected by two main breakwaters (Fig. 2). The Zeebrugge breakwater constitutes a conventional rubble mound breakwater with an armour layer of 25 ton grooved cubes.

Figure 2. Location of the prototype run-up measurement system on the NW breakwater at the Zeebrugge harbour (Belgium).
Figure 3. Crosssection of the Zeebrugge rubble mound breakwater with the instrumentation.
A measurement jetty of 60 m length is constructed on the NW breakwater (Fig. 3). It is supported by a steel tube pile at the breakwater toe and by two concrete columns on top of the breakwater.

Run-up is measured using six vertical stepgauges, placed along the breakwater slope. At the bottom, the stepgauges are attached to an armour unit. At the top they are supported by the jetty. Each stepgauge has a number of electrodes, spaced vertically at 20 cm intervals. Each submerged electrode produces an output voltage. The summation of these voltages leads to an output signal that contains the information about the water level with a 20 cm resolution. Using the six stepgauges, this information is available at six positions along the breakwater slope. Specially developed software computes the water surface profile on the slope as the polygon connecting the water surface levels measured by the six stepgauges. The instantaneous run-up level is taken as the intersection of the slope with an extrapolated line through the highest two water surface levels measured at that instant. (Figure 4)

![Figure 4. Definition of wave run-up Ru as detected by the stepgauges.](image)

A device to measure overtopping will be installed on the breakwater in autumn 1998. Overtopping will be measured by a screen, catching the overtopping water which will then be collected in a container (Fig. 5). The container will be continuously emptied by a weir. The volume of water in the container, as well as the discharge over the weir will be calculated from the water surface level in the container.

![Figure 5. Prototype measurement of overtopping.](image)
Wave data are obtained from two wave rider buoys close to the breakwater, at 165 m and 215 m in front of the breakwater, and from three wave rider buoys located at 5 km, 30 km and 45 km from the structure.

4.2 Petten (The Netherlands)
The Petten sea dike is situated in the northern part of The Netherlands (Fig. 6). The Petten coastal region is very suitable for a measurement campaign as the iso-baths are approximately parallel to the coastline. The bathymetry is characterised by a bar and a dike onshore.

The Petten sea dike consists of a lower slope, made of basalt stones on approximately a 1:3.5 slope. Above the lower slope an asphalt berm (1:13.5) and an asphalt slope (1:2.75) form the higher protection. Figure 7 shows the crosssection of the dike.

![Figure 6. Location of the prototype run-up measurement system on the Petten sea dike (The Netherlands).](image)

![Figure 7. Cross section of the Petten sea dike (distorted scale).](image)

Figures 8 and 9 show the bathymetry and the instrumentation.

Data concerning the wave climate are collected by wave rider buoys (Mp2 and Mp4) and by directional wave riders (Mp1 and Mp5). Just in front of the bar, a wave staff and a water level meter (Mp3) measure the incoming waves. In front of the dike the waves are measured by a wave staff and a pressure sensor (Mp6 and Mb6). The wave run-up is measured, using a staff gauge placed along the slope of the sea dike (Mp7). The staff gauge consists of a number of electrodes spaced at 10 cm intervals. The vertical distance between the electrodes is approximately 3.5 cm.
5 FURTHER PROJECT DESCRIPTION

5.1 Laboratory investigations
Both the Zeebrugge and the Petten site will be modelled in scale model tests. Run-up levels and overtopping discharges will be measured. In the scale model tests, both in-situ measured spectra and standard spectra will be used. Special attention will be paid to the influence of the foreshore bathymetry.

Two dimensional and three dimensional tests will be carried out.

5.1.1 Two dimensional testing
Deviations between the scale model results and the prototype measurements will be determined and the influence of different scale effects will be investigated. This may lead to changes in building models for the two sites. The models will then be re-built and the basic tests re-run.
5.1.2 Three dimensional tests
Three dimensional tests will be carried out for models of the Zeebrugge and the Petten site. The scaling will be as close as possible to the scales used in the two dimensional tests.
These tests will attempt to validate the prototype results and continue to investigate the influence of such parameters as wave height, period, water depth, angle of wave attack, directional spreading, currents, foreshore bathymetry and structure geometry.

5.1.3 Link between prototype and laboratory results
One of the conclusions of the MAST II project ‘Full scale dynamic load monitoring of rubble mound breakwaters’, was that wave run-up is underpredicted by model tests. This may be due to several factors, such as: measuring systems, wind, roughness, randomness of sea conditions, etc... The purpose of the comparison between prototype and laboratory results is to quantify these effects in order to allow better predictions of run-up levels and overtopping quantities from laboratory tests.

5.2 Numerical modelling
It has to be expected that numerical models will play a very important role in future research and design of coastal structures. Therefore it is of paramount importance that these models are as reliable as can be achieved. Up to now, these models have been calibrated against scale model test results only. In the OPTICREST project, they will also be calibrated against full scale data.

5.3 Outlook
Existing design techniques for sloping coastal structures, which include the use of mathematical and physical models have not prevented severe failures. Such failures have disastrous consequences, such as loss of life, loss of business, damage to property, economic ruin, ... Reliable design methodologies are essential. Full scale measurements of run-up and overtopping will provide better insights in the phenomena and will lead to better mathematical and physical models. This will lead to a better design method of the crest of sloping coastal structures. With our coast being used more than ever before, these results will be very valuable.

6 ACKNOWLEDGEMENTS
This research originated during the EC MAST II project MAS2-CT92-0023 ‘Full scale dynamic load monitoring of rubble mound breakwaters’. The run-up and overtopping research will go on in the EC MAST III project MAS3-CT97-0116 ‘The optimisation of crest level design of sloping coastal structures through prototype monitoring and modelling’, coordinated by J. De Rouck. The financial support by the EC is greatly acknowledged.
Also the financial support of the government of both Belgium (Flanders) and the Netherlands is acknowledged.

WAVE RUNUP AND REFLECTION ON COASTAL STRUCTURES IN DEPTH-LIMITED CONDITIONS

Joel R. Rathbun, Daniel T. Cox, and Billy L. Edge

Abstract

An experimental study was performed to measure the effects of depth-limited conditions on wave runup and reflection from coastal structures. The measurements are compared with existing empirical formulas. An existing model to predict wave runup is shown to overpredict the runup and a clear trend of increased wave runup in depth-limited conditions is shown. A new empirical model is presented that includes the effects of depth-limited conditions on wave runup. Existing models to predict wave reflection based on the surf similarity parameter are shown to fail to collapse the measured data onto a single line. A recently developed model based on a number of parameters is shown to accurately predict wave runup in cases where no wave breaking occurred before the structure. However, at the shallower water depths where wave breaking occurred seaward of the structure, the model underpredicted the reflection coefficient. This model was modified to increase its accuracy in depth-limited conditions based upon the laboratory results presented in this study.

Introduction

Wave runup and wave reflection are two important variables that have to be taken into account by engineers in designing safe and effective coastal structures. A number of researchers have proposed empirical formulas to quantify these variables; however, there have been relatively few studies undertaken with depth limited conditions. These conditions are of practical interest due to the large number of coastal structures present throughout the world that are located in areas where these types of conditions occur during storms.

From the few studies that have included shallow water cases, some researchers have found that wave runup and reflection tend to decrease in depth-

1Dept. of Civil Engineering, Texas A&M University, College Station, TX 77843 USA; Tel: (409) 842-3627 Fax: (409) 862-3627 Email: dtc@arlo.tamu.edu.
limited conditions (e.g., Seelig and Ahrens, 1995; Van der Meer and Janssen, 1995). Interestingly, Kobayashi and Raichle (1994) found that the overtopping rate for a coastal revetment located inside the surf zone was underestimated by prediction methods developed for deep water cases. Similarly in an extensive investigation on overtopping rates of vertical walls in shallow water conditions, Besley et al. (1998) found that in cases where wave breaking occurred due to depth-limited conditions, previously developed methods significantly underestimated overtopping discharge. This leads to an apparent contradiction as it has been generally thought that higher levels of wave runup cause increased overtopping.

This study seeks to shed some light on the discrepancy between models that predict decreasing runup with decreasing depth and models that predict increasing overtopping with decreasing depth. A laboratory investigation of wave runup and reflection on a coastal structure in shallow water with both breaking and non-breaking waves was undertaken. Empirical models for both wave runup and wave reflection on riprap revetments were evaluated. A brief description of the experiment and the essential findings of this research are presented in this paper. A full description of the experiment and a detailed analysis and discussion of the findings is presented in Rathbun (1998).

Experimental Setup

The experiments were conducted in the long wave flume at Texas A&M University. The dimensions of the flume were 32 m long by 0.9 m wide by 1.2 m deep. The flume was equipped with a flap type wavemaker capable of generating irregular waves. A mild slope, 1:35, was installed over most of the length of the flume, consisting of sections of marine plywood coated with an epoxy paint mounted on an aluminum frame. The edge of the mild slope was caulked to the side of the flume to ensure that no wave energy was transmitted to the water below the mild slope. The toe of the mild slope was located 10.73 m from the wavemaker. A capacitance type wave gage consisting of two wires strung between a steel backbone was installed along the slope of the revetment to measure the water line oscillation along the slope of the revetment. The wires were placed as close to the rocks on the revetment as possible, without actually touching any rocks. The average distance between the wires and the stones on the revetment was approximately 0.75 cm.

The model coastal structure that was used for the tests was an impermeable revetment consisting of a plywood board supported by a steel frame, on which a filter layer and armor layer were placed. This type of impermeable revetment was chosen as it is a common type of coastal structure found throughout the world. The revetment was located on the mild slope, 27.28 m from the wavemaker. Test runs were made on revetments with two different slopes, 1:1.5 and 1:3, during the course of the investigation. A thin layer of silicone was spread over the plywood board to hold the bottom layer of filter stone from sliding down the slope for the steeper 1:1.5 case. During construction
of the revetment, the armor stones were individually placed on the revetment to ensure a high degree of interlocking between adjacent stones. Both the filter and armor layers were two stone dimensions in thickness. The filter stone was river stone gravel and the armor stone was crushed granite. The specific gravity of the armor and filter stone was 2.65 and 2.50 respectively with the median rock size of 278.2 g for the armor stone and 23.8 g for the filter stone. These rock sizes produced an armor layer thickness of 9.4 cm and a filter layer thickness of 4.2 cm.

The control signal for the wavemaker was derived from the TMA spectral form using a random-phase scheme. The value of the peak enhancement factor, $\gamma$, used to generate the TMA spectrum was $\gamma = 3.3$. Additional tests were performed using a narrower spectrum, $\gamma = 20$, but these test runs are not discussed in this paper. The interested reader is referred to Rathbun (1998). The free surface elevation at nine wave locations and the runup along the slope of the revetment was recorded at a rate of 25 Hz for the duration of each test. The majority of the tests were 615.36 seconds in duration. This resulted in approximately 400 to 600 runup events per test run depending on the wave period. A small number of shorter tests were performed to gage the effects of the test length on the results. These tests were 327.68 seconds in length, resulting in approximately 250 runup events per test run.

The incident and reflected wave conditions were resolved at three locations in the flume using the method of Goda and Suzuki (1976) modified for three gage pairs. The first set of three wave gages, array A, was located at the toe of the mild slope 15.75 m from the toe of the structure and 10.32 m from the wave maker. Array B was located 2 m seaward of the toe of the structure and array C was located at the toe of the structure. The location of each array corresponds to the location of the gage closest to the structure at which the incident and reflected waves were resolved. The separation between the gage closest to the structure and the middle gage at each gage array was 30 cm and the separation between the middle gage and the gage farthest from the structure was 50 cm.

A measure of the percentage of broken waves at the toe of the structure, $Br$, was obtained by visual observation. The observer stood immediately adjacent to the tank and counted the number of waves that were broken at the toe of the structure out of a series of 100 waves. For the majority of the tests, $Br$ was recorded for two successive counts of 100 waves and the results were averaged. For the small number of tests that were shorter in duration $Br$ was recorded for only one series of 100 waves. After some initial observation and discussion, two observers could obtain $Br$ to within a difference of 3% or less of each other. Only waves that reached the structure as white water bores were recorded as broken. If a wave broke over the sloping foreshore and reformed before reaching the structure, it was not counted as broken. For the surf conditions encountered in this investigation, this phenomenon occurred infrequently.

Test runs were made at three water depths, $d_s = 0.400, 0.200$ and 0.105 m, at the toe of the structure with the 1:1.5 revetment in place and at two water depths, $d_s = 0.200$ and 0.105 m, with the 1:3 revetment in place. Table 1 outlines the range of variables that were tested during the investigation. $\theta$ is the slope of
the structure, \( d_s \) is the depth at the toe of the structure, \( H_{mo} \) is the incident significant wave height at the toe of the structure defined as \( 4.004\sqrt{m_o} \) where \( m_o \) is the zeroth moment of the wave spectrum. \( \xi_{Lo} \) is the surf similarity parameter given as \( \xi_{Lo} = \tan\theta (H_{mo}/L_o)^{1/2} \) where \( L_o \) is the deepwater wavelength given as \( L_o = gT_p^2/2\pi \) where \( T_p \) is the peak wave period, and \( g \) is the acceleration due to gravity. The measured reflection coefficient, \( K_{rm} \), is defined as \( K_{rm} = (E_i/E_r)^{0.5} \) where \( E_i \) is the incident wave energy and \( E_r \) is the reflected wave energy at the toe of the structure.

**Wave Runup**

The most common approach taken for wave runup prediction has been to relate the relative runup to the surf similarity parameter. Typically the deep water wavelength, \( L_o \) is used to define the surf similarity parameter, \( \xi_{Lo} \). However, Ahrens and Heimbaugh (1988) found that a more accurate model could be developed with a surf parameter using the local wavelength. This new surf parameter is defined as \( \xi_{lp} = \tan\theta (H_{mo}/L_p)^{1/2} \) where \( L_p \) is the local wavelength found using linear wave theory. In Fig. 1 the relative runup, \( R_{2\%}/H_{mo} \), is plotted against \( \xi_{lp} \). The two percent runup elevation, \( R_{2\%} \), is defined as the runup elevation above SWL that is exceeded by two percent of the individual runup elevations in the time series. Also shown is the prediction model proposed by Ahrens and Heimbaugh (1988) given as

\[
\frac{R_{2\%}}{H_{mo}} = \frac{a\xi_{lp}}{1 + b\xi_{lp}}
\]

where \( a \) and \( b \) are empirical coefficients given by Ahrens and Heimbaugh as \( a = 1.154 \) and \( b = 0.202 \). Note that in (1), \( R_{2\%} \) has replaced \( R_{max} \) where \( R_{max} \) is the maximum runup elevation above SWL in the time series. The \( R_{max} \) values that Ahrens and Heimbaugh’s model used were derived from test runs with a length of 256 s, that is from 100-200 waves. For tests of short duration such as this, \( R_{max} \) will probably be close to \( R_{2\%} \) of the present tests (Van der Meer and Stam 1993). As can be seen from this figure, the model overpredicts the relative runup observed in the test runs for \( \xi_{lp} > 2.5 \).
One of the principal concerns of this research was the effect of depth limited conditions on wave runup. The figure shows that, in general, as the water depth is decreased the relative runup increases for a given value of the surf similarity parameter. This is in contrast to the work of Van der Meer and Janssen who suggest using a reduction factor for conditions with a shallow foreshore.

The effect of depth-limited conditions on wave runup may be better illustrated by considering the percentage of broken waves at the toe, in other words, the percentage of waves that break on the sloping foreshore before reaching the structure and reach the structure as white water bores. Fig. 2 shows the relative runup, $R_{290}/H_{m0}$, as a function of the surf similarity parameter, $\xi_{lp}$, with the data grouped according to the percentage of broken waves at the toe of the structure, $Br$. The data are divided into three groups: $Br = 0$, $0 < Br < 40$ and $Br > 40$. It can be seen in Fig. 2 that as $Br$ increases the relative runup increases for a given value of the surf parameter.

A parameter that describes the wave conditions at the toe of the structure that can be used in a formula to predict wave runup other than $Br$ is required because methods to predict $Br$ are not readily available. A common parameter that is often used to define if breaking condition exist is the ratio of the wave height to the water depth -- in this case $H_{m0}/d_s$. For the tests performed in this investigation the onset of broken waves at the toe of the structure occurred at approximately $H_{m0}/d_s = 0.4$ and the percentage of broken waves increased sharply with increasing $H_{m0}/d_s$ after that point.
The relative runup, $R_{2\%}/H_{mo}$, as a function of $\xi_{lp}$ is shown in Fig. 3 with the data divided into groups of $H_{mo}/d_s < 0.4$ (non-breaking waves) and $H_{mo}/d_s > 0.4$ (breaking waves). It can be seen in Fig. 3 that for cases where $H_{mo}/d_s > 0.4$ the relative runup is higher for a given value of $\xi_{lp}$. Curves of a form similar to Equation (1) were fit to all of the data points and as well, to only the points where $H_{mo}/d_s < 0.4$ (non-breaking cases). The coefficients $a$ and $b$ are $a = 2.108$ and $b = 0.939$ when the curve is fit to all of the data and $a = 2.181$ and $b = 1.062$ for the curve fit to the data where $H_{mo}/d_s < 0.4$. This curve is also shown in Fig. 3 with $a = 2.181$ and $b = 1.062$. The $R^2$ statistic (the square of the correlation coefficient) when Equation (1) is used to predict the relative runup for all of the test cases is $R^2 = 0.373$. If only the cases where $H_{mo}/d_s < 0.4$ are considered, the $R^2$ value using Equation (1) to predict the relative runup is $R^2 = 0.384$.

The underprediction of Equation (1) for cases with depth-limited conditions (breaking conditions) when the empirical coefficients $a$ and $b$ are determined from cases without depth-limited conditions (non-breaking cases) can be accounted for through the use of an enhancement factor based on $H_{mo}/d_s$. The resulting model takes the form of the existing equation developed from the test runs where $H_{mo}/d_s < 0.4$ (non-breaking cases) divided by an enhancement factor in cases where $H_{mo}/d_s > 0.4$. This new model is given as

$$
\frac{R_{2\%}}{H_{wv}} = \frac{a_\xi_{lp}}{1 + b_\xi_{lp} \gamma_{ds}}
$$

where $\gamma_{ds}$ is the enhancement factor based on $H_{mo}/d_s$. $\gamma_{ds}$ is given by
The empirical coefficients $a$ and $b$ remain $a = 2.181$ and $b = 1.062$. The values for the coefficients associated with the enhancement factor were found to be $c = 0.220$ and $d = 0.389$. The $R^2$ value for this model fit to the laboratory data was $R^2 = 0.567$, an improvement of 52% over the $R^2$ value found using Equation (1) with no enhancement factor.

The effectiveness of the new model can be seen in Fig. 4 where $R_{2\%}/H_{mo}$ multiplied by the enhancement factor $\gamma_{ds}$ as a function of $\xi_{dp}$ along with the new model, Equation (2), is shown.

Other wave breaking parameters may be used to describe the wave conditions at the toe of the structure. Allsop et al. (1995) found that wave overtopping of vertical walls may be underestimated in cases where equations describing non-breaking waves are used in cases where breaking waves predominate due to a shallow sloping foreshore. For simple vertical walls on a shallow sloping foreshore, a wave breaking parameter, $h_{m^*}$, was defined which dictates whether waves at the structure are dominated by what the authors termed impact waves (breaking) or by deflecting/pulsating waves (non-breaking). $h_{m^*}$ includes the deepwater wave steepness along with the ratio of the water depth to the wave height and is given by

$$h_{m^*} = \left( \frac{d_s}{H_s} \right) \left( \frac{2\pi H_s}{gT_m^2} \right)$$

(5)
The formulation of $h_m^*$ reflects the fact that waves are more likely to break if the wavelength or the wave height is large compared to the water depth. The authors found that deflecting (non-breaking) waves dominate when $h_m^* > 0.3$ and impacting (breaking) waves dominate when $h_m^* < 3$.

The wave breaking parameter $h_m^*$ can be modified using $T_p$ in place of $T_m$ and $H_{ma}$ in place of $H_s$. This new parameter, $h_p^*$, defined as

$$h_p^* = \left( \frac{d_s}{H_{ma}} \right) \left( \frac{2\pi H_{ma}}{gT_p^2} \right)$$

may be more advantageous for use in a practical design formulation for two reasons. First, $T_p$ is more stable than $T_m$ measured either spectrally or statistically and is less susceptible to distortion by measurement/calculation errors (Durand and Allsop 1997). Second, most modern wave forecast models predict $H_{ma}$ rather than $H_s$ and many field measurements are reported as $H_{ma}$.

A similar methodology that was followed when developing a prediction model with an enhancement factor based on $H_{ma}/d_s$ can be used to formulate a model with an enhancement factor based on $h_p^*$. This new model is given by

$$R_{2\%} = a \gamma_b \left( 1 + b \frac{H_{ma}}{d_s} \right)^{-\gamma_b}$$

where $\gamma_b$ is the enhancement factor based on $h_p^*$. $\gamma_b$ is given by

$$\gamma_b = \begin{cases} 
1 - (0.25 - h_p^*)^c & \text{for } \gamma_b < 0.25 \\
1 & \text{for } \gamma_b \geq 0.25 
\end{cases}$$

With no enhancement factor, the coefficients of the model if only the tests runs where $h_p^* \geq 0.25$ (the non-breaking cases) are considered are $a= 2.075$ and $b=0.990$ with an $R^2$ value of 0.500. A value for the enhancement factor coefficient of $c = 1.380$ was found. The $R^2$ value found using Equation (7) to predict the
relative runup was \( R^2 = 0.652 \). This represents a 74\% improvement over \( R^2 = 0.373 \) that was found for using Equation (1) with coefficients based on all of the test runs (non-breaking and breaking cases). \( R_{2\%}/H_{mo} \) multiplied by the enhancement factor \( \gamma_b \) as a function of \( \xi_{lp} \) along with Equation (7) is shown in Fig. 5.

![Fig. 5. \( R_{2\%}/H_{mo} \times \gamma_b \) as a Function of \( \xi_{lp} \) with Equation (7)](image)

The addition of a wave steepness term \( (2\pi H_{mo}/gT_p^2) \) to a depth term \( (d/H_{sw}) \) in the enhancement factor resulted in a slightly improved model for wave runup. The \( R^2 \) value of the model with an enhancement factor based on \( h_p^* \) was \( R^2 = 0.652 \) compared with \( R^2 = 0.567 \) for the model with an enhancement factor based on \( H_{mo}/d_s \). This represents an additional improvement of 15\%.

Table 2 is a summary table showing the formulas that have been developed to predict the runup along with the values of the empirical coefficients. Also shown in the table are the \( R^2 \) values for each model.

**Wave Reflection**

The measured reflection coefficient at the toe of the structure, \( K_{rn} \), is a function of \( \xi_{lp} \), the surf similarity parameter found using the local wavelength at the toe of the structure. In Fig. 6 the data are grouped according to \( d_s \). In this figure, a trend of higher reflection coefficients for a given value of the surf similarity parameter with decreasing depth can be seen. The measured reflection coefficients for the test runs where \( d_s = 0.105 \) m are generally higher than the test runs where \( d_s = 0.20 \) m which are in turn generally higher than the test runs where \( d_s = 0.40 \) m. Interestingly, this trend can also be seen in Fig. 7 where \( K_{rn} \) is plotted as a function of \( \xi_{lo} \) although the effect of \( d_s \) is not as pronounced. When \( R_{2\%}/H_{mo} \) is plotted as a function of \( \xi_{lo} \) with \( d_s \) indicated, the effect of \( d_s \) on \( R_{2\%}/H_{mo} \) is not as evident.

FIG. 6. \( K_{rm} \) as a function of \( \xi_{lp} \) with \( d_s \) Indicated

A different approach to describe the effects of depth-limited conditions on wave reflection was employed than was used to describe wave runup in depth-limited conditions. There are several limitations to using the surf similarity parameter to parameterize wave reflection. For example, with all variables fixed, the observed reflection coefficient increases with an increasing wave height, while most models based on the surf similarity alone predict the opposite (Seelig and Ahrens 1995). Additionally, the reflection, which has been shown here and
by others (e.g., Davidson et al., 1996; Ward and Ahrens, 1992) to be influenced by the water depth at the toe of the structure, has been typically ignored in prediction models. For these reasons, the method of Seelig and Ahrens (1995) was analyzed in detail to see whether it could be used to describe wave reflection in depth-limited conditions without modification, and if the model failed in depth-limited conditions, what modifications would be required to extend the model to include cases where depth-limited conditions exist.

Seelig and Ahrens (1995) make use of $H_{mo}/d_s$ as a water depth parameter in their formulas. As was discussed earlier and shown in Fig. 2, $H_{mo}/d_s$ can be used to describe the wave conditions at the toe of the structure and correlates well with $Br$. $Br$ increases sharply from zero for values of $H_{mo}/d_s > 0.4$. The measured and predicted reflection coefficients found using the model of Seelig and Ahrens is shown in Fig. 8. Here the data points are separated into groups of less or greater than $H_{mo}/d_s = 0.4$. It is clear from the figure that the model underpredicts the reflection coefficient for values of $H_{mo}/d_s > 0.4$. Seelig and Ahrens' formulation for breaking conditions contains $H_{mo}/d_s$ as a depth term with an empirical coefficient. This formula may be adjusted as

\[ Kr = 1 - \exp \left[ -0.06 (\xi_{Lo})^{2.4} - a \left( \frac{H_{mo}}{d_s} \right) \right] \]  

where $a$ is the empirical coefficient associated with the depth term. The correction factor $fr$ is given by
\[ \frac{f_r}{0.16 + \left( -0.4 + 0.5(P) \ln \left( \frac{D_{50}}{H_{mo}} \right) \right)} \] (11)

Seelig and Ahrens (1995) suggested a value for \( a \) of 0.5 for cases where \( H_{mo}/d_s < 0.4 \) and 0.6 for cases where \( H_{mo}/d_s > 0.4 \). This coefficient was reevaluated using the present data for the cases where \( \xi_{LP} < 2.5 \) and \( H_{mo}/d_s > 0.4 \). Based on the analysis of this subset of tests it is recommended that the empirical coefficient, \( a \), be raised from 0.6 to 0.76. The \( R^2 \) value for the measured data where \( H_{mo}/d_s > 0.4 \) and \( \xi_{LP} < 2.5 \) with the predicted values using Equation (10) with \( a = 0.76 \) is \( R^2 = 0.823 \). This compares with \( R^2 = 0.720 \) for the measured data where \( H_{mo}/d_s > 0.4 \) and \( \xi_{LP} < 2.5 \) with the predicted values using Equation (10) with \( a = 0.5 \), a difference of 13%.

Seelig and Ahrens' formula for non-breaking also contains a depth term. This equation may be adjusted as

\[ K_r = \frac{1}{1 + \lambda^{1.37} \exp(0)} \] (12)

where

\[ \lambda = \frac{d_s \cot \theta}{L_p} \] (13)

and
\[
\alpha = 2.29 \left( \cot \theta \right)^{0.3} \left[ \frac{D_{50}}{L_p} \right]^{0.15} \left( 1 + \frac{H_{mo}}{d_s} \right)^b + \frac{P^{0.4}}{(\cot \theta)^{0.7}} \]
\] (14)

where \( P \) is the Van der Meer permeability factor, and the empirical coefficient for the depth term, \( b \), is given in Equation (14). Based on an analysis of the tests where \( \xi_{lp} > 4 \) and \( H_{mo}/d_s > 0.4 \), it is recommended that the coefficient \( b \) be lowered from 1.5 to 1.2. The \( R^2 \) value for the non-breaking cases using to predict the reflection is \( R^2 = 0.239 \). Using Equation (12) and the new value for \( b \) of 1.2, \( R^2 = 0.481 \), an improvement of 64%.

The method for predicting reflection coefficients for transition cases where \( 2.5 < \xi_{lp} < 4.0 \) remains unchanged from Seelig and Ahrens (1995) except that the new formulation for shallow water cases where \( H_{mo}/d_s < 0.4 \) is to be used. The transitional reflection coefficient \( K_{tr} \) is given by

\[
K_{tr} = \left( \frac{4 - \xi_{lp}}{1.5} \right) K_{rb} + \left( \frac{\xi_{lp} - 2.5}{1.5} \right) K_{rnb} \] (15)

where \( K_{rnb} \) is the predicted reflection coefficient for non-breaking waves given by Equation (10) and \( K_{rb} \) is the predicted reflection coefficient for breaking waves given by Equation (12).

The reflection coefficients for the transitional cases where \( 2.5 < \xi_{lp} < 4.0 \) are predicted using Equation (15) with the modified formulas. The \( R^2 \) value for the transition cases using Equation (15) and the original formulas of Seelig and Ahrens is \( R^2 = 0.748 \), and \( R^2 = 0.794 \) for the transitional cases using the new formulations.

The measured and predicted reflection coefficients for all of the test runs are shown in Fig. 9. The data are separated according to \( H_{mo}/d_s \). The data points indicated by a solid dot are the cases where \( H_{mo}/d_s < 0.4 \) (no wave breaking before structure). The predicted reflection coefficients for these points were determining using the original methods of Seelig and Ahrens (1995). The data points indicated by a circle are the cases for which \( H_{mo}/d_s > 0.4 \) (wave breaking before structure). For these points the modifications to the methods of Seelig and Ahrens (1995) for depth-limited conditions was used.

Conclusions

Accurate methods to predict wave runup and wave reflection from coastal structures that are both robust and relatively simple to use are required by engineers to design safe and cost effective protection systems. Many studies have been undertaken to quantify these parameters; however, there have been relatively few investigations performed with depth-limited conditions.
Previously developed models to predict 2% wave runup level, which are almost exclusively based on some form of the surf similarity parameter, accurately predict the general trend of increasing wave runup with increasing surf similarity parameter. However, some of the models overpredict $R_{2\%}$ (Ahrens and Heimbaugh 1988) while others underpredict $R_{2\%}$ (Van der Meer and Janssen 1995).

A clear trend of increasing wave runup with decreasing depth for a given value of $\xi_{f,p}$ was observed. This could have serious implications for design engineers since empirical models that are based solely on model tests undertaken in relatively deep water may be non-conservative for design cases where the revetment is located in the surf zone.

A new empirical model to predict the 2% runup level on coastal revetments was presented that incorporates the effects of depth-limited conditions. The model takes the form of existing models (Ahrens and Heimbaugh 1988) that had been tested and employed often in the coastal field, and makes use of a new enhancement factor to account for the effects of depth-limited conditions.

The empirical formulas of Seelig and Ahrens (1995) for wave reflection from coastal structures accurately predicted the reflection coefficients for the cases where the water depth at the toe of the structure was relatively deep and no wave breaking occurred before the structure. However, at the shallower water depths where wave breaking occurred over the sloping foreshore in front of the structure, the model underpredicted the reflection coefficients. A modification to empirical coefficients of the depth terms, $H_{mo}/d_s$, in the formulas was made for cases where $H_{mo}/d_s > 0.4$ to extend the model to accurately predict the reflection coefficient in depth-limited conditions.

WIND EFFECTS ON RUNUP AND BREAKWATER CREST DESIGN

Josep R. Medina

Abstract

Estimation of the run-up and overtopping rates corresponding to breakwaters is a critical aspect for designing. Although it is widely assumed that onshore winds significantly increase runup and overtopping, very few design rules and experimental data have been published to estimate the effects of wind on runup and overtopping. A conventional and several cuenco amortiguador breakwater cross sections were tested at the UPV wind and wave test facility using wind velocities up to 10 m/s. A neural network modeling using simulated annealing was developed to analyze the experimental results. A preliminary analysis of the results found that wave overtopping was sensitive to wind speed (U>0), while runup seems sensitive only to high wind speed (U> 8 m/s). The runup measurements using capacitance wave gauges placed along the slope are dependent on the distance from the theoretical profile; therefore, a pair of wave gauges placed at Dn59/3 and 2 Dn59/3 were used to calculate the measured runup on the conventional breakwater. A significant discrepancy was found between the visual observations of runup on the conventional breakwater and the measured runup using the capacitance wave gauges; it seems that capacitance wave gauges underestimate the runup because of the alteration of the capacity of the water due to air intrusion during the breaking process.

Introduction

Runup and overtopping are two very important issues in planning and designing mound breakwaters. Both the overestimation and the underestimation of runup and overtopping rates of sloping structures during a lifetime have a major impact on the long-term economic efficiency, they unnecessarily increase construction costs or damage to ships, equipment and property protected by the structure. Runup

1) Professor, Departamento de Transportes, Univ. Politécnica de Valencia, Camino de Vera s/n, 46022 Valencia, SPAIN. // E-mail: jrmedina@tra.upv.es
and overtopping depend on a variety of structural and environmental variables; armor roughness, structural shape, water depth, bottom slope and core permeability must be taken into consideration for an adequate estimation of the runup during its lifetime. Furthermore, wind waves (heights, periods and directions), long waves (tides, storm surges, shelf waves, seiches, etc.), and onshore winds must be properly characterized in order to define the environmental conditions at the construction site.

Although it is widely assumed that onshore winds significantly increase runup and overtopping, very few design rules and experimental data have been published to estimate the effects of wind on runup and overtopping. SPM(1984) provided the following empirical correction factor for overtopping rates to take into account the winds

\[ k = 1.0 + W_f \left( \frac{h - d_s}{R} + 0.1 \right) \sin \alpha \]  

in which \( \alpha \) is the structure slope, \( h \) is the height of the structure crest from the bottom, \( d_s \) is the depth at the structure toe, \( R \) is the runup on the structure that would occur if the structure were high enough to prevent overtopping corrected for scale effects, and \( W_f \) is an empirical coefficient depending on wind speed (\( W_f = 0.0 \), \( 0.5 \) and \( 2.0 \) for wind speed = 0, 30 and 60 miles per hour). However, the wind correction factor given by Eq. 1 can only be used as a general guide with little reliability because no reference to experimental observations is given by SPM(1984).

Ward et al.(1994 and 1996) used the wind and wave test facility at Texas A&M University (32.0 m-long, 0.6 m-wide and 0.9 m-deep). The effects of strong onshore winds on runup and overtopping of both smooth and rough coastal revetments were studied. Wind speeds of 6.5 m/s (50% of blower capacity) showed little effect on runup and overtopping, but wind speeds of 12 m/s (75% of blower capacity) or higher greatly increased both runup and overtopping. The maximum wind speed used in the experiments by Ward et al.(1994 and 1996) was 16 m/s. One of the most relevant final comments of Ward et al.(1994) was that scaling relationships need to be explored to allow runup and overtopping to be considered and applied to prototype coastal structures.

Troch et al.(1996) compared runup and rundown measurements obtained from the prototype monitoring system of the Zeebrugge breakwater, using vertically placed step gauges, with measurements on scaled models from a number of laboratories. Compared to the laboratory runup measurements, it appears that runup on prototype is about 50% higher than runup estimated in laboratories. On the contrary, wave rundown on the prototype was in accordance with laboratory data. An obvious difference between the prototype and laboratory experiments compared by Troch et al.(1996) is the onshore wind, which is present in the prototype but not in the laboratories; therefore, there is a point to support the idea that onshore wind may be the main factor used to explain the
difference in dimensionless runup obtained in the prototype and laboratories.

The spray of salt-water particles transported by strong winds over breaking waves, usually related to high runup and overtopping events, may also cause significant losses in coastal areas (see Matsunaga et al., 1994); experiments in wind tunnels seem to be of critical importance to provide adequate design guidelines to face these phenomena. Matsunaga et al. (1994) and Hashida et al. (1996) used a wind and wave test facility of 32.0 m-long, 0.6 m-wide and 1.30 m-deep. The wind speeds used ranged from 9 m/s to 19 m/s.

Because of the importance of accurate estimates of runup and overtopping rates for adequate breakwater crest designing, within the project OPTICREST (see Rouck et al., 1998) prototype measurements of runup, overtopping and spray will be taken at Zeebrugge (Belgium) and laboratory tests will be conducted in the wind and wave facility at the Universidad Politécnica de Valencia (UPV). This paper shows some preliminary results from tests on deep water models of breakwaters: (1) cuenco amortiguador type and (2) Zeebrugge type. The dimensions of the UPV wind and wave facility are 30.0 m-long, 1.2 m-wide and 1.2 m-deep, and the maximum wind speed used in the experiments was 10 m/s.

Wave and Wind Tunnel Testing

Most of the work published on wind tunneling is refers to experimental information useful for solving aerodynamic problems for the aeronautical industry. Compared to supersonic and hypersonic wind tunnels, low-speed wind tunnels are facilities using U<150 m/s; however, our problem belongs to a very special case of the relatively small nonaeronautical group classified as boundary-layer wind tunnels (BLWT) which typically use air at atmospheric pressure and operating speeds in the range of 10 m/s to 50 m/s (see WTMBS, 1987). Aeroelastic simulations in BLWT for buildings and structures and experiments in meteorological and environmental wind tunnels are under relatively similar constrains to those necessary for modeling waves, run-up, overtopping and spray; however, maritime applications have additional problems like the variations of MWL induced by wind and the resonant infragravity waves in wave flumes and basins. As a first approximation, Froude and Reynolds numbers appear to be more important than Cauchy, Rossby and Mach numbers for modeling run-up and overtopping.

Fig. 1 shows a longitudinal cross section of the UPV wind and wave test facility (dimensions in cm). The wavemaker is a piston type hydraulic controlled able to generate regular and irregular waves without active absorption. The power of the blower is controlled manually to fix a specific wind speed for each test; the wind speed is measured between the air intake and the model. Only regular waves were used in the experiments described in this paper; the maximum wind speed was 10 m/s and the number of waves was selected to prevent multireflected waves from attacking the
model. The time series for controlling the wavemaker movement were calculated using the classical frequency domain transfer function for piston movement (see Goda, 1985) with an additional linear transition function in the time domain to prevent unrealistic accelerations of the wave paddle at the beginning and the end of each test. The maximum estimated incident wave heights attacking the model was compared to the maximum measured and visual runup.

Figure 1. Longitudinal Cross Section of the UPV Wind and Wave Test Facility

The appropriate scaling relationships between wind speed, wave celerity and wave group velocity are not known for a proper modeling of the runup and overtopping phenomena (see Ward et al., 1994). Therefore, Froude similarity was chosen and a variety of wind speeds in the range of 0 to 10 m/s were used to study runup in the UPV wave and wind test facility. A neural network modeling was used to analyze the results given the lack of knowledge about the proper dimensionless variables to be considered and the number of significant structural variables to be taken into account.

Neural Network Modeling Using Simulated Annealing

The Neural Network (NN) systems belong to a group of relatively new optimization techniques commonly used in artificial intelligence (see Ansari and Hou, 1997). Neural networks (NN), simulated annealing (SA), genetic algorithms (GA) and fuzzy systems (FS) are some of the new optimization techniques which have proven to be very effective in solving difficult optimization problems. In particular, the NN are a computing device inspired by the function of the neurological system of the brain; they are composed of many parallel and interconnected computing units named artificial neurons. There are a variety of NN models which may be classified (see Kosko, 1992) depending on whether they learn with supervision and whether they contain feedbacks. On the one hand, the human brain belongs to the group of highly complex unsupervised NN with feedbacks; on the other hand, the relatively simple supervised feedforward NN is the most common structure used for NN modeling.

Usually, a supervised feedforward multilayer NN with only one hidden layer and a backpropagation learning algorithm is used for NN modeling of laboratory
experiments. Mase et al.(1995) used a NN model with backpropagation to re-analyze laboratory measurements first examined by Van der Meer(1988) in assessing the stability of rubble-mound breakwaters. Van Gent and Van den Boogaard(1998) used a NN model with backpropagation to analyze horizontal forces on vertical breakwaters measured by a group of laboratories. The number of artificial neurons in the first layer is fitted to the number of input variables (structural and environmental variables), the number of neurons in the third layer is fitted to the number of output variables (structural response variables), and the number of neurons in the hidden layer has to be subjectively chosen to avoid both over-simplicity and overlearning. If the number of neurons in the hidden layer is too small, the NN may be too simple to properly describe the relationship between input and output variables. If the number of neurons in the hidden layer is too large, the NN model fits the data used for learning but it does not fit the test data which are not used in the learning process. Therefore, the NN has not captured the characteristics of the underlying process and it is said that the NN has overlearned. The overlearning problem in this kind of NN modeling is related to the ratio between number of parameters in the NN model and the number of data sets used in the learning process; if this ratio is higher than 10%, the overlearning problem is likely to occur. Because the number of NN parameters roughly grows linearly with the product of the number of neurons in the input layer by the number of neurons in the hidden layer, the complexity of the model is greatly limited by the amount of data available. Furthermore, because the backpropagation algorithm used in the NN teaching is a gradient descent method, the model may probably find a local optimum NN instead a global optimum NN.

In order to reduce the shortcomings in the use of the gradient descent backpropagation algorithm, a simulated annealing (SA) algorithm has been implemented to define the appropriate NN for modeling the results of the runup experiments described in this paper. The SA is a common tool in artificial intelligence (see Ansari and Hou, 1997); SA simulates the process in which liquids crystalize: at high temperatures the energetic particles are free to rearrange, while at low temperatures the particles lose mobility, finally reaching a state of equilibrium, having minimum energy. The entropy of a substance decreases monotonically during annealing, leading the substance to an ordered crystalline structure if the temperature is slowly lowered to relax to thermal equilibrium at each temperature. Alternative implementations of the SA concept are described by Laarhoven and Aarts(1992) who also provide a review of SA methods and their applications. In the tests presented in this paper, incident and reflected waves were separated using the new LASA method (see Medina, 1998) which is a time-domain method able to deal with nonstationary and nonlinear wave trains using local approximations and simulated annealing.

In this paper, a NN structure similar to that used by Mase et al.(1995) was considered, but instead of using a backpropagation algorithm, a SA algorithm was used in the NN learning process. Two-parameter artificial neurons similar to those used by Mase et al.(1995) were considered; the sigmoidal curve was defined by one threshold parameter and one amplification parameter for the logistic function. Each connection
between neurons of consecutive layers has its corresponding weighting parameter. In addition to the common multilayer feedforward NN structure (named principal NN), a parallel structure of boolean parameters was considered to either activate or deactivate the parameters of the NN (named activation structure). Each parameter of the principal NN has its corresponding boolean activation parameter in the activation structure. If a boolean parameter is set to “1” the corresponding parameter in the principal NN works normally; on the contrary, if a boolean parameter is set to “0” the corresponding parameter in the principal NN works with the corresponding defect value. The defect values are zero for the weighting parameters in connections among neurons, zero for threshold parameters in neurons, and one for amplification parameters of the logistic function in neurons. The use of a feedforward NN associated with a parallel activation boolean structure allows for an optimization of the NN topology. The SA algorithm will not only optimize the parameters of the NN, but also the topology, disconnecting parameters, neurons, and inputs if they are not relevant to improve the NN model. Fig. 2 shows a typical NN model using SA for optimization; in addition to the disconnected input and hidden neurons, some of the remaining active neurons have one or no active parameters.

![Figure 2. Typical NN Model Using Simulated Annealing](image)

The NN model after the SA optimization is a parsimonious NN. The ratio between the number of NN active parameters and the number of data sets used for the learning process ranged from 3% to 5%; therefore, it is easy to understand why no overlearning problem was detected in any of the applications made in this paper. The use of a SA algorithm to optimize the NN model provided more than just good models to relate input variables (H, Ir, ...) with output variables (runup); it gave a clear
indication of what input variables were irrelevant for modeling the process under study. This characteristic is quite convenient when NN modeling is used to analyze phenomena and processes which are little known, as is the case of the influence of wind on runup and overtopping considered in this paper.

In order to obtain the parsimonious NN mentioned above, certain details of the most critical aspects of the SA algorithm used in this paper must be described. Medina (1998) defines a SA algorithm in seven steps: (1) cost function, (2) generation mechanism, (3) initial solution, (4) initial control parameter, (5) reduction of control parameter, (6) length of Markov chains, and (7) stop criterion. In this paper, the most critical points are the cost function and the generation mechanism; the initial solution was a principal NN of parameters with random values in a given interval and the activation structure with all activation parameters set to "1". Steps 4 to 7 may be critical given time constraints, but in this case a reasonably good NN model can be obtained in a few minutes with a personal computer.

The cost function used in this paper for the SA algorithm has two components: the relative mean squared error and the ratio between the number of active parameters and the number of data sets used for the NN learning process. If only the relative mean squared error is used as a cost function, the resulting NN model using SA would be a least squares model similar to that obtained with the backpropagation algorithm. It may pose as an additional advantage for the SA algorithm because it prevents becoming trapped in a local minimum. However, the main advantage of the SA algorithm is obtained when a factor measuring parsimony is added to the cost function; in this case, the SA not only find good estimates of the NN parameters, but SA also eliminates those which are not significant to explain the relationship between input and output variables. The relative weight between the two factors in the cost function is decided by the operator; in this paper, the weight of relative mean squares error factor was three times the weight of the parsimony factor. Indeed, although the relative weight of the parsimony factor was very low, the impact on the NN topology is significant.

The generation mechanism defines the new NN in the neighborhood of the old NN. In this paper, a random change of parameters and magnitude of parameters, as well as a random change of the boolean parameters in the activation structure is made to create the new NN in the neighborhood of the old NN. However, the probability of changes in the activation structure must be controlled for an adequate exploration of the search space. During the first Markov chains, when the temperature is high and the NN parameters are far from the optimum, the activation structure must be set to "1" to prevent its anticipated convergence to a sub-optimal solution. Once the SA has found a reasonably good NN model, a solution similar to what would be obtained using a backpropagation algorithm, then a small probability of change from "1" to "0" and from "0" to "1" is fixed for the parameters in the activation structure. With this small probability of activation and disactivation of parameters and connections between neurons, the SA also explores alternative NN topologies by pruning the useless NN connections.
Experiments with *Cuenco Amortiguador* Breakwater Models

Fig. 3 shows the two *cuenco amortiguador* type breakwater cross sections tested in the UPV wave and wind tunnel shown in Fig. 1. The *cuenco amortiguador* concept is a special breakwater crest design introduced two decades ago in Spain by Aguado-Gallego and Sánchez-Naverac (1978). The idea was to reduce the breakwater crest elevation in cases where the aesthetic conditions were very restrictive, as is the case in many touristic areas. During the last two decades, several *cuenco amortiguador* type of breakwaters have been built in Spain (Fuengirola, Marbella, Torre del Mar, Denia, etc.). The design rules currently used in Spain for this type of breakwaters are based on a series of scale model tests provided by Aguado-Gallego and Sánchez-Naverac (1978) with regular waves without wind. These authors identified twelve structural and environmental variables, not the wind, but the experiments only covered a limited number of cases. The main conclusion was that breakwater crest elevation could be reduced by about 30% with respect to the currently used Iribarren rule: *crest elevation is approximately equal to 1.5 the design wave height*. However, it is obvious that the crest width and cap elevation depends critically on runup and overtopping which are related to onshore winds. Therefore, a series of experiments were conducted to check the influence of onshore winds on the runup as measured on the crown wall of the *cuenco amortiguador* breakwater cross section shown in Fig. 3, which is related to the overtopping rate of the conventional armor.

The armor was built of angular quarystones for deep water conditions; the median weight was $W_{so} = 130g$, the slope was $3/2$ and the armor, filter and core stones were the same as those used in the tests described by Medina (1992). In the experiments described in this paper, a conventional and a D-armor cross section were also tested but no significant difference in runup was observed; therefore, in this paper the test results refer only to the conventional armor section shown in Fig. 3. Based on the preliminary results found by Aguado-Gallego and Sánchez-Naverac (1978), the structural variables selected to be analyzed in this paper were the armor crest elevation and the total width of the *cuenco*. The higher the armor crest elevation on the SWL (a) and the wider the *cuenco amortiguador* (b+c), the lower the runup measured on the crown wall. The
selected environmental variables were: wave height, Iribarren's number and wind speed. The armor crest elevation refers to the SWL and was fixed to \( \{a\} = 4.0 \text{ D}_{n50} \) for the first series of experiments; however, the tests were repeated increasing and decreasing the water level by \( 1.35 \text{ D}_{n50} \) in order to analyze the influence of a change in the armor crest elevation. Three \textit{cuenco amortiguador} widths were considered in the experiment: \( \{b+c\} = 5.0 \text{ D}_{n50}, 6.5 \text{ D}_{n50} \) and \( 10.0 \text{ D}_{n50} \).

Because of the special profile of the \textit{cuenco amortiguador} breakwater, the runup measured on the crown wall is directly related to the overtopping rate on the crest of the armor layer. Therefore, the effects of onshore wind on runup measured on the crown wall of the \textit{cuenco amortiguador} breakwaters may be considered similar to the effects of wind on the overtopping of conventional breakwaters. If the volume of water overtopping the armor layer is small, the overtopped water is drained through the \textit{cuenco amortiguador} without reaching the crown wall and the measured runup is null. On the contrary, if the overtopped volume is large, the runup on the crown wall increases with increasing overtopping rates. The runup was visually measured on a scale fixed on the crown wall and was defined as the distance between the maximum water elevation on the crown wall and the SWL; if the water did not reach the crown wall, the runup was considered zero.

375 tests with regular waves were completed using wind speeds between 3 and 10 m/s; in addition, 875 tests were completed without wind. In only 25% of the tests the observed overtopping rate was large enough to reach the crown wall; in the other 75% of the tests, the measurement of runup was Ru=0. NN modeling is usually appropriate to analyze multivariable nonlinear relationships between input and output variables when there is a large amount of data and the knowledge about the underlying process is low (see Kosko, 1992). However, a first direct application of the NN methodology using SA described above gave only a poor result with a correlation coefficient lower than 60% between measured Ru and estimated Ru. The main reason for this poor result was attributed to the extremely high nonlinear relationship between the measured Ru (the output variable) and the structural and environmental variables (input variables), with 75% null Ru in the data.

The analysis of the poor results obtained with the first direct application of the NN methodology shown above led to a second NN modeling considering a chain of two different NN for two different purposes. The first NN were used as classifiers of data in two groups: input associated with Ru=0 and input associated with Ru>0. The second NN were used to estimate the Ru when the first NN identified conditions for reaching the crown wall (Ru>0). This NN modeling using a chain of two different neural networks gave satisfactory results with a correlation coefficient between measured Ru and estimated Ru higher than 90%. About 80% of the data were randomly chosen for the NN learning process while the rest of the data was used for testing the NN model. The ratio between the number of parameters in the NN using SA ranged from 3% to 5% and no overlearning problem was detected. Fig. 4 compares the observed Ru on the crown wall and the estimated Ru using the described NN modeling.
Five input variables were used in both NN: wave height (H), Iribarren's number (Ir), wind speed (U), crest elevation (a) and cuenco amortiguador width (b+c). It is interesting to point out that the SA process eliminated only the input wind speed (U) from the NN used as classifier; this fact suggests that the wind speed is not relevant for predicting if the water will reach the crown wall or not. However, the wind speeds were not eliminated from the NN which predicted the Ru once the conditions were classified as Ru>0 by the first NN. This asymmetric behavior suggests that onshore wind has an irrelevant effect on runup of conventional breakwaters but a significant effect on large overtopping discharges of conventional breakwaters.

**Experiments with the Zeebrugge Type Breakwater Model**

Troch et al. (1996) described the prototype monitoring system of the Zeebrugge breakwater, equipped with high precision vertical step resistance wave gauges to measure runup and rundown. Fig. 5 shows the deep water Zeebrugge type breakwater cross section tested in the UPV wind and wave facility (dimensions in cm); the armor layer was made of regular cubes instead of the antifer cubes placed in the Zeebrugge breakwater. The nominal diameters of the armor layer, secondary layer and core were D_{50}=6.00 cm, 1.71 cm, and 1.26 cm respectively. The runup was measured visually placing cubes with different colors at different levels, using two capacitance wave gauges placed along the slope at distances of 2 cm and 4 cm from the theoretical profile, and using two wave gauges placed vertically through the armor layer. The maximum elevation of water on the armor was directly measured by the two inclined wave gauges and by visual observation; the vertical wave gauges provided additional measurements at fixed points, but this additional information is not analyzed in this paper.
A series of tests with regular waves, changing wave height (H), Iribarren's number (Ir), and wind speed were carried out in the UPV wind and wave facility. 385 data sets relating the input conditions (H, Ir and U) and the output (Ru) were used to apply the NN methodology using SA described above. However, before starting the NN modeling of runup corresponding to this conventional breakwater, it was first necessary to clarify what should be considered the runup of a wave breaking on a sloping structure. Visual observation of runup may be biased in comparison to measurements of runup taken with wave gauges. On one hand, the human eye is subjective in estimating the maximum elevation of the water level on the slope. On the other hand, it is impossible to place the wave gauge exactly in the external profile of the armor where the runup should be measured, and wave gauges are not calibrated to take into consideration the air intrusion generated during the breaking process.

The Ru measured by the two inclined wave gauges were highly correlated but biased; usually, the runup measured by the wave gauge nearest to the theoretical profile were higher. Therefore, a linear estimation of the runup on the theoretical profile was calculated from the runup measurements taken by the two wave gauges parallel to the slope at distances 1/3 $D_{n50}$ and 2/3 $D_{n50}$ respectively. Fig. 6 compares this linearly estimated runup versus visual observations of runup and measured runup by the wave gauge closest to the theoretical profile (sensor 4). Because measured runup decreases depending on the distance of the inclined wave gauge from the theoretical profile, and it is impossible to place the wave gauge exactly in the theoretical profile, the two wave gauges linearly estimated runup were considered in Fig. 7 as the actual measured runup of the sloping structure. Fig. 6 clearly shows a significant bias between measured and visual observations of runup on a conventional sloping structure. In this case, the wave gauges measured the capacity of the instrument in the water and were unable to take...
into consideration the air intrusion always present during the breaking process. Therefore, runup measured on a prototype scale should be expected to be higher than runup measured in the laboratory with wave gauges, although the measured runup in the laboratory was corrected to take into consideration the distance of the wave gauge from the theoretical profile. Additionally, a precise description of the experimental setup and the variables is necessary to compare results from different laboratories.

![Figure 6. Comparison of Visually Observed vs Measured Runup](image)

The visually observed runup was significantly higher than the linearly calculated runup based on the measurements taken by the two wave gauges placed parallel to the slope, but the dispersions of the visual observations shown in Fig. 6 were also much higher. The NN modeling methodology described previously was applied to the input-output data sets using the linearly calculated runup as the output \( R_u \) on the sloping structure. Wind speed was not eliminated as a significant input variable by the SA process, but the NN produced \( R_u \) very sensitive only to inputs \( H \) and \( I_r \). According to the result of the NN modeling, \( R_u \) was insensitive to low wind speed and increased slightly only to high wind speed (\( U > 8 \text{ m/s} \)).

Fig. 7 compares the output of the NN model and the runup measured using the two wave gauges parallel to the slope; the overlearning problem was not detected, the correlation coefficient was higher than 90% and the ratio number of parameters to number of data sets was lower than 5%.
Conclusions

Deep water model tests on breakwaters models of the cuenco amortiguador type and a Zeebrugge type were conducted in the UPV wind and wave facility using regular waves and windspeeds up to 10 m/s. The parsimonious neural network models obtained by simulated annealing were found to be very effective in modeling both the runup and the overtopping of conventional breakwaters. The preliminary results from the tests described in this paper are qualitatively in agreement with those obtained by Ward et al. (1996) referring to runup, in the sense that runup is affected only by high onshore wind speeds (U> 8 m/s). Contrary to the results obtained by Ward et al. (1996), a significant influence of onshore winds on overtopping was also found for low wind speeds. The NN modeling using SA not only provided adequate models but also guided the research indicating the most significant variables to be considered in describing the processes under study. Therefore, the NN methodology presented in this paper may be useful not only to analyze runup and overtopping, but also to analyze other little known phenomena.

Acknowledgements

This research was funded by the Dirección General de Investigación Científica y Técnica (Spanish Ministry of Education) and the E. C. through grant PB94-0534 and MAS3-CT97-0116 OPTICREST Project. The author wishes to acknowledge the assistance of José Andreu, Jesús Ceniceros and José A. González in collecting the laboratory data. Additionally, it should be mentioned that Vicent Esteban designed the new UPV wind facility, José Aguilar and Juan J. Navarro renewed the UPV wavemaker software, and Adolfo Conesa and Juan J. Conesa developed the NN software.

Some Design Aspects of an Absorbing 3D Wavemaker

Hemming A. Schäffer

ABSTRACT

A new absorbing multidirectional wavemaker is under development at the Danish Hydraulic Institute. In this process numerous aspects of the design and control of multielement wavemakers as well as the theory for wave generation and active absorption have been considered. This paper focuses on two specific and specialized points. First, the influence of finite segment width on the wave field generated is analysed for different types of paddle front. In this connection a new criterion for the truncation of directional spectra to be generated is suggested. Second, the appearance and reduction of aliasing problems for 3D active absorption is discussed. Aliasing appears due to the spatial sampling typically used for obtaining a hydrodynamic feedback in the absorption procedure.

INTRODUCTION

A traditional wavemaker is controlled independently of the waves present in its vicinity. Thus, if the waves generated by the wavemaker are reflected from some boundary or construction in the flume or basin, then full re-reflection takes place when these waves return to the wavemaker. The result is an undesirable distortion of the incident wave field.

An absorbing wavemaker attempts to eliminate this problem by including some hydrodynamic feedback signal in the paddle control. Simultaneously with the usual wave generation, reflected waves are absorbed by moving the paddle appropriately.

Absorbing wavemakers for wave flumes are now routinely used in a number of laboratories. For multidirectional wavemakers the simplest option is to use independent absorption control systems for each wavemaker segment. This gives a quasi-3D system, which does not account for wave obliqueness in the absorption procedure. Nevertheless, a quasi-3D system provides a significant improvement over a traditional segmented wavemaker. In very recent years, fully 3D systems have been pursued. Wave obliqueness is accounted for through a coupling between the control of neighbouring paddle segments. For a review of active absorption methods with emphasis on 3D systems, see Schäffer and Klopman (1997).

1 Danish Hydraulic Institute, Ågern Allé 5, DK-2970 Hørsholm, Denmark, e-mail: has@dhi.dk
At the last ICCE, we presented a fully 3D theory for active absorption of multidirectional waves (Schäffer and Skourup, 1996). Within the framework of linear waves, this theory was developed in the wavenumber-frequency domain \((k_y, \omega)\), using the wavenumber component along the wavemaker. The result was a 2D transfer function \(F(k_y, \omega)\), relating the amplitude of the wavemaker position \(X_a(k_y, \omega)\) to the amplitude of the surface elevation measured along the wavemaker \(A(k_y, \omega)\). The same transfer function appeared in the combined generation/absorption problem. Phase relations were accounted for, since \(F\), \(X_a\) and \(A\) were complex. In order to obtain a physically realisable representation, a 2D digital recursive filter was developed. This filter was designed to have a transfer function approximating \(F(k_y, \omega)\), thus giving the wavemaker paddle position \(X(mA_y, nAt)\) as output when provided with the surface elevation \(\eta(y, mA_y, nAt)\) measured along the wavemaker as input. Here, \(y\) is the coordinate along the wavemaker and \(t\) is time. The space-time domain was sampled at \((y, t) = (mA_y, nAt)\) where \(Ay\) equals the individual paddle width of the segmented wavemaker. A wave elevation gauge was assumed to be mounted on each segment. Schäffer and Skourup tested the absorption algorithm in a numerical wave tank based on the Boundary Integral Equation Method and concluded that the system gave a significant improvement over a quasi-3D system.

One of the shallow water facilities at Danish Hydraulic Institute is now being upgraded with a multidirectional wavemaker and the active absorption system is an important part of this development. The new wavemaker is scheduled to be ready in 1999 and thus the practical performance of the system will be published at a later occasion. The present paper reports a number of investigations made in connection with the design of the multidirectional wavemaker front.

SELECTED DESIGN CONSIDERATIONS

The active absorption depends on the elevation measured directly on the paddle front of the wavemaker. This makes the local wave field very important and it gives a renewed interest in phenomena like evanescent modes and spurious wave generation due to finite paddle width. Since the surface elevation is measured at discrete points in space, aliasing problems must also be considered.

Spurious Waves and Evanescent Modes for Different types of paddle front

The finite spatial resolution \(\Delta y\) of a segmented wavemaker results in spurious waves (see eg Sand, 1979). Let the wavelength along the wavemaker be \(L_y = 2\pi|k|l\) and let the wave direction be \(\theta\) then if \(\frac{L_y}{\Delta y} > \frac{\sin \theta}{(1 + \sin \theta)}\), these appear only as evanescent modes confined to the vicinity of the wavemaker. For high frequencies and large obliqueness, the resolution becomes very coarse, and spurious progressive waves are generated. Since spurious waves in general influence the local wave field and since spurious progressive waves contaminate the whole wave basin, it is interesting to know how large they get. This depends on the variation of the paddle front, and thus we have studied three different types of paddles with a) a constant, b) a linear and c) a cubic spline variation between the discrete points at which the position is controlled. Type a) is often called 'the staircase approximation', while b) is known as a vertically hinged paddle. Type c) requires a flexible paddle and it has probably never been used in practice.

One problem with the flexible paddle is that it needs to be sufficiently rigid to sustain the wave forces. We have estimated that the power required to bend the paddle is consequently in the same order of magnitude as the power required to generate the waves. However, we have
included the flexible paddle in the analysis anyway as it represents the best interpolation one could possibly obtain for this type of problem.

In this paper, we shall refer to the three types of paddle fronts by the shape of their segments, namely as constant, linear and spline elements, respectively. For $L_y/\Delta y=5$, Fig. 1 shows a sketch for each of the three types of elements in comparison with the sinusoid to be approximated.

![Sketch of different types of paddle fronts](image)

**Figure 1.** Different types of paddle fronts considered: constant, linear and cubic spline elements. Resolution: $L_y/\Delta y=5$.

Part of this investigation has been made before (Sand, 1979, types a) and b)), with the emphasis on progressive spurious waves. The purpose of the present analysis is twofold. First, we establish a more elaborate condition than just cutting at $L_y/\Delta y=\sin \theta / (1 + \sin \theta)$ when truncating a directional spectrum to be generated. The condition suggested limits the amplitude of progressive spurious waves and it depends on the type of wave paddle. This further supports the decision on which paddle type to chose in multidirectional wavemaker design. Second, we calculate the local wave field in detail for use in connection with active absorption.

Let the paddle position, $X(y_m,t)$ be given as a sinusoid with amplitude $X_a$ sampled at equidistant points,

$$X(y_m,t) = X_a \exp \left[ i (\omega t - k \cdot y_m) \right], \quad y_m = m\Delta y$$  \hfill (1)

![Definition sketch](image)

**Figure 2.** Definition sketch.
see Fig. 2 for a definition sketch. The continuous position, \( X(y,t) \) is then determined by the type of paddle front, i.e. the type of interpolation. Generally, we may write

\[
X(y,t) = \xi(y)X_0 \exp[\omega t], \quad \xi(y_m) = \exp[-ik\Delta y]
\]  

(2)

For constant elements, we have

\[
\xi(y) = \xi(y_m), \quad y_{m-1/2} \leq y \leq y_{m+1/2}
\]  

(3)

For linear and spline elements the interpolation can be written as

\[
\begin{align*}
\xi(y) &= A(y)\xi(y_m) + B(y)\xi(y_{m+1}) + \\
&+ C(y)\xi''(y_m) + D(y)\xi''(y_{m+1}), \quad y_m \leq y \leq y_{m+1}
\end{align*}
\]  

(4)

where

\[
A(y) = (y_{m+1} - y)/\Delta y, \quad B(y) = (y - y_m)/\Delta y
\]  

(5)

For spline elements, we get

\[
C(y) = \frac{\Delta y^2}{6} A(A^2 - 1), \quad D(y) = \frac{\Delta y^2}{6} B(B^2 - 1)
\]  

(6)

while these cubic terms vanish for linear elements, i.e. \( C(y) = D(y) = 0 \). For the spline case, it may be verified that (3) and (4) ensure continuity in both \( \xi(y) \) and \( \xi''(y) \) at \( y = y_m \). Further requiring that also \( \xi'(y) \) is continuous at \( y = y_m \) gives a linear system of \( N = L/\Delta y \) equations relating \( \xi''(y_m) \) to \( \xi(y_m) \), assuming an integer number of elements per wavelength along the wavemaker. Due to periodicity of the problem, the coefficient matrix involved is circulant, i.e. each row is identical to the previous one except for being rotated one place to the right. Using the Discrete Fourier Transform, this linear system can be solved for any value of \( N \) to give

\[
\xi''(y_m) = \xi(y_m) \frac{\cos(k\Delta y) - 1}{\cos(k\Delta y) + 2}
\]  

(7)

It may be shown, that both this and the following results can also be obtained under the assumption that \( N \) is a rational number. For continuity reasons we further conjecture that also irrational values of \( N \) are allowed. For simplicity, however, we shall maintain the assumption of integer \( N \) in the following derivations. Expanding \( \xi(y) \) in a Fourier series

\[
\xi(y) = \sum_{n=-\infty}^{\infty} a_n \exp[ink\Delta y], \quad a_n = \frac{1}{L} \int_{y}^{L} \xi(y) \exp[-ink\Delta y] dy
\]  

(8)

it turns out that all but every \( N \)th coefficient vanish, and the remaining ones appear for \( n = pN - 1 \), where \( p \) is an integer. The result may generally be expressed as
\[ \xi(y) = \sum_{p=-\infty}^{\infty} a_p \exp[-ik_{yp}y], \quad k_{yp} = k_x - pk_{\Delta y}, \quad k_{\Delta y} = \frac{2\pi}{\Delta y} \]  

(9)

irrespective of the type of paddle front. After quite some algebra, we get

\[
 a_p = \begin{cases} 
 \beta_p, & \text{constant elements,} \\
 \beta_p^2, & \text{linear elements,} \\
 \frac{3}{2 + \cos(k_x \Delta y)} \beta_p^4, & \text{spline elements,}
\end{cases}
\]

(10)

where the first two results were given by Sand (1979). It appears that in all three cases the power of \( \beta_p \) equals the order of the interpolating polynomial plus one. The primary component given by \( p=0 \) represents the desired motion, while all other components are spurious modes due to finite resolution. The perfect sinusoid recovers for \( N \to \infty \) (or \( k_x \Delta y \to 0 \)) for which \( a_0 \to 1 \) and \( a_p \to 0, \ p \neq 0 \). Figure 3a shows \( |a_p| \) for \( p \in [-2, 2] \) versus \( 1/N = k_x / k_{\Delta y} \) for constant elements. Similar curves are shown in Fig. 3b for linear elements and in Fig. 3c for spline elements, where \( c_1, c_2 \) and \( c_3 \) are hardly visible. While increasing the order of interpolation clearly improves the results when \( 1/N \) is small, the main spurious component dominates over the primary component for any type of interpolation when the resolution is more coarse than corresponding to the Nyquist limit, i.e. when \( 1/N > 1/2 \). This illustrates the importance of resolution and the limited possibility for improvements by high order interpolation. Irrespective of the type of interpolation all paddles move in phase if \( 1/N = 1 \) and the wavemaker reduces to a long-crested wavemaker. This is in line with (9), since for \( N \to 1 \), we have \( k_{\Delta y} \to 0, \ a_1 \to 1 \) and \( a_p \to 0, \ p \neq 1 \).

Figure 3. Fourier coefficients \( |a_p| \) versus \( 1/N = k_x / k_{\Delta y} \) for \( p \in [-2, 2] \).

Left plot: constant elements; middle plot: linear elements; right plot: spline elements.
While the above results give an indication on how well the ideal sinusoid is reproduced by a given type of segmentation, it does not show which waves will be generated. Summing up the solution (see e.g. Dean and Dalrymple, 1984) for each sinusoidal paddle mode, the surface elevation of the waves generated by the paddle movement from (9) can be written as

\[ \eta(x, y, t) = X \sum_{p} a_p \sum_{j=0}^{\infty} e_{jp} \exp \left[ i \omega t - k_{sip} x - k_{yp} y \right] \]  

(11)

where

\[ e_{jp} = \frac{k_j}{k_{sip}} c_j, \quad k_{sip} = \sqrt{k_j^2 - k_{yp}^2}, \quad \omega^2 = gk_j \tanh k_j h \]  

(12)

Here \( k_j \) and \( c_j \) are the wavenumber and the Bessel transfer function, respectively. These are real for \( j=0 \) and imaginary for \( j>0 \) representing evanescent modes. For a piston-type wavemaker, we have

\[ c_j = \frac{2 \sinh^2 k_j h}{k_j h + \sinh k_j h \cosh k_j h} \]  

(13)

see e.g. Schäffer (1996) for other types of wavemakers. While \( j>0 \) gives evanescent modes for any value of \( p \), progressive modes require that \( j=0 \) and that \( p \) is sufficiently small as to get \( |k_{yp}|<k \). Singularities appear in the transition from progressive to evanescent modes, since the square root in (12) vanishes when

![Figure 4. Singularities for spurious wave amplitudes, see (14).]
\[ \left| \frac{p}{k} \frac{\Delta y}{\sin \theta} \right| = 1 \]  

(14)

where \( \theta \) is the angle between the wavenumber vector and the wavemaker orthogonal. These singularities are shown in Fig. 4 for \( p = \pm 1, \pm 2 \). Swapping signs for \( p \) and \( \theta \) gives the same image but mirrored in the abscissa. The singularity for \( p=0 \) is outside the range of the figure, since it appears for \( \theta = \pm 90^\circ \). Obviously, it is desirable to stay away from the singularities, since at these points the mode in question can be expected to grow until nonlinearity or dissipation put an end to it. A criterion often used in multidirectional wave generation is that no progressive spurious modes should be allowed. This criterion is met (and only met) by staying to the left of the singularity curve for \( p=1 \) (and for \( p=-1 \) for negative \( \theta \)) in Fig. 4, i.e. requiring \( k / k_{\Delta y} < 1/(1 + \sin \theta) \). However, theoretically this may still give arbitrarily high evanescent mode amplitudes and this is one possible source of cross modes sometimes seen to build up near the wavemaker eventually ruining the physical experiment.

For comparison with Fig. 4 and the figures shown later, contours of resolution, \( k / k_{\Delta y} = 1/2, 1/5 \) and \( 1/10 \) versus \( k / k_{\Delta y} \) and \( \theta \) are shown in Fig. 5.

Usually, the desired wave is progressive, and omitting the zero’s for the subscripts \( j \) and \( p \) on the wavenumber components, we have

\[ \eta_{00}(x, y, t) = A_{00} \exp[(\omega t - k_x x - k_y y)], \]

\[ A_{00} = \frac{X_0 a_0 c_0}{\cos \theta}, \quad (k_x, k_y) = k(\cos \theta, \sin \theta) \]  

(15)

Figure 5. Hyperbolas showing constant resolution.
Sand (1979) concentrated on the number of evanescent modes as well as on the Fourier coefficients for the paddle motion, $a_p$. However, as pointed out by Christensen (1995), it is rather the magnitude of the resulting waves which is interesting from a wave generation point of view. Generating spurious waves is not a problem as long as their magnitude is sufficiently small. Thus, we look at the amplitude, $A_{0p}$, of the dominant mode ($j=0$) for the $p$'th spurious wave relative to the desired wave amplitude, $A_\infty$. From (11), we get

$$\frac{A_{0p}}{A_\infty} = \frac{a_p}{a_0} \frac{\cos \theta}{\sqrt{k^2 - k_{vp}^2}}$$

which is again singular when (14) is satisfied. As a rational criterion for whether or not we should include a given desired wave component in the generation of a multidirectional sea state, we suggest to require

$$|A_{0p} / A_\infty| \leq \epsilon$$

This requirement should be met for all values of $p$ given some small value of the parameter $\epsilon$. For each $p$ (17) produces two limiting curves, one on the progressive-wave side of the singularity and one on the evanescent-mode side. Including also the singularities, Fig. 6 shows the results using $\epsilon = 0.2$ for a constant element wavemaker and $p = \pm 1, \pm 2$. The shading indicates the allowable combination of direction, $\theta$, and scaled wavenumber, $k/k_{\Delta\nu}$. The grouping of curves

![Figure 6. Limiting curves for wave generation defined by (17) with $\epsilon = 0.2$. Paddle type: constant elements. Thick curves repeat the singularities from Fig. 4.](image)
Figure 7. As Fig. 6, but for linear elements.

Figure 8. As Fig. 6, but for cubic spline elements.
Figure 9. Contours of a narrow directional spectrum.

Figure 10. Contours of a wide directional spectrum.
in sets of three for each value of $p$ is more evident in Fig. 7 which shows similar results but for linear elements. The range of applicability is somewhat increased, but mainly for small. The limit of what a flexible paddle front could provide is seen in Fig. 8 showing the results for cubic spline elements. Although the improvement is evident, we note that again the advantage is quite small for waves with oblique mean direction.

For comparison with the allowable regions in Figs. 6-8, Figs. 9 and 10 show two examples of directional spectra. For both spectra the frequency variation is a Pierson-Moskowitz spectrum and the directional distribution is proportional to $\cos^2 \theta (\theta / 2)$. Ten equidistant contours are shown between the directional spectral peak value and zero. In Fig. 9 the directional distribution is quite narrow with $s=40$ corresponding to a directional spread of $\sigma_d=13^\circ$. The spectral peak is at $k/k_{\text{ay}}=1/2$ e.g. corresponding to a peak frequency $f_p$ at 1.25Hz for a segment width of $\Delta y=0.5m$ (using the deep water dispersion relation). In comparison with the allowable regions in Figs. 6-8 it appears that the linear segments show a significant improvement over the constant ones (the staircase approximation) and the cubic splines give yet an improvement. However, shifting the mean direction in Fig. 9 to for example $30^\circ$, this advantage disappears as only one side of the directional distribution can be generated. In Fig. 10 the directional distribution is quite wide with $s=6$ ($\sigma_d=32^\circ$), while the peak is now at $k/k_{\text{ay}}=1/4$ corresponding to $f_p=0.88Hz$ assuming $\Delta y=0.5m$ and deep water theory. For this case the difference between the three types of paddle front is rather small even for zero mean direction.

**Spatial Aliasing**

Collecting for example surface elevation time series usually involves a discrete sampling of a continuous measurement. In order to avoid aliasing, a suitable lowpass filter is applied to the analogue signal before the digital sampling takes place. The situation is quite different when measuring the surface elevation at equidistant points along the wavemaker. In this case, the surface elevation is sampled directly in discrete space. Thus, no underlying continuous measurement is available for eliminating aliasing in the sampling process. Assuming that the sampling interval equals the segment width, aliasing takes place for $L_s/\Delta y < 2$, (equivalent to the Nyquist frequency). Aliasing wraps wavenumbers $k_s$ to

$$\tilde{k}_s = k_s + nk_{\Delta y}$$

where $n$ is determined so that

$$-\frac{k_{\Delta y}}{2} < \tilde{k}_s < \frac{k_{\Delta y}}{2}$$

Assuming that $k_s$ is inside the Nyquist range, the spurious wavenumbers $k_{sp} = k_s - pk_{\Delta y}$ given in (9) are all outside this range and aliasing wraps them back to get $\tilde{k}_{sp} = k_s$. Naturally, sampling the Fourier series for the paddle position (9), the original expression in (2) recovers as can be confirmed by checking that for all types of elements we have

$$\sum_{p=-\infty}^{\infty} a_p = 1$$

(20)
For the surface elevation in (11), however, the transfer function $e^{jp}$ modifies the terms in the summation so that the sampled elevation varies with type of element. This modification, however, is not a problem as it can be easily computed.

Other sources of short waves contaminating the system through aliasing must be anticipated. Nonlinearity is bound to give higher harmonics, both directly in the wave generation itself and indirectly through reflections from possible fixed or floating structures. Since the waves from these sources are unknown, we are not able to compensate for their influence. Consequently, a 3D active absorption system based on a discretely spatially sampled surface elevation will misinterpret very short waves as longer waves and thus try to absorb these longer waves, which do not exist. In this attempt, the system will generate unwanted waves.

Since the surface elevation is sampled both in space and time, the dispersion relation in principle makes it possible to overcome the spatial aliasing by lowpass filtering in the time domain. The frequency domain transfer function of such a lowpass filter transforms into the wavenumber domain, $k$. However, the desired effect is to restrict energy to small values of the wave number projection, $k_y$. Since for progressive waves $k \geq k_y$, the aliasing problem can be solved by eliminating frequencies for which $L\Delta y < 2$ (or $k / k_{\Delta y} > 1/2$), where $L = 2\pi / k$ is the wave length.

Unfortunately, this requires a quite severe filtering, which we have found to impose unacceptable limits to the range of application for the active absorption system. Note, however, that wave generation and active absorption can be separated so that the filtering only affects the active absorption range and not the generation range.

In search for other means of reducing the potential problem of aliasing, we examine the effect of spatial averaging between consecutive surface elevation gauges. Let the gauge distance equal the segment width and let each gauge be centred between two control points, i.e. at $y = (m + 1/2) \Delta y$. (This arrangement is not feasible for constant elements, as the paddle position is discontinuous at these points.) Spatial averaging between two gauge signals is equivalent to a multiplication in the $k_y$ domain by the transfer function

$$H_1(k_y \Delta y) = \cos \left( \frac{k_y \Delta y}{2} \right)$$

as depicted in Fig. 6a. This is a notch filter, which has the desirable property that it removes all energy at the Nyquist wavenumber $k_y / k_{\Delta y} = 1/2$ (and uneven multiples of 1/2), and the undesirable property of no reduction of energy for integer values of $k_y / k_{\Delta y}$. In combination with this spatial averaging, the time domain lowpass filtering as mentioned above can be less restrictive with a slightly higher cut-off frequency. However, as we still do not find this combination satisfactory, we shall investigate the consequences of doubling the number of surface elevation gauges placing these at $y = (m + 1/2) \Delta y / 2$. Aliasing now follows (18) and (19) with $\Delta y / 2$ in place of $\Delta y$ and spatial average among two neighbouring gauges corresponds to the transfer function

$$H_2(k_y \Delta y) = \cos \left( \frac{k_y \Delta y}{4} \right)$$

as shown in Fig. 6b. Combining (21) and (22), we get
Figure 11. Transfer functions (21)-(23) for spatial averaging reducing aliasing problems.

\[ H_3(k_y\Delta y) = \cos \left( \frac{k_y\Delta y}{2} \right) \cos \left( \frac{k_y\Delta y}{4} \right) = \frac{1}{2} \cos \left( \frac{k_y\Delta y}{3} \right) + \frac{1}{2} \cos \left( \frac{k_y\Delta y}{4} \right) \]  

Here the first version is given by \( H_3 = H_1 H_2 \) as obtained by two consecutive spatial averages between two neighbouring values, while the second formulation is found by considering the process as one spatial average between four neighbouring gauges. By this combination, we have obtained a stop band as seen in Fig. 6c. Consequently the supporting time domain filter can use a much higher and less restrictive cut-off frequency and still significantly reduce the contamination of the active absorption system due to short-wave aliasing. This solution has been chosen for the new multidirectional wavemaker under construction at DHI. A more elaborate analysis involving variable coefficients in the spatial averages did not show an overall improvement.

CONCLUSIONS

With regard to the type of wavemaker paddle front (Fig. 1) no differences appear in the limitations for multidirectional wave generation if the traditional cut-off in frequency and direction is used i.e. requiring no progressive spurious waves. A more elaborate criterion has been proposed, which reduces the application range slightly for very oblique waves in order to avoid large evanescent spurious waves. These could be the source of destructive cross modes and would in particular be unwanted when using surface elevation signals at the paddle front for hydrodynamic feedback to and active absorption system. On the other hand the new criterion permits a wider frequency range for very small obliqueness and increasingly much so for the more sophisticated segment type.

Both progressive and evanescent spurious waves should be recognized in surface elevation measurements at the paddle front for active absorption. In this connection aliasing of short-wave energy due to finite segment width and in particular due to other sources should be recognized. Means of reducing the aliasing problem have been discussed. A combination of better spatial resolution of elevation measurements and time-domain low-pass filtering in the active absorption system is suggested.

Generation of Double Peak Directional Wave 
by Dual Mode Snake-Type Wave Maker

Tetsuya Hiraishi and Katsuya Hirayama

Abstract

The dual-mode snake-type directional random wave maker has been developed in order to reproduce double peak directional waves, long period waves and directional waves with oblique principal wave direction. Results from a series of wave generation tests demonstrate that the dual-mode generator system is suitable to reproduce the target wave conditions with good accuracy.

Introduction

Various types of directional random wave generators have been developed to reproduce experimentally the wave condition similar to real sea waves. Especially, the recent development of active absorption theories of multi-directional waves (Ito, K., et al., 1996) has made it possible to install a directional wave generator with three generator faces (multi-face directional wave generator) (Ito et al., 1996, Hiraishi et al., 1995). A wide area in the basin is possible to be employed as the effective test area (Funke et al., 1987) by the establishment of multi-face wave generators.

Meanwhile, recent systematic and large-scale field observation (Nagai et al., 1993) demonstrates that the directional spectrum observed offshore often has two peaks at different directions as shown in Figure 1. Each peak direction is usually apart more than 90° each other. Such double-peak directional waves are considered to be composed of 'wind wave' component with relatively short periods and 'swell' with long periods. Reproduction of double-peak directional waves is of great importance to carry out experimental study on the stability of offshore structures and navigating ships. A new type directional wave maker has been developed for the generation of double peak directional waves as well as the multi-face wave generation with active absorption (Hirakuchi et al., 1992).

Moreover, long period waves with period longer than swell become important for estimation of the stability and safety of floating structures and large cargo vessels moored to berths. Because long waves' periods are near to natural periods of the system composed of a ship and mooring ropes, their

1 Wave Laboratory, Port and Harbour Research Institute, Nagase 3-1-1, Yokosuka, Japan 239-0826
penetration into harbors may cause large surge motion and breakage of the ropes by resonance (Hiraishi, 1997a). Periods of long waves range usually from 50 to 100 s in prototype (Hiraishi, 1997b). The main energy of long period waves propagate as free waves from the offshore area. A standard spectrum of long period waves has been proposed to estimate influences of long period waves in harbor planning (Hiraishi, 1998).

The proposed profile of a standard spectrum includes the short period components (wind wave and swell) and long period wave components. The spectral density of long period wave components is constant and its level is determined by results in field observation. In order to reproduce the long period components evaluated in the standard spectrum, relatively large stroke are necessary. The newly developed directional wave maker should be also applicable to the generation of combination of short and long period waves.

The following section describes the applicability of the newly developed wave generator with segmented piston-type paddles.

Frame of Dual-Mode Snake-type Wave Generator

Figure 2 shows a conceptionsal design of the directional wave generator with double faces and with double operation modes. The generator consists of 50 and 30 drive shafts respectively on each side. Figure 3 shows cross section of the wave maker. The generator is named "Dual-mode snake-type wave generator" because of two generator faces. A paddle 130cm height is attached
Figure 2  Arrangement of Dual-mode serpent type wave generator

Figure 3  Cross section of wave generator unit
between adjoining two drive shafts. Wave paddles are displaced by the mechanical screw shaft system. The maximum water depth and wave height for generation is 100 and 30cm respectively. Each wave paddle is equipped with two wave sensors on its surface to measure the variation of water surface elevation at the front to carry out the active wave absorption for obliquely propagating waves (Ito et al., 1996). The side walls of the basin are covered with the wave dissipating layer composed of the wave energy absorbing material (Takayama et al., 1991). The wave energy absorbing layer is available to prevent waves reflected at the side walls without the generator faces and generated backward paddles. The generation face indicated below in Fig.3 is named "First face", and the right face "Second face" Photograph 1 shows the overview of the dual-face serpent type wave generator.

The operation modes consist of the following two methods:

(a) Multi-face Mode:

The both of First and Second faces are operated as a single generator system to make single-peak multi-directional waves. The same target directional wave condition is given to the both faces with different phases. The paddle displacements in the both faces are synthesized according to the single summation model (Takayama and Hiraishi, 1989) for directional wave generation. During operation, the re-reflected oblique wave components from wave paddle are prevented by the active wave absorption motion. The effective test area is much larger than a single face directional wave maker. The image of effective test area in the dual-mode generator is shown in Fig.3 as an area surrounded with broken lines.

A connecting removable pannel is attached at the corner between First and Second faces. The width of the pannel is variable corresponding to the positions of the adjoining paddles in the both faces. The position-shifted
(b) Separation Mode:

Each of First and Second face is operated in the different target wave condition in the separation mode. Therefore, First face wave maker is available to the generation of directional wind waves with short periods when Second face generates ‘swell’ with longer periods. For the generation, both faces are controlled with the active absorption function. The double peak directional waves are reproduced in the separation mode. Long period waves with the periods longer than those in swell are generated in the separation mode. A rigid pier was installed at the corner connecting First and Second face. Therefore, no wave is induced due to motion of the corner part. The pier becomes a guide walls to the both faces. In the separation mode, both faces are applicable to reproduce the directional waves with long period wave components by employing the long driving shafts of 100cm.

Experimental Evaluation of Applicability of Wave Generator

(a) Absorption of Oblique Wave

One of the important functions of the generator is the active absorption function to oblique waves. Ito et.al.(1996) has already investigated the applicability of three-point measurement array system for active absorption. We investigated applicability of the active absorption system of the dual-mode serpent type wave generator operated in the separation mode. Figure 4 shows location of wave gages to measure incident and reflected wave heights. In the test, the oblique regular waves were generated from Second face. The wave angle in the basin is defined as the normal propagation angle from First generator face becomes 0°. The wave angle normal to Second face is defined to be 90°.

In the oblique wave absorption test, the angle of waves generated from Second face became 135°. Figure 5 shows the wave profiles measured in the wave gages W.1 and W.2 in case of the operation in the active absorption. The target wave height and period in the generation signal is 5.0cm and 2.0sec respectively. The water depth is 60cm. The generated wave train may be reflected on First surface if the active absorption function does not work. In Fig.5 for the active absorption methods, the wave heights measured at W.2 were small. Their heights were about 0.5cm in the maximum, which corresponds to 10% of the height of waves measured at W.1. Therefore, the active absorption function for oblique waves is suitable in the basin.
Figure 4 Measurement point of oblique wave profile

Figure 5 Wave profile measured at W. 1 and W. 2

(b) Directional Waves Generated in the Multi-face Mode

Figure 6 shows the arrangement of wave gage array to analyze the directional spectrum. The extended maximum entropy principle (EMEP, Hashimoto et al., 1994) was mainly employed to obtain the directional spectrum from simultaneously measured wave profiles. The Bretschneider–Mitsuyasu type frequency spectrum and the Mitsuyasu–type directional function (Goda, 1985) is applied to form the directional spectrum. Directional spectrum is given generally by,

\[ S(f, \theta) = S(f) G(\theta; f) \]  

(1)
The Bretschneider–Mitsuyasu spectrum \( S(f) \) is expressed as,

\[
S(f) = 0.257H_v^3T_{1/3}(T_{1/3})^{-3} \exp[-1.03(T_{1/3})^{-4}]
\] (2)

where \( f, T_{1/3}, H_v \) represents the frequency, significant wave height and period. The Mitsuyasu directional function is expressed as,

\[
G(\theta; f) = G_0 \cos^{2.5} \left( \frac{\theta}{2} \right)
\] (3)

where \( \theta \) is the azimuth measured from counterclockwise from the principal wave direction. \( G_0 \) is a constant to normalize the directional function.

\[
G_0 = \left( \int_{\theta_{\text{max}}}^{\theta_{\text{min}}} \cos^{2.5} \left( \frac{\theta}{2} \right) d\theta \right)^{-1}
\] (4)

The parameter \( S_{\text{max}} \) represents the angular spreading parameter (Goda and Suzuki, 1975) which may give the energy concentration to the principal wave direction. The smaller \( S_{\text{max}} \) corresponds to the wider spreading of wave energy. Goda and Suzuki (1975) has suggested the parameter \( S_{\text{max}} \) becomes about 10 for the normal wind waves. The location of wave gage array is included in the effective test area for First face generator.

Figure 7 shows comparison of the target and experimentally obtained contour map of directional spectrum at the center of basin for waves generated in condition of \( S_{\text{max}}=5 \). In the figures, the vertical and horizontal axis represents the frequency and wave direction respectively. During generation, Second face is working as the wave dissipating layer with active absorption. If the obliquely propagating components may be reflected at Second face, the obtained directional function may be distorted by the effect of obliquely reflected waves in energy contour map for wave with oblique principal direction because of the wide spreading of wave energy with \( S_{\text{max}}=5 \). The obtained directional spectrum contour in Fig.7 becomes symmetric, which means the effects by reflection waves are negligible. The obtained wave spectral contour in the left figure becomes similar to the target ones in the right. Therefore, the dual mode snake–type wave generator is applicable to reproduce directional waves with wider spreading of wave energy.

One of the large advantages to employ the dual–mode snake type wave generator is the possibility to make directional waves with oblique principal wave direction \( \theta_p \). We tested the applicability of generation of directional waves with the principal direction of \( \theta_p = 45^\circ \). In order to generate the directional waves of \( \theta_p=45^\circ \), the appropriate motion of connecting board is inevitable.
Figure 8 shows comparison of the target and obtained directional spectrum in contour expression. The right and left figure represents the target and obtained wave energy contour map respectively. The obtained contour becomes similar to the target one. The peak of spectrum density appears at $\theta = 45^\circ$ at the both cases of target and obtained contours. We compared the directional function at the peak frequency to have a detail check of the principal wave direction. The input parameter $S_{\text{max}}$ for synthesizing wave signals is 25.

Figure 9 shows the directional function at the peak frequency $f_p$ of the target and obtained directional waves. In the figure, the profiles analyzed in

![Figure 6](image6.png)

**Figure 6** Measurement point of directional wave spectrum generated in multi-face mode

![Figure 7](image7.png)

**Figure 7** Comparison of measured and target directional spectrum in energy contour map
Figure 8  Measured and target directional spectrum for case of oblique principal wave direction

Figure 9  Comparison of directional function at peak frequency $f_p$ of measured and target waves with oblique principal direction
EMEP and in the Extended Maximum Likelyfood Method (EMLM) (Isobe, 1988) are indicated in the dot and broken line respectively. The directional function profile analyzed in EMEP agrees with the target one indicated in the solid line. Meanwhile, the profile analyzed in EMLM shows the peak lower than the target. The method of EMEP is more appropriate to obtain the directional spectrum from the wave data simultaneously measured in a wave gage array than the method of EMLM. The peak angle of obtained directional function agrees well to the target of 45°. The multi-face mode operation of the serpent type wave generator is applicable to generate the directional waves with the oblique principal wave direction expressed as $\theta_p = 30^\circ, 45^\circ$ and so on.

(c) Long Period Wave

In order to investigate the efficiency and stability of floating structures in oceans, the reproduction of long period waves is important. Figure 10 shows comparison of the obtained and target frequency spectrum of uni-directional random waves including the long period wave components. The uni-directional waves were generated from Second face and First surface was employed as a fixed guide wall. In the figure, the solid line represents the target frequency spectrum. The target spectrum has a constant level in the long period wave range. The broken line represents the experimentally obtained spectrum. The

![Figure 10: Measured and target wave frequency spectrum including short and long period wave component](image-url)

**Figure 10**  Measured and target wave frequency spectrum including short and long period wave component
obtained spectrum agrees well with the target even in the range of long period waves. Therefore, the generator with long stroke is expected to be applied to generate the uni-directional wave condition with free long period wave components in the experimental basin.

(d) Double-peak Directional Wave

In the evaluation tests, wind waves are generated by First-face and swell by Second face. The propagating angle of wind waves and swell is 0° and 90° respectively. The target period of generated wind waves and swells is 1.33 and 2.0 sec respectively. Figure 11 shows the measured directional spectrum at the basin center. The target conditions of wind wave and swell component is indicated as 'WAVE-1' and 'WAVE-2' respectively in the upper-left side table. In the figure, the two-dimensional directional spectrum is represented. The two-dimensional directional spectrum is given by,

\[ G_\theta(\theta) = \int_0^\pi S(\theta,f)df \quad (5) \]

The profile analyzed in EMEP has peaks at the same to the target angles. The energy level of swell component at \( \theta = 90^\circ \) is slightly smaller than the target. In the wind wave components generated by First surface, the obtained peak angle and energy level agrees well with those of target spectrum. Therefore, the double-peak directional waves can be reproduced with good accuracy in dual-face directional wave generator.

Figure 12 shows comparison of the directional function at the peak frequency of swell components. The directional function's peak angle and energy level agree with those of target respectively. For the wind wave components, the peak angle slightly differs from the target, however, the differences are less than 20°. Considering the directional function at peak frequency, the dual-mode snake type wave generator is expected to be applicable to generate double-peak directional random waves.

Figure 13 shows the frequency spectrum measured at the gage W.1. In the case for Fig.13, the target significant wave period for wind waves and swell is 1.0 and 2.2 sec respectively. In the figure, the target frequency spectrum is represented in the solid line and the obtained by the broken line. The frequency spectrum of generated waves agrees well with the target spectrum and they have spectral profiles with two peaks typically observed in the double-peak directional wave condition in the field (Nagai et al., 1993). The good agreements in the directional function and frequency spectrum profile between the measured and target double-peak directional waves demonstrate the possibility of the generator to reproduce the complicated sea conditions composed of wind waves, swell and long period waves.
Figure 11 Comparison of two dimensional directional spectrum of measured and target double-peak directional wave

Figure 12 Comparison of directional function at $f_p$ of measured and target double-peak directional wave
CONCLUSIONS

A Dual-mode snake type wave generator has been newly developed. The generator is composed of First and Second faces and is operated in the multi-face and the separation mode. The generator is available to reproduce:

i) directional waves with oblique principal direction,
ii) long period waves,
iii) double-peak directional waves,

Extreme Multi-Directional Waves

T.B. Johannessen¹ & C. Swan²

Abstract

The present paper concerns the nonlinear description of large waves in which the wave energy is spread in both the frequency and the directional domains. A new series of experimental observations are briefly described in which a large number of deep-water focused wave groups were generated in a large wave basin. For each combination of frequency bandwidth and directional spread the intensity of the wave, measured in terms of a linear amplitude sum, was varied from a near-linear condition to the limit of incipient wave breaking. Comparisons between this laboratory data and a new fully nonlinear, multi-directional, numerical model are used to validate the modelling procedure and highlight the importance of the directionality. In particular, the results show that for a given linear amplitude sum an increase in the directional spread leads to a reduction in the magnitude of the nonlinear wave-wave interactions. Conversely, the maximum nonlinear crest elevation, observed just prior to the onset of wave breaking, increases with the directional spread assuming the frequency bandwidth remains constant. From a practical perspective, the paper demonstrates that an accurate representation of an extreme ocean wave requires a model that incorporates nonlinearity, unsteadiness and directionality. The present model satisfies these requirements.

1. Introduction

It is well known that the largest ocean waves, which are by definition highly nonlinear, do not arise as part of a regular wave train, but occur as individual events within a random or irregular sea. Indeed, field data confirms that the most severe storms are typically characterised by a relatively broad-banded frequency spectrum implying a

¹ Senior Engineer, Kvaerner Oil and Gas, Oslo, Norway
² Reader, Department of Civil and Environmental Engineering, Imperial College, London, SW7 2BU.
wide distribution of energy within the frequency domain. As a result, the largest waves, arising due to the constructive interference or focusing of the frequency components (see Tromans et al., 1991), only arise at one point in space and time and are thus commonly referred to as transient waves. More recently, it has also been shown that such waves will have a significant distribution of energy in the directional domain. For example, Jonathan et al. (1994) have considered several severe storms arising in the northern North Sea, and show that the wind waves have a typical directional spread corresponding to a normal distribution with a standard deviation of 30°.

Having established that large wave events are nonlinear, transient and directional, it is perhaps surprising to note that the commonly applied design solutions either include the nonlinearity or the unsteadiness, but seldom both, and typically neglect the underlying directionality. For example, a linear random wave theory provides a first approximation to the dispersive properties of a sea state, and hence models the transient nature of individual waves, but entirely neglects the nonlinearity. In contrast, a nonlinear regular (or steady) wave theory, either based upon a Stokes’ expansion (Fenton, 1985) or a stream function formulation (Dean, 1965), includes the nonlinearity but neglects the unsteadiness. More recently, an alternative design solution proposed by Baldock and Swan (1994) includes both the nonlinearity and the unsteadiness, and has been shown to be effective in a wide range of water depths (Smith and Swan, 1996). However, even in this latter model the omission of directionality represents a serious restriction.

Evidence as to the importance of directionality in the evolution of large waves has recently come to light in comparisons between two-dimensional laboratory data and field measurements. For example, Baldock et al. (1996) provides observations of extreme two-dimensional wave groups, produced by the focusing of energy due to frequency dispersion. These results show that the nonlinear wave-wave interactions may increase the maximum crest elevation by as much as 30% above that predicted by the linear sum of the underlying wave components. In contrast, the analysis of field data (Rozario et al., 1993) suggests that while nonlinearity is undoubtedly important, the corresponding increase in the maximum crest elevation is substantially less than 30%. An obvious explanation for this difference lies in the directionality of the field data.

The present paper will address this point and will provide comparisons between a fully nonlinear, multi-directional, wave model and a new series of laboratory observations undertaken in a large wave basin. Section 2 commences with a brief description of the numerical model; while section 3 outlines the nature of the experimental study. Comparisons between these results are provided in section 4, with particular attention given to both the maximum crest elevations and the underlying water particle kinematics. In section 5 some additional numerical calculations are provided to examine the nature of the nonlinear wave-wave interactions arising in the vicinity of the largest wave crests, and in particular their dependence upon the directionality of the wave field. The paper concludes in section 6 by highlighting the practical implications of the present study.
2. Numerical Modelling

The numerical model outlined within this section is an extension of the two-dimensional time-stepping formulation originally proposed by Fenton and Rienecker (1980). In its original form this scheme represents one of several potential flow solutions, each capable of accurately modelling the evolution of a two-dimensional nonlinear wave train (e.g. Longuet-Higgins and Cokelet, 1976, Dold and Peregrine, 1984, and Dommermuth et al., 1988). In the context of the present study the scheme outlined by Fenton and Rienecker (1980) was adopted because, although it is less efficient (computationally) than many of the other schemes, it is expandable to three-dimensions. Assuming that a fluid flow is both inviscid and irrotational a velocity potential, \( \phi \), defined by \( \mathbf{u} = \nabla \phi \), where \( \mathbf{u} \) is the velocity vector, can be expressed as:

\[
\phi(x, y, z; t) = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \left( A_{nm} \cos(nk_x x) + B_{nm} \sin(nk_x x) \right) \frac{\cosh(k_{nm}(z + d))}{\sinh(k_{nm}d)}
\]

where \((x, y, z)\) are the usual Cartesian co-ordinates with \( z \) defined vertically upwards from the mean water level, \( z = -d \) defines the bottom boundary, and \((x, y)\) are the horizontal co-ordinates which are orientated such that the \( x \)-axis defines the mean wave direction (see section 3 below). Furthermore, \( k_{mn} = \sqrt{(nk_x^2 + mk_y^2)} \) where \((k_x, k_y)\) define the large fundamental length scales, \( \lambda_x = 2\pi/k_x \) and \( \lambda_y = 2\pi/k_y \), over which the solution is assumed periodic in the \( x \) and \( y \) directions respectively. Likewise, the free surface elevation, which must be similarly periodic in space, is given by:

\[
\eta(x, y, t) = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \left( A_{nm} \cos(nk_x x) + B_{nm} \sin(nk_x x) \right)
\]

Both equations (1) and (2) utilise the fact that the experimental wave fields are symmetric in \( y \) (see section 3 below), although this is not a formal necessity. Furthermore, the series coefficients \( A_{nm}, B_{nm}, a_{nm}, b_{nm} \) are assumed to be functions of time only. In this form the velocity potential satisfies the governing field equation \( \nabla^2 \phi = 0 \) representing mass continuity and the bottom boundary condition corresponding to a flat impermeable bed \( (\phi = 0 \text{ on } z = -d) \). The remaining constraints represent the nonlinear free surface boundary conditions (both kinematic and dynamic) evaluated on the water surface \( (z = \eta) \). After some re-arrangement these can be written as:

\[
\Phi_t = -g \eta + \frac{1}{2} \left( \Phi_x^2 + \Phi_y^2 + \Phi_z^2 \right)
\]

\[
\eta_t = \Phi_z - (\Phi_x \eta_x + \Phi_y \eta_y)
\]

where \( g \) is the acceleration due to gravity.
Longuet-Higgins and Cokelet (1976) were the first to note that in this form the right hand side of equations (3) and (4) involve no time derivatives. As a result, if an initial spatial description of the water surface elevation, \( \eta(x,y,z) \), and its associated velocity potential, \( \phi(x,y,z) \), are known, it is possible to time-march the solution such that \( \eta \) and \( \phi \) can be defined at all subsequent times. In the present cases the initial conditions, at some early time prior to the occurrence of a large wave event, can be calculated from linear or second-order theory on the basis that the wave group is fully dispersed. To apply this procedure it must be assumed that no significant wave energy lies above the truncation wave numbers \( N_k \) and \( M_k \). Provided this is indeed the case, equations (3) and (4) can be solved at \( 2N(M+1) \) spatial locations in order to define the time derivatives of the coefficients \( \left( A_{m_n}, B_{m_n}, a_{m_n}, b_{m_n} \right) \). This corresponds to a grid spacing equal to half the wavelength of the shortest wave component. Once the time derivatives of the coefficients have been determined, the solution can be time-stepped using the Adams, Bashford, Moulton formulation (Gear, 1971) and the solution procedure repeated.

Within the present scheme the time derivatives of the free surface coefficients may be evaluated using a Fast Fourier Transform (FFT). Unfortunately, the time derivatives of the velocity potential are functions of \( \eta \), and must be evaluated by solving a set of linear simultaneous equations using a lower-upper (LU) matrix decomposition. As a result, the numerical formulation is time consuming, and requires parallel computing power for the steepest directional wave cases. The present numerical formulation was implemented on a Fujitsu AP1000 parallel computer. On this machine the most computationally demanding wave groups may be evaluated accurately with run times of up to 16 hours. Full details of this numerical procedure are given in Johannessen and Swan (1998a).

3. Experimental Investigation

The purpose of the experimental study was to investigate a large number of focused wave groups in which the underlying wave components were spread in both the frequency and the directional domains. The experimental work was undertaken in the wide wave basin at the University of Edinburgh. This facility has a plan area of 25m x 11m, a uniform water depth of 1.2m, and is equipped with 75 numerically controlled wave paddles each 0.3m wide. To limit the occurrence of reflected waves, large passive absorbers were located at the downstream end of the wave basin and along one of the side-walls. A sketch showing the layout of this facility is given on figure 1.

Preliminary tests confirmed that within this facility waves could be generated within a directional range of \( \theta = \pm 45^\circ \) and a frequency range of \( 0.6 \text{Hz} \leq f \leq 1.7 \text{Hz} \). Within the present tests, three separate frequency spectra were investigated. The first corresponds to a broad-banded spectrum (denoted by case B), and includes waves within the period range \( 0.6s \leq T \leq 1.4s \); while the second corresponds to a narrow-banded spectrum (denoted by case D), and includes waves within the period range \( 0.8s \leq T \leq 1.2s \). The third spectrum (denoted by case C) is intermediate to cases B and D and corresponds to a period range of \( 0.7s \leq T \leq 1.3s \). Within each of these cases a large number of wave
components, of equal amplitude, were uniformly spaced within the respective period range. This gives a corresponding amplitude spectrum, $a(f)$, which, in each case, decays according to $f^{-2}$ (figure 2a).

Figure 1: Experimental apparatus.

Figure 2a-b: Experimental amplitude spectra. (a) In the frequency domain, (b) In the directional domain.
To quantify the directional spread of the wave components, the Mitsuyasu spreading parameter, $s$, was employed, where the directional amplitude spectrum, $a(\theta)$, is defined by:

$$a(\theta) = \lambda \cos^s (\theta/2)$$

(5)

where $\theta$ denotes the wave direction measured relative to the $x$-axis and $\lambda$ is a normalising coefficient. For each of the three frequency spectra, 6 directional spreads were adopted ($s=\infty$, 150, 45, 25, 10, 4); where $s=\infty$ corresponds to a unidirectional wave field, $s=150$ a very long-crested wave field, and $s=4$ a short-crested wave field. Graphical representations of these directional spreads are given on figure 2b. For each combination of frequency and directional spread a minimum of 4 input amplitude sums ($A$) were employed, where $A$ corresponds to the linear sum of the component wave amplitudes. To address the widest range of wave conditions, the input amplitudes for each case were increased from $A=20$ mm (corresponding to a linear wave group) to $A=A_{\text{max}}$, where the latter values correspond to the onset of incipient wave breaking. In total some 88 individual wave groups were considered. A full discussion of this data is outside the scope of the present paper and is given in Johannessen and Swan 1998b.

For each of the wave fields described above, the surface elevation was sampled at 45 spatial locations in the vicinity of the linearly predicted focus position ($x=0$, $y=0$). These measurements were made using standard surface-piercing wave gauges that are estimated to have an accuracy of $\pm 1$ mm. In addition, for a number of selected wave cases (15 in total) the $x$-component of the horizontal wave-induced velocity was recorded at closely spaced vertical elevations underneath the measured position of the maximum crest elevation. This velocity data was obtained using a one component laser Doppler anemometer that was estimated to have an accuracy of $\pm 2\%$.

As part of our preliminary measurements, considerable time was spent calibrating and validating the wave basin. The usual problems associated with wave reflections, which are notoriously strong in many wave basins, did not pose a significant problem in the present study. This is because the nature of a focused wave group is such that the waves are almost completely dispersed when they reach the downstream absorbers. Consequently, any energy reflected or scattered from the wave absorbers is negligible when compared with the energy density in the vicinity of the extreme event. The success of the calibration process is clearly demonstrated in figures 3a-3c. These results concern the narrow-banded wave spectrum (case D), with the largest possible directional spread ($s=4$, corresponding to a very short-crested sea state), and an input amplitude of $A=20$ mm. This represents the smallest input amplitude and should, therefore, be in good agreement with a linear model. Figure 3a concerns the time-history of the water surface at the focus position, $\eta(t)$; figure 3b describes a spatial description of the surface elevation along the centreline $\eta(x)$; and figure 3c describes the horizontal velocity profile, $u(z)$, beneath the maximum crest elevation. In all cases the measured data is in very good agreement with the linearly predicted behaviour. Agreements of this type are essential if one is to interpret the nature of the nonlinear wave-wave interactions arising with larger input amplitudes.

4. Discussion of Results

Figures 4a-4c again concern the narrow-banded spectrum (case D) with a large directional spread (s=4), but now corresponds to a highly nonlinear wave group with an input amplitude of A=93mm. In this case the measured data is compared to the results of the numerical model (section 2), a linear solution, and a second-order solution based upon the wave-wave interactions identified by Longuet-Higgins and Stewart (1960) and further considered by Sharma and Dean (1981). In each of these figures the results of the numerical model are in very good agreement with the measured data. Furthermore, figure 4a, which concerns the time-history of the water-surface elevation measured at the position of the maximum crest elevation, suggests that the largest wave crest occurs after the linearly predicted focus event (t=0). Similarly, figure 4b, which presents a spatial description of the water surface elevation at the time of the maximum crest elevation, suggests that the largest wave crest also occurs downstream of the linearly predicted focus (x=0). These shifts in the focus time and position are consistent with those observed in unidirectional wave groups (Baldock et al., 1996). Furthermore, comparisons between the measured data and both the linear and the second-order solutions, suggest that significant energy shifts occur in the vicinity of the largest wave event.

In figure 4c comparisons with the horizontal velocity data, recorded beneath the largest wave crest, again confirm that the numerical model provides the best description of the measured data. However, the data also appears to be in reasonable agreement with the second-order solution, with the exception of a 15% under-prediction that arises very close to the water surface. This latter result is in marked contrast to the unidirectional data presented by Baldock et al. (1996).

To further examine the success of the numerical model, figure 5 again concerns frequency spectrum D, with s=4 and A=93mm. In this figure, time-histories of the water surface elevation are presented at four spatial locations: x=0, or the linearly predicted focus position; x=0.6m; x=1.2m, which is the observed position of the maximum crest elevation; and x=1.8m. At each of these locations the numerical model is in good agreement with the measured data, and is shown to be very different from either the linear or the second-order solutions.

To isolate the effect of the directional spread, two further comparisons were undertaken. Firstly, the linear sum of the component wave amplitudes generated at the wave paddles were held constant (A=55mm), and the global maximum crest elevations measured for a range of directional spreads for each frequency spectrum. This data is presented on figure 6a. Comparisons between these results clearly suggest that the effect of introducing a directional spread is to dramatically reduce the maximum crest elevation. Furthermore, the bulk of this reduction occurs between a unidirectional wave group (1/s=0, where s is again the Mitsuyasu spreading parameter) and a long-crested wave group with small directional spread. Since the local increase in the crest elevation (above that predicted by linear theory) arises due to the nonlinear wave-wave interactions, and almost certainly involves a shift of energy into the higher frequencies, the data presented
Figure 5: Evolution of a nonlinear wave group.

- experimental data; o numerical model; ---- linear theory;
  ---- second-order theory.
on figure 6a represents a weakening of the nonlinear wave-wave interactions due to the underlying directionality. Although further analysis of this data is required, it is believed that this effect is caused by a reduction in the absolute wave front steepness and curvature. This is due to the fact that in a directional wave this steepness can be distributed around the perimeter of the wave, and is not constrained in one plane. If this is indeed the case, it clearly explains why extreme unidirectional waves (generated in the laboratory) appear more nonlinear than those observed in the open ocean.

The data presented on figure 6a also has implications for the limiting wave height. If increasing directionality reduces the nonlinearity, this perhaps implies that a larger linear amplitude sum (A) is required to induce incipient wave breaking. To examine this point, a second set of comparisons were undertaken in which the amplitude of the wave components generated at the wave paddles was progressively increased until there was evidence of incipient wave breaking in the vicinity of the focus position. This allowed the variation in the maximum possible crest elevation, for a given underlying frequency bandwidth, to be recorded as a function of the directional spread. This data is presented on figure 6b and clearly suggests that the limiting crest elevation increases with the directional spread. Indeed, figure 6b suggests that the difference between a unidirectional wave group (1/s=0) and a short-crested wave group (with 1/s=0.25) can lead to an increase in the limiting crest elevation by as much as 25%.

Figures 6a-6b: Maximum crest elevation. (a) A=55mm, (b)A=A_{max}. 
5. **Nonlinear Interactions and Energy Shifts**

To examine the nature of the nonlinear wave-wave interactions and the associated energy shifts, the numerical model was used to simulate the narrow-banded spectrum (case D) with four different directional spreads. In each of these cases the input amplitude sum (A) was such that the largest waves were on the limit of wave breaking. Details of the directional spreads and the input amplitudes are given in Table 1.

Table 1: Numerical simulations

Applying a Fast Fourier Transform to the numerically predicted time-history of the water surface elevation, \( \eta(t) \) at the position of the largest wave crest allowed the frequency content to be accurately defined. The results of this analysis, applied to each of the wave cases given on Table 1, are present on figure 7. In addition, the solid line indicated above the power spectra defines the linear input of the wave components generated at the paddles (for \( s=4, A=93\text{mm} \)), while the dashed lines indicated on the right hand side of the figure define the range of the second-order frequency sum terms.

![Figure 7: Frequency spectra.](image-url)
These results clearly suggest that there is a ‘loss’ of energy from within the linear input range. However, this energy is not primarily transferred to the second-order frequency-sum terms, as one might expect, but appears as significant energy at frequencies just larger than the upper limit of the linear input range (i.e. \( f \approx 1.3 \text{Hz} \)). Furthermore, although the energy distribution within the linear input range varies between the four cases, due to the different linear amplitude sums; the energy immediately outside the linear range appears to be virtually identical. Given that each of these waves is on the limit of incipient wave breaking, it would seem plausible that the growth of energy within these high frequencies plays a major role in defining the characteristics of extreme wave groups. Furthermore, the energy level indicated on figure 7 appears to represent a threshold value beyond which wave breaking will occur. Detailed analysis of these observed energy transfers is provided by Johannessen and Swan (1998b).

6. Concluding Remarks

The nonlinear evolution of a large number of directional wave groups has been investigated experimentally, and a new numerical model shown to be in good agreement with the laboratory data. The principle advantage of this numerical model is that it represents the only solution that rigorously includes nonlinearity, unsteadiness and directionality. Furthermore, it does not require a detailed description of the nonlinear water surface profile (something which is seldom available in practice) since it is based upon a linear description of the underlying wave spectrum. From a practical point of view the results presented in this paper confirm that for a given linear crest height (or input amplitude sum, \( A \)) and frequency bandwidth, the effect of increasing directionality is to significantly reduce the nonlinearity of a wave group. This explains the significant differences between two-dimensional wave flume experiments and field data. However, as a consequence of this reduced nonlinearity, the maximum nonlinear crest elevation that may be obtained, before further growth is limited by wave breaking, increases with the directionality of the wave field provided the frequency bandwidth is held constant. This has important implications for the specification of a ‘design’ wave, and highlights the need to fully include the nonlinearity, unsteadiness and directionality in both model testing and numerical calculations.

Low Frequency Surf Zone Response to Wave Groups

Merrick C. Haller 1, Uday Putrevu 2, Joan Oltman-Shay 2, and Robert A. Dalrymple 1

Abstract

The nearshore potential vorticity balance of Bowen and Holman (1989) is expanded to include the forcing from wave group-induced radiation stresses. Model results suggest that the forcing from radiation stresses can drive oscillations in the longshore current that have a spatial structure similar to linear shear instabilities of the longshore current. In addition, the forced response is nearly resonant when the forcing has scales \((k, \sigma)\) similar to the linearly most unstable mode. Thus, we suggest that the wave groups may provide an initial perturbation necessary for the generation of shear instabilities of longshore currents and enough forcing to overcome frictional damping.

Analysis of data from the SUPERDUCK (1986) field experiment reveals that wave groups were present on days when strong low frequency surf zone motion (shear waves) existed. In addition, some of these groups are shown to have periods and longshore spatial structures comparable to the observed shear wave motions suggesting that incident wave groups are present on this open coast with the required spatial and temporal structure to initiate the low frequency oscillations in the longshore current.

1 Introduction

Shear waves are low-frequency \((10^{-3} \text{ to } 10^{-2} Hz)\) vortical motions of surf zone currents. The kinematics of these waves are closely linked to the mean longshore current (Oltman-Shay et al., 1989). Bowen and Holman (1989) suggested that shear waves are generated due to a shear instability of the mean longshore current. Subsequent

work (see Shrira et al., 1997 for a complete set of references) has shown that the shear instability model is capable of explaining many of the observed characteristics. However, the instability theory fails to predict the following two features — both related to the effects of bottom friction. First, the instability theory predicts a low-frequency cutoff below which no shear waves are generated (Dodd, 1994; Shrira et al., 1997). Second, instability theory predicts that shear waves should be damped by friction on planar beaches. Both of these predictions are at odds with observations at Duck, NC and Santa Barbara (Leadbetter), CA beaches (Dodd et al., 1992).

Recently, the work of Shrira et al. (1997) showed that both shortcomings of the instability theory could potentially be explained by an explosive instability mechanism. In particular, they showed that shear waves that would otherwise be damped out by friction could grow due to resonant triad interactions provided their initial amplitudes exceed a critical value. However, how such initial (small amplitude) shear waves are generated remains unexplained. In this paper, we show that the direct forcing from wave groups could provide the initial amplitudes required by the resonant interaction model of Shrira et al. (1997). This mechanism follows earlier work by Hamilton and Dalrymple (1994).

The outline of this paper is as follows. Section 2 discusses the theoretical formulation. An example calculation in section 3 shows that direct forcing from wave groups leads to a larger response at shear wave scales, which may provide the initial amplitudes required by the resonant interaction model. In section 4 we analyze data from the SUPERDUCK experiment and find that there is evidence that the forcing required to set up these initial oscillations existed. Data from the experiment at Leadbetter Beach (a planar beach) could not be used in the wave group analysis because the offshore wave array was too short to resolve wave group scales. The final section is devoted to a few concluding remarks.

2 Theoretical formulation

The depth-integrated, short-wave-averaged equations of horizontal momentum read

\[
\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = -g \frac{\partial \eta}{\partial x} + \tau_x - \frac{\tau_{b_{xx}}}{\rho h},
\]

\[
\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} = -g \frac{\partial \eta}{\partial y} + \tau_y - \frac{\tau_{b_{yz}}}{\rho h},
\]

where \(u\) and \(v\) are depth-averaged horizontal velocities in the cross-shore \((x)\) and longshore \((y)\) directions, respectively; \(\eta\) is the free surface displacement; \(g\) is the acceleration due to gravity; \(\tau_{b_\alpha} (\alpha = x, y)\) are the bottom shear stresses; and \(h\) is the total depth (it includes wave-induced set-down and set-up). Finally, \(\tau_x\) and \(\tau_y\) represent the forcing due to the radiation stresses.
We consider the case of a long straight coast. We separate all quantities into steady and time varying parts and assume that steady terms are independent of the longshore coordinate, e.g.,

\[ \eta(x, y, t) = \eta_0(x) + \eta_1(x, y, t), \]  

(3)

where \( \eta_1 \) represents the small \( (|\eta_1| \ll |\eta_0|) \) modulation effect of the wave groups. All other quantities are defined in an analogous fashion. We assume that the steady current has only a longshore component. That is, we assume

\[ u = u_1(x, y, t) \]  

(4)
\[ v = V(x) + v_1(x, y, t). \]  

(5)

Following Dodd et al. (1992), we parameterize the bottom friction using a linear law. In particular, we assume that \( \tau_{xz} = \rho \mu u \) and \( \tau_{yz} = \rho \mu v \), where \( \mu = \frac{2C_f U_0}{\eta} \) is the friction coefficient, and \( U_0 \) is the amplitude of the orbital velocity of the incident short waves and is assumed constant.

These definitions for velocity and bottom shear stress are now substituted into equations (1) and (2). The resulting equations are separated into steady and unsteady parts. We find that the steady problem reduces to the familiar cross-shore momentum balance determining wave set-up and set-down, and the longshore momentum balance governing the generation of the mean longshore current. The unsteady problem is of particular interest here since it governs the dynamics of the low frequency motion in the nearshore.

Following Bowen and Holman (1989), we make the rigid lid assumption, thus, the nondivergence of the continuity equation allows us to introduce a transport stream function, \( \Psi \), such that \( \Psi_y = -u_1 h \) and \( \Psi_x = v_1 h \) (subscripts \( x, y \) denote partial differentiation). This leads to the following equation for the stream function:

\[
\left( \frac{\partial}{\partial t} + V \frac{\partial}{\partial y} + \frac{\mu}{h} \right) \left( \frac{\Psi_x h_x}{h^2} - \frac{\Psi_y h_y}{h} - \frac{\Psi_{xx} h_x}{h} \right) + \Psi_y \left( \frac{V_x}{h} \right) + \frac{\mu h_x \Psi_x}{h^3} = \frac{\partial \tau_{x,1}}{\partial y} - \frac{\partial \tau_{y,1}}{\partial x},
\]

(6)

where subscripts denote partial differentiation (except for the definition of \( \tau_{\alpha,1}, \alpha = x, y \)). For simplicity, we concentrate on periodic solutions. Hence, we assume that the stream function may be expressed as

\[ \Psi = \Re \{ \psi(x) e^{i(kt-\sigma t)} \}, \]

(7)

where \( \sigma = 2\pi/T \) \( (T = \text{wave period}) \) represents the wave frequency and \( k = 2\pi/L \) \( (L = \text{longshore wavelength}) \) is the wavenumber. The amplitude of the stream
function, $\psi(x)$, is in general complex. In addition, the forcing due to radiation stresses will also be assumed proportional to $e^{i(ky-\sigma t)}$, and expressed as

$$\frac{\partial \tau_{x,1}}{\partial y} - \frac{\partial \tau_{y,1}}{\partial x} = \Re \{ F(x, k) e^{i(ky-\sigma t)} \}.$$  

(8)

Note that the homogenous version of (6) ($F = 0$) is an eigenvalue problem. Nontrivial solutions for $\psi$ exist only for certain values of the eigenvalues, $\sigma$. These frequencies represent the natural frequencies of the system. If the system is forced at (or near) these frequencies, then there is the potential for a large response.

In general, the natural frequencies of (6) are all complex, whereas the forcing frequency has to be real. Therefore, the possibility of exact resonance is somewhat limited for this system. However, there is still a potential for a large response if the frequency mismatch is small.

### 3 An example calculation

In this section we present an example calculation that illustrates the nature of the forced response. First, we need to specify the longshore current, the wavenumber and frequency of the forcing, and the friction factor. Wherever possible, we choose these parameters such that they are representative of those measured at Santa Barbara's Leadbetter beach. We make this choice because, as mentioned in the introduction, Dodd et al. (1992) found that the shear instability theory predicts that shear waves should be damped out by friction on this planar beach.

![Figure 1: Cross-shore variation of the modeled longshore current (solid line) using the model of Longuet-Higgins (1970), circles represent measured data from Leadbetter Beach, Santa Barbara, February 4, 1980. Note: $x = 0$ is the position of the mean shoreline.](image)
Figure 2: a) Linear growth rate and the b) dispersion relation for the most unstable modes of the homogeneous system for the longshore current profile shown in Figure 1.

The longshore current profile used in our calculations (along with the measured current values) is shown in Figure 1. To first get an estimate of the natural frequencies of the system, we solve the inviscid, homogeneous version of (6) (i.e. $\mu = 0$, $F = 0$). The results are shown in Figure 2. Figure 2a shows the growth rates of the most unstable mode for each wavenumber and Figure 2b shows the real part of the frequency. Dodd et al. (1992) obtained a similar dispersion curve and stated that it compares reasonably well with observations, however, they also found that the inclusion of realistic bottom friction will damp out the instability. Thus, the observations are unlikely to have resulted due to an instability of the longshore current profile. Here we investigate whether radiation stress forcing could have provided the small amplitude shear waves required of the explosive instability mechanism.
Figure 3: The variation of kinetic energy (KE) as a function of the forcing frequency for a forcing spatial scale of \( k = 0.0566 \text{ rad/m} \). Shown is the forced system response (equation 6, \( F = 0.05h_x e^{-(x-x_b)^2} \)) for the frictional dissipation coefficient: \( \mu = 0.00372 \).

Shira et al., 1997. To do that we have to first specify the forcing function. In our example calculation (6), we use

\[
F = -0.0025 i g k h_x e^{-(x-x_b)^2},
\]

where \( x_b \) is the distance from the mean shoreline to the breaker location. We obtained this form of the radiation stress forcing term based on the stationary forcing used by Bowen (1969, see Eq. 32). In its present form, we have assumed the forcing to be longshore propagating and have limited the forcing amplitude to a region very close to the zone of initial breaking. This was done in order to include in a simple way the tendency for the breaker line to oscillate in the cross-shore direction with the modulations of the incident waves which destroys most wave grouping shoreward of the initial breaking region. However, the results are not sensitive to the form of the forcing decay away from the breaker line.

As a measure of the forced response, we use the total kinetic energy averaged over a wavelength and period and integrated over \( x \):

\[
\overline{KE} = \int_0^\infty \frac{1}{TL} \int_0^T \int_0^L \frac{(u_1^2 + u_2^2)}{2} dy \, dt \, dx.
\]

The variation of shear wave kinetic energy, as a function of forcing frequency, is shown in Figure 3 for a forcing spatial scale of \( k = 0.0566 \text{ rad/m} \). This \( k \) value has the largest growth rate in the unforced, homogeneous system (Figure 2a) and the value of \( \mu = 0.0269 \text{ m/s} \) is suggested by the model-data comparisons of Dodd.
Figure 4: a) Velocity distribution from solution of homogeneous system, $k = 0.0566 \, \text{rad} \cdot \text{m}^{-1}$. b) Velocity distribution from solution of forced system including dissipation, $k = 0.0566 \, \text{rad} \cdot \text{m}^{-1}$, $\mu = 0.00372$.

It is important to note that, though not shown here, the $\mu$ value does not alter the frequency of the maximum kinetic energy (0.0027 Hz); the peak frequency consistently falls near the resonant frequency of the unforced system ($\sigma/2\pi = 0.0027 \, \text{Hz}$ in Figure 2b). A comparison of the forced and free shear wave velocity fields is presented in Figure 4a and b. Figure 4a shows the velocity field of the free, undamped, shear instability ($\mu = 0, F = 0$). The magnitude and pattern of this field is remarkably similar to the forced, damped shear wave field (Figure 4b, $\mu = 0.00372$, $F$ as defined in eq. 9). Note that the longshore phase difference between the two figures is arbitrary.

Figures 3 and 4 suggest an alternative shear wave generation mechanism for a
beach such as Leadbetter where shear waves cannot be generated from an instability of the longshore current (assuming realistic frictional damping). These figures show that given forcing with spatial and temporal scales near those of the shear waves, the system can preferentially excite frequency-wavenumber scales that satisfy the free system and generate wave patterns with similar magnitude and form to the free, undamped shear waves. It is then plausible that these forced motions could resonantly grow via the explosive instability mechanism suggested by Shrir a et al. (1997).

4 Field Data Analysis

The results from the calculations in Section 3 suggest that if wave group energy is present near the most unstable shear wave mode (from linear theory) in frequency-wavenumber space, the possibility of a near-resonant surf zone response to this forcing exists and an explosive instability generation can occur. In the following, field data from the SUPERDUCK experiment are analyzed for the presence of radiation stress forcing at the scales of shear waves.

The SUPERDUCK experiment was conducted by the U.S. Army Corps of Engineers in October of 1986 at Duck, North Carolina. The beach at this site trends NW-SE and is centrally located within a 100-km barrier spit (Crowson et al., 1988). The beach slope is typically 1:20 in the surf zone and decreases to 1:200 offshore. In addition, the bathymetry is characterized by a three-dimensional bar system which often becomes linear during storms (Lippmann, 1989).

Surf zone velocity records were obtained from a longshore array of ten Marsh-McBirney bidirectional electromagnetic current meters located approximately 55 m offshore from the mean shoreline in the trough of the bar (Oltman-Shay et al., 1989). The array had a minimum sensor separation of 10 m and total longshore extent of 510 m.

The incident wave climate was obtained by a linear array of 10 bottom-mounted pressure sensors located approximately 800 m offshore in 8 m water depth and spanning 255 m in the longshore direction. The array elements had a minimum sensor separation of 5 m. The wave fields measured during the experiment were highly variable but often consisted of longer period swell from the south along with shorter period wind-generated waves from the north and the surf zone usually extended approximately 100 m from the shoreline. Data for all sensors were sampled at 2 Hz during 4-hour measuring periods centered about high and low tides and the 4-hour tidal range was ~ 20 cm with a shoreline excursion of 2 m.

The work of Oltman-Shay et al. (1989) showed that the vortical motions, due to shear instabilities of the longshore current (or shear waves), reside in the lower end of the infragravity band (0.001 < f < 0.01 Hz) with longshore wavelengths 100 < L < 1000 m. Typical two-dimensional (f,k) spectra of measured surf zone velocities (u,v) from the SUPERDUCK data set contain a ridge of energy spanning this range of frequencies and wavelengths.
Offshore Wave Groupiness

To look for radiation stress forcing with similar scales to shear waves, we examine the incident wave envelopes associated with wave groups using the pressure records from the offshore (8 m depth) array. Each of the pressure records were divided into sections 2048 s in length, demeaned and then detrended (using a least squares quadratic fit). The pressure records were converted to records of water surface elevation using the pressure response factor according to linear theory. The wave records were then bandpass filtered (0.06 – 0.30 Hz) to remove low (infragravity) frequency and high (wave harmonics, turbulence) frequency energy outside of the wind wave band. Time series of wave envelopes were computed from the filtered wave records using the Hilbert transform method (Melville, 1983). The specific data runs used in the present analysis represent a subset of the entire SUPERDUCK data set. Data selection was based on whether energetic shear wave motions were present in the nearshore current records during the data run and by data quality and availability considerations. The incident wave conditions during the data runs used herein are considered typical for the field site. If a groupiness factor for each record is defined by $\sqrt{2 \cdot \sigma_A / \bar{A}}$, where $\sigma_A$ is the standard deviation of the wave envelope, $\bar{A}$ is the mean, and $GF$ varies from 0 $\to$ $O(1)$ then the average $GF$ for these records is $\sim 0.75$; suggesting significant wave grouping was present offshore of the surf zone on the days analyzed herein. In addition, previous work using data from this field site has indicated that wave grouping can persist into the surf zone (List, 1991; Haller and Dalrymple, 1995).

Offshore Wave Groups and Surf Zone Shear Waves

Phase and coherence between the wave group time series of the offshore pressure sensors were calculated and plotted, as a function of sensor alongshore separation, to estimate the longshore scale and propagation direction of the incident wave groups. The offshore wave group phase and coherence plots were then compared with the (surf zone) shear wave phase and coherence plots computed from the longshore current records. All cross-spectra were computed using the standard Fast Fourier Transform method after first dividing each time series into 13 ensembles 2048 s in length with 50% overlap and tapering with a Hamming window. The number of spectral components was then reduced by half using a 2-point average resulting in a resolution of $\Delta f = .001$ Hz and 44 degrees of freedom (d.o.f.).

Using the longshore current records, the range of frequencies which contained spatially coherent shear waves was determined for each data run (usually 0.001 – 0.006 Hz). Typically, the shear waves demonstrated strong coherence for longshore distances of $\sim 200$ m. Oltman-Shay et al. (1989) showed that cross-shore current records also indicated coherent shear waves of similar scale. However, offshore wave group spatial coherence was found to typically be less than 100 m. The tendency for wave groups to have low spatial coherence is not unexpected since wave grouping is likely a random process and is therefore broad banded in wavenumber at a given frequency. This is in contrast to shear waves, which are the result of
a resonant process and tend to be narrow banded in wavenumber. In addition, wave group spectra tend to exhibit more statistical uncertainty than the original wave/current records and very long wave records are needed in order to obtain truly stationary estimates of wave grouping (Nelson et al., 1988). To limit the processing of incoherent data, the offshore array was limited to six closely spaced sensors with a maximum lag of 90 m. The nearshore array was similarly limited to five sensors with a maximum lag of 130 m.

Using the wave group cross-spectra, the range of existing shear wave frequencies were searched for the presence of spatially coherent wave groups. Relatively few
cases were found in which the offshore wave groups were clearly shown to have scales similar to shear waves. In many cases the wave groups did not exhibit significant coherence. In addition, there were cases where coherent wave groups existed but with scales different from shear waves and those will not be discussed here. The cases which best demonstrate that wave groups can exist offshore at similar spatial scales as shear waves are shown in Figures 5-6.

For comparison, the relative phase and coherence vs. longshore lag of the shear waves is plotted together with those of the offshore wave groups. The slope (+/-) of phase vs. lag indicates the direction of propagation (upcoast/downcoast) for the given motion and the figures show that the offshore wave groups at these frequencies were propagating in the same direction as the shear waves. The comparisons of coherence indicate that wave groups lose coherence at much shorter distances than shear waves (~ 50 m). The 85% confidence interval is also shown for reference (dashed line). The relative phase for lags which did not demonstrate coherence above the 85% confidence level are not plotted.

**Surf Zone Wave Groups and Shear Waves**

The computations in Section 3 assumed that incident wave heights had a longshore progressive 2-D structure near the breaker line that swiftly decayed shoreward due to wave breaking. It is expected that any wave grouping present at the offshore array would persist and possibly increase in amplitude towards the breaker line due to shoaling. However, since the offshore array was about eight surf zone widths ($x_b$) from the shoreline, the cross-shore current records measured at the nearshore array (located ~ $x_b/2$) were also examined for any evidence of wave grouping persisting shoreward of the breaker line. To do this, it was necessary to assume that, in the range of incident wave frequencies ($0.06 < f < 0.3$ Hz), the auto-spectra of the $u$ velocities have the same shape as sea surface elevation spectra at the same location, since there were no pressure sensors in the nearshore (longshore) array. Figure 7 indicates this assumption is reasonable. The choice of cross-shore velocities for the wave group analysis was made because the $u$ auto-spectra were more energetic at incident wave frequencies due to the near normal incidence of the waves at this nearshore location. The $u$ velocity records were converted to surf zone wave (current) envelopes in the same manner as the offshore wave records (neglecting the pressure to water surface conversion).

A result from the phase and coherence analysis of the surf zone wave envelopes is shown in Figure 8. The linear phase progression in the longshore direction demonstrates that a certain amount of wave grouping was present in the surf zone during the data run taken the morning of October 18. It should be noted that the bandpass filtering operation was tested with different windows (Hamming, Hanning) to rule out the possibility of leakage of the energetic shear wave motions into the incident wave band during filtering. The offshore wave envelopes did not show strong spatial coherence at this frequency suggesting that wave grouping was locally induced during this data run.

The results of the cross-spectral analysis for this subset of SUPERDUCK data
Figure 7: Comparison of auto-spectra of cross-shore velocity and water surface elevation from nearly co-located surf zone sensors. Data is from October 18 at 1140 EST.

Figure 8: Comparison of (a) relative phase vs. lag, (b) coherence vs. lag for shear waves (o) and surf zone wave groups determined from cross-shore velocity records (x) at frequency 0.003 Hz. Dashed line represents 85% confidence interval, 44 d.o.f.. Data is from October 18 at 1140 EST sensors LX 1-5.

demonstrate that wave grouping at shear wave and other scales can exist in the field. The calculations presented in Section 3 indicate that the response to such forcing will occur primarily at shear wave scales and that the velocity field will closely resemble the velocity field under free shear waves. Thus, it is likely that direct forcing from wave groups might provide the initial perturbations required for shear wave growth.
5 Conclusions

The inclusion of a forcing term due to wave group induced radiation stresses in the nearshore potential vorticity balance of Bowen and Holman (1989) shows that incident wave groups can force a surf zone response similar to shear waves. If the forced response has similar scales \((k, \sigma)\) to the linear most unstable mode, the response is nearly resonant.

Field data were examined for the presence of wave group forcing with scales similar to the observed shear waves. Analysis of phase and coherence shows that wave grouping of shear wave scales was sometimes present during the SUPERDUCK experiment. The results suggest that wave grouping can exist to perturb the nearshore velocity field at temporal and spatial scales of the shear instabilities.

In addition, it is interesting to view the results presented here in light of the recent work of Shira et al. (1997). Their work indicates that the range of unstable scales for shear waves excited by the explosive instability mechanism is much larger than that determined by the linear instability mechanism. This suggests that the presence of any of a wide range of coherent wave group spatial scales can force any of a wide range of initial instabilities to feed the explosive instability mechanism. Also, they show that the explosive instability occurs, even when all linear instabilities are damped by bottom friction, as long as the initial perturbations exceed a certain amplitude.

The wave group forcing mechanism presented here and the results of Shira et al. (1997) provide a possible explanation for the observation of shear wave instabilities at Leadbetter Beach, CA. Dodd et al. (1992) found that linear instability theory did not predict instabilities for that beach unless the frictional damping was decreased by decreasing the friction coefficient, \(c_f\), to unrealistic values. In light of the above, it can be hypothesized that the shear waves observed at Leadbetter Beach may have been generated via the explosive instability mechanism with wave groups providing the initial instabilities.

Wave Dynamics and Revetment Design on a Natural Reef

Thomas Jensen¹, Peter Sloth¹ and Vagner Jacobsen¹

Abstract

In connection with hydraulic studies of a new coastal resort development on the south-east coast of Bali in Indonesia, a three-dimensional (3D) physical model study was carried out. The study was aimed at the determination of the wave transformation over a shallow natural reef in front of the resort and for the design of the rubble mound revetments to be built for coastal protection. Due to the heavy wave breaking on the reef, physical model tests were the only viable avenue for obtaining a reliable design of the revetment structures located behind the shallow reef area. The stability of the armour layer as well as the overtopping of the revetments were equally important aspects of this part of the study, since not only should the resort be protected against storm waves, but visitors should also be able to comfortably visit the coastal areas during more normal wave conditions.

This paper mainly concerns the wave dynamics on the reef. Due to the limited water depth the wave conditions were dominated by heavy wave breaking and the associated release of the bound long-period wave components in the wave groups of the incident wave train. These long-period wave components caused a dynamic water level set-up with long-period variations in front of the revetments (surf beats). The depth-limited wave conditions on the reef and the dynamic water level set-up had major influence on the evolution of damage and overtopping of the revetments and made the design of the revetments particularly complex.

Introduction

Bali Turtle Island Development Project is a major tourism-related coastal development project located on the south-east coast of Bali, Indonesia. The site location is shown in Figure 1. The project involves around 3.7 km$^2$ of land reclamation constructed on an existing reef facing the Lombok Strait, which connects to the Indian Ocean. The completed reclamation will include three artificial lagoons, four artificial pocket beaches, six artificial headlands and a causeway/bridge connection to the Balinese mainland. Figure 2 shows the existing and the reclaimed Turtle Island and Figure 3 shows an aerial photo of the land reclamation in progress.
Figure 2. The existing and the reclaimed (light shaded) Turtle Island.

Figure 3. Aerial photo of the reclamation works in progress.
To aid the contractor, Penta Ocean Construction Company, in the detailed design works for Bali Turtle Island Development, hydraulic investigations were carried out by Danish Hydraulic Institute (DHI). The overall project involved the following aspects:

- Determination of environmental design conditions (waves, water levels, etc)
- Hydraulic design of the primary revetment protection using physical modelling
- Assessment of impact upon navigation
- Spreading of dredged material
- Water quality impact assessment
- Coastal impact assessment (beach stability and sediment morphology)
- Environmental monitoring during dredging.

This paper concerns the physical modelling used for design and optimisation of the revetments and for studying the wave transformation over the reef in front of the extended Turtle Island. An overview of the development project as a whole and detailed information on the other aspects of the project are given in the accompanying ICCE '98 paper by Driscoll et al (1998) as well as in Driscoll et al (1997) and Sloth et al (1997).

Physical Modelling

One of the challenges faced in the project was the design of the revetments used as coastal protection of the headlands. Due to the heavy wave breaking and complex wave dynamics on the reef in front of the revetments, the design procedure was far from trivial. Physical model tests were the only viable avenue for obtaining a reliable design of the revetment structures located behind the shallow reef area. The physical model tests comprised the following two tasks:

- Wave transformation tests
- Revetment stability and overtopping tests

In addition to predicting the necessary information on the wave conditions on the reef for revetment design, the results of the wave transformation tests were used to calibrate numerical models used for the prediction of eg beach stability (see Driscoll et al, 1998).

The purpose of the revetment stability and overtopping tests was to optimise the design of the revetments to be built as coastal protection of the headlands on the extended Turtle Island. This optimisation involved the determination of the required size of stones for the revetment armour as well as the determination of the optimum crest height of the revetments to obtain both an aesthetic design and acceptable levels of overtopping discharge. Not only should the resort be protected against storm waves, but visitors should also be able to admire the scenery at sea and comfortably visit the area during more normal wave conditions. Therefore, both stability and overtopping were equally important aspects of the investigations in the physical model.
The model was constructed in scale 1:40 in one of DHI's wave basins, and covered a prototype area of approximately 1200 m by 1200 m. The extent of the physical model is shown in Figure 4. Based on detailed local surveys, the reef was modelled to detail out to a water depth of 13 m relative to Port Datum (PD–LAT) corresponding to 14.3 m relative to mean sea level (MSL). Figure 5 shows a sketched cross-section of the reef, and Figure 6 shows the overall layout of the physical model.
All model tests were carried out with long-crested, irregular waves (Pierson-Moskowitz spectra) with significant wave heights ($H_{m0}$) ranging from $H_{m0} = 1$ m to $H_{m0} = 5$ m and peak periods ($T_p$) of between $T_p = 8$ s and $T_p = 17$ s. Two different water levels were used in the tests, one corresponding to mean high water spring (+1.1 m MSL or approximately 1.5 m of water depth on the reef), and one corresponding to the 25-year design water level (+2.1 m MSL or approximately 2.5 m of water depth on the reef). Two different angles of wave incidence were investigated in the tests, 135°N (head-on waves) and 155°N (oblique waves). Only the results obtained with the 25-year design water level (+2.1 m MSL) and head-on waves (135°N) are addressed in this paper. The applied wave conditions at the boundary of the physical model were based on an extensive numerical model study of the nearshore wave climate, in which offshore wave conditions from the Indian Ocean were transformed into the area of interest. This aspect of the study is described further in Sloth et al (1997). The following extreme wave conditions were identified:

- 1-year condition: $H_{m0} = 3.0$ m, $T_p = 12.7$ s
- 10-year condition: $H_{m0} = 4.0$ m, $T_p = 12.7$ s
- 100-year condition: $H_{m0} = 4.5$ m, $T_p = 12.7$ s
During the tests, waves were measured at nine locations on the reef (see Figure 6). The incident waves were determined by reflection analysis using an array of five wave gauges in front of the reef. In the revetment stability and overtopping tests, the overtopping discharge and the stability of the revetment armour were monitored for a number of different revetment configurations (size of armour stone, crest height and crest width). A sketch of the general layout of the revetments test section is shown in Figure 7. Figure 8 shows a photo of the revetment test section.

Figure 7. Cross-section of revetment test section.

Figure 8. Photo of revetment test section.
Wave Dynamics on the reef

During severe wave conditions, a relatively large rise in the mean water level on the reef was observed. This stationary water level set-up increased with the incident significant wave height ($H_{m0,i}$) reaching approximately 0.4 m for the 25-year wave conditions.

In addition to this stationary water level set-up, a dynamic set-up was also observed on the reef. When the individual waves in a wave group break, the bound long waves associated with the wave groups are released on the reef as free long waves. These long waves cause a dynamic water level set-up or surf beat. Figure 8 shows wave spectra of surface elevations measured outside the reef (WG12) and on the reef (WG2) for four different incident wave conditions. The long-period waves on the reef are seen clearly in the spectra obtained at WG2 as substantial energy at frequencies below 0.05 Hz (periods (T) longer than 20 s).

![Figure 8. Measured wave spectra on the reef and outside the reef.](image-url)
The dynamic water level set-up caused by the long-period waves on the reef is also seen in the time series in Figure 9, which shows the measured surface elevations at WG12 (outside the reef) and at WG2 (on the reef). For WG2 low-pass filtered and high-pass filtered signals (for T < 25 s and T > 25 s) are also shown. It is seen from Figure 9 that for this incident wave condition, the amplitude of the dynamic set-up is occasionally in the order of 1 m.

It should be noted that even though the model (as any other physical model) cannot be deemed totally free of model effects, the observed dynamic set-up was proven not to be significantly influenced by eg seiching of the laboratory basin or re-reflections from the wave paddle.

Figure 9. Time series of surface elevations on the reef ($H_{m0,i} = 4.0$ m, $T_p = 12.7$ s).
Prototype wave measurements presented by Sulaiman et al (1994) for the reef off Sanur Beach just north of Turtle Island on the Balinese mainland (see Figure 2) also showed the presence of long-period wave components on the reef.

Since the long-period waves on the reef were generated by the wave breaking, the amount of long-period energy on the reef increased with the incident significant wave height ($H_{m0,i}$). This can be seen in Figure 10, which shows the standard deviation of the long-period wave components ($T > 25$ s) at WG13 on the reef as a function of $H_{m0,i}$. The standard deviation has been derived from time series low-pass filtered at 0.04 Hz.

![Dynamic Set-up on the reef (T > 25 s)](image)

Figure 10. Standard deviation of the dynamic set-up on the reef versus $H_{m0,i}$.

So far only the long-period wave components ($T > 25$ s) have been addressed, but also the short-period wave components ($T < 25$ s) were analysed. The wave parameters presented in the following have been derived from time series where all energy with periods longer than 25 s has been removed by high-pass filtering. For the three different wave periods investigated in the wave transformation tests, Figure 11 shows wave parameters ($H_{m0}$, $H_{max}$, $H_{mean}$ and $T_z$) at WG13 on the reef as a function of the incident significant wave height, $H_{m0,i}$.

$H_{m0}$ is the spectral estimate of the significant wave height on the reef (calculated as four times the standard deviation of the surface elevation). The three parameters $H_{max}$ (the maximum wave height), $H_{mean}$ (the mean wave height) and $T_z$ (the mean zero-crossing period) have been estimated from zero-crossing analysis of the high-pass filtered time series.
It should be noted that due to the altered wave height distribution on the reef, the presented $H_{m0}$-values on the reef do not necessarily correspond to $H_{1/3}$, which is often used to define the significant wave height as the average of the highest one-third of the waves in a sea state.

From Figure 11, it is seen that irrespective of the incident wave period, the mean zero-crossing period on the reef approaches a constant value of approximately 6 s. This general reduction in wave period is a consequence of the heavy wave breaking occurring over the reef. The changes in wave period and reduction of wave energy on the reef can also be seen from the recorded surface elevations and the wave spectra on the reef (Figures 9 and 8, respectively). The wave spectra on the reef cover a wider range of frequencies than the incident spectrum. The field measurements at Sanur Beach by Sulaiman et al (1994) also showed broader wave spectra and reduction in wave period on the reef.

Figure 11 also shows that the incident wave periods have minor influence on the wave heights on the reef. The effect of depth-limited waves is clearly illustrated, since the maximum wave height on the reef is reached for an incident significant wave height of approximately $H_{m0,i} = 2$ m, corresponding to less than the 1-year wave condition outside the reef.

Figure 11. Wave conditions at WG13 on the reef (short-period wave components).
Consequences of Wave Dynamics on Revetment Design

The following two phenomena induced by the shallow reef were particularly crucial with respect to design and optimisation of the revetment structures:

- The depth-limited wave condition
- The dynamic water level set-up

Depth Limited Waves – Size of Revetment Armour Stones:

The maximum wave condition on the reef was reached for a significant wave height outside the reef of approximately $H_{m0} = 2$ m, which is substantially lower than the 1-year wave condition outside the reef.

As a consequence of this depth-limited wave condition on the reef, the more frequent wave conditions will impose almost the same wave impacts on the structure as rare events such as the 25-year design condition. This means that the damage induced by the 25-year condition outside the reef will also be induced by a ‘normal’ wave condition with a return period of less than one year. Since the damage to the revetment armour is cumulative, it was of paramount importance to weigh the consequences of the depth-limited waves into the considerations of an appropriate design criterion for the damage to the revetment armour. Furthermore, the depth-limited wave conditions eliminated any use of empirical formulae for predicting the necessary size of the armour stones to be used on the revetments.

Basically, the depth-limited wave conditions cause the design waves for the structure to occur more often, and as a consequence of this, the probability of failure of the structure within a given lifetime increases. Therefore, a ‘no damage’ criterion was adopted for the design of the revetment armour. This means that no progressive damage to the revetment armour should occur for the maximum wave condition on the reef. This ‘no damage’ design criterion led to the recommendation of revetment armour stones somewhat larger than expected.

Dynamic Set-up – Revetment Crest Dimensions:

With the highest amplitudes of the dynamic set-up (surf beat) exceeding 1 m for the most severe wave conditions, it is evident that the long wave energy on the reef was a crucial parameter as regards the overtopping on the revetments. Any use of existing empirical formulae for predicting the consequences of a given revetment profile with respect to overtopping was eliminated due to these special conditions.

Basically, the dynamic set-up on the reef results in increased water level in front of the structure, and thereby a lower revetment free board. Hence, the overtopping is increased dramatically. The results of the model tests led to the recommendation of a revised crest height and crest width of the revetments to meet the requirements of acceptable overtopping.
The effect of long waves on the design of coastal structures has previously been addressed by eg Kamphuis (1996) and Kamphuis (1998), the latter also presented at ICCE '98. Kamphuis argues that the presence of long waves and the resulting increase of water level in front of a structure cause an increase of the design wave height for a structure in shallow water. Essentially, this means that in areas with more typical slopes towards the coastline the design wave height in shallow water is not only a function of the water depth at the toe of the structure but also a function of the long wave activity. However, this is not seen from the results of the present model study (see Figures 10 and 11) because of the relatively wide and shallow reef.

Conclusions

In connection with hydraulic studies of the Bali Turtle Island Development Project, 3D physical modelling was carried out for determination of the wave transformation over the shallow reef in front of the new resort and for the design of the rubble mound revetments to be built for coastal protection.

In the design of the revetments, stability of the armour layer as well as overtopping of the revetments were equally important aspects, since not only should the resort be protected against storm waves, but the aesthetic value of the design should also be taken into account.

The physical model study showed that the maximum wave height on the reef was limited by the water depth on the reef and that this wave height corresponded to less than a 1-year wave condition outside the reef. This depth-limitation eliminated the use of any empirical formulae for predicting the necessary size of the stones for the revetment armour, and made the implementation of a 'no damage' design criterion essential.

The presence of significant amounts of long wave activity (dynamic set-up) was identified on the reef as a consequence of the heavy wave breaking and the associated release of bound long waves into free waves. This dynamic set-up caused a significant increase of the overtopping on the revetments and prevented the use of existing empirical formulae for overtopping prediction.

The present case study is a perfect example of a study in which the use of physical modelling as a design tool was essential in order to develop a sound and viable solution to a problem which offhand may seem rather simple to the design engineer.

The study also illustrates how important non-linear wave phenomena such as bound long waves released by wave breaking can be for the design of a coastal structure. For many years the importance of these non-linear wave phenomena on for example movements of floating bodies and seiching in harbours has been recognised, but their effect on the design of coastal structures such as rubble mound revetments and breakwaters in shallow water has to some extent been neglected. The present study clearly shows that when designing coastal structures in shallow water, the effect of long waves should be taken into account.

RESTON, VIRGINIA 20191-4400
Abstract: This proceedings, Coastal Engineering 1998, contains over 270 papers presented at the 26th International Conference on Coastal Engineering which was held in Copenhagen, Denmark, June 22-26, 1998. The proceedings is divided into five parts: 1) characteristics of coastal waves and currents; 2) long waves and storm surges; 3) coastal structures; 4) coastal processes and sediment transport; and 5) coastal, estuarine, and environmental problems. The individual papers include such topics as the effects of wind, waves, storms, and currents as well as the study of sedimentation, erosion, and beach nourishment. Special emphasis is given to case studies of completed engineering projects. With the inclusion of both theoretical and practical information, these papers provide the civil engineer and professionals in related fields with a broad range of information on coastal engineering and coastal processes affecting design and operations in the coastal zone.

LONG WAVES IN FLUME EXPERIMENTS

J. William Kamphuis, M.ASCE

Abstract

This paper addresses the influence of long waves on the design wave height of structures in shallow water. Wave heights, wave periods, depths of water at the structure, time of wave measurement, length of the wave-guides were all varied in 29 series of two-dimensional hydraulic model tests. The results indicated that long wave activity is an important design parameter for breakwaters in shallow water. The wave height at breaking and long wave reflection from the structure are the primary parameters influencing long wave activity.

Introduction

This paper is based on two-dimensional hydraulic model tests to determine the design wave for structures in shallow water. An earlier paper - Kamphuis (1996) reported that design wave height was not simply related to the depth of water at the structure toe, as is normally assumed. Design depth was found to be the sum of the water depth and a fraction of the breaking wave height. A preliminary expression for design depth was given as:

$$d_{des} = d_r + 0.1H_b$$  \hspace{1cm} (1)

1 Faculty of Civil Engineering, Delft Technical University, Netherlands; Department of Civil Engineering, Queen's University, Kingston, Ontario, Canada, K7L 2R4. Tel: 613-545-2148, E-Mail: kamphuis@civil.queensu.ca
where \( d_T \) is the depth of water at the toe of the structure. The wave height, \( H \) is determined from the wave spectrum \( (H_{m0}) \) and \( H_b \) is the breaking \( H_{m0} \) wave height. This is a significant increase in design depth for structures in shallow water, considering that \( H_b \) can be much greater than \( d_T \). Further research is now underway to determine the actual physical causes that modify design depth. Part of that research is the analysis of long wave activity near the structure and that is the basis of the present paper.

The Tests

An initial set of tests was performed in 1995. The experimental setup is shown in Fig. 1. Water level fluctuations were recorded for 16 sets of conditions (Table 1). Each test consisted of water level records at 64 locations (one stationary probe and a rack of 9 moving probes placed at 7 locations). Six to 11 different incident wave spectra with offshore wave heights \( (H_{m0}) \) varying from 0.04 to 0.18 m were tested. Subsequent to these tests, other data sets were obtained in 1997 to provide better estimates of wave setup, to determine the increase of long wave activity with time, to isolate the influence of length wave guides and to test the actual breakwater stability. Each of the 1997 tests used 16 wave gauges at fixed locations. The test parameters for all tests are summarized in Table 1.

Table 1
Test Conditions

The numbers refer to the 1995 tests (each with 6 to 11 incident wave heights). (*) denotes 1997 tests (each with 3 incident wave heights). (t) denotes tests for time dependence (at 2, 5, 10 and 20 minutes). (G) denotes tests with different lengths of wave guides (27, 18 and 9 m).

The basic 1997 tests were a repetition of selected 1995 tests, except that a more realistic model breakwater was used. In 1995 a large, high rubble mound structure was used that could not be damaged and was overtopped only by the highest waves. The 1997 the rubble mound addressed stability and was therefore more realistic, sustained damage and was not so high. Three offshore wave heights were run for each 1997 test. To determine time dependence of the long wave, the waves were measured beginning at 2, 5, 10 and 20 minutes after the start of the test for Tests 11, 12 and 16. The standard measurement time used in all other tests was to begin recording of the waves 5 minutes after the start of the test. Finally, the effect of the lengths of the wave guides were tested for Tests 12,
Figure 1 - Experimental Setup

Figure 2 - Wave Height Profile
15 and 16, using the original guide length of 27.1 m and shorter lengths of 18.3 and 9.5 m (thus roughly 27, 18 and 9 m).

**Primary analysis**

Preliminary analysis of each data set consisted of frequency analysis. For the 1997 tests wave setup was determined. Zero-crossing analysis was performed for some of the 1995 records. Figure 2 presents the frequency analysis of Test 7. Test results for six offshore incident wave heights are shown, varying from 5.4 to 14.4 cm. It is seen that $H_{mo}$ decreases after breaking and then increases close to the structure. This increase in $H_{mo}$ is due to long wave activity. To investigate this further, the long- and short wave components of the signal needed to be separated. Wave spectrum analysis showed that a minimum in the wave spectrum occurred at about $f_p/2$ as shown in Fig. 3. This was used to filter the water level signal to produce separate short wave and long wave signals (Figs. 4 and 5).

**Wave Setup and Seiche**

The first physical process that could modify the design depth in Eq. 1 would be wave setup. The measured wave setup at the structure, however, was much less than $0.1 H_b$ as shown in Fig. 6 and thus the depth modification in Eq. 1 cannot be explained by wave setup alone. The details of the wave setup analysis will be presented in another paper.

During the tests, it was noticed that the highest short waves at the structure always coincided with the crest of the long wave and therefore it can be expected that the long wave has an influence on the design depth. Particularly because the wave generator did not have capability to absorb long wave energy, it is first necessary to see if any of the long wave activity is due to resonance of certain frequencies with the wave flume (seiche). The natural frequencies of the wave flume in Fig. 1 were therefore determined by eigenvalue analysis. These natural periods were found to be as in Table 2. The peak periods of the long waves were found to be unrelated to these natural periods. There were no peaks in the measured long wave spectra at either the fundamental frequency or its harmonics. Clearly seiche was not a consideration in these tests.

Figure 3 - Separation of Long- and Short Wave Spectra at $f_p/2$

Figure 4 - Short Wave Height Profile
Figure 5 - Long Wave Height Profile

Figure 6 - Measured Wave Setup at Structure Toe
Long Wave Profiles

The long wave profiles (Fig. 5) can be adequately described by combining an absorbed and a standing long wave. At the structure:

\[ H_{LW} = H_{LW,I} + H_{LW,R} = H_{LW,A} + H_{LW,S} = H_{LW,A} + 2H_{LW,R} \]  \hspace{1cm} (2)

where \( H_{LW} \) is \( H_{mo} \) of the long wave, I denotes incident, R is reflected, A is absorbed and S is standing.

To keep it simple, we used the approach of Lamb (1932) who solved the linearized long wave equations to show that the standing long wave envelope over a sloping bottom may be approximated by a Bessel function. This approach is also illustrated by Shah and Kamphuis (1996). For the present tests, the expression needed some adjustment because \( d_T \) was not zero. The absorbed long wave portion is assumed to consist of a bound long wave up to the breaking point and a free long wave up to the structure. The shoaling expression for the bound long wave of Longuet-Higgins and Stewart (1964) was found to overestimate the shoaling, because the 1:50 foreshore slope does not allow the shoaling long wave to reach equilibrium. The free long wave was found to obey Green's Law. Offshore, the trough of the bound long wave accompanies the highest waves in the group, but close to the structure, the crest of the long wave accompanies the highest waves. This represents a 180° shift from outside the breaker to the shore, noted also by other authors. The detailed work on the long wave profiles will be presented in another paper.

Long Waves at the Structure

To determine the influence of long waves on structural stability and design conditions, we investigated the long wave action at the toe of the structure. The long wave height there may be expressed as:

\[ H_{LW} = f(H_b, d_s, T, g, \mu, \rho, m, t, L_g) \]  \hspace{1cm} (3)

where \( H \) refers to \( H_{mo} \), \( H_{LW} \) is the long wave height at the structure, \( H_b \) is the breaking wave height, \( T \) the peak period of the short wave, \( g \) the gravitational acceleration, \( \mu \) and \( \rho \) are the dynamic viscosity and density of the water, \( m \) is the slope of the foreshore, \( t \) is time and \( L_g \) is the length of the wave guide. Note that \( d_b \) was not used in this function, since it is closely related to (not independent of) \( H_b \) as shown in Fig. 7.

Dimensional analysis of Eq. 3 yields:
Figure 7 - Breaking Wave Height and Breaker Depth

Figure 8 - Long Wave Height at the Structure and Breaking Wave Height
\[
\frac{H_{LW}}{H_b} = \phi \left( \frac{H_b}{gT^2}, \frac{d_s}{H_b}, \frac{\sqrt{gH_bH_b}}{\mu / \rho}, \frac{m, T}{T}, \frac{I_g}{gT^2} \right)
\]  

(4)

where the ratios represent relative long wave height, steepness of the short waves, relative depth at the structure, wave height Reynolds number, foreshore slope, the number of waves and the relative length of the wave guides. In these tests, typical model Reynolds numbers are of the order of \(10^6\) and viscous scale effects are expected to be small. The foreshore slope was kept constant at 1:50. That is quite similar to prototype slopes, but its effect was not specifically tested.

The long wave height at the structure was closely related to the breaking wave height, as shown in Fig. 8. Thus the ratio \(H_{LW}/H_b\) is valid as a basic dependent variable. Both the 1995 and the basic 1997 data sets are plotted in Fig. 7. It is seen that there is a difference between the two sets of results. The 1995 set results in \(H_{LW} = 0.46H_b\) and the 1997 results give \(H_{LW} = 0.40H_b\).

**Effect of Depth at the Structure and Wave Period**

Figure 9 shows that the depth of water at the structure does not seem to affect the results, but the influence of wave period is substantial as shown in Fig. 10. When \(H_{LW}/H_b\) is plotted against the wave period related steepness parameter \(H_b/gT^2\), as in Fig. 11, it is seen that there are again two different populations for the 1995 and 1997 data.

A reflection coefficient was defined (at the structure) as:

\[
K_R = \frac{H_{LW,R}}{H_{LW,T}} = \frac{\frac{1}{2} H_{LW,S}}{(H_{LW,A} + H_{LW,S} - \frac{1}{2} H_{LW,S})} = \frac{H_{LW,S}}{(2H_{LW,A} + H_{LW,S})}
\]

(5)

Fig. 12 shows that the effect of \(H_b/gT^2\) on \(K_R\) is very similar to its effect on \(H_{LW}/H_b\). Thus most of the dependence of \(H_{LW}/H_b\) on \(H_b/gT^2\) must be explained by long wave reflection. From detailed analysis of the long waves, it was shown (to be published) that, on average \(H_{LW,A} = 0.26H_b\) for both the 1995 and 1997 tests. For the 1997 tests, \(H_{LW,R} \approx 0.07H_b\) on average. Thus, using Eq. 2, \(H_{LW} = \{0.26 + 2(0.07)\}H_b = 0.40H_b\), which is the same as in Fig. 8. For the 1995 tests \(H_{LW,R}\) was found to be 0.12\(H_b\), which would result in \(H_{LW} = 0.50H_b\). However, the scatter in these results was much greater – the standard deviation of the coefficient is 0.06. Therefore \(H_{LW} = 0.46H_b\) in Fig. 8 corresponds well and the difference between the two sets of results can be completely ascribed to the difference in long wave reflection between the high 1995 breakwater and the
Figure 9 - Effect of Depth of Water at the Structure on $H_{L,W}/H_b$ (1995 data)

Figure 10 - Effect of Wave Period on $H_{L,W}/H_b$ (1995 data)
Figure 11 - Effect of $H_b/gT^2$ on $H_{LW}/H_b$

Figure 12 – Long Wave Reflection Coefficient
lower 1997 breakwater that was damaged in the later stages of the tests. If we assume the 1997 tests to be typical of a functioning breakwater, it would appear that long wave height at a structure in shallow water may be approximated by

\[ H_{LW} \approx 0.4 H_b \] (6)

This is substantial. For structures in very shallow water, the resulting long wave height can easily exceed \( d_r \), which would mean exposure of the toe of the structure and extensive overtopping.

**Effect of Time of Measurement and Length of Wave Guides**

Figure 13 shows the effect of time of measurement on the long wave activity for Test 12B. It is seen that the results of 2, 10 and 20 minutes compare quite closely with the standard time of 5 minutes used in all the other tests. When the coefficients of all such analyses are summarized as in Fig. 14, it is seen that there is no discernible effect of time of measurement. Analysis of the lowest and highest values shown in Table 3 indicates that if there is any increase in long wave activity with time, it is only marginal.

To test the effect of the length of the wave-guides, the incident waves varied a little from test to test and therefore it was necessary to analyze \( H_{LW}/H_b \). Figure 15 shows no great effect. Analysis of the highest and lowest values in Table 4 shows that the 27 m wave guides resulted most often in the highest long waves, but does not show a consistent decrease in long wave height with wave guide length.

Figure 15 – Length of Wave Guides
Conclusions

The following conclusions with respect to long waves may be drawn from the work presented here. The experiments were performed with a rubble mound breakwater structure placed in shallow water, fronted by a constant 1:50 slope.

a) The wave height decreased from the breaker to the structure, but increased very close to the structure.
b) The increase in wave height was due to long wave activity.
c) Long wave height at the structure was related to:
   - breaking (short) wave height.
   - wave period, most likely through the variation in long wave reflection coefficient with wave steepness.
d) Long wave height was not related to:
   - depth of water at the structure.
   - resonant wave action (seiche) in the wave flume.
   - the time when the long wave activity is measured.
   - to the length of the wave guides.

With respect to design wave height for the structure in shallow water:

e) Kamphuis (1996) has shown that the design wave height is not simply related to depth of water at the structure, but to a design depth.
f) Design depth at the structure in shallow water was shown to be substantially increased by a function of breaking wave height.
g) The design depth increase postulated in Kamphuis (1996) cannot be due to wave setup alone.
h) The long wave activity near the structure is more than sufficient to be the cause the increase in design depth.

PROBABILISTIC MODEL FOR TSUNAMI-WAVE ELEVATION ALONG THE ALBORÁN SEACOAST

M. González and R. Medina

Abstract

In this study the tsunami-wave run-up along the Alborán Seacoast (Spain) have been evaluated. An indirect statistical method has been used to estimate the tsunami risk along the southeastern Spanish coast. This method can be summarized as: (1) analysis of the global neotectonic setting, the geodynamic processes as well as seismicity of the region; (2) tsunami source model; (3) generation, propagation and run-up numerical models; and (4) the risk model. The purpose of this study is to establish tsunami-wave elevation at the shoreline versus the return period curves for different locations along the Alborán seacoast. It is concluded that, the tsunamis generated in the Alborán basin have a medium-to-low intensity, with the most important elevations in the Málaga, Adra and Melilla areas.

Introduction

The Alborán seacoast is located along the southwestern Mediterranean Sea and occasionally, this area is affected by tsunami water waves (see figure 1 where some of the tsunamigenic epicenters are shown).

During the last few decades, the southeastern coast of Spain (Almería, Málaga and Marbella) has suffered an enormous transformation due to the tourism “boom” and the demand for coastal use. For this reason, a great number of infrastructures have been built (marinas, beaches, highways, boardwalks, hotels, etc.), which could be affected by tsunamis. The objective of this study is to establish the tsunami-wave elevation risk along the Alborán Sea. Since the frequency of occurrence, location, and magnitude of tsunamigenic earthquakes are random, the risk analyses must be based on probabilistic considerations.
Tsunami hazard has been investigated using various approaches. Where historical information and measurements regarding tsunami inundation are available, a direct statistical analysis has been used (Houston, 1977; Wiegel, 1970); where such data are scarce the concept of indirect analysis has been applied. The indirect approach, as carried out by Houston et al. (1974) and García et al. (1975), consists essentially of utilizing: (1) the historical information available in order to estimate the frequency of tsunamis of various intensities at the sources, and (2) the knowledge of tsunami wave propagation based on hydrodynamic considerations to compute the risk of a tsunami at the site.

The catalog of tsunamis that have occurred along the Alborán seacoast includes only a few events, since tsunamis are rather infrequent and since, in the past, positive scientific attention to these natural phenomena was scarce or even absent in the Alborán seacoast as in many other countries. Given this, no data concerning the source parameters (bed sea dislocations, source area, etc.) are available. In this study, a tsunami risk analysis following the idea of Houston et al. (1974) and García et al. (1975) is performed. However, seismological and probabilistic models similar to Lin et al. (1986) are used in order to determine the seabed dislocations in the source area.

The indirect method applied in this study can be summarized as:

- Selection of the tsunamigenic sources and seismic parameters.
- Tsunami source model (seismological model).
- Hydrodynamic numerical models (generation, propagation and run-up).
- Risk model.

**Tsunamigenic Sources**

Taking into account the global neotectonic setting, the geodynamic processes as well as the seismicity of the considered region, it is possible to determine potential tsunamigenic
