The above processes do partly affect the magnitude of the sediment transports and they all affect the sediment balances on a scale of kilometres to tens of kilometres. Implementation of the above mentioned effects is therefore necessary in order to be able to fine-tune the model on the basis of the detailed balances.

General conclusions

From the trial applications performed with the pilot-version of the model it was concluded that:
- the rather simple and straight-forward formulations of both the wave-induced as tide-driven longshore transport proved to be able to ‘simulate’ to a large extent the results of more complicated models;
- the way the cross-shore transport is taken into account in the model and specifically the explicit formulation of an equilibrium profile proved to have an advantage compared to standard approaches (especially for applications in which the interaction between cross-shore and longshore transport is complicated);
- the method of representing spatial and temporal climates seems to be an effective way to characterise the main driving forces of the model;
- the first application of the model for the Dutch coast yielded promising results;
on the basis of a simple schematization procedure for the wave- and tidal climate, both the direction and magnitude of net yearly transports showed a fair agreement with the results of a more in-depth study [Van Rijn, 1995];
- the behaviour-oriented multi-layer model provides a conceptual tool which seems to be able to ‘model’ to a large extent the evolution of a coastal system.

With respect to the conceptual approach it was concluded that:
- since both the longshore and the cross-shore transport processes are linked to the offshore hydraulic conditions, the effect of changing conditions (e.g. sea level rise) will be taken directly into account in the model and no other assumptions (e.g. Bruun-rule) have to be made;
- the use of more layers (compared to a single line-model) has the advantage that processes such as the bypass of sediment around the seaward tip of a groyne can be taken into account in a more correct way. However, the impact of structures for a case with more layers becomes far more complicated; in order to model this correctly, additional processes have to be accounted for);
- in a simple way both the effects of ‘soft’ and ‘hard’ management strategies can be taken into account, is an important advantage of the model as most of the natural coastal systems are influenced by human intervention; This makes it a useful tool for coastal management decisions;
- the auto-nourishment option (used to maintain at least a specific minimum shore line position by computational nourishments) proved to be a valuable tool to estimate the relative effect of structures and other human interference on the nourishment needs.

**Future work**

In order to update the present pilot-version of the PONTOS-model to a version that can be applied for practical cases, the following extensions are foreseen:
- to improve the input and assessment of the hydraulic conditions, the link between cross-shore profiles and layer schematization as well as the model output;
- to incorporate the processes which have been conceptually developed until now in an update of the mathematical model, yielding a version capable of simulating coastal evolution at a higher level of reliability;
- to improve the formulations for the interaction between tide- and wave-induced currents in the surf zone;
- to extend the model in seaward direction by adding one layer as a characterisation of the behaviour of the shelf, this in order to incorporate the effect of withdrawal of large quantities of sediment for land reclamation purposes;
- to perform a more integrated validation of the model concept.

Parameterizing Beach Erosion/Accretion Conditions

John P. Ahrens¹, affiliate member and Edward B. Hands²

Abstract

A simple method to parameterize beach erosion and accretion processes is presented. The parameterization is accomplished by combining important findings from two studies on the initiation of sediment movement, with near-bottom velocities estimated from nonlinear wave theory. This synthesis allows the development of a simple schematization or model based on only two variables that provides considerable insight on cross-shore sediment movement. Once calibrated, the model shows surprising skill (0.94) in predicting erosional or accretionary profile changes on sand beaches and is general enough to predict observed onshore movement of gravel during storms. If linear wave theory is used, the ability to discriminate between erosional and accretionary events declines.

Introduction and Background

Analysis by Ahrens and Hands (1998) showed clearly that shoreline erosion or accretion could be predicted quite well using the ratio of two velocities. Symbolically, we have:

\[ U = \frac{U_{d_{\text{max}}}}{U_{\text{crit}}} \]  

where \( U_{d_{\text{max}}} \) is the maximum near-bottom orbital velocity of the wave and \( U_{\text{crit}} \) is the critical velocity required to initiate sediment movement under the wave. Two versions of \( U \) were developed, denoted \( U_c \) and \( U_t \), for the maximum near-bottom velocity under the crest and trough respectively. Near-bottom maximum velocities under waves were calculated using Dean's (1974) Stream Function Wave Theory (SFWT). Critical velocities for the initiation of sediment movement are calculated as follows:

\[ u_{\text{crit}} = \sqrt{8 \Delta g d_{s0}} \text{, for } d_{s0} \leq 2.0 \text{mm} \]  

¹ Coastal Consultant, 6702 Springfield Drive, Mason Neck, Virginia 22079, USA
² Research Physical Scientist, USAE Waterways Experiment Station, CHL, 3909 Halls Ferry Road, Vicksburg, Mississippi 39180, USA
where \( g \) is the acceleration of gravity, \( d_{50} \) is the median sediment diameter, \( T \) is the wave period, and \( \Delta = (\rho_r - \rho)/\rho \), where \( \rho_r \) is the density of the sediment and \( \rho \) is the density of water. Eqs. 2 and 3 are based on research by Hallermeier (1980) and Komar and Miller (1974), respectively.

Although not developed in Ahrens and Hands (1998), their analysis indicated that it was possible to make good approximations of \( U \) using only two variables. This was accomplished by generating an extensive synthetic data set using SFWT and Eqs. 2 and 3 above. Regression analysis and dimensional analysis were used to obtain the following equations:

\[
U_{zent} = 0.46AgT^{1/4}(\pi d_{50})^{3/4} \text{ for } d_{50} > 2.0 \text{ mm}
\] (3)

\[
U_{c} = 0.132N_s^{0.466}(d/L_o)^{-0.0506} \exp[-3.523(d/L_o)]
\] (4)

\[
R^2 = 0.970, N = 392, \text{ max. % error = 36.1\%}, \text{ rms % error = 22.2\%}
\]

and for the trough:

\[
U_{t} = 0.519N_s^{0.447}(d/L_o)^{0.569} \exp[-5.049(d/L_o)]
\] (5)

\[
R^2 = 0.993, N = 392, \text{ max. % error = 29.4\%}, \text{ rms % error = 16.3\%}
\]

where \( N_s \) is the stability number commonly used to measure the stability of rubble structures, \( d \) is the water depth and \( L_o \) is the deep-water wave length. The negative sign in Eq. 5 is used to indicate an offshore directed velocity.

Hudson, et al. (1979) shows how the stability number evolves from dynamic and dimensional considerations from a combination of a Froude Number and a density ratio. The combination accounts for the most important forces on an armor unit, i.e., form drag and submerged weight. An investigation of rubble-mound stability might involve stability numbers in the range of 1.0 to 3.0, but for this study the range was about 1 to 60,000. For investigating sediment movement under waves, it is more appropriate to refer to \( N_s \) as a mobility number. The mobility number is defined:

\[
N_s = H/(\Delta d_{50}).
\] (6)

Madsen (1998) notes the similarity between the mobility number for shallow water wave conditions and the Shields parameter, i.e.,

\[
N_s = H/\Delta d_{50} = gH/g\Delta d_{50} \propto u^2_{x, max}/\Delta gd_{50}
\]

The Shields parameter is the ratio of the drag forces that initiates sediment movement and the resisting force of the submerged weight.
The ranges of variables in the synthetic data set were:

\[ 0.002 \leq \frac{d}{L_o} \leq 0.2 \]
\[ \frac{H_b}{4} \leq H \leq H_b \]
\[ 0.1 < \frac{d_{so}}{d} < 100 \text{ mm}, \quad \rho_s = 2.65 \text{ gr/cm}^3 \]
\[ \rho = 1.000 \text{ gr/cm}^3 \text{ (fresh water) and } \rho = 1.025 \text{ gr/cm}^3 \text{ (sea water)} \]

Eqs. 4 and 5 have captured, in a simple formulation, some of the essential information about sediment movement under waves from three important studies, Dean (1974), Komar and Miller (1974) and Hallermeier (1980). The equations are a function of just two dimensionless variables which in turn are a function of six dimensional variables. None of the dimensional variables appears in both dimensionless variables, i.e. the dimensionless variables are independent and unusually effective in describing erosional and accretionary processes. The profile adjustment variables used here are the height and period of the wave, size and density of the sediment, and depth and density of the water. These variables seem like the minimum set required to predict profile response to waves and at the same time in many situations they may well be all the information available. This discussion is quite simplified because it assumes that sediment movement responds only to the near-bottom velocity produced by wave motion. Obviously, many other variables could be important at the selected site of application, such as the slope of the bed, the presence of other currents, and the bedform.

Findings

a. The Big Picture

Fig. 1 provides perspective on the implications of Eqs. 4 and 5. Fig. 1 shows \( U_c \) and \( U_t \) for three values of relative depth as a function of mobility number. The following features of Fig. 1 are noted:

1.) \( U_c \) and \( U_t \) are small for small mobility numbers and large for large mobility numbers, indicating increasing sediment movement under waves with increasing mobility numbers.

2.) \( U_c \) and \( U_t \) are quite asymmetrical about \( U = 0 \) for \( \frac{d}{L_o} = 0.02 \) and 0.002, suggesting the accretional properties of long waves, i.e. because for a given mobility number the absolute value of \( U_c \) is much greater than \( U_t \).

3.) \( U_c \) and \( U_t \) are almost symmetrical about \( U = 0 \) for deeper water, e.g., \( \frac{d}{L_o} \geq 0.2 \), suggesting the erosional characteristics of short-period waves because the absolute values of \( U_c \) and \( U_t \) are about the same, but the offshore flow under the trough lasts longer than the landward directed flow under the crest.

4.) Because sediment characteristics are contained only in the mobility number, the figure shows how wave conditions that might be erosive for fine-grained sediment could be accretive for large sediment: e.g. sediment with a high mobility
could move shoreward under the crest and offshore under the trough, whereas sediment with a lower mobility number could be below the threshold for offshore movement and be constrained to move shoreward under the crest.

All of the characteristics noted above are consistent with current understanding of sediment movement under waves.

![Graph showing $U_c$ and $U_t$ as functions of mobility number, for three values of relative depth, from Eqs. 4 and 5.]

**b. Depth of Breaking Calculations**

In order to test the ability of Eqs. 4 and 5 to predict erosional or accretional events on beaches, it is necessary to select a depth of application. The following procedure is used to select this depth:

The maximum or breaking wave height, $H_b$, consistent with SFWT can be estimated by:

$$H_b/d \approx 0.171(L_o/d) \{\tanh[0.73(2\pi d/L_o)]\}$$

$$R^2 = 0.9997, \, N = 10$$

max. % error = 1.16%

rms % error = 0.72%

over the range, $0.002 \leq d/L_o \leq 2.0$

Eq. 7 was developed using regression analysis. To estimate $H_b$ from deep water conditions the breaker height index formula of Kaminski and Kraus (1993), is used:
Combining Eqs. 7 and 8 gives a relative depth of breaking as:

\[
d_b/L_o = 0.109 \ln \left(\frac{l+x}{l-x}\right)
\]

where \(x = 2.69(H_o/L_o)^{0.72}\).

Fig. 2 shows a plot of Eq. 9 with the relative depth at breaking as a function of deep-water wave steepness. The figure indicates that almost any deep-water steepness will yield a relative depth at breaking within the range required for Eqs. 4 and 5, i.e. \(0.002 < d/L_o < 0.2\). For convenience, the relative depth at breaking calculated using Eq. 9 will be referred to as the reference depth.

Fig. 2 Relative depth at breaking as a function of deep-water wave steepness

c. Field Beach Profiles

Kraus, et al. (1991) used a field data set to develop criteria to discriminate between erosional and accretionary type beach profiles; these data are tabulated in Kraus and Mason (1991). Data are from beaches all over the world, collected by many researchers, and include observations of 99 distinct wave conditions. Deep-water significant wave heights were in the range \(0.08 \leq H_o \leq 7.90\) m, wave periods were in the range \(2.0 \leq T \leq 15.3\) sec, and sediment sizes were in the range \(0.17 \leq d_{50} \leq 3.5\) mm for
these observations. Wave periods are associated with either the deep-water significant wave height or deep-water spectral peak. For the field data set, the deep-water significant wave height is used in Eqs. 8 and 9; this approach is used to adapt equations developed for monochromatic waves to the irregular wave conditions of nature. The procedure yields relative depths (reference depth) near the seaward limit of the surf zone. Erosional profiles were defined as having no berm and at least one pronounced bar; accretionary profiles were defined as having a prominent berm and no bar formations.

Accretionary or erosional type profiles are denoted in Fig. 3 as functions of \( U_c \) and \( U_t \), calculated using Eqs. 4 and 5 respectively. Surprisingly, \( U_t \) discriminates well between erosional and accretionary profiles, without the need to use \( U_c \), at a value around -2. Interestingly if \( U_t \leq -2 \) erosion profiles will occur even if \( U_c \) is quite large. If a value of \( U_t = -2.0 \) is used as a threshold level, see Fig. 3, then there are three miscategorized erosion and three miscategorized accretion observations in a data set of 99, for a prediction skill of 0.94. Skill is the ratio of correct predictions to total observations, Seymour and Castel (1989). If linear wave theory is used to calculate \( u_{d_{max}} \), the ability to predict erosional and accretionary beach conditions declines to a skill of 0.88. The difference in skill may not seem great, but consider that the \( U_t \) approach corrects 6 of the 12 miscategorized observations using linear theory.

Fig. 3 shows a line for \( U_t = -2.0 \), as the best discrimination value between erosional and accretionary conditions. Above the discrimination line is a line given by \( U_t = -1.51 \), which is the smallest value which has only accretionary conditions above it, i.e. it is the limit for erosion. There is also a line for \( U_t = -2.27 \), which is the smallest
value which has only erosional conditions below it, i.e. it is the limit for accretion. These lines have been transferred to Fig. 4, using Eq. 5, which shows erosion/accretion conditions as a function of $N_s$ and $d_b/L_o$. Above the upper limit curve is a region on the plane where erosion would be expected, below the lower limit curve is a region where accretion would be expected, and between the two is a transition region where both accretionary and erosional profiles are observed. The transition region is somewhat weighted toward accretionary profiles with 10 observations, as opposed to 6 observations of erosional profiles. If linear wave theory is used to establish a transition region, for the data of Kraus and Mason (1991), it contains 42 observations, 26 erosional and 16 accretionary. Clearly, the $U_t$ approach is more effective in defining a transition region.

![Image: Fig. 4 $N_s$ vs. $d_b/L_o$ plane showing beach condition regions defined by $U_t$ values]

Another perspective on the information shown in Fig. 4 can be obtained by using Eq. 9 to transform the relative depth at breaking to deep-water wave steepness. This transformation is shown in Fig. 5 for the limit curves and a curve for the approximate limit of sediment movement. The limit for sediment movement was calculated by setting $U_c = 1.0$ in Eq. 4; this limit helps add scale to the figure.

d. Offshore Dumping of Gravel for Beach Nourishment

Zenkovich and Schwartz (1987) discuss offshore dumping of gravel in the Black Sea. Gravel was dumped by barge in depths of 4 to 6 m and storm wave conditions brought this material up to the shoreline over the next year or so to provide effective
Typically the deep-water wave steepness in a storm is in the range, $0.03 \leq H_s/L_0 \leq 0.06$. Eqs. 7 and 8 can be used to calculate breaker heights, which for this range of steepness is $H_b/d \approx 0.76$ and in these water depths give $3.04 \leq H_b \leq 4.56$ m. The size of the gravel was not given in Zenkovich and Schwartz (1987), but sediment with median diameters in the range of $5 \leq d_{so} \leq 76$ mm is normally regarded as gravel. This range of breaker heights and sediment sizes gives mobility numbers in the range $24 \leq N_s \leq 553$. Fig. 5 shows that this range of mobility numbers and wave steepness generally fall into the accretionar region, which is consistent with the on-shore movement of the gravel observed by Zenkovich and Schwartz. The curve for the limit to sediment movement suggests that coarse gravel might have remained at depths of 4-6 m rather than move onshore. If find sand, say $d_{so} = 0.2$ mm, had been dumped at these depths mobility numbers in the range $9,152 \leq N_s \leq 13,818$ would have been obtained and Fig. 5 indicates this is an erosional condition; i.e., the sand would have moved offshore during storms.

![Fig. 5 N_s vs. H_s/L_0 plane with beach condition regions defined by U_t and U_c](image)
Fig. 5 provides a rather comprehensive view of erosion/accretion processes on 
beaches and is easier to interpret than Fig. 4. Fig. 5 shows that when the deep-water 
waves are steep, erosional conditions dominate, but there is a window of accretional 
conditions for gravel that was confirmed by the research of Zenkovich and Schwartz 
(1987). When deep-water steepness is quite small, say $H_{JL}/L_0 = 0.001$, accretional 
conditions dominate. At this steepness erosion will occur only for median sediment 
diameters smaller than used in the development of this model, i.e., $d_{50} = 0.1$ mm.

**e. A Further Simplification and Application**

Fig. 5 suggests that a further simplification could be made in predicting erosional 
and accretionary conditions by determining the equations of the discrimination curve, the 
accretion limit curve, erosion limit curve, and the limit of movement curve directly as 
$N_s = f(H_{so}/L_0)$. This functional relation was determined using regression analysis, with the 
following results:

For $U_c = 1.00$, approximate limit of movement,

$$N_s = 93.2(H_{so}/L_0)^{0.113} \exp[7.89(H_{so}/L_0)]$$  \hspace{1cm} (10)

$R^2 = 0.9998$, $N = 99$, $0.1 \leq H_{so}/L_0 \leq 0.001$

and for $U_t$

$$N_s = C_o(H_{so}/L_0)^{-0.854} \exp[10.1(H_{so}/L_0)]$$  \hspace{1cm} (11)

$R^2 = 0.9999$, $N = 99$, $0.1 \leq H_{so}/L_0 \leq 0.001$

and where:  $C_o = 30.8$, $U_t = -1.51$, erosion limit  
$C_o = 62.1$, $U_t = -2.00$, best discrimination value  
$C_o = 83.0$, $U_t = -2.27$, accretion limit

Eq. 11 discriminates between erosional and accretionary conditions exactly the 
same way as Eq. 5 and has exactly the same 16 observations in the transition region as 
Eq. 5. However, Eq. 11 is easier to use than Eq. 5 because there is a direct link between 
the mobility number and wave steepness. Fig. 6 illustrates an application of Eq. 11.

In Fig. 6, beach condition regions are shown as a function of $H_{so}$ and $T$ for two 
beaches, one with $d_{50} = 0.2$ mm and one with $d_{50} = 0.3$ mm, and using $A = 1.65$. Using 
the 0.2 mm beach as a reference, it can be seen that the transition region moves up for the 
0.3 mm beach expanding the accretion region and reducing the erosion region. The figure 
provides a very clear idea of what wave conditions cause erosion or accretion and 
provides a simple way to compare the response of beaches with different size sand to 
various wave conditions. Fig. 6 could be used to assess the value of nourishing a 0.2 mm 
beach with somewhat coarser sand. The limit on wave steepness is $H_{so}/L_0 = 0.08$. 

A question and a comment made at the conference can be addressed in this section. The question in essence was, can this model predict erosion of gravel beaches? The related comment observed, in part, that gravel beaches do in fact suffer erosion, however, they recover very quickly, Nicholls (1998). Fig. 7 shows the beach condition regions for a beach composed of small gravel, i.e., $d_{50} = 5$ mm. The figure indicates that small gravel will erode, but that $H_{m0}$'s would probably have to be in the range of $10 - 15$ m. There is a very large accretion region in Fig. 7 indicating that most wave conditions are accretionary for a 5 mm beach and supporting Nicholl's observation that gravel beaches recover from erosion very quickly. Fig. 7 also shows a small region where no onshore/offshore sediment movement would be expected. For the 0.2 mm and 0.3 mm beaches shown in Fig. 6, there is no region of no movement shown because wave heights for this region were always less then 0.1 m.

Summary and Conclusions

This paper uses nonlinear wave theory to predict cross-shore sediment movement under waves in shallow water. This synthesis of wave theory and sediment movement initiation criteria allows much of the present understanding of cross-shore sediment movement to be schematized or modeled using only two dimensionless variables, i.e., a mobility number and relative depth. When calibrated, the model shows surprising skill (0.94) in predicting erosional or accretionary beach profiles. The model is sensitive enough to distinguish between strong and weak erosional/accretionary tendencies. A wide range of sediment sizes was included in the development, which allows consideration of not only sand, but also gravel-sized particles. The model also provides
an interesting and useful perspective on cross-shore sediment movement under waves as functions of a mobility number and relative depth or a mobility number and deep-water wave steepness.

![Graph](image)

Fig. 7 Beach conditions for $d_0 = 5.0$ mm as a function of $H_{se}$ and $T$

It is the characteristics of nonlinear waves and specifically, the near-bottom velocities under the troughs, that accounts for the high skill of the model in predicting erosion/accretionary beach conditions. If linear wave theory is used to predict near-bottom velocities, the ability of the model to discriminate between erosional and accretionary beach events declines from a skill of 0.94 to 0.88.

The reference depth used to apply the model is near the outer limit of the surf zone. Surprisingly, the dimensionless version of the reference depth is easy to calculate, Eq. 9, as function of only deep-water wave steepness. When near-bottom velocities under a trough are more than twice the velocity required to initiate sediment movement, at this depth, the beach experiences erosion. If this ratio of velocities is less than two, then accretionary or possibly static profile conditions exist on the beach. Prediction of erosion or accretion is not improved by knowledge of the near-bottom fluid movement under the crest.
Simplifications were possible at three stages in the development of this model:
First, the recognition that much of the physics of sediment movement under waves in shallow water could be summarized using only two variables, i.e., a mobility number and either relative depth or deep-water wave steepness. Second, the discovery that erosional or accretionary conditions, or a transition region could be discriminated using only Eq. 5, related to movement under the trough. Third, that a direct relationship between the mobility number and deep-water wave steepness could be developed, Eq. 11, that could be used to define beach conditions.

Appendix, Definition of Symbols

- $d$ - water depth
- $d_b$ - water depth at wave breaking
- $d_{50}$ - median grain diameter
- $d_b/L_0$ - relative depth at breaking, referred to as reference depth
- $g$ - acceleration of gravity
- $H$ - wave height
- $H_o$ - deep-water monochromatic wave height or significant deep-water wave height for field wave conditions, depending on context
- $H_b$ - maximum or breaking wave height
- $L_0$ - deep water wave length = $gT^2/2\pi$
- $N_s$ - mobility number, Eq. 6
- $\%$ error = $[(predicted - observed)/observed]*100$
- rms - root mean square
- SFWT - Stream Function Wave Theory
- $T$ - monochromatic wave period or characteristic wave period for field wave conditions, depending on context
- $u_{d_{max}}$ - maximum near bottom velocity due to waves
- $u_{crit}$ - critical velocity required to initiate sediment movement
- $U$ - ratio $u_{d_{max}}/u_{crit}$, in general
- $U_c$ - value of $U$ under crest
- $U_t$ - value of $U$ under trough
- $\rho_s$ - density of sediment
- $\rho$ - density of water
- $\Delta$ - $(\rho_s-\rho)/\rho$

DETERMINING DEPTH FROM REMOTELY-SENSED IMAGES

Robert A. Dalrymple, F. ASCE, Andrew B. Kennedy, James T. Kirby, M. ASCE, and Qin Chen, M. ASCE

Abstract Remotely-sensed images can provide synoptic or nearly synoptic data for large areas of the sea surface. Photographic and, more recently, radar measurement techniques can resolve the pattern of waves on the water surface and can provide a very dense sampling of kinematical variables of interest, ranging from a complete picture of the wave phase (in the case of single photographs) to horizontal velocity components at the water surface resulting from wind, tides, or waves (in the case of advanced radar techniques). When applied in the coastal zone, these images contain surface waves that are propagating over a complex bottom bathymetry and current field, and that are affected by a combination of shoaling, refraction, diffraction and nonlinear processes. This paper examines two methods to determine bathymetry from surface elevation information. The first is to examine the ability of linear dispersion relationship models to determine bathymetry, in cases with refraction and diffraction, and the second, based on lagged correlation method (and several images), is more generally useful for application.

Introduction

Remote sensing of the ocean surface can provide a great deal of information about the sea. Since World War II, it has been desirable to make use of images of the sea surface to deduce the bathymetry and nearshore current structure of a region of interest. The advantages of remote sensing systems for bathymetric and current surveys are that they can be more rapid than ground based methods, the cost per survey is lower, and it is less hazardous (in terms of exposure to the elements or hostile activity).

There are a variety of possible remote sensing systems. Satellites now provide wind speed and wave heights by altimetry. Aircraft with radars: synthetic aperture radar (SAR) and interferometric SAR (INSAR) provide the ability to measure waves and currents. Some bathymetric data is being gleaned from the modulation of currents by the bottom from SAR data now, such as the ARGLOSS BAS system in the Netherlands. LIDAR, using lasers from helicopters, such as the U.S. Army Corps of Engineers’ SHOALS system (Lillycrop, Parson, and Irish, 1996), can provide bathymetric information at a rate of 5 km² per hour, with accuracies of ±3 m horizontally

¹all at the Center for Applied Coastal Research, University of Delaware, Newark, DE 19716 USA
and ±15 cm vertically in water depths of 40 m or less—provided that the water is reasonably clear. Turbidity affects the depths to which this methodology can be used.

An image of the water surface will contain information about the wave length of the surface waves, $L(x, y)$, which may vary with position, denoted by the horizontal coordinates $x$ and $y$. Methods based on simple approaches (such as using the linear wave dispersion relationship to estimate local water depth from local estimates of wave length and period) provide an initial indication of the variation of depth in intermediate water depths, where nonlinearity is weak and currents typically are not the leading order factor in determining wave properties. The usual linear wave theory dispersion relationship is $\sigma^2 = gk \tanh kh$, where the wave angular frequency $\sigma = \frac{2\pi}{T}$, where $T$ is the wave period and the wave number $k$ is $\frac{2\pi}{L}$. The wave period, assumed to be constant over the image, is determined from assuming a deep water wave length in a portion of the image or some other means.

Rearranging the dispersion relationship, 

$$h(x, y) = \frac{1}{k(x, y)} \tanh^{-1} \left( \frac{\sigma^2}{g} \right)$$

Gleaning the wave length, $L(x, y)$, from an image, however, is not without error. There may be errors in the measurement technique and there may also be errors in how the wave period is determined.

Taking the derivative of the above equation and then dividing by $h(x, y)$, we have the relative error in depth as a function of the relative error in the wave angular frequency and the wave number.

$$\left( \frac{dh}{h} \right) = 2 \left( \frac{\sinh 2kh}{2kh} \right) \left( \frac{d\sigma}{\sigma} \right) - \left( 1 + \frac{\sinh 2kh}{2kh} \right) \left( \frac{dk}{k} \right) = f(kh) \left( \frac{d\sigma}{\sigma} \right) - g(kh) \left( \frac{dk}{k} \right),$$

which defines two functions, $f(kh)$ and $g(kh)$, which determine the relative contributions of the percentage errors in angular frequency and wave number to the percentage error in the depth. These error terms are equal to two in shallow water, meaning that any errors in wave length determination are multiplied by this factor of two. What is worse is that these terms grow exponentially with $kh$. (Errors in wave length lead to the same size errors in wave number, as $\frac{dk}{k} = -\frac{dL}{L}$.) Figure 1 shows how $f(kh)$ and $g(kh)$ grow with depth. Clearly, the relative depth becomes far more sensitive to error as the depth increases.

Close to shore, nonlinearity can become a dominating factor in determining wave properties. Further, since waves are rapidly evolving and do not correspond well to any particular permanent form solution, it is likely to be difficult to parameterise nonlinear effects in a useful form. (Grilli and Skourup (1998, this proceedings) have examined the depth inversion of nonlinear periodic waves using a fully nonlinear boundary element method.)

This paper reports on bathymetry determination from ”remotely sensed” (actually synthetically generated) images using two different methods. First, we determine the ability of the linear wave theory to determine the bathymetry from water surface elevations obtained by wave models over given bathymetry. Then we utilize a maximum
entropy method with a time series of synthetic images taken over a short period of time (comparable to a wave period).

**Hilbert Transform**

**REF/DIF 1** is a forward scattering parabolic wave model (Kirby and Dalrymple, 1983, 1984, 1992) that predicts refraction and diffraction. This model was run with a simple idealized geometry (the Berkhoff, Booij, and Radder (1982) basin test, denoted BBR, which includes oblique wave incidence on a 1:50 planar beach with an elliptical shoal), using the BBR wave conditions, and surface elevations were computed by the model on a 200 by 200 grid (each grid is 0.125 m x 0.125 m). These surface elevations (which have been shown to agree with measurements extremely well) were then used as the "remotely sensed" data and analysed for bathymetry.

To obtain the phase of the waves within the "image," a Hilbert transform was used along the 200 onshore grid lines. The Hilbert transform converts real time series into complex series from which the phase may be obtained. [In Matlab, this involves three steps: unwrap(phase(hilbert(data))). The unwrap command ensures that the phase increases monotonically, instead of staying in the range $-\pi$ to $\pi$.] The horizontal gradient of the phase over the image then provides the local wave numbers, from which the depths are determined using the linear theory dispersion relationship and the given wave period ($T=1$ s).

Figure 2 shows the results for the BBR data set. Note that the depth inversion (using a linear dispersion relationship in **REF/DIF 1**) gives quite good results except in the focusing/diffraction region behind the shoal, where very sharp ridges of unreal channels and bars occur. This is due to the fact that the wave length determination
is difficult where waves are short-crested and diffraction is strong.

Figure 2: Depth inversion of REF/DIF 1 output for BBR data set, showing the actual bathymetry (dashed lines) and the determined bathymetry (solid lines).

Applying a 2-D Fourier smoothing algorithm to the determined depths removes the sharp changes in depth produced by the focusing, as shown in Figure 3. (Note that we do introduce boundary effects due to the assumed spatial periodicity required by the Fourier filtering.) However, in the middle of the figure, the shoal is clearly and accurately picked out by the depth-inversion algorithm.

No remotely-sensed image will be as free of noise as model output. Variations in the field data will occur due to spectral sea effects, wind, capillary waves, specular reflections, etc. Therefore we introduced random noise to model output to determine the effect on the inversion algorithm. Figure 5 shows the bathymetry deduced by surface elevation data which have a 10% normally distributed random variation added. While the results are not as good as the no-noise case, the depths are reasonably well delineated. More noise results in seriously degraded bathymetry.

Additional examinations of the method included determining the errors involved with increasing the random noise and using the incorrect wave period. Further these comparisons were carried out with data from the linear REF/DIF 1 run along with a nonlinear model computation (using a composite dispersion relationship that fits the deep water Stokes relationship to a shallow water form). The variation of error introduced by these noise and period effects are shown in Figures 7 and 8.

While comparisons of linear and nonlinear versions of REF/DIF to the laboratory data show important differences, the bathymetry obtained from linear and nonlinear
synthesized surface data using the linear dispersion relationship for both cases show no real differences over the shoal and that the shoal is accurately found, even in the presence of noise introduced into the surface wave image. This method is extremely sensitive to the wave period, however.

All tests here have been done with a single frequency incident wave. A spectral sea state is best treated by the next method, which requires a sequence of images in time to determine wave frequencies.

Lag-Correlation Methods

Sequential images of a water surface taken at reasonably short time intervals show waves of varying directions and wave numbers propagating through space at their characteristic phase speeds. This is the basis of the lag-correlation methods, where the sequential images are used to determine a relationship between wave number and frequency, and thus to estimate depth. For large spatial records where the wave number spectrum is constant over the image and sequential images are available, wave number spectra and the associated phase speeds may be easily determined using standard Fourier techniques. However, in coastal regions, wave lengths and directions may change significantly over several wave lengths, making direct methods like this impossible. In this case, different methods must be used to estimate the wave number spectrum and associated phase speeds. Note that here the spectrum is characterised
in terms of wave number rather than frequency, which is much more natural given the form of the data. The methods used here will make the assumption that the wave field is approximately stationary over a window of about two peak wave lengths. Although this assumption becomes invalid near the shore, and in areas with strong changes in bottom topography, it remains reasonable for many situations.

To aid analysis, the surface elevation data contained in the windows of interest is transformed into auto and cross correlation functions (e.g. Bendat and Piersol, 1986, Balakrishnan, 1995). Auto correlation functions of some window of data show the correlation of an image with itself at different spatial lags. If sequential images of the same window are compared, a cross-correlation function results. Autocorrelation functions contain information about the wave number spectrum to within a 180 degree directional ambiguity, while the addition of cross-correlation functions resolves this ambiguity and provides information about phase speed. Auto and cross correlation functions may also be easily constructed from a given wave number spectrum and dispersion relationship. For full and accurate records of auto and cross correlation functions, the wave number spectrum and dispersion relationship may be easily found, and the depth may be deduced from this. However, window sizes are assumed to be only about two peak wave lengths, and because of way they were constructed from data, correlation functions with high lags become unreliable. Therefore, since full records are unavailable, more approximate methods must be used to find the wave number spectrum and, more importantly, the dispersion relationship and therefore the depth.

One Horizontal Dimension

As a first test, the lag-correlation method was tested for one horizontal dimension. Spatial images of the water surface were generated using a fully nonlinear extended
Figure 5: 2-D Smoothed Depth inversion of REF/DIF 1 output for BBR data set, showing the actual bathymetry (dashed lines) and the smoothed bathymetry (solid lines).

Boussinesq model (Wei et al., 1995) over a bar-trough topography (Figure 9). The surface was then divided into overlapping windows with a length of about two peak wave lengths. Unbiased auto and cross correlations, which include a factor to correct for finite record length, were then computed in these windows. Ten sequential images were used to provide data; multiple auto and cross correlations were thus averaged to reduce error. However, there remained significant error for high spatial lags, and all correlations for lags greater than 2/3 of the window size were considered unreliable and discarded.

The inverse problem was then solved on a window by window basis. In each window, the measured auto and cross correlations were assumed to come from a spectrum that had either a JONSWAP or TMA type form (results were almost identical for both). The unit spectrum of this form was defined by a peak wave number, $k_p$, and a peak enhancement factor, $\gamma$. In order to specify the dispersion relationship for calculating cross correlations, a depth $h$ also needed to be specified. Initially, of course, none of these were known, although a reasonable estimate could be made for the peak wave number. Initial guesses were made for each which were then iterated until the squared error between the measured and estimated auto and cross correlations was at a minimum. The depth at this minimum was then assumed to be the inversion depth.

Figure 9 shows actual and estimated depths for an incident spectrum with peak $T_p = 7s$ and height $H_{RMS} = 0.025m$. The time lag between sequential images was 2s. Agreement is quite good, although small scale features cannot be reproduced.
Figure 6: 2-D smoothed depth inversion of REF/DIF 1 output for BBR data set, along transect 80, showing the actual bathymetry, the inferred bathymetry (no smoothing (very wavy line)), and the smoothed bathymetry.

Furthermore, some scatter is clearly visible. This is likely due to a finite record length, and the resulting error in the correlation functions. Errors are greatest for deeper depths because here, the dependence of phase speed on depth is small. Thus, small errors in estimating phase speed or wave number will be magnified.

Figures 10-11 show inversions performed over the same topography as RMS wave heights increase. The time series of input waves to the Boussinesq model remained identical except for a multiplicative factor. Nonlinearities would, of course become evident as waves evolved. The main effect of this nonlinearity is to overestimate water depth wherever wave heights are large. This is because of amplitude dispersion, which increases with phase speed. Evidently, as shown by Grilli and Skourup (1998), using a nonlinear celerity would increase accuracy.

Two Horizontal Dimensions

For two horizontal dimensions the general problem remains the same: find a wave number spectrum and associated depth to best match the measured auto and cross correlation functions. However, it is more difficult to define a two dimensional wave number spectrum in terms of a few parameters - particularly if the spectrum has more than one dominant wave number or direction.

Accordingly, a more general technique was used to estimate the wave number spectrum in each window. The maximum entropy technique of Lim and Malik (1981) has been shown to be useful for finding the maximum entropy spectrum for two dimensional wave number problems from incomplete autocorrelation data. This technique uses two dimensional FFT's to transform between autocorrelation and wave number space, and again between wave number space and constraint space until a maximum entropy spectrum is reached that satisfies the measured constraints on the autocorrelation function. A variant of this method was used to compute the wave number
spectrum directly from the autocorrelation function. In some cases, the method may be slow to completely converge, but it was found that complete convergence was not necessary to accurately invert depths. As long as the peak of the wave number spectrum was in the correct location, results continued to be accurate.

Once the wave number spectrum had been computed, the depth in each window was iterated until the cross correlation function resulting from the maximum entropy spectrum best matched the measured function. A 180 degree ambiguity with respect to the wave number spectrum had to be specified, but this was a minor concern. Figure 12 shows estimated and actual depths for the Berkhoff, Booij and Radder (1982) experiment described earlier. Once again, agreement is quite good, although the depth at the top of the shoal is overestimated, due to nonlinearities and/or a finite window size. Figure 13 gives a one dimensional slice through the shoal, and clearly shows the overprediction of depth on top of the shoal. This is almost certainly because depth is assumed to be constant throughout the analysis windows, an assumption that is violated in the region of the shoal.

Next, to test the effect of inaccuracies in the measurements, Gaussian noise with a standard deviation of 10 percent of the wave height was added to the data. Depths were then estimated as before. Figure 14 shows the computed and measured depths. These are virtually identical to those computed earlier. This insensitivity is because the maximum entropy technique transforms white noise in the data into a noise floor in the wave number spectrum. This noise has no strong correlation with depth and thus does not affect greatly estimates of depth. Figure 15 shows a slice through the shoal and again the results are almost identical to the no noise case.

Abstract: This proceedings, Coastal Engineering 1998, contains over 270 papers presented at the 26th International Conference on Coastal Engineering which was held in Copenhagen, Denmark, June 22-26, 1998. The proceedings is divided into five parts: 1) characteristics of coastal waves and currents; 2) long waves and storm surges; 3) coastal structures; 4) coastal processes and sediment transport; and 5) coastal, estuarine, and environmental problems. The individual papers include such topics as the effects of wind, waves, storms, and currents as well as the study of sedimentation, erosion, and beach nourishment. Special emphasis is given to case studies of completed engineering projects. With the inclusion of both theoretical and practical information, these papers provide the civil engineer and professionals in related fields with a broad range of information on coastal engineering and coastal processes affecting design and operations in the coastal zone.

On the predictability of nearshore bar behaviour

Stefan Aarninkhof¹, Claire Hinton² and Kathelijne Wijnberg³

Abstract

The analysis of field observations of surf zone dynamics has revealed some 'unexpected' behaviour of the coastal system, generally referred to as 'free behaviour', which is behaviour that is unrelated to similar patterns in the external forcing. Present-day process-based modeling concepts are not capable to deal with these free modes of behaviour. In order to assess the validity of model-based predictions of bar dynamics, the relative importance of free behaviour versus forced response in the surf zone needs to be addressed. This work aims to contribute to the debate, by investigating the sensitivity of breaker bar behaviour to chronology effects from coastal profile modeling at a multiple-barred beach, with probabilistic forcing conditions. The results show chronology effects merely affect the predicted height of the bars, rather than their location which is remarkably consistent over the various runs. The latter observation has raised the question up to what extent predicted bar behaviour is controlled by model characteristics (concept, parameter settings), rather than system and forcing characteristics.

Introduction

Over the years, nearshore sand bar behaviour was believed to show a rather consistent pattern of delayed response to the wave energy input, featuring a rapid straightening of the outer bar during storms, and a gradual development of a crescentic bar pattern via some intermediate stages during subsequent periods of low-energy exposure (e.g. Wright and Short, 1984; Lippmann and Holman, 1990). However, another field observation of bar behaviour has been presented by Southgate and Möller (1998). They applied a fractal

analysis technique to the Duck, NC, data base (10.5 years of monthly cross-shore surveys) to indicate the existence of self-organized (or free) behaviour in a coastal system. They arrive at the conclusion that the profile behaviour has a fractal structure and is uncorrelated to the input variations, but only within a certain time window. The width of this time window varies with the cross-shore location, featuring a maximum of 30-40 months well inside the surf zone. Within these time windows, the process of self-organization seems to be dominant, while outside, the profile behaviour is well-correlated to the forcing factors.

Considering the vast amount of plans for human interference in coastal systems (like large-scale land reclamations, artificial islands in sea and beach nourishments), the need for model-based predictions of coastal behaviour on the time scale of years to decades is evident. It would be interesting to see how the present generation of process-based profile models predict bar behaviour on these time scales, and up to what extend they are be able to deal with the types of 'unexpected' behaviour as given above. In the end a model-based investigation of bar dynamics might contribute to our understanding of the balance of free versus forced behaviour in coastal systems. This study is a first start to addressing these questions.

Concepts in relation to morphodynamics of breaker bar systems

Bed dynamics in the coastal zone occur at various time scales. At the smallest scale bedforms like ripples and mega ripples evolve (minutes to hours). Moving up, the evolution of features like nearshore bars becomes apparent (days to years). Channels on ebb deltas may evolve over decadal time scales, while at a time scale of centuries, we may for instance observe the steepening of the shore face, or changes in the global shoreline orientation. In this paper, the ripple scale is referred to as 'micro-scale', the nearshore bar scale (and tidal channel scale) as 'meso-scale', and the larger scales as 'macro-scale'.

Physical processes at a certain scale level will be in dynamic interaction with coastal behaviour of a similar scale. This is what is called the primary-scale relationship (De Vriend, 1991), see Figure 1.

Fig. 1: Primary-scale relationship (after De Vriend, 1991)
A physical process at a certain scale acts as an extrinsic condition (or constraint) for dynamics at a lower scale level, whilst it is just noise for dynamics at a higher level. Within one scale level, a feedback between response and forcing is observed. For example, for the nearshore bars, wave energy input generates a flow field (FF) in the nearshore zone, causing sediment transport (ST) gradients across the bars and hence morphologic changes (MC), which again affect the nearshore flow field, see Figure 2. Furthermore, a coastal system is stochastically forced, dissipative and features various components which are highly non-linear (like transport rates). It is because of these characteristics that a coastal system might easily allow for unpredictable behaviour in a deterministic sense (De Vriend, 1998), i.e. the system develops very complex patterns that could be modeled in detail, however, without being able to predict when and where they occur (cf. turbulence).

These considerations allow us to schematize the coastal system of consideration, viz. that of nearshore bars. The morphodynamics at this scale level are supposed to be in dynamic interaction with the incoming wave energy and tide-induced variations in water level elevation. Larger scale phenomena like sea level rise and variations in the tidal current pattern act on the system as a constraint via the macro level, as they are affected by features at this higher level. Also, physical constraints like jetties are considered as a macro-level induced constraints, while a weak constraint might result from the lower level by means of bed-form induced friction. Besides forced response, possibly represented by the consistent tendency of bars to straighten during storm conditions, free behaviour needs to be taken into account. This results in the schematization as given in Figure 2. Though the meso-level breaker bar system also affects the lower and higher scales, these relations have been ignored in Figure 2.

![Fig. 2: Schematization of a meso-scale coastal system](image)

In order to assess the predictive skills of profile models, the relative importance of forced response versus free behaviour needs to be determined, which requires the analysis of bar behaviour from both field observations and model simulations.
Positioning of present study

As stated, the predictability of breaker bar behaviour needs be assessed along two different ways:

1. By analyzing bar dynamics from field observations, in relation to the forcing conditions. This requires long time series of bar morphology, with high resolution in time. ARGUS-stations, which collect hourly video observations of the nearshore zone (Holman et al., 1993), provide such type of data. Different techniques to quantify bathymetry from video observations are presently under development, based on the inverse modeling of wave dissipation patterns (Aarninkhof et al., 1997) or wave celerities (Stockdon, 1997).

2. By investigating breaker bar behaviour from simulations with a process-based coastal profile model, both in terms of the sensitivity to various model parameters, as well as regarding the effect of different forcing sequences with similar statistics.

On the longer term, we aim at a comparison of both approaches, however, the present paper only discusses an initial step into the second approach. It concerns a model-based investigation of bar dynamics at Noordwijk, The Netherlands. Multiple model runs have been made, using different time series of hydrodynamic conditions with nevertheless similar statistical characteristics. If a considerable variability in final profile evolution over the various runs is observed (indicating the importance of chronology effects), the system’s response is interpreted to be forced. Alternately, the dynamical quantities of the system might show fractal statistics (in space or time), indicating self-organized response or free behaviour.

The present work treats the sensitivity of model-predicted bar behaviour to chronology effects. To that end a model regarding a multiple-barred coastal system has been set up and calibrated, which will be the subject of the next sections.

1DV-model simulations of bar dynamics at Noordwijk, The Netherlands

Description of model concept

To do the model simulations, Delft Hydraulics’ 1DV coastal profile model UNIBEST-TC has been applied. The UNIBEST-TC model consists of a wave, flow, transport and bed level change module, for which the initial formulations are given in Roelvink and Stive (1989). Although they arrive at a satisfactory calibration of the hydrodynamics in terms of wave height, wave set-up and flow moments, the Bailard transport formulation did not result in a correct description of transport rates, despite an extension of the original Bailard formulation to account for additional stirring of sediment by surface breaking-induced turbulence which penetrates toward the bottom. Consequently, the development and migration of the outer bar were (amongst others) simulated insufficiently.
Later on, the formulation for the breaking-induced turbulence was replaced by the roller concept after Svendsen (1984), and, for heuristic reasons, a breaker delay function was introduced (Roelvink et al., 1995). Moreover, the transport formulations were modified according to Ribberink and Van Rijn (see Van Rijn et al., 1995) without however, significantly changing the basic concept of the quasi-steady transport model. These new formulations allowed for the modification of transport rates by means of breaker delay and slope effects (Bosboom et al., 1997), that finally resulted in the mimicking of cyclic bar behaviour. However, a robust validation of these formulations has not been performed yet.

Model set-up

The numerical model has been set up for a characteristic profile along the Central Dutch coast. Bed elevations along this coast have been surveyed yearly since 1963, which makes its long-term behaviour relatively well understood. A profile at Noordwijk was chosen because this site is also monitored with ARGUS cameras, which gives a reference to short- and medium-term behaviour. The actual profile applied was surveyed in 1980 and extends to 2500 m off-shore; it features 3 bars, which exhibit cyclic behaviour over about a 4 year time span (Wijnberg, 1995).

Time series for the off-shore hydrodynamic conditions have been generated from a wave-climate, measured 6 km off-shore of Noordwijk in 18 m water depth, at 3-hour intervals during a 12-year period of time. The statistics of the wave heights and angles of incidence that occur in the time series obey the frequencies of occurrence as prescribed by the measured wave climate. The adjoining wave period and mean water level elevation have been chosen accordingly, depending on the randomly selected wave height and angle of incidence. At presence, tidal variations are not accounted for, which allows for a simplification of the problem by means of a reduction of the number of independent variables.

The computational grid extends from 2500 m off-shore (14.9 m water depth) to the dune foot; wave conditions measured at 6 km off-shore are translated to the seaward boundary of the model, taking into account the effects of shoaling and refraction. The horizontal grid spacing decreases towards the shore so that a higher resolution is obtained in the active zone, yielding a total of 147 grid points. The time step characteristically amounts 0.25 days for short term runs (180 days).

Sensitivity of bar behaviour to model parameters

Three model parameters are of particular importance in view of bar behaviour, viz. the breaker parameter $\gamma$, the breaker delay parameter $\lambda$, and the subaquous angle of natural repose $\tan(\phi)$. $\gamma$ merely affects the migration of bars, while $\lambda$ and $\tan(\phi)$ are important with respect to the growth, maintenance, and damping of bars. Their role in the model formulations, as well as their effect on final profile evolution is shortly discussed here.
The wave breaking parameter $\gamma$ stems from the Battjes-Janssen wave propagation model and affects the maximum local wave height $H_{\text{max}}$, which is determined as a function of local water depth $h$ and wave steepness, according to

$$H_{\text{max}} = \frac{0.88}{k} \tanh\left(\frac{\gamma h}{0.88}\right) \quad \text{(Eq. 1)}$$

where $k$ is the wave number. Waves smaller than $H_{\text{max}}$ are assumed to be non-breaking and Rayleigh distributed, while all waves higher than $H_{\text{max}}$ are breaking. An increase of $\gamma$ allows for higher wave heights at a certain depth, hence shifting the process of wave dissipation to more shallow water. Consequently, an increase of undertow-induced offshore directed transport rates is induced, yielding a faster off-shore migration of the breaker bars. Figure 3 illustrates this, showing the final profile evolution after 50 days in case of a constant wave height $H_{\text{ms}} = 1.5 \text{ m}$.

![Fig. 3: Effect of breaker parameter $\gamma$ on final profile evolution](image)

The concept of breaker delay (Roelvink et al, 1995) was introduced based on field observations of breaking waves, which showed that waves - having inertia - need a distance of the order of one wave length to actually start or stop breaking. Roelvink et al. accounted for this by replacing the local water depth $h$ in Eq. 1 with a seaward weighted reference depth $h_r$. Consequently, slightly higher waves are allowed at the seaward flank of breaker bars while the concept also allows for ongoing wave breaking in the trough - because of the seaward weighted water depth - hence shifting the undertow currents somewhat towards the trough. The latter allows for offshore-directed sediment transport towards the bar crest, which originally suffered from heavy erosion in the concept without breaker delay. In this way some sediment accumulates in the region close to the bar crest, yielding a better-preserved bar shape. Figure 4 shows the effect of breaker delay after 50 days of constant forcing conditions with $H_{\text{ms}} = 1.5 \text{ m}$. 

![Fig. 4: Effect of breaker delay](image)
Fig. 4: Effect of breaker delay on final profile evolution

The subaqueous angle of natural repose $\tan(\phi)$ accounts for slope effects (Bosboom et al., 1997) and affects the computed transport rates in two ways. First, the threshold criterion for the initiation of motion is adapted using the Schoklitsch factor. With increasing $\tan(\phi)$, the non-dimensional critical shear stress $\theta_c$ (according to Shields) decreases in case of upslope transport, and increases for downslope transport. In other words, upslope transport is stimulated with increasing $\tan(\phi)$, downslope transport hindered. Second, bed load transport rates are affected by means of a Bagnold multiplication factor $\beta$, which increases with increasing $\tan(\phi)$ in case of upslope transport, and decreases in conditions of downslope transport. Again, upslope transport rates are facilitated by increasing values of $\tan(\phi)$, downslope rates hampered. Both modifications to the computed transport rates result in the same effect: a higher value of $\tan(\phi)$ stimulates accumulation of sediment around the bar crest, hence bar development, a lower value causes the damping of bars.

Figure 5 shows the effect of different subaqueous angles of natural repose on the final profile evolution after 50 days in case of a constant wave height $H_{mm} = 1.5$ m. The values of $\tan(\phi)$ are constant along the beach profile, though generally, they are set to decrease somewhat in off-shore direction, to facilitate the damping of bars at deeper water.

Fig. 5: The effect of $\tan(\phi)$ on final profile evolution
Selection of appropriate model settings

As a robust validation of the modified transport module has not been performed yet, the present model can be considered as a (for heuristic reasons) modified version of the original model according to Roelvink and Stive (1989). The heuristic element lies in the transport formulation, and is dealt with by adopting appropriate settings of the wave breaking parameters and the slope effect. Though this might enable a satisfactory representation of cyclic bar behaviour, it does not guarantee that the morphodynamic concept of the model is fully correct.

Lacking local field data on surf zone hydrodynamics, the model has been tuned by carefully choosing the parameters of relevance as mentioned above, such that it represents medium-term bar behaviour reasonably well. Whenever possible, default settings have been applied. In order to obtain sufficient damping of bars at deeper water, the value of \( \phi \) needed to be lowered to \( 9.1^\circ \) at deeper water as compared to \( 12.4^\circ \) at the waterline. The resulting bar behaviour is shown in Figure 6.

![Fig. 6: Bar behaviour in calibrated model](image)

Clearly, the erosion and formation of the steep berm around the waterline are not realistic. This might be attributed to the absence of tidal variations, cf. Southgate (1995). However, in view of bar behaviour, the 4-year bar cycle is clearly recognized while a new bar is being generated in the upper part of the profile.

Overview of model runs

In order to test model-predicted bar behaviour on its sensitivity to chronology effects, multiple model runs have been made with statistically similar input conditions. The sequence of wave events was randomly generated as described above. The statistics of each time series were determined by means of its mean wave height, the standard deviation around the mean and the lowest respectively highest wave of the series.
Statistics of various series show good comparison, as can be seen from 5 representative cases in the table below.

Table 1: Wave height statistics of generated time series

25 Randomly generated time series at 3 hour intervals have been generated for use in the short-term computations, yielding 25 different profile evolutions after 180 days. Each of the 25 time series were then sorted based on wave height, both ascending and descending. This again yielded 25 different realizations of bathymetry after 180 days for both sortings.

Results of short-term (180 days) tests on chronology

In case of the random wave input, general bar behaviour seems to be consistent throughout the 25 cases. All of the three bars migrate seaward, over rather similar distances of about 75 m. Figure 7 shows the mean profile evolution after 180 days, averaged over 25 runs (lower panel), as well as the cross-shore variability in final profile evolution by means of the standard deviation of final bottom elevation over 25 runs and its extreme realizations (upper panel). Maximum variability occurs around the initial location of the bars and their final positions, indicating that the system has not run through a full cycle yet. Moreover, it points out that the horizontal variability (i.e. the variability in the final location of the bars) is rather weak, whereas the vertical variability is more significant: the standard deviation amounts up to 10-15% of the absolute changes of bottom elevation, which is in good correspondence with values found by Southgate (1995). Vertical variability slightly decreases towards the shore.
The results of the runs with sorted input conditions are given in Figure 8. Analogous to the upper panel of Figure 7, the upper and middle panel of Figure 8 show the cross-shore variability in final profile evolution expressed in terms of the standard deviation and extreme realization over 25 runs, for the cases of ascending and descending wave heights respectively. The lower panel visualizes the mean profile evolution for both cases, averaged over 25 runs.

Again, the observed mean bar behaviour is remarkably consistent: after 180 days, all bars have migrated off-shore over a distance of about 75 m, though the bar-shape tends to be
better preserved in the case of ascending wave heights. The variability in final profile evolution clearly differs amongst the 2 cases: the system exposed by ascending wave heights shows moderate variability over 25 runs, which is rather constant along the profile, featuring relatively minor extremes around the initial and final locations of the bars. The case of descending wave heights, on the other hand, shows large variability around the outer bar which drops to almost zero through the central and inner surf zone, indicating very consistent behaviour of the middle and inner bar over the 25 runs.

Discussion

The results described above generally show a decrease of vertical variability in bottom elevation towards the shore, indicating a weaker response of inner surf zone morphodynamics to chronology-related variations in the input conditions. This can be explained from the presence of the outer bar, which filters the wave climate for the central and inner region of the surf zone with respect to high waves, hence reducing the temporal variations in the central and inner surf zone wave conditions. Apparently, the behaviour of the inner bars is not only controlled by the forcing conditions, but also by internal parameters like the height of the outer bar, which might more easily allow for free behaviour in this region. This observation is in accordance with Southgate (1998) who states that ‘generally, fractal responses are found at locations ... where the temporal variations of wave forcing conditions are relatively weak’.

The important role of the outer bar in view of central and inner surf zone morphodynamics is also observed from the runs with sorted wave height input. Significant changes of the outer bar are assumed to be induced by the highest waves of the input time series, therefore the outer bar, in case of descending wave heights, is affected at the very beginning of the simulated time period, whilst in the case of ascending waves, this occurs only at the end of the 180-days period. Consequently, the height of the inner bars after 180 days is more reduced in case of descending wave heights, as they are exposed to more energetic wave conditions during the simulation period. This again stresses the importance of internal system parameters like the height of the outer bar in view of the morphodynamics of the central and inner region of the surf zone.

Nevertheless, though it seems like the observed vertical variability in bottom elevation along the cross-shore profile can be explained reasonably well, the absence of variability in the final position of the bars has not been explained yet. Particularly, the close correspondence between the position of the outer bar resulting from runs with ascending and descending waves respectively - suggesting that bar migration depends on the cumulative amount of energy input rather than the sequence of events – would indicate that chronology is of hardly any importance to the morphodynamics of the outer bar at Noordwijk. This seems counter-intuitive since bars are expected to migrate onshore during periods of low-energetic conditions, and off-shore during storms. Hence the question is raised up to what extent predicted bar behaviour is controlled by model characteristics (concept, parameter settings), rather than system and forcing characteristics.
Apparently, this might be not the only source of unpredictability that arises when addressing the possibility of model-based predictability of long-term bar behaviour. Generally, we can identify 4 possible sources of unpredictability:

1. The limited time horizon of predictability of wave conditions.
2. The numerical discretization of model equations.
3. The model concept, i.e. the dimension of the concept (1DV in the present case) and the schematization of real-world physics in terms of model equations.
4. The complexity or 'irregularity' of natural beach behaviour.

The first source is related to the limited horizon of predictability of weather conditions (characteristically up to 10 days), hence wave conditions, and forms a fundamental limitation to the deterministic predictability of bar behaviour, both from model runs and field observations. However, knowing statistics on the wave climate from long-term field measurements, the probabilistic approach based on randomly generated, realistic time series of wave events seems the best way to cope with this problem.

Also the second source is fundamentally related to the application of a process-based modeling approach. Even in case of a 'perfect' model concept, small errors, caused by the inevitable discretization of model equations, tend to accumulate to become significant in case longer-term computations, justifying the question which part of the model prediction is realistic behaviour and which part can be considered to be error-induced noise. The unrealistic damping of bars after 1 cycle can be attributed to this accumulation of errors, either concept- or discretization-related. Given a certain model-concept, the application of sufficiently small computational steps and the careful selection of parameter settings are ways to reduce this source of unpredictability as much as possible.

The third source of unpredictability seems to play an important role in the present study. Although the model predicts the 4-year bar cycle reasonably well, some essential characteristics of bar behaviour as observed in the field are clearly missing in the present model. The absence of onshore migration (and adjoining growth) of bars during periods of low-energetic conditions and the weak sensitivity of the behaviour of the outer bar to chronology effects can be mentioned in this respect. Further investigation of the present model concept and parameter settings in terms of bar behaviour is necessary to improve acceptability of a model-based approach to assess the predictability of bar behaviour.

Questions to be addressed in this respect are: What are the governing processes causing the consistent off-shore movement of sand bars? What is the effect of the initial profile? Would long-period swell affect the predicted bar behaviour? Would the same behaviour be observed at different sites?

Regarding the fourth aspect, it might be questioned whether process-based numerical models will ever be capable to predict natural 'irregular' behaviour, commonly referred to as free behaviour of coastal systems. Nevertheless, a fundamental understanding of the relative importance of forced response versus free behaviour will help to assess the validity of model-based predictions of coastal morphodynamics. Both the analysis of
ARGUS video-based observations of bar behaviour and the investigation of model-based predictions are expected to attribute to the assessment of this balance.

Conclusion

The present study has attempted to contribute to our understanding of sand bar dynamics by means of coastal profile modeling of a multiple-barred beach with probabilistic forcing conditions. In the case of 180-days simulations, chronology effects turn out to play a role throughout the surf zone, the importance of which increases with distance offshore. Chronology effects merely affect the predicted height of the bars, rather than their final location which is remarkably consistent over the various runs. Moreover, the onshore migration of bars during periods of low-energetic wave conditions was not clearly observed. These observations raise the question up to what extent predicted bar behaviour is controlled by model characteristics (concept, parameter settings), rather than system and forcing characteristics. Further investigation of the model concept and a sensitivity analysis, more extensively than the one presented in this paper, are needed to address this problem.

Acknowledgements

The present study has been performed in the PACE project, in the framework of the EU-sponsored Marine Science and Technology Programme (MAST-III), under contract no. MAS3-CT95-0002. It was cosponsored by the NICOP fund, DELFT HYDRAULICS and Utrecht University. The ARGUS video technique has been developed with funds generated by the Coastal Imaging Lab, Oregon State University.

Abstract

Restrictions imposed by the physical size of testing facilities has limited the range of trials undertaken on field instruments and little is known about interactions between the observed processes and large frames used to deploy equipment in the sea. Further, limited information on the physical processes from the field leads to ambiguity in interpretation of field data. This paper describes tests of the autonomous multi-sensor instrument STABLE, and process studies conducted in the Deltaflume (230 m long, 5 m wide and 7 m deep) of the Delft Hydraulics Laboratory. Regular and random waves with a specified time history and height up to 1.5 m, were used to test instrument performance and to examine sediment processes under waves on beds of medium ($D_{so} = 0.329$ mm) and fine sand ($D_{so} = 0.162$ mm). Selected results from studies of hydrodynamics, bedforms and suspended sediments are presented.

Introduction

Instruments used to measure near-bed hydrodynamic conditions and sediment dynamics in field situations are usually tested and calibrated in relatively 'small-scale' laboratory facilities where it is not always possible to simulate natural processes accurately. In many instances the physical size of these calibration facilities has restricted the range of trials undertaken and frequently little is known about the interactions between the observed processes, the instruments, and the bulky frames used to deploy instrumentation in the sea. Further, instrumentation frequently provides only limited information on the processes under investigation leading to ambiguity in some aspects of field data interpretation. Whilst some of these deficiencies can be addressed through recourse to numerical modelling, recent field experiments have highlighted an urgent requirement to examine critically the performance of

state-of-the-art field instrumentation in a range of controlled experimental conditions at full-scale.

Figure 1  (a) Schematic plan of the Deltaflume research facility; (b) Deltaflume before filling showing the medium sand bed in situ; (c) 1 m regular waves in the Deltaflume, test A4b.

This paper describes research undertaken in the large Deltaflume facility, Figure 1, of Delft Hydraulics during a six-week period in July and August 1997. The work aimed to evaluate the performance of the autonomous multi-sensor frame STABLE (Sediment Transport And Boundary Layer Equipment, Humphery & Moores, 1994), Figure 2, and to measure in detail, bed sediment response to forcing by waves.

Figure 2  STABLE: (a) deployment in the Deltaflume; (b) plan view; and (c) side view
During tests, *in situ* measurements of wave characteristics, flow turbulence, bedforms and vertical suspended sediment concentration profiles were obtained in regular and irregular waves conforming to the JONSWAP spectrum. Hydrodynamic conditions below, approximating to and exceeding the threshold for resuspension of the bed material were examined. Independent measurements of wave-induced flow and vertical suspended sediment concentration profiles were obtained from locations adjacent to the side-wall of the *Deltaflume*.

**Equipment and Methods**

**The *Deltaflume***

The Delft Hydraulics Laboratory *Deltaflume* is 230 m long, 5 m wide and 7 m deep, *Figure 1*. Regular and irregular waves with a height up to 2 m can be generated according to a required time history. During the present tests, 10 cm discus-shaped electromagnetic current meters were fitted to the side-wall of the flume at heights \( z = 25 \text{ cm}, 50 \text{ cm}, 100 \text{ cm}, 150 \text{ cm} \) and 250 cm above the bed at a distance \( y = 120.9 \text{ m} \) from the wave generator. Two resistive wave measurement probes positioned at \( y = 117.9 \text{ m} \) and at 120.9 m (*Figure 1a*) were used to measure wave height, \( H \). Data from these instruments were logged at 25 Hz. Delft software was used to calculate a number of wave parameters including wave period, \( T \), and in the case of random waves, significant wave height, \( H_s \) and peak wave period, \( T_p \).

Samples of suspended sediment were obtained at 10 heights above the sand bed using a pump-sampling device deployed using vertical guide rails at \( y = 121.5 \text{ m} \). The sampling device consisted of 10 intake nozzles (diameter 4 mm) orientated at \( 90^\circ \) to the wave orbital motion. Each nozzle in the array was connected to a plastic pipe through which a mixture of water and sediment was drawn to the surface by means of a peristaltic pump. The resulting water/sand mixture from each sampling position in a given array was collected in 10 litre buckets.

**Sediment beds**

Two sandy test beds were studied: (a) medium sand (median grain diameter, \( D_{50} = 0.329 \text{ mm} \)); and (b) fine sand (\( D_{50} = 0.162 \text{ mm} \)). The sandy beds were approximately 30 m long, 5 m wide and 0.5 m deep, and were placed at \( y = 105 \text{ m} \) in the *Deltaflume*, (*Figure 1*). Both ends of the test beds were tapered to reduce erosion. To minimise bed disturbance, drainage was laid beneath the sediment bed to allow the free passage of water during filling of the *Deltaflume*. The sandy beds were compacted by mechanical vibration. After filling and prior to taking any acoustic measurements, large waves were generated for approximately 4 hours to force remaining air out of the bed and to develop equilibrium bedforms.
Instrumentation on STABLE measured waves, flow turbulence and suspended sediment concentrations. A Digiquartz pressure sensor with integral pressure housing was used to measure the water-depth at wave frequencies at \( z = 170 \) cm. Near-bed fluid motion induced by waves was measured using Valeport Series 800 electromagnetic current meters (ECM’s) with a diameter of 10 cm and a resolution of \( \pm 0.1 \) cm/s. ECM sensors were arranged in pairs set at 90° to each other at \( z = 30 \) cm, \( 60 \) cm, and \( 91 \) cm. Horizontal separation between each ECM sensor was 20 cm. Measurements of flow turbulence were also obtained at \( z = 30 \) cm using a SonTec acoustic Doppler velocimeter, ADV, Ocean Probe operating at approximately 5.0 MHz. Measurements of horizontal and vertical wave induced fluid motion were measured using POL coherent Doppler sensors.

Bedforms beneath STABLE were measured using an acoustic ripple profiler (ABP) and a sector scanning sonar (SSS) device (Bell & Thorne, 1997). Acoustic backscatter, ABS, instruments (Thorne & Hardcastle, 1997) operating at 1.0 MHz, 2.0 MHz, and 4.0 MHz, were located 15 cm in front of the ECM sensors at \( z \approx 128 \) cm. These instruments measured the vertical suspended sediment concentration profiles, \( \bar{C} \) profiles, from the bed to \( z \approx 120 \) cm at intervals of 1 cm. A vertical array of pump sampling nozzles was also fixed to the STABLE frame. A calibrated volume meter was then used to determine approximately, the suspended sediment concentration at each sampling height, (Bosman et al., 1987; Havinga, 1992). Subsequent analysis of samples in the laboratory gave dry weight sediment concentration values and the suspended sediment grain size at each sampling height. ECM and PSI data were sampled at 8.0 Hz and ABS1, ABS2 and ABS3 data were sampled at 4.0 Hz over a period of approximately 19 minutes. ADV data were sampled at 25.76 Hz during the same period. A schematic illustration of the experimental set-up is given in Figure 3 and a summary of all hydrodynamic and morphodynamic variables measured during Deltaflume tests is given in Table 1. Further details of STABLE and the Deltaflume are given by Williams et al., (1998a).
Variables | Instrumentation | Accuracy | Sampling frequency
--- | --- | --- | ---
Water temperature | Thermistor | ± 0.05°C | 0.016Hz
Water (dynamic) pressure | Pressure sensors | ± 0.15% | 8Hz
Water velocity | ECM’s | ± 0.2cm/s | 8Hz
Turbulence | ECM’s | ± 0.2cm/s | 8Hz
Turbulence | SonTec ADV | ± 0.1cm/s | 25Hz
Vertical flow component | Coherent Doppler | ± 0.1cm/s | 8Hz
Horizontal flow cross-correlation | Coherent Doppler | ± 0.1cm/s | 8Hz
Horizontal flow component | Coherent Doppler | ± 0.1cm/s | 8Hz
Free surface elevation | Surface following gauge | ± 2.5cm | 10Hz
Free surface elevation | Resistance type gauge | ± 1cm | 10Hz
Suspended sediment | ABS (1.0; 2.0; 4.0MHz) | 0.001g/l | 4Hz
Suspended sediment | Pump sampling | ± 20% | -
Bed morphology | DH ripple profiler | ± 2mm | 1cm grid
Bed morphology | Sector scanning sonar | ± 2mm | 0.016Hz
Bed morphology | Acoustic ripple profiler | ± 2mm | 0.032Hz
Orientation of STABLE | Compass & inclinometers | ± 1° | 0.016Hz

Table 1: Hydrodynamic and morphodynamic variables measured during Deltaflume tests

Measurements programme

The sequence of experimental conditions was chosen to run from low to high wave conditions so that erosion of the bed was minimised. Surveys showed that the depth of sediment either side of the STABLE deployment site remained approximately constant throughout the tests. Six separate synchronised data logging systems were needed to handle the diverse and extensive data from the various sensors deployed on STABLE and in the Deltaflume. All data sets were time and date stamped to allow easy cross-referencing. Table 2 summarises the range of wave conditions in the Deltaflume during tests on the medium and fine sand beds.

Results and discussion

In this section only selected results from the experiments in the Deltaflume are presented in order to illustrate the breadth and detail of the present study. The range of data acquired during the experiments was very extensive and it is possible here only to present a fraction of the results currently obtained. Since the main thrust of the work has been to assess the performance of sensors on the STABLE frame at approximately field-scale, attention here is
focussed primarily upon results that aid in this assessment exercise. Work examining C profiles is currently in review (Williams et al., 1998b).

Hydrodynamics

In order to assess instrument performance, comparisons have been made between the STABLE ECM's and the ADV. ECM data were calibrated and despiked and corrected for misalignment using a modified form of the method described by Soulsby et al. (1991). Values for the zero-mean orthogonal flow components $u$, $v$ and $w$ were calculated using the method described by Williams et al. (1997). In the case of the ADV, values for $u$, $v$ and $w$ were also corrected for misalignment using the rotation angles determined for the ECM's and knowledge of the position of the instrument on the STABLE frame.

Figure 4 shows power spectra on log-log axes derived using a fast Fourier transform for $u$ and $w$ components measured above the fine sediment bed by the ECM's and by the ADV during: (i) test $f08a$ (regular waves, $H = 1.0$ m, $T = 5.0$ s); and (ii) test $f10a$ (irregular waves, $H_s = 1.0$ m, $T_p = 5.3$ s). In the case of regular waves, $u$ spectra show peaks at approximately wave, half wave and quarter wave frequencies. A broad peak in $u$ spectra spanning the frequency range $0.1$ Hz to $0.3$ Hz is measured for the irregular waves. In contrast, spectra for the $w$ component are much flatter. However, there are peaks in energy corresponding to those in the $u$ spectra. These are attributed to wave asymmetry.

Figure 4 Typical $u$ and $w$ power spectra for 1.0 m regular and irregular waves:

- $ECM$ spectra; $ADV$ spectra.
In all cases the spectra derived from ECM and ADV time-series are broadly similar over the frequency, \( f \), range 0.001 Hz to 0.3 Hz. At frequency values greater than 0.7 Hz, ECM and ADV spectra diverge significantly, demonstrating the high frequency cut-off attributable to the larger sampling volume and lower sampling frequency of the STABLE ECM system. These results demonstrate that broadly speaking, the ADV and the ECM's give comparable results across a wide frequency band.

If one considers the implication of these results in the context of current-only or wave-current situations, then failure of the ECM's to measure all the high frequency energy has consequences when ECM data are used to derive estimates of the bed shear stress, \( \tau \) using the eddy correlation, \( EC \), turbulent kinetic energy, \( TKE \), or inertial dissipation, \( ID \), approaches. Specifically, the present ECM's system will always underestimate \( \tau \). However, since the total amount of energy missing from the ECM spectra is estimated to be less than 3% of the total, estimates of \( \tau \) are unlikely to be seriously in error. The relative importance of these errors in the context of sediment transport in the marine environment is almost insignificant when one considers the imprecision with which entrainment threshold, settling velocity and bedform dimensions are known.

**Bedforms**

*Figure 5* shows long-crested vortex ripples on the medium sand bed measured using the SSS. The side-walls of the Deltaflume and imprints left in the sand by STABLE feet are clearly visible. Of particular relevance to the present study is the proof provided by *Figure 5* and other images, that ripple geometry is unaffected by the presence of the rig. This result confirms unequivocally that STABLE has no detectable influence upon the process of ripple formation in wave-only conditions.

*Figure 5* SSS image of long-crested vortex ripples on the medium sand bed.
Temporal changes in ripples on the medium sand bed measured during test A13a and A14a using the ARP, \((H = 1.0 \text{ m}, T = 5.0 \text{ s})\), are illustrated in Figure 6. This figure shows vortex ripples migrating up the flume towards the wave generator a distance of approximately 10 m in 80 minutes.

![Figure 6](image)

**Figure 6** Temporal and spatial variation in \(h_r\) and \(\lambda_r\) measured by the ARP

Values for ripple height, \(h_r\), and wavelength, \(\lambda_r\), measured using the ARP are found to be in good agreement with predicted vortex ripple dimensions in regular wave conditions (Nielsen, 1992). Whilst some of the temporal variability in ripple geometry may be attributed to random wave conditions during the tests, the migration of ripples shown in Figure 6 probably results from a compensating current near the bed and from wave asymmetry. The ability to monitor continuously the bed geometry directly beneath STABLE is clearly demonstrated by Figure 6. It is considered that in future field deployments of STABLE, measurements from the ARP and the SSS will prove to be invaluable in characterising the local micro-morphology of the sea bed.

**Suspended sediments**

Typical \(\overline{C}\) profiles measured from STABLE and from the Deltaflume using the pump-sampling equipment on are shown using log-log axes in Figure 7a for. (a) regular waves above the medium and fine sand beds [tests A11a and f11a], and (b) for irregular waves above the medium and fine sand beds [tests A10a and f07a]. For the \(\overline{C}\) profiles considered here, time-averaged suspended sediment concentration, \(\overline{C}\), values measured at the sampling
position closest to the bed span a range from approximately 0.01 g/l to 10.0 g/l. In most cases, $\bar{C}$ values measured during the experiments by the volume method and in the laboratory differ by less than 50%. However, at a given height above the bed, differences between $\bar{C}$ values measured from \textit{STABLE} and from the \textit{Deltaflume} frequently exceed 100%. These differences are thought to arise owing to the combined effect of different sampling locations relative to bedforms, side-wall effects, zero datum errors and flow turbulence generated by \textit{STABLE}.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure7.png}
\caption{(a) $\bar{C}$ profiles measured above bed of medium and fine sand in regular and irregular wave conditions; and (b) $\bar{C}$ profiles for separate grain size fractions, \textit{test A11a}.}
\end{figure}
Figure 7b shows normalised $C$ profiles for separate grain size fractions measured during test A11a on the medium sand bed. In common with other published data, $C$ values at any given height increase with decreasing grain size and demonstrate that suspended sediments are composed principally of the fine fraction of sediments comprising the bed. Detailed study and modelling of $C$ profiles has been undertaken by Williams et al. (1998b).

An example of data from the 20 MHz ABS instrument is shown in Figure 8. This figure shows the response of the medium sand bed to a group of 8 waves during random wave conditions and is typical of other results. Modulation at approximately the wave frequency is evident as is a general increase in the average suspended sediment concentration. It is also seen that by the passage of the fifth wave appreciable quantities of suspended sediment are present at $z = 0.6$ m. Also evident is a parcel of suspended sediment in the region $0.4 \leq z < 1.0$ m under wave 7 in the group. This suspended sediment is surrounded by fluid containing little in suspension and may be the manifestation of vortex detachment from ripples on the bed. A similar but much smaller volume of suspended sediment is also evident under wave 8. It is considered that both suspension structures are related where the structure beneath wave 7 is the remnant of the first structure. These data provide a fascinating insight into the intricacies of inter-wave period sediment resuspension processes and a major study to quantify these mechanisms is currently underway.

**Figure 8** Example of data from the 20 MHz ABS instrument showing resuspension by a wave group.
Summary

This paper describes experiments conducted in the Deltaflume of Delft Hydraulics to evaluate the performance of field instrumentation used to measure near bed hydrodynamic conditions and sediment dynamics from the large tripod frame STABLE. Tests were conducted on beds of medium ($D_{50} = 0.329\text{mm}$) and fine ($D_{50} = 0.162\text{mm}$) sand under regular and irregular waves of sufficient size to re-suspend the bed material. Measurements of waves, turbulence, vertical suspended sediment concentration profiles and bed morphology were obtained using a comprehensive suite of state-of-the-art acoustic and electromagnetic sensors and in situ samples of sediment in suspension were obtained by pump sampling.

In order to illustrate the nature and quality of the measurements, selected results from the experiments pertaining to bedforms (vortex ripples), to hydrodynamic conditions close to the bed and to suspended sediments have been presented. These data will make possible critical evaluation of the performance of field instruments and will aid interpretation of existing data sets from past deployments in the field. Furthermore, the data will aid the study of the detailed processes leading to the mobilisation and resuspension of sandy sediments in wave conditions and provide a rigorous test case for existing and future numerical models of sediment entrainment and suspension. Exploitation of the Deltaflume data set is already underway through the European MAST 3 project INDIA and the UK EPSRC Programme COSMOD. In the future it is also planned to make these data available to researchers through the publication of a CD-ROM.

Abstract

This paper presents the experimental results obtained at prototype scale in the Large Oscillating Water Tunnel (LOWT) facility of WL | Delft Hydraulics with graded sediment subjected to non-linear waves and linear waves plus current flows. The objective of this experiment is to increase our present understanding and physical insight of the basic mechanisms of bed-load and suspended load transport in oscillatory flow conditions when graded sediments are present in the bed. The sediment bed consists of a mixture of two well sorted sands (two fractions) that have been used before in the tunnel in order to make comparisons possible. Net sediment transport rates, time averaged suspended sediment profiles, time dependent concentrations in the suspension and sheet flow layers as well as time dependent velocity profiles are measured. Moreover, the sediment bed composition before and after each test is recorded in order to calculate the transport rate of each sediment fraction. Selected results are presented here. Full details are included in the data report (Hamm et al., 1998). The data will be used for the development of mathematical model formulations for graded sediment transport.

Introduction

The Large Oscillating Water Tunnel (LOWT) facility of WL | Delft Hydraulics in de Voorst, The Netherlands enables experiments at full scale including horizontal oscillatory flows with superimposed currents. The test section is 14 m long, 1.1 m high and 0.3 m wide. Most of the research in the tunnel during the last decade was carried out using unsieved dune sand with a median diameter of 0.21 mm and a narrow size distribution (Ribberink and Al-Salem, 1994 and 1995, Ribberink et al., 1994, Katopodi
et al., 1994). Two types of oscillatory flow conditions were generally used, namely regular second-order Stokes waves and sinusoidal waves with superimposed net currents. In the majority of the experiments the plane-bed regime with sheet-flow conditions was observed.

Since three years, specific attention is paid to the influence of the grain size in combined wave-current conditions. Experimental programmes were carried out with median diameters of 0.13 mm and 0.32 mm keeping the geometric standard deviation unchanged (Janssen and Ribberink, 1996, Dohmen - Janssen et al., 1998).

The flume is now also used to study sediment transport with sands containing heavy minerals with a density >2.9 kg/l which are naturally found in the field. These tests show that these heavy minerals, have clearly different transport properties than light minerals and induce armouring effects (Tánczos et al., 1997).

The present experiments actually include two Series named K and L. In Series L, the previous experiments of Tánczos et al. (1997) were completed by using mixtures of light sand and zircon with the same grain size but distinctly different density. These tests are reported by Manso et al.(1998). In Series K described in the present paper, a mixture of two sand types with median diameters of 0.13 mm and 0.32 mm has been used and the hydrodynamic conditions have been chosen in close connection with previous experimental series in the tunnel. This makes comparisons with available data possible and increases the scope and possibilities of the present work.

**Experimental set-up and programme**

**Hydraulic conditions**

The experimental programme consisted of 3 asymmetric wave conditions and 2 sinusoidal waves/net current conditions, which are summarised in Table 1. Two 2nd-order Stokes waves conditions were chosen with different root-mean square velocities, \( u_{rms} \) (K1 and K2). The 2nd order Stokes wave can be described with

\[
(1) \quad u(t) = u_1 \cos(\omega t) + u_2 \cos(2\omega t),
\]

the root-mean square velocity yields:

\[
(2) u_{rms} = \sqrt{0.5 * (u_1^2 + u_2^2)}
\]

Where \( u_1 \) and \( u_2 \) are the first- and second-order components of the horizontal velocity, respectively. \( \omega \) is the angular frequency of the wave (=2\pi/T). The wave period \( T=6.5 \) s was the same for both conditions. The degree of asymmetry \( R \), defined as \( (u_1+u_2)/2u_1 \) was 0.66.
Also a different asymmetric wave was used called the sawtooth wave (K3). The only difference between the sawtooth and the 2\textsuperscript{nd}-order Stokes wave is a 90 degree phase shift of the second harmonic component. The sawtooth wave can be described by:

\[ u(t) = u_1 \cos(\omega t) + u_2 \cos(2\omega t + \pi/2) \]

Even when the values of \( u_1 \) and \( u_2 \) are the same, the third order velocity moment is very different, i.e. zero for the sawtooth wave and non-zero for the 2\textsuperscript{nd}-order Stokes wave. It is therefore interesting to investigate the difference in net transport rates caused by a sawtooth wave and by a 2\textsuperscript{nd}-order Stokes wave, with the same period and the same root-mean square velocity.

The last two conditions were combined sinusoidal waves/current conditions (K5 and K6). The net current velocity at 10 cm above the bed \( <u> \) and the amplitude of the sinusoidal velocity \( \bar{u} \) were different for each condition. The oscillation period \( T=7.2 \) s. was the same for both conditions. All conditions correspond to the sheet flow regime and lie within the constrictions of the tunnel.

(1) measured at 0.10 m above the initial bed

**Sediment properties**

The sand used in the present experiments consisted of a 50%-50% mixture of the fine (\( D_{50} = 0.13 \) mm) and the coarse sand (\( D_{50} = 0.32 \) mm) with hardly any overlap as can be seen from the \( D_{90} \) of the fine sand (0.182 mm) and the \( D_{10} \) of the coarse sand (0.217 mm). The characteristics of the mixture derived from sieve-analyses (figure 1) are \( D_{10} = 0.097 \) mm, \( D_{50} = 0.194 \) mm, \( D_{90} = 0.406 \) mm with a density of 2650 kg/m\(^3\). Analysis of the sand in the Visual Accumulation Tube (VAT) gives a median fall velocity of \( W_{s,50} = 20.3 \) mm/s for the mixture.
Measurement programme and instruments

The measurement programme was designed as comprehensively as possible making use of several kind of instruments to measure time-averaged as well as time-dependent quantities. In order to achieve that goal, it was necessary to repeat the hydraulic conditions several times, each run being devoted to a particular instrument.

![Grain-size distribution of the mixture](image)

Figure 1. Grain-size distribution of the mixture

The measurements were especially delicate and more time consuming compared with previous measurements with uniform sand. For graded sand, the bed composition changes with time and thus replacement of the bed was necessary to restore the designed bed composition for the next runs. Thus, the upper layer of the sand bed (~5 cm) had to be removed from the tunnel and replaced with new sand every few tunnel runs. Considerable effort was also required for the extraction of the bed samples and their analysis in the settling tube.

The measurements required to obtain the net, time-averaged transport rates (global and per fraction) were performed first for the five hydraulic conditions. Then, the suction system was installed to measure the vertical profile of time-averaged concentrations in suspension for three hydraulic conditions (K2, K5 and K6). Finally, detailed time-dependent measurements over the vertical were performed for two hydraulic conditions (K2 and K5) by installing successively four instruments described below.

Bed levels along the tunnel were measured before and after each run using a bed level profiling system. Additionally, the weight of the sand collected in the traps was measured underwater.

The upper layer of the sand bed in the test section was sampled using a siphoning system. A perspex cylinder (height about 12 cm) with a diameter of 100 mm was stuck into the sand bed for about 5 cm. Next the sand-water mixture within the cylinder was siphoned out of the tunnel, and the sand water mixture was collected in buckets. The grain size distribution and the percentage of the fine and the coarse fraction, present in each sample
was determined by using a settling tube (Visual Accumulation Tube, VAT). Samples from
the sand collected in the traps were also subjected to the same analysis.

The time-averaged concentration \(\langle c(z,t) \rangle\) in the suspension layer was measured using a
transverse suction system able to extract samples of a mixture of sand and water at ten
locations over a vertical simultaneously. The concentration was determined and the
sample was then put into the VAT to get the grain-size distribution of the suspended
sediment.

Time-dependent sediment concentration \(c(z,t)\) was measured over the vertical both in the
suspension layer (for \(z > 0.01\) m) using an optical concentration meter (OPCON) and in
the sheet flow layer using a conductivity concentration meter (CCM). The OPCON is
based on the extinction of the infra-red light when concentrations are in the range 0.1-50
g/l. The CCM is able to measure large sand concentrations in the range 100-1500 g/l on a
sensing volume with a height of 1 mm.

Finally, time-dependent flow velocity components over the vertical were measured thanks
to an acoustic doppler velocity meter (ADV) able to work even in high concentrations of
sediment and a laser doppler flow meter (LDFM). In total, 41 runs were performed to
achieve the measurement programme. The number of runs per hydraulic condition is
provided in table 1.

**Experimental results**

**Net sediment transport rate**
The net sediment transport rates were measured for all five flow conditions. The
sediment continuity equation was solved twice (starting either from the left or the right-
hand-side) using as boundary conditions the sand volumes collected in the sand traps
(given the sand porosity). This gives two estimates of the actual occurring transport rate in
the middle of the tunnel for a specific test and the mean value is used. Figure 2 gives an
example of such a result for test K5. In table 2, the net transport rates averaged over
several runs are presented. Moreover, the standard deviation and the relative error are
provided. They are comparable to the previous experiments (see i.e. Katopodi et al., 1994).

Cloin (1998) compared these results with available previous experiments performed with uniform sand (Katopodi et al., 1994, Janssen and Ribberink, 1996 and Dohmen-Janssen et al., 1998) and with similar hydraulic conditions (see figure 3). She also performed an analysis of the sediment transport per fraction, which is presented hereafter, in order to understand the main features of this comparison.
Figure 3. Comparison of the net sediment transport rate with previous experiments using uniform sediment. up: test K1, K2 and K3, middle: test K5 and down: test K6

Bed composition

An important part of the experiment was the estimation of the bed composition before and after each test. This information was necessary to estimate the transport rate per fraction and also explain the suspended sediment behaviour. Unfortunately, large scatter was observed in the bed composition data. The bed composition before the test was not completely uniform along the tunnel owing either to non uniform mixing of the two sand fractions or to inaccuracies of the sampling method. The bed composition after the tests did not show the same trends for all the tests of each condition. This might be
again due to the sampling method or due to the fact that the upper layer of the bed was not changed after each test.

A detailed analysis of the bed composition data as well as an evaluation of the sampling method can be found in Cloin (1998). Despite of the large scatter of the data, she was able to calculate the transport rate per sediment fraction for all flow conditions. Figure 4 shows the result obtained for test K5.

![Figure 4: Net sediment transport per fraction along the test section for the test K5.](image)

Then, she compared the measured sediment transport per fraction with the previous measurements with uniform sand (figure 3) by attaching to each fraction an estimated uniform-based sediment transport. This estimation was computed by multiplying the volume percentage of occurrence of the fraction considered in bed material with the transport rate of the fraction assumed to be alone, this transport being derived from the measurements with uniform sands. She was thus able to show that for sinusoidal waves with a net current, the fine fraction is hidden by the coarse fraction and the coarse fraction is more easily transported than in the case of uniform coarse bed material. The hiding is larger in case of higher mean velocity and smaller oscillating velocity. For second-order wave conditions, the fine fraction is also hidden by the coarse fraction for the strongest case (K1) but the coarse fraction is not influenced by the fine fraction in both cases.

**Vertical sorting of the grain sizes**

The sand samples extracted from the flow (suspension layer) with transverse suction present a strong reduction of the median diameter with elevation for all three conditions.
examined (K2, K5 and K6). The coarsest sand found near the bed has a $D_{50}$ of only 0.13 mm while the $D_{50}$ of the original sand in the bed was 0.21 mm. This shows that only sand belonging to the finer fraction was set into suspension. The median diameter for all conditions decreases with elevation reaching a minimum of 0.08 mm. The two tests per condition give similar results, except for K2 where the two tests are considerably different for elevations higher than 2 cm. The sand of the first test is much finer than that of the second. It is clear that for the two tests the bed composition was not the same.

**Sediment concentrations**

a) Time-averaged concentrations

Time-averaged suspended sediment concentrations were measured with transverse suction for K2, K5 and K6. The concentrations for all conditions follow a power law (straight best fit lines), as has been found for all previous measurements in the tunnel under sheet flow conditions. For all cases the concentrations are larger than the concentrations measured previously with well sorted sand of $D_{50} = 0.21$ mm for the same flow conditions. Time-averaged suspended sediment concentrations were also computed from the time dependent OP6CON signal for K2 and K5. The two tests of K2 give somewhat different results, with the first test showing larger concentrations than the second. This indicates different bed composition during the two tests. For K5 the different tests show a rather good agreement. Comparison with transverse suction concentrations shows a satisfactory agreement for K5, differences for K2. Again, the rather variable bed composition for K2 may have played a role. The time-averaged concentrations computed from the CCM time dependent signal show an almost constant value of about 1350 g/l in the pick-up layer below the bed level. Above the bed the concentration decays rapidly to values less than 100 g/l in a distance of 3-5 mm (thickness of the sheet flow layer).

The vertical profile of the concentrations measured with the three instruments spans a distance from ~ 1 cm below the bed up to ~ 25 cm above the bed and covers the pick-up, the sheet flow and the suspension layers. For both conditions (K2 and K5) the concentration profile shows a transition from a convex shape (pick-up layer) to a concave shape (suspension layer), reflecting the presence of different mechanisms in the mixing process. The profile obtained during test K5 is shown on figure 5.

b) time-dependent concentrations

The time-dependent concentration was measured at different elevations with OP6CON (suspension layer) and CCM (sheet flow and pick-up layers) for K2 and K5. In the sheet flow layer the concentration is in phase with the free stream velocity. The same also holds for the suspension layer although a phase shift growing with elevation can be
observed. In the pick-up layer the concentration follows the opposite behaviour (i.e. min concentrations at max velocities and max concentrations at zero velocities). The concentration in the sheet flow layer shows sharp peaks at the moments of the flow reversal a feature found before in measurements with uniform sand. In general the shape of the time dependent concentrations was the same as with well sorted sand with the same D$_{50}$. Figures 6 and 7 show the results obtained for test K5.

Figure 5: Time-averaged concentration profiles - test K5

Figure 6: Time-dependent horizontal velocity at 10 cm above the initial bed (test K5)
Flow velocities

Time dependent velocities were measured at different elevations for K2 and K5 with ADV and laser (LDFM). Velocity profiles could not be measured satisfactorily with laser for condition K5 because the suspended concentration was large and was blocking the laser beams almost for the entire depth.

The ADV signal in general was disturbed but we could measure close to the bottom (see figure 8 illustrating a typical result). Although the net ADV profile data present
The ADV signal in general was disturbed but we could measure close to the bottom (see figure 8 illustrating a typical result). Although the net ADV profile data present much scatter, for the second order Stokes condition K2 a small net current in the crest direction was distinguished as well as the asymmetry induced boundary layer streaming in the opposite direction. For the wave and current condition K5 the profile was logarithmic. These findings are in accordance with previous measurements in the tunnel.

Comparison of ADV and laser measurements for K2 showed a systematic difference which is small in the time dependent values but significant when averaged over the wave period. In Katopodi et al (1994), a similar mismatch was found when comparing laser and EMF (electromagnetic flow meter) measurements for waves and currents. Although the two cases are not directly comparable, they both concern asymmetric flows (K2 second order Stokes, series E current and sinusoidal waves).

**Conclusions**

An experimental investigation of graded sediment transport was conducted in the Large Oscillating Water Tunnel of WL I Delft Hydraulics under various hydraulic conditions with plane bed. The sediment bed consisted of a mixture of two well sorted sands (two fractions) that have been used before in the tunnel. The experiment concerned measurements of net sediment transport rates, bed composition change, time averaged suspended sediment profiles, time dependent concentrations in the suspension and sheet
flow layers and time dependent velocity profiles. A detailed presentation of the measurements and results is presented in the data report (Hamm et al, 1998). Furthermore, net transport rates per sediment fraction were calculated by Cloin (1998) based on the bed composition data.

The data set has then been used by Cloin (1998) to compare with previous experiments using uniform sands. She also used it for the experimental verification of various transport formulae as well as time dependent models of sediment transport of graded sediment in sheet-flow conditions. This work is being extended to enlighten the influence of size and density in selective transport mechanisms. The examination of the gradation characteristics of the suspended sand samples and their linking with the characteristics of the bed samples is also scheduled (Katopodi et al., 1999).

As seen from the bed composition results, the used bed sampling technique did not prove very accurate and should be improved, possibly by taking cores out of the bed or colouring one of the fractions. Moreover, it would be very useful if the measurements concerning the two well sorted sands that constitute the sediment mixture of this experiment were completed such that all the quantities measured for series K could be compared with measurements of sand consisting out of one fraction only (see Hamm et al, 1998).

Phase-lag effects in oscillatory sheet flow

C. Marjolein Dohmen-Janssen¹, Gizella van der Hout¹, Jan S. Ribberink²

Abstract

It is often assumed that in sheet flow conditions the transport rate in oscillatory flow behaves quasi-steady, i.e. showing a direct relation with the instantaneous flow velocity (e.g. Ribberink et al., 1994). In this paper it will be shown that this assumption is not always valid.

Therefore a new semi-unsteady sand transport model is developed which takes into account phase-lag effects of the sediment on the net transport rate. In order to verify this new semi-unsteady model and two existing quasi-steady models, new experiments were performed in the Large Oscillating Water Tunnel (LOWT) of Delft Hydraulics. Together with earlier experiments these measurements form a data set of net sand transport rates of uniform sand for three different grain sizes ($D_{50} = 0.13; 0.21$ and 0.32 mm) in combined wave-current sheet flow conditions.

The verification shows that phase-lag effects become important for a combination of fine sand, large flow velocities and small wave periods. Under these conditions the quasi-steady models cannot predict the behaviour of the net transport rates correctly and the predictions of the new semi-unsteady model show much better agreement.

Introduction

Sheet flow corresponds to conditions of high velocities when ripples are washed out and the bed becomes flat. In those conditions the majority of the sand transport takes place in a thin, high-concentrated layer close to the bed, i.e. the sheet flow layer.

Because of the small thickness of this layer it is generally assumed that the response time of the sand transport process to changes in flow conditions is small compared to the wave period. If that is the case, it can be expected that the time-dependent sediment transport rate depends directly on the instantaneous flow velocity or bed shear stress. This assumption is applied in all quasi-steady models.

If the response time of sediment particles is not small compared to the wave period, the sediment concentration may lag behind the velocity. This will be caused by the fact that both the sediment entrainment from the bed into the flow and the settling of the particles back to the bed takes time. The latter depends on the settling time of a particle and on the height to which the particle is entrained, which is expected to be determined by the flow velocity. Therefore it is expected that phase-lags will become important if sediment is entrained relatively high into the flow (large oscillatory velocities) and slowly settles down to the bed (fine sand) while the available fall time is short (small wave period). Moreover, it is expected that if phase-lags occur, the net transport rates are reduced. This can be explained as follows: If the transport behaves quasi-steady, the net (wave-averaged) transport rate under asymmetric oscillatory flow will always be in direction of the largest velocity, due to the non-linear relation between velocity and sand transport rate. If the sediment concentration lags behind the flow velocity, part of the sediment that is picked-up under a certain half wave cycle, may still be entrained into the flow and transported in opposite direction during the successive half wave cycle.

A new semi-unsteady model is developed to take into account the effect of phase-lags on the net transport rates. The model is called semi-unsteady, because it accounts for phase-lag effects, without describing the complete time-dependent velocity and concentration profiles. Apart from the new semi-unsteady model, also two existing quasi-steady models are presented, in order to compare the differences between these two types of models. The three transport models are verified against experimental data.

The set-up of the experiments and the measured net transport rates are presented first. Next the two existing quasi-steady models are described shortly and the new semi-unsteady model is presented. Finally, the behaviour of the measured net transport rates is discussed in relation with the predictions of the three transport models.

New experiments

Two new sets of sand transport experiments were carried out with uniform sand of different grain sizes. The experiments were performed in the Large Oscillating Water Tunnel (LOWT) at WL | DELFT HYdraulics from October 1996 to January 1997. The mean grain sizes of the two sands were 0.32 and 0.21 mm for series I and J respectively. The experiments are a follow up of the previous experimental series with 0.21 mm sand (Series E: Katopodi et al., 1994) and 0.13 mm sand (Series H: Janssen and Ribberink, 1996 and Janssen et al., 1997). The measurements of these four series can be considered as one consistent data set on sediment transport under combined wave-current flow in the sheet flow regime.

The LOWT of WL | DELFT HYdraulics is a large-scale facility that allows experiments to be performed at full scale (1:1). It consists of a large U-shaped tube, with a long horizontal test section and two vertical cylindrical risers. One of them is open to the air; the other riser contains a steel piston. The piston sets the water in motion and induces an oscillating water motion in the test section. The test section is 14 m long, 0.3 m wide and 1.1 m high. A 0.3 m thick sand bed can be brought into the test section, leaving 0.8 m for the oscillating water flow above the bed.
Underneath both risers a sand trap is constructed. The range of oscillatory velocities is 0.2-1.8 m/s; the range of periods is 4-15 s.

A recirculation flow system for the generation of a net current is connected to both cylindrical risers. The maximum superimposed net current velocity in the test section is about 0.5 m/s. A third sand trap is constructed in this recirculation system. A picture of the LOWT is given in Figure 1.

![Figure 1: Large Oscillating Water Tunnel](image)

The characteristics of the three sands, used in the experimental series are:

- Series H: \(D_{10} = 0.10\) mm, \(D_{50} = 0.13\) mm, \(D_{90} = 0.18\) mm
- Series E/J: \(D_{10} = 0.15\) mm, \(D_{50} = 0.21\) mm, \(D_{90} = 0.32\) mm
- Series I: \(D_{10} = 0.22\) mm, \(D_{50} = 0.32\) mm, \(D_{90} = 0.46\) mm

The test conditions consisted of different combinations of a sinusoidal oscillatory flow and a net current. A condition is characterised by the wave period \(T\) (s), the velocity amplitude \(u_a\) (m/s) and the mean current velocity \(u_m\) (m/s) measured at 10 cm above the bed. For the present series I and J the conditions are mainly the same as in the previous experimental series with unsieved dune sand with \(D_{50} = 0.21\) mm (Series E) and fine sand with \(D_{50} = 0.13\) mm (Series H).

For every condition net (wave-averaged) transport rates were measured, together with the flow velocity at 10 cm above the bed. Net transport rates were derived from measured bed level changes and the weight of the sand, collected in the traps.

The measured net transport rates are based on measurements over the full width of the tunnel. However, the velocities are measured in the centreline of the tunnel. Due to boundary layer effects the net current velocities in the centreline are somewhat
higher than the width-averaged values. Therefore the net transport rates are corrected such that they correspond to the measured velocities in the centreline of the tunnel (see e.g. Van der Hout, 1997). Table 1 presents the measured wave periods and flow velocities, together with the corresponding net transport rates, expressed in m$^2$/s, i.e. volume of sand per unit width per second.

For conditions E1–E4, H6, H9, and H11 also time-dependent measurements were carried out: During the wave cycle both flow velocities and sediment concentrations at different levels above the sand bed were measured. Moreover, video recording were taken to determine the bed level variation during the wave cycle. These time-dependent measurements are not included in this paper (see e.g. Katopodi et al., 1994; Ribberink et al. 1994; Janssen et al., 1997 and Janssen and Van der Hout, 1997).

**Quasi-steady model of Bailard (1981)**

Bailard applied the theoretical energy consideration of Bagnold (1963) to determine the sand transport rate. He assumed that the sediment transport rate is proportional to the available fluid power, which is equal to the work done by the fluid, i.e. the absolute value of the fluid shear stress times the velocity.

The model consists of a bed load and a suspended load component. Each component includes a term that depends on the bed slope. The bed slope terms are not included here, because the sand bed in the experiments is horizontal. The equation reads:

$$q_s(t) = \frac{c_r}{(s-1)g} \left( \frac{e_b u^3(t)}{\tan \varphi} + \frac{e_s}{w_{\text{fall}}} |u^3(t)| u(t) \right)$$

Here $q_s$ is the sediment transport rate, $t$ is time, $c_r$ is a friction factor, $s$ is the relative density ($s = \rho_s/\rho$ with $\rho_s$ the density of the sediment and $\rho$ the density of water), $g$ is the gravity acceleration, $u$ is the horizontal velocity, $\varphi$ is the angle of internal friction and $w_{\text{fall}}$ is the fall velocity. The coefficients $e_b (= 0.1)$ and $e_s (= 0.02)$ are efficiency factors for the bed load and the suspended load transport.

In the present study the friction factor is calculated as a combined wave-current friction factor, as described by Ribberink (1998). The bed roughness height is considered to be equal to the grain diameter, i.e. $k_s = D_{50}$.

**Quasi-steady model of Ribberink (1998)**

The quasi-steady model of Ribberink is a bed load model. However, Ribberink considers all transport in the sheet flow layer as bed load. In sheet flow conditions the majority of the transport is transported inside the sheet flow layer, which means that the total transport will only be slightly larger than the bed load component, defined in this way.

Ribberink assumed the sand transport rate to be proportional to the difference between the actual time-dependent bed shear stress and the critical bed shear stress. The bed shear stress is expressed in terms of the (dimensionless) Shields parameter:

$$\theta(t) = \frac{\tau_b(t)}{\rho (s-1) g D_{50}}$$

Here $\tau_b$ is the time-dependent bed shear stress and $D_{50}$ is the mean grain diameter. The sand transport rate is normalised by the parameter $\sqrt{(s-1) g D_{50}^3}$. This gives the following expression for the sand transport rate:

$$q_s(t) = m \sqrt{(s-1) g D_{50}^3} \left( \frac{\theta(t)}{\theta_{cr}} \right)^n \frac{\theta(t)}{|\theta(t)|}$$

The values of the coefficients $m$ and $n$ are based on many data from laboratory and field experiments with steady and oscillatory flows: $m = 11$, $n = 1.65$. 
New semi-unsteady model

As mentioned in the introduction, phase-lag effects are expected for fine sand, large oscillatory velocities and small wave periods. Moreover, phase-lag effects are expected to reduce the net transport rate. Therefore a new-semi unsteady model is developed which predicts the same net transport rates as the quasi-steady model of Ribberink if phase-lag effects are small and smaller net transport rates if phase-lag effects become important.

This is realised by introducing a correction factor $r$ to the calculated net transport rates of the model of Ribberink. The correction factor $r$ is equal to 1.0 if no phase-lag effects occur and decreases for increasing phase-lag effects.

The correction factor $r$ is defined as the ratio of the net sand transport rate, including phase-lag effects ($real$ net transport rate) to the net sand transport rate when phase-lag effects are neglected ($equilibrium$ net transport rate). These transport rates are calculated as follows:

$$q_r(t) = \int_0^h u_x(t) \cdot c(z, t) \, dz$$  \hspace{1cm} (4)

Here $h$ is the water depth, $u_x(t)$ is the periodic velocity outside the wave boundary layer, (free-stream velocity) and $c$ is the sediment concentration. The time-dependent sediment concentration profile $c(z, t)$ is derived from an advection-diffusion equation. Nielsen (1979) showed that this equation can be solved analytically if a constant sediment mixing coefficient $s$ is used. The advection-diffusion equation reads:

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial z} \left[ w_{f,t} c + s \frac{\partial c}{\partial z} \right]$$  \hspace{1cm} (5)

The equilibrium sand transport rate is equal to the product of the free-stream velocity and the equilibrium concentration profile, while the real sand transport rate is equal to the product of the free-stream velocity and the real concentration profile.

To derive the time-dependent equilibrium concentration profile, it is assumed that the concentration profile adjusts itself instantaneously to changes in flow velocity. This corresponds to a solution of the advection-diffusion equation for which the term $\partial c/\partial t$ is set zero. The time-dependent real concentration profile is derived without this assumption, which corresponds to the solution of the complete advection-diffusion equation, i.e. including the term $\partial c/\partial t$.

The bottom boundary condition for the equilibrium concentration profiles is based on the assumption that the bottom concentration is instantaneously related to the flow velocity. Using a coefficient $a$ and exponent $b$ this can be expressed as follows:

$$c(0, t) = a |u(t)|^b$$  \hspace{1cm} (6)

For the real concentration profiles the bottom boundary condition is based on the assumption that the pick-up rate of sediment is directly related to the instantaneously velocity. This implies that the concentration gradient is instantaneously related to the flow velocity.
The advection-diffusion equation only has an analytical solution if \( b \) is even. In the present study \( b = 2 \) is chosen, giving a transport rate proportional to \( u^3 \). This is close to the value of 3.3 in the model of Ribberink (1998), which results for negligible values of the critical Shields parameter, as is the case in sheet flow conditions.

Applying all these considerations results in the following expressions for the real and the equilibrium sand transport rate, i.e. \( q_{s,r} \) and \( q_{s,eq} \), respectively:

\[
q_{s,r}(t) = \sum_{k=0}^{N} u_k \cos(k \omega t) \left[ \sum_{k=0}^{2N} \frac{c_{bb}}{w_{fall}} \left( P_k \cos(k \omega t + \varphi_k) + Q_k \sin(k \omega t + \varphi_k) \right) \right]^{\frac{1}{4}}
\]

\[
q_{s,eq}(t) = \sum_{k=0}^{N} u_k \cos(k \omega t) \left[ \sum_{k=0}^{2N} \frac{c_{bb}}{w_{fall}} \cdot \frac{Q_k}{P_k} \right]^{\frac{1}{4}}
\]

With:

\[
\hat{c}_{b0} = a \left( u_0^2 + \frac{1}{2} u_1^2 \right)
\]

\[
\hat{c}_{b1} = a \left( 2u_1 u_0 \right)
\]

\[
\hat{c}_{b2} = a \left( \frac{1}{2} u_1^2 \right)
\]

\[
P_k = \frac{1}{2} + \left[ \frac{1}{16} + \left( \frac{k \varepsilon_0 \omega}{w_{fall}^2} \right)^2 \right]^{\frac{1}{4}} \cos(\frac{1}{2} \alpha_k)
\]

\[
Q_k = \left[ \frac{1}{16} + \left( \frac{k \varepsilon_0 \omega}{w_{fall}^2} \right)^2 \right]^{\frac{1}{4}} \sin(\frac{1}{2} \alpha_k)
\]

\[
\alpha_k = \arctan \left( \frac{4k \varepsilon_0 \omega}{w_{fall}^2} \right)
\]

\[
\varphi_k = \arctan \left( \frac{Q_k}{P_k} \right)
\]

Here \( \omega \) is the angular frequency of the wave (= \( 2\pi/T \), with \( T \) the wave period) and \( u_k \) is the \( k^{th} \) harmonic of the horizontal velocity. In the present analysis only \( u_0 \) and \( u_1 \) are considered (sinusoidal oscillatory flow plus a net current), because all experimental conditions consist of sinusoidal oscillatory flow combined with a net current.

As mentioned before, the correction factor \( r \) is defined as the ratio of the net real sand transport rate to the net equilibrium sand transport rate. These net sand transport rates can be determined by averaging Eqs.(8) and (9) over time.

From these equations it can be seen that the difference between the equilibrium and the real transport rate (and thus the value of the correction factor) is fully determined by \( \varepsilon_0 \omega / w_{fall}^2 \) called the phase-lag parameter \( \varphi \). The ratio of sediment mixing coefficient to fall velocity \( \varepsilon / w_{fall} \) can be considered as a characteristic length \( \delta \) to which particles are entrained. Therefore the phase-lag parameter can be written as:
In order to calculate the phase-lag parameter $p$ and thus the real and equilibrium sand transport rates and the correction factor $r$, either the value of the sediment mixing coefficient ($\varepsilon_s$) or the characteristic height to which particles are entrained (δ) must be known.

In the present study δ is assumed to be equal to the thickness of the sheet flow layer $\delta_s$. The latter is defined as the distance between the top of the non-moving sand bed during the wave cycle and the level where the time-averaged concentration is equal to 8 vol%. Values of $\delta_s$ were derived from concentration profiles, as measured in the LOWT of WL | DELFT HYDRAULICS (e.g. Katopodi et al., 1994; Janssen et al., 1997; Janssen and Van der Hout, 1997).

It was found that the fine sand ($D_{50} = 0.13 \text{ mm}$) behaved systematically different than the two coarser sands ($D_{50} = 0.21$ and 0.32 mm sand). Therefore two equations have been derived for the sheet flow layer thickness as a function of the maximum Shields parameter:

$$\frac{\delta_s}{D_{50}} = 4.5 (7.5 \theta_{\text{max}} + 0.90) \quad \text{for } D_{50} = 0.13 \text{ mm}$$

$$\frac{\delta_s}{D_{50}} = 2.9 (4.5 \theta_{\text{max}} + 0.065) \quad \text{for } D_{50} \geq 0.21 \text{ mm}$$

The maximum Shields parameter $\theta_{\text{max}}$ is based on the amplitude of the oscillatory velocity and a wave friction factor, using $k_s = D_{50}$.

Figure 2: Reduction factor of equilibrium sand transport ($r$) as a function of phase-lag parameter ($p$) for a situation of sinusoidal oscillatory flow and a net current
Figure 2 shows the value of the reduction factor $r$ as a function of the phase-lag parameter $p$ for a situation of a sinusoidal oscillatory velocity and a net current, i.e. for $u(t) = u_0 + u_c \cos(\omega t)$. This figure shows that the reduction factor decreases for increasing values of $p$, which means that the difference between the real and the equilibrium net transport rates is large for large values of $p$. This can be explained as follows: The value of $p$ is large for large values of the height to which particles are entrained ($\delta$) and small values of the fall velocity ($w_{\text{fall}}$) and the wave period ($T$). As explained in the introduction, this corresponds to large phase-lag effects.

**Behaviour of measured net transport rate and verification of sand transport models**

In order to study the behaviour of the measured net transport rates and to verify the predictions of the three sand transport models, the measured and computed net transport rates are plotted as function of the grain size, the amplitude of oscillatory velocity and the wave period.

**Grain size influence**

Figure 3 shows the net sand transport rate as a function of the grain size for the following flow condition ($H_6, E_2, II$):

- $T = 7.2 \text{ s}$
- $u_a = 1.5 \text{ m/s}$
- $u_m = 0.25 \text{ m/s}$

![Figure 3: Measured and computed net sand transport rate as a function of grain size](image)

The figure shows that the two quasi-steady models predict increasing net transport rates for decreasing grain size. This is in qualitative agreement with the measurements for medium and coarse sand. The magnitudes of the net transport rates for medium and coarse sand are predicted quite well by the model of Ribberink (1998) and overpredicted by the model of Bailard (1981).
The situation for fine sand is very different: The measurements show decreasing net transport rates for a grain size decrease from 0.21 to 0.13 mm. This may be explained by relatively large phase-lag effects due to the small settling velocity of the fine sand and the large oscillatory velocity, resulting in relatively large entrainment heights of the sediment particles.

In the new-semi unsteady model the small settling velocity and large oscillatory velocity result in a large value of the phase-lag parameter \( p \), corresponding to a small value of the reduction factor \( r \). That is why the net transport rate for the fine sand, predicted by the new semi-unsteady model is much smaller than for the model of Ribberink. Consequently, the new semi-unsteady model agrees much better with the measured net transport rate of fine sand.

For the medium and the coarse sand the predicted net transport rates of the new semi-unsteady model are almost equal to those of the quasi-steady model of Ribberink, indicating that phase-lag effects are small.

**Flow velocity influence**

The three panels of Figure 4 show the net sand transport rate as a function of the amplitude of the oscillatory velocity for three different grain sizes. In all cases the wave period is equal to 7.2 s and the net current velocity is equal to 0.25 m/s.

This figure shows that the two quasi-steady models predict increasing net transport rates for increasing oscillatory velocities. Again this is in qualitative agreement with the measurements for medium and coarse sand. For these two sand types the magnitudes of the measured net trans-

![Graph](image-url)

**Figure 4:** Measured and computed net sand transport rate as a function of amplitude of oscillatory velocity.
port rates are again overpredicted by the model of Bailard and predicted quite well by the model of Ribberink. Moreover, the semi-unsteady model gives almost the same results as the model of Ribberink for these two cases, indicating that phase-lag effects are not very important.

Again the situation is different for the fine sand: For small oscillatory velocities, the model of Ribberink predicts the measured net transport rates quite well. The model of Bailard largely overpredicts the measured net transport rates. The new semi-unsteady model gives almost the same results as the model of Ribberink, indicating that phase-lag effects are small. This can be explained by the fact that particles are not entrained very high into the flow for these low velocities.

However, for increasing oscillatory velocities, the increase in measured net transport rates is much smaller than predicted by the quasi-steady models, which may again be explained by increasing phase-lag effects. This is confirmed by the fact that the difference between the predictions of the new semi-unsteady model and the model of Ribberink increases for increasing oscillatory velocities, indicating that phase-lag effects become indeed more important. The predictions are thus again improved by including phase-lag effects.

*Wave period influence*

Figure 5 shows the net sand transport rate as a function of the wave period:

- The upper panel shows the results for fine sand and a relatively low oscillatory velocity of 0.7 m/s.
- The middle panel shows the results for fine sand and a relatively large oscillatory velocity of 1.1 m/s.
- The lower panel shows the results for medium sand and a relatively large oscillatory velocity of 1.1 m/s.

The net current velocity is equal to 0.25 m/s in all cases. All figures are plotted at the same scale to allow intercomparison between the three plots.

Figure 5 shows that the two quasi-steady models predict slightly increasing net transport rates for decreasing wave periods, due to the increase in wave friction factor. This is in qualitative agreement with the measurements for:

- Fine sand, \( u_a = 0.7 \text{ m/s}, \; T \geq 7.2 \text{ s} \)
- Medium sand, \( u_a = 1.1 \text{ m/s}, \; T \geq 7.2 \text{ s} \)

For these conditions the magnitudes are overpredicted by the model of Bailard and predicted quite well by the model of Ribberink.

For the other conditions the measurements show decreasing net transport rates for decreasing wave periods. This may again be explained by phase-lag effects, which become larger for shorter wave periods.

For fine sand with an oscillatory velocity of 0.7 m/s (upper panel) the measurements show that a decrease in wave period from 7.2 to 4 s leads to a decrease in net transport rate of about 30%. This can be explained by phase-lag effects: despite the relatively small oscillatory velocity, the wave period is so small and the sand so fine that phase-lag effects still occur.
The new semi-unsteady model predicts a similar phase-lag effect, which therefore results in improved predictions, compared to the model of Ribberink.

A phase-lag effect also seems to be present in the measurements for medium sand with an oscillatory velocity of 1.1 m/s and a wave period of 4 s (lower panel). The new semi-unsteady model predicts a much smaller phase-lag effect than observed in the measurements, indicated by the very small reduction in net transport rate, compared to the model of Ribberink.

For the conditions with fine sand and an oscillatory velocity of 1.1 m/s (middle panel) the measured net transport rate for a wave period of 7.2 s is predicted somewhat better by the new semi-unsteady model than by the model of Ribberink. Apparently phase-lag effects do occur for this condition.

For a wave period of 4 s the measured net transport rate is strongly reduced, compared to the transport rate for a wave period of 7.2 s. This can be explained by large phase-lag effects. The new semi-unsteady model agrees indeed much better with the measurement than the model of Ribberink. However, the measured net transport rate is still overpredicted, indicating that the phase-lag effects are somewhat larger than predicted by this model. This may be partly caused by the fact that the quasi-steady model predicts increasing net transport rates for decreasing wave periods, due to the increase in wave friction factor. It is not clear whether this is true. Only for the condition with a wave period of 12 s the predicted net transport rate does not agree at all with the measurement.

Figure 5: Measured and computed net sand transport rate as a function of wave period.
A different mechanism, which has not received any attention yet, may be responsible for this strong overprediction of the model, i.e. the limited pick-up rate of sand from the bed.

Video recordings of the bed level variation during the wave cycle show that several layers of sand grains are eroded from the bed. The thickness of the total eroded layer appears to be larger for increasing wave periods. Also, the concentration measurements in the sheet flow layer show that the sheet flow layer thickness is larger for a longer wave period. Existing expressions for the thickness of the sheet flow layer (e.g. Wilson, 1989; Sumer et al., 1996), as well as the formulae used in this study (Eq.(18)), assume that the thickness of the sheet flow layer only depends on the Shields parameter, which slightly decreases for increasing wave periods, due to the decrease in wave friction factor.

Both observations indicate that, at least for large velocities and fine sand, the amount of sand entrained into the flow and thus the sand transport rate depends on the wave period. The phenomenon of limited pick-up rate is not included in the presently used quasi-steady and unsteady sand transport models and needs further experimental investigation.

Conclusions

It is often assumed that in sheet flow conditions the response time of sediment particles is small with respect to the wave period, because the majority of the sand is transported in the thin sheet flow layer, close to the bed. This quick sediment response would result in a quasi-steady behaviour of the sand transport rate, i.e. a direct relation between the instantaneous sand transport rate and the instantaneous flow velocity.

However, measurements in a LOWT show that for fine sand, large oscillatory velocities and small wave periods the net transport rate is smaller than what could be expected from a quasi-steady behaviour. This may be explained by the presence of phase-lag effects: For large oscillatory velocities the sediment is entrained relatively high into the flow. If the entrained sand is very fine it settles down to the bed slowly and if the wave period is small this will result in a relatively large phase-lag between velocity and concentration. This means that sediment, which is entrained during the positive half wave cycle, can be transported in opposite direction during the successive half wave cycle, resulting in a reduction in net sand transport rate.

The fact that even in sheet flow conditions phase-lag effects can occur is explained by a new semi-unsteady model. This new model was developed using the bed load model of Ribberink and a phase-lag correction factor, which was based on an analytical solution of the advection diffusion equation for sediment concentration (Nielsen, 1979).

The phase-lag effects can be characterised by a phase-lag parameter \( p \), defined as:

\[
p = \frac{\varepsilon_s \omega}{w_{\text{fall}}} = \frac{\delta_s \omega}{w_{\text{fall}}} = 2\pi \frac{\delta_s}{w_{\text{fall}} T}
\]

Here \( \varepsilon_s \) is the sediment mixing coefficient, \( \omega \) is the angular frequency of the wave (\( = 2\pi/T \), with \( T \) the wave period), \( \delta_s \) is the sheet flow layer thickness and \( w_{\text{fall}} \) is the fall velocity of the sediment. It turned out that for \( p > 0.8 \) phase-lag effects become
significant (i.e. reductions in net transport rates, compared to the quasi-steady behaviour, of 40% or more).

In general the quasi-steady model of Ribberink (1998) agrees quite well with the measurements. The model of Bailard overpredicts the measured net transport rates. However, generally the behaviour is predicted qualitatively correctly.

Only for fine sand, large oscillatory velocities and small wave periods the behaviour is different than predicted by the two quasi-steady models and both the model of Bailard and the one of Ribberink overpredict the measured net transport rates. For these conditions the new semi-unsteady model shows a better agreement with the measurements.

CROSS-SHORE GRADED SEDIMENT TRANSPORT: GRAIN SIZE AND DENSITY EFFECTS

R.L. Koomans\textsuperscript{1}, R.J. de Meijer\textsuperscript{1}, and L.B. Venema\textsuperscript{1}

Abstract
Sediment sorting processes (sorting on grain size and density) are the result of local hydrodynamic conditions. In this paper two measuring techniques are described which derive \textit{in situ} time dependent and time averaged distributions of sediment sorted on grain size and density. The technique on measuring grain size of the sediment is described in more detail. The sediment distributions give information on the local hydrodynamic conditions on different time scales. Measurements from the field serve as a test case of describing the depth of closure from measurements of sediment composition.

Introduction
Coastal sediments are rarely composed of one type of sediment. Grain sizes may vary from cobbles, gravel and coarse sand to fine sand, silt and clay; densities show variations from about 1.6 kg l\textsuperscript{-1} for certain carbonates to heavy minerals as dense as cassiterite (7.4 kg l\textsuperscript{-1}). Seldomly however, one observes all varieties mixed at one localised spot. Variations in currents, waves and/or wind tend to concentrate certain sediments at specific locations according to the hydrodynamic properties of a sediment. In turn the variations (gradation) in grain size and density reflect the changes in transport conditions.

Sorting occurs due to differences in settling and pick up of grains with different size, density and shape. In settling the fall velocity of grains is determined by an equilibrium between gravity and friction forces, depending on the size, density and shape of the grain. In entrainment, sorting is due to differences in the exposure of the grain to the fluid and gravity acting on the grain.

Figure 1 presents fall and entrainment velocities as function of grain size and density. The upper part of Figure 1 shows that with small grain sizes, density

\textsuperscript{1} Nuclear Geophysics Division, KVI, University of Groningen, Zernikelaan 25, 9747 AA Groningen, The Netherlands
variations have little impact on the fall velocity of a grain (Cheng, 1997) but with increasing grain size, density effects become more important. The lower part shows the critical peak value of the orbital velocity near the bed needed to entrain a grain as a function of density and grain size, based on the formula given by Komar and Miller (1975). For small grain sizes, changes in the entrainment velocity are small with varying density, but for larger grain sizes (>100 μm) density is the most important parameter determining the entrainment velocity.

A comparison between both figures shows that settling and entrainment processes are affected differently by grain size and density variations. Whilst grain-size variations will have a larger effect on the settling velocity, variations in density will have relatively larger effects in the entrainment velocity.

Already in 1949, Inman pointed out that the effects of sorting, reflected in the median grain diameter of the sediment may give information on the conditions under which the sediment was transported and deposited. Also other studies have been conducted describing hydrodynamic conditions based on sediment distributions. Veenstra and Winkelmolen (1976) describe size, shape and density sorting patterns of sediments of the coast of Dutch the barrier island of Ameland, which is also object of study in this paper. Their data show that in the offshore area (deeper than 12m) a coarse sediment population is the result of an earlier high-energy situation during the post-glacial transgression and can not been transported under present hydrodynamic processes. The sediments between this offshore area and the beach show a rather narrow size spectrum and sorting occurs mainly on density and shape.

Studies on the relation between size gradation and hydrodynamics were carried out by various authors (e.g. Guillén and Hoekstra, 1996, Swift et al., 1971).
Guillén and Hoekstra describe a model of the equilibrium distribution of grain-size classes across the cross-shore coastal profile of the Dutch barrier island Terschelling (adjacent to Ameland). They state that the shape of the grain-size distribution curve depends on the hydrodynamic processes acting on the profile and serves as a fingerprint of the system. They observed that the median grain size of the sediment and the distribution of grain-size fractions show a break in their cross-shore distribution at approximately 6m depth across the shore face of Terschelling. This depth is considered to be the closure depth of the profile because it corresponds to the seaward limit of the shallowest and high mobility part of the littoral profile during the studied period.

Hallermeier (1981) extensively describes the expected maximum water depth for significant effect on the sand bottom by surface waves (later referred to as closure depth). In his description, he takes account of sand characteristics and wave parameters to calculate a seaward limit of intense sediment transport and extreme bottom changes. The concept is based on the observation that cross-shore sediment transport decreases seaward and becomes almost negligible beneath a certain depth (closure depth). Since this depth of closure is dependent on the movement of sediment, the position of the depth of closure along the cross-shore profile is a function of density, grain size, shape and time. Figure 2 schematically indicates the shore profile and the border of initiation of motion (depth of closure) as function of grain size and density. Large, heavy grains are harder to transport than small, light grains and, for equal wave conditions, the initiation of motion occurs at a shallower water depth, higher on the profile. Similarly heavier grains have a shallower closure depth than light grains of the same diameter. Investigations of selective transport processes of heavy minerals under shoaling waves (Tánczos (1996), May (1973), Stapor (1973)) showed that selective transport processes are rather rule than exception and start directly at the initiation of motion of sediments. Therefore, measurements of changes in sediment gradation provide information on the initiation of motion.

Measurements of sediment characteristics in the field to determine hydrodynamic conditions have been conducted since 1949 (Inman, 1949). However, these measurements lacked high spatial resolution and were too time consuming for regular measurement campaigns. With the techniques described in this paper, high-resolution in situ measurements can be conducted and makes an approach of describing hydrodynamic conditions from sediment characteristics fruitful.

![Figure 2: The seaward limit of significant sediment transport is dependent on grain size and density.](image-url)
This paper presents variations of grain size and density along profiles in the field and in the laboratory. The data consist of high density, *in-situ* measurements of grain size and density using a towable seabed detector MEDUSA (de Meijer *et al*, 1996 and de Meijer, 1998). The grain size and density variations are derived from the intensity of friction sound and natural radioactivity. The sensor that utilises the relation between friction-sound and grain size will be explained in more detail. Data is collected on the foreshore of the Dutch Frisian Island of Ameland and in the Großer Wellenkanal (GWK) in Hannover, Germany. The aim of the present study is to measure sediment distributions to extract information on the local hydrodynamic conditions on different time scales. Measurements from the field serve as a test case of describing the depth of closure from measurements of sediment composition.

**Experimental techniques**

The heavy mineral concentration of the sediments in the field survey is determined from the concentrations of the naturally occurring radionuclides of the decay series of $^{238}\text{U}$ and $^{232}\text{Th}$. In heavy minerals, the concentrations of $^{238}\text{U}$ and $^{232}\text{Th}$ are two orders of magnitude higher than in light minerals. Although the actual concentrations of $^{238}\text{U}$ and $^{232}\text{Th}$ depends on the mineral composition of the heavy mineral suite, it was found that the heavy minerals near the Dutch Frisian Islands have a quite constant radiometric fingerprint (de Meijer *et al*, 1990, de Meijer and Donoghue, 1995). The total concentration of heavy minerals (THM) is hence calculated from the values listed in de Meijer *et al* (1990). The radiometric variations in the sand of the flume at GWK are not related to the heavy mineral concentration only, but also to grain-size variations (Figure 3). Figure 3 shows a decreasing activity concentration of $^{40}\text{K}$ as function of grain size whereas there is no clear difference in the average activity concentration of $^{40}\text{K}$ in the light and heavy fraction. The $^{238}\text{U}+^{232}\text{Th}$ activity concentration also decreases with increasing grain-size, but here the light and heavy fractions differ two orders of magnitude in the $^{238}\text{U}+^{232}\text{Th}$ concentration. The grain-size dependence of the $^{238}\text{U}+^{232}\text{Th}$ concentration may also reflect the grain-size distribution of the heavy fraction.

![Figure 3: Activity concentrations of $^{40}\text{K}$, $^{238}\text{U}$ and $^{232}\text{Th}$ as a function of grain-size compared to the average concentrations in the light and heavy mineral fractions.](image)

Measurements with the MEDUSA detector system were carried out at GWK, Hannover and the seafloor near the Island of Ameland. Natural radioactivity is measured with a highly sensitive gamma-ray detector in the standard set-up as described in de Meijer (1998) and the system yields activity concentrations of the three nuclides as long as it is in contact with the bed.
The measurements of friction-sound were carried out with a microphone inside the detector casing. The microphone records noise that the detector generates when the casing slides over the sediment. It was originally included in the detector system together with the water depth sensor to monitor the contact of the detector with the sediment, but the signal variations proved to be consistent with grain size variations and reproducible during several surveys. This triggered the question which variations caused the changes in sound level. Part of this paper deals with the interpretation of the friction-sound measurements and the data of the experiments in the GWK will show that the friction sound level is indeed a quantitative indicator of grain-size variations on the bed.

The experiments in the Large-scale Wave Flume (300×5×7 m³) (Grosser Wellenkanal Hannover) in Germany were conducted as part of the EU MAST-III-program SAFE. In these experiments, profile development and sediment transport under storm conditions were studied. The sediment was rather coarse (d_{50}=280μm) and not well sorted (d_{10}/d_{50}=3). For the wave conditions, a TMA-wave spectrum with H_{m}=0.9 m and T_{m}=6 s was used that was repeated after every 0.5h. The experiments started with a smooth-bed profile with a slope 1:20 and with a water depth of 5m.

![Image of Ameland location](image)

*Figure 4: Geographical location of Ameland and an overview of lines towed near Ameland and of the concentrations of total heavy minerals (THM) along these lines. The map is given in UTM coordinates.*

**Results**

**Seafloor mapping**

In June-July 1995, a survey was carried out using a MEDUSA- detector system towed by a vessel of Rijkswaterstaat. During this survey lines were towed between position RSP18 (beach pole 18) on Terschelling and the eastern tip of Ameland at depths of 1-25m. The barrier island Ameland is located in the northern part of the Netherlands just north of the Dutch Wadden Sea and flanked on both sides by a tidal inlet (Figure 4). The near-shore zone of Ameland is characterised by the presence of a bar system with an overall slope between the high water line and the off shore of about 1:400.
This paper presents the data collected in an area between the two ebb-tidal deltas in front of the coast of Ameland.

Figure 5: Average profile, heavy-mineral concentration and sound-level variations as function of distance to the coast of Ameland.

Figure 4 shows the distribution of total heavy mineral concentrations (THM) along the towed lines. A coast-parallel region of high concentrations of heavy minerals (up to 5% by mass) is visible a few kilometres off the coast. Seawards of this region the heavy mineral content of the sediment decreases. The heavy-mineral concentration seems to be constant in long shore direction. This distribution triggers the question if the concentration of heavy minerals is solely the result of cross-shore processes.

The mean of all survey data is presented as a cross-shore distribution in Figure 5. In the lower part of the figure, profile data show the position of a breaker bar at a water depth of 2.5-5m and a rather concave seaward slope with a slight convex "bump" between 610 and 613 km. At a position of 611.5 km, the slope steepness seems to increase. The heavy-mineral concentration (middle figure) shows an increased concentration just landwards of the breaker bar, a steep decrease on the breaker bar and again an increase up to position 609.8 km. From this position, the heavy-mineral concentration shows a decreasing trend to position 612 km, where it remains constant towards deeper water. The sound level shows a rather low, constant signal from the breaker bar towards position 612 km. From hereon the sound level doubles in intensity towards position 613 km, followed by a decreasing trend further seawards.

In the case of the heavy minerals of Ameland the density and grain-size distributions were measured by Tánzos (1996): \( \rho_{50} = 3.5 \text{ kg/l} \) and \( d_{50} = 110 \mu\text{m} \). Taking the density of quartz sand to be \( \rho_q = 2.65 \text{ kg/l} \), the heavy-mineral concentrations are converted to bulk densities. The corresponding values are indicated in the right-hand scale. From the figure one notices that small changes in density can be measured.
It is remarkable that large variations in sound level and heavy mineral concentrations occur in the region of convex bump in the profile. Seawards from this position, the heavy mineral concentration remains constant, while the recorded sound levels show an increase.

![Graph showing profile, heavy mineral concentration, and sound level distribution](image)

**Figure 6: Profile, heavy mineral concentration and sound level distribution after 17h of storm conditions in the laboratory experiments at GWK, Hannover.**

**Laboratory experiments**

The wave conditions of the experiments in the GWK were planned to be erosive at the beach face and during the experiment, a breaker bar developed at x=220m and at a water depth of 1-2m (Figure 6). "Seawards" of the breaker bar, the morphology is characterised by a smooth region without ripple structures, followed by a region with relatively large ripple structures. Again, MEDUSA is used to derive sediment characteristics along the profile.

For the sand in the flume the activity concentrations are very low and the total count rate rather than the individual radionuclide distribution is presented. The total count rate on the breaker bar is lower compared to other parts of the profile. Seawards from the breaker bar, the total count rate increases. In the smooth region, where the ripple structures are absent, the total count rate shows a maximum. In the region with ripple structures, "seawards" from the "flat zone" the count rate remain constant. The sound level shows variations that are almost opposite to the heavy-mineral concentration pattern. The sound level is high on the breaker bar, shows a decrease in the region where the ripple structures are absent, increases and remains constant towards deeper water. It is remarkable that the scatter in sound level is low in the
region where ripples are absent.

Assessment of the relation between friction-sound and grain size

To investigate a possible relation between sound level and grain size of sediment, samples of the sediment top layer were collected at various locations of the bed after the water was drained from the flume. After drying and sieving, the grain-size distribution was derived. The $d_{50}$ values are presented in the top part of Figure 6 together with the sound-intensity level. The two data sets show a remarkable correspondence in behaviour; the more because the sound level is likely produced by the upper grains of the sediment whilst, even in careful scooping of sediment, layers of several millimetres thick are collected.

A statistical analysis of the correlation between grain-size and sound level measurements of three different datasets from the wave flume experiments, show a significant correlation ($r^2=0.7$, with 41 degrees of freedom). To test the importance of grain size in the measured sound levels, two samples of sediment from the profile, with different sound-level characteristics, were glued on a wooden plate over which the detector was towed. Since the measurements with the calibration plate were conducted out of the water and the acoustic properties of the plate and natural sediment are different, only relative values may be compared. This small experiment confirms that larger grain sizes show larger sound levels than smaller grain sizes.

Table 1: Sound levels of two types of sediment with different grain size. Statistical uncertainties, 1 STD, are given in brackets.

The sound level exhibits a spiky behaviour, mainly, in the region of the ripples; in the smooth region and on the "seaward" part of the breaker bar such spikes are hardly present. A Fourier transform was applied to filter small scale variations in the sound level (<5 metres) from the signal, testing the hypothesis that small scale variations are correlated to ripple structures. Figure 7 shows the filtered signal in comparison with the $d_{50}$ value. Apparently, the small-scale variations on the sound level do not have an influence on the large-scale trend of sound level. It seems that the large-scale trend in sound level reflects the grain-size variations of the bed while sound level variations correlated with small-scale changes in morphology (like ripple structures) are superimposed on this trend. Whether these small-scale variations are directly the result of "bumping" on morphologic features or arise from the grain-size variations due to sorting within ripple structures is not clear.

**Synthesis**

It is remarkable that on the coast of Ameland large variations in radiometry and sound level occur in the region of the convex bump in the profile. Seawards from this position, the heavy mineral concentration becomes constant, while the sound level shows an increase. These changes in sound, which are related to grain size, and THM are probably caused by a difference in sediment population compared to the sediments near shore. During the fast sea level rise after the last glacial period, the barrier islands showed a fast landward retreat and part of the profile was "overstepped". This lower part of the profile shows sediments that are sorted by hydrodynamic conditions that are different from present day hydrodynamics. Since the transgression slowed down, the sediment distribution could come in equilibrium with present day hydrodynamic conditions (Veentra and Winkelmolen, 1976; Guillén and Hoekstra, 1996) and sediments could be sorted by grain size, density and shape. The change in slope steepness of the profile reflects the change between the relict profile from the transgressive phase and the "recently" reworked part of the coastal profile (Swift, 1971).

During the process of coastal retreat, the recently reworked part of the profile eroded older sediments and heavy minerals remained as a lag deposit. The increase in heavy mineral content from the concave bump up to the breaker bar is probably the result of sorting of these lag deposits by processes due to wave shoaling (Tanczos, 1996; May, 1973). The constant sound level shows that the grain size is rather constant in this region and sorting will mainly occur on density and shape. Landward of the bar system the heavy mineral content increases while the breaker bar itself is depleted of heavy minerals. Here light sediments are transported and build the breaker bar, while heavy minerals remain in the eroding parts as lag deposits.

To compare the sediment distributions on the profile of the field measurements and the laboratory experiments, the sediment characteristics are plotted as a function of a scaled dimensionless waterdepth in Figure 8. The dimensionless waterdepth is derived by dividing the waterdepth by the maximum wave height. In the upper left part of Figure 8, a clear change in heavy-mineral grading occurs at a $d/H_{\text{max}}$ $\approx 2$. Seaward from this location, the heavy-mineral concentration is constant, while the concentration shows a landward increase. It is remarkable that this depth (11 m) coincides with the long-term closure depth (9-11 m) for this region calculated from wave data (Westlake, 1995).
Experiments on graded sediment transport showed that sorting occurs at the initiation of motion. At a water depth $>11\text{m}$, sediment is not transported and sorting does not occur, while at shallower water depths, light minerals start to move and heavy minerals remain as a lag deposit or are transported at smaller transport rates. At this location where light minerals start to be transported, sorting is initiated. In the lower left part of Figure 8, a similar behaviour of sediment sorting can be observed. At a $d/H_{\text{max}} > 2$ sediment composition is constant, while at shallower depths sediment sorting is initiated. The sorting pattern from the laboratory experiments is solely generated by cross-shore sediment transport processes. Since this pattern is comparable with the measurements of the seafloor, it seems that the sediment distribution on the seafloor is predominantly the result of cross-shore processes.

For the GWK measurements a major change in sound level can be observed at a $d/H_{\text{max}} \sim 2$. This depth was indicative for the depth of initiation of motion. However, sound level variations for the field survey are somewhat different from the sorting patterns measured with radiometry. Here, the large sound levels at $d/H_{\text{max}} > 2$ are the coarse relict sediments of the transgressive phase while the lower sound levels at $d/H_{\text{max}} < 2$ reflect sediments that are sorted by present day processes.

Both measuring techniques give different information on the depth where significant sorting processes start. The radiometric measurements comprise the upper 20 to 30 cm of the sediment bed (maximum penetration depth of $\gamma$-radiation in sand).
and will therefore describe time scales of at least a few weeks, while the measurements of sound level only describe the upper grains of the sediment bed. The results of the laboratory study have shown that sorting of the upper layer of the sediment reach equilibrium for the specific wave conditions in a few hours. Therefore, the sound level measurements reflect only a local closure depth on a very small time scale.

Conclusions

Measurements on the seafloor near Ameland and measurements in the flume at GWK, Hannover show corresponding (scalable) distribution patterns of sediment sorting by density and grain size. The wave-flume experiments indicate that these distributions can be predominantly the result of cross-shore hydrodynamic processes. Heavy minerals tend to be concentrated seawards of the bar system in a region of fine-grained sediments just landward from where sediment motion is initiated.

The technique of deriving grain size by measuring the friction noise of the MEDUSA detector seems promising and would allow a synoptical, in-situ measurement of grain-size parameters. Together with the measurement of heavy-mineral content by means of natural radioactivity, MEDUSA allows the measurement of as well density and grain size. These two sedimentological parameters play an important role in sediment transport processes. Applying these techniques both in the field and the laboratory offers a handle to study these in more detail in laboratory experiments and in the field.

The results from the present investigation suggest that by the applied methodology the depth of initiation of motion can be measured in the field for different time scales.

Outlook

Further research on the correlation between friction-sound measurements and grain size will focus on frequency dependent sound measurements. At the moment, friction-sound measurements comprise a summation of all the sound frequencies. A sensor for measuring frequency specific friction-sound will be tested. For a refining of the sediment distributions in the radiometric measurements of the wave flume, a refinement of the fingerprint of the sediments will be conducted to allow a clear distinction between heavy mineral and grain-size distribution. Therefore the heavy and light sediment fractions will be split into separate grain-size fractions and measured for its radionuclide content.

Acknowledgements

The present investigation is part of the research programme of the Nuclear Geophysics Division of the KVI. The experiments in the Grosser Wellenkanal, Hannover were conducted as part of the MAST-III project SAFE. The measurements on the seafloor near Ameland were partly financed by the KUST*2000 programme of Rijkswaterstaat (the Dutch Ministry of Transport, Water Management and Public Works).

Cross-shore sediment transports on a cut profile for large scale land reclamations

Martijn Onderwater\textsuperscript{1}
Dano Roelvink\textsuperscript{2}
Jan van de Graaff\textsuperscript{3}

Abstract

When building a large scale land reclamation, the safest way is to shift the existing profile over the required distance of the reclamation project, up to a depth of say 20 m. This way the profile in cross-shore direction does not change and therefore also cross-shore sediment transports will be the same as before the land reclamation was made. A large disadvantage however is that a very large amount of material is needed for realising the reclamation. This makes the reclamation very costly.

To reduce the amount of material a cut profile can be applied. Above a certain depth (say CD -8 m) the cross-shore profile will be the same as the existing profile, but below this depth a relatively steep profile (say 1:50) is constructed. By doing this, material saving up to 40\% can be achieved. A disadvantage of this cut profile is that a relatively steep profile has been made, which will affect the sediment transports.

In this study the effect of a cut profile are investigated by using the numerical model UNIBEST-TC of DELFT HYDRAULICS for the computation of wave energy dissipation and cross-shore sediment transports. As an example the 'Plan Waterman', a plan for a land reclamation between Hook of Holland and Scheveningen, is used in this study. Various different cut profiles have been studied and it is found that especially relatively large waves, which break at the edge of the cut-off, have large influence on the cross-shore sediment transports. It is concluded, that the cut-off should at least be applied at CD-12 m if large changes in the coastal system are not desired.

Introduction

People often want to live near water and all over the world the areas near the sea get more and more occupied by structures. For this reason there is a trend to reclaim land by making an artificial island near the existing coast or a peninsula against the existing coast. Examples are the recently opened airport in Hong Kong and the 'Plan Waterman', a plan to extend the Dutch coastline between Hook of Holland and Scheveningen. This plan is also known as the 'Plan New Holland'.

In most cases an extension of the coastline is made by dredging material from relatively deep water near the coast and dumping the material in the nearshore section. The safest way is to shift the existing cross-shore profile over the distance of the land

\textsuperscript{1} Alkyon Hydraulic Consultancy & Research, De Deel 21, 8302 EK Emmeloord, The Netherlands (formerly MSc student Delft University of Technology)
\textsuperscript{2} WL|Delft Hydraulics, Rotterdamseweg 185, 2629 HD Delft, The Netherlands
\textsuperscript{3} Delft University of Technology, Stevinweg 1, 2628 CN Delft, The Netherlands
reclamation. This way large changes in cross-shore sediment transports are avoided because the beach profile keeps the same shape. However, to make a land reclamation this way, a lot of material has to be dredged, which makes the land reclamation project expensive.

There is also another way to construct the land reclamation. On a certain level beneath mean sea level (is Chart Datum; CD) a cut-off can be applied. This means, that the cross-shore profile will not be shifted completely over the distance needed for the reclamation. In the near shore area the design profile will have the same shape as the existing beach profile. Then, from a certain level beneath CD, the design profile will have a constant and relatively steep slope until it reaches the existing beach profile. By doing this, a lot of material is saved when making the land reclamation. In Figure 1 a cut profile is shown with the definitions as used in this paper.

![Figure 1. Two methods of making a large scale land reclamation](image)

When a cut profile is applied, wave heights and sediment transports will change in comparison with the situation where no cut profile is applied. When a cut profile is being applied, one of three mechanisms will occur:

- there will be erosion;
- the cross-shore profile will stay stable;
- there will be accretion.

Without any study, the most likely mechanism will be erosion in the nearshore section until a profile shape is reached, which comes close to the profile before the land reclamation. This means eventually a retreat of the waterline, which is, in case of the Dutch policy, not desired.

During this study the numerical model UNIBEST-TC of DELFT HYDRAULICS is used for investigating the influence of a cut profile. To make computations as realistic as possible, the "Plan Waterman" is used as a practical example. In order to get realistic results, the numerical model has been calibrated for the existing situation without the land reclamation before computations on a cut profile are carried out.

Then various computations are done for investigating the influence of a cut profile on the sediment transports and the development of the cross-shore profile. These
computations have been subdivided into two parts:

- Initial computations;
- Morphological computations.

Initial computations are used for investigating the effects of a cut profile on the way waves approach the shoreline and the resulting cross-shore sediment transports along the profile.

Morphological computations are done over a period of 10 years. These computations are done by using measured wave conditions from a station near Hook of Holland.

In this study cross-shore transports are only considered; changes in shore parallel sediment transports are not taken into account.

The 'Plan Waterman'

In the western part of The Netherlands there is a large need for more land, especially for housing and recreation. Besides the reshuffle of existing areas, also the possibility to create new land in the North Sea is still open. This plan of land reclamation is known as the 'Plan Waterman'.

The 'Plan Waterman' is a plan for extending the Dutch coast between Hook of Holland and Scheveningen over an average distance of about 2 km, varying from 1500 m at Scheveningen to about 3 km at Hook of Holland and with a total area of 3000 hectares (see Figure 2).

Figure 2. Overview of the 'Plan Waterman'.

The total volume, which has to be nourished for the realisation of the 'Plan Waterman' can roughly be estimated by assuming 25 m$^3$ necessary for 1 m$^2$ of the reclamation (from CD -20 m to CD +5 m). For the 'Plan Waterman' the total volume is then estimated at 750*10$^6$ m$^3$.

When applying a cut-off in this situation, a lot of material and therefore money can be
saved. As a reference profile, a shifted profile is chosen, which coincides at a depth of CD -20 m with the existing profile. The beach profile of the land reclamation is continued up to CD +5 m.

In Table 1 is shown how much (in %) is saved by applying a cut profile.

Table 1. Savings to achieve by applying a cut-off.

From this table it is obvious, that most savings are achieved when the cut-off is made steep and on small depth. On large depths less savings can be achieved by making a steep slope. This is because the slope of the cut-off is shorter at larger depth.

Environmental conditions

To be able to make realistic computations with the UNIBEST model, it is necessary to describe the real situation properly. In this chapter the environmental conditions, as used in the numerical model are discussed shortly.

Cross-shore profiles

Since 1964, every year profile measurements are taken along the Dutch coast to determine the position of beach profiles perpendicular to the shoreline. These profiles are called the ‘JARKUS’ profiles. The location of these profiles are marked by bench marks along the whole coast of Holland. The area of this study starts near Scheveningen at km 102 and ends at Hook of Holland at km 118.

Grain sizes

For this study, the average value of grain-sizes measured along the coast between Hook of Holland and Scheveningen is used (Table 2).

Waves

Wave conditions from the nearby EURO-0 platform were used for model
computations. A time series with measured waves and water levels from 1979 to 1991 was analysed and a time series, which represents the average wave climate of these 13 years of measurements was assembled. The measured wave climate from the EURO-0 platform is shown in Figure 3.

![Wave climate as measured at the EURO-0 platform.](image)

**Figure 3. Wave climate as measured at the EURO-0 platform.**

**Tide levels**

The tidal range along the part of the Dutch coast as considered is in the order of 1.5 m during neap tide and 2.0 m during spring tide conditions. Water levels as measured at EURO-0 were taken into account.

At the EURO-0-platform the water level is measured in combination with wave heights. These water levels contain the astronomical tide and also water level changes, caused by wind. Because of storm set up the water level tends to be higher with larger wave heights.

**Currents**

Because currents are mainly present in the longshore direction and not in cross-shore direction as investigated in this study, currents are not be taken into account during the calculations.

**Model calibration**

Before any transport computations on a cut profile can be made, the model has to be calibrated. By slightly changing the models parameters, the model is tuned.

For the calibration of the numerical model, the morphological behaviour of an existing beach profile along the coast between Scheveningen and Hook of Holland is used. In this profile a longshore bar is present at about 450 m from the reference point. The bar moves in seaward direction with a speed of approximately 40 m/yr. This bar behaviour is used to compare the outcomes of the numerical model with the measured profiles, because the speed and shape of the bar are easily to be compared. The quality of the calibration is judged by:

- The movement of the sand bar;
The bed level changes near the waterline;
Global volume changes along the profile.

By changing parameters such as bed roughness, internal friction angle and wave parameters the model has been adjusted in a way that it represents the existing profile development in a satisfying way. Figure 4 shows the results of the calibration of the profile as chosen.

![Graph showing bed level changes](image)

Figure 4. Results of the calibration of the UNIBEST-TC model.

**Initial effects of a cut profile**

Before the effect of a cut profile on a morphological time scale can be understood, it is worthwhile to investigate the most important processes. Therefore initial computations are performed. For various different wave conditions and cut profiles the distribution of wave height, wave energy dissipation and cross-shore sediment transports are determined. In this chapter some of the results are shown. The results are compared to a profile without a cut-off, which is used as the zero-alternative.

It was found, that especially the location of breaking waves has large effect on the occurring processes. Relatively high waves will suddenly break on the edge of the cut-off, which then leads to large energy dissipation over a small distance. Waves which break onshore of the cut-off, show a more gradual energy dissipation.

For explaining the most important processes in more detail results of computations on a cut profile with \( d_{\text{cut}} = 6 \) m and \( a_{\text{cut}} = 1:50 \) are discussed. First a wave height distribution with \( H_{m0} = 1.75 \) m is discussed, which does hardly result in wave breaking on the edge of the cut-off. Secondly a wave height distribution with \( H_{m0} = 2.75 \) m is discussed. This wave height gives breaking on the edge of the cut-off. The results are compared to the zero-alternative.

**No breaking waves on the edge of the cut-off**

The results of initial computation for deep water wave conditions of \( H_{m0} = 1.75 \) m are shown in Figure 5. In this figure the wave height, energy dissipation and sediment transport distributions along the cross-shore profile are shown.
Figure 5. Results of initial computations without wave breaking on the edge of the cut-off.
The wave height $H_{m0}$ distribution

Because the water depth offshore of the cut-off is larger than the depth at the same location along the profile of the zero-alternative, also the wave height is still larger along the cut-profile. Differences are however small.

In the breaker zone more breaking waves and more dissipation due to bottom friction occur in case of the cut profile. Closer to the shoreline the differences between the wave heights in the two profiles vanish. Notice, that the difference between the two profiles is notable up to approximately 150 m from the waterline (that is 350 m onshore of the cut-off).

Energy dissipation

Wave energy dissipation as used in the UNIBEST-TC model is based on Battjes & Janssen (1978).

Offshore of the cut-off water depths are still relatively large in both cases and energy dissipation due to wave breaking hardly occurs here. Onshore of the cut-off larger wave heights are present in case of the cut profile. This leads to larger energy dissipation for the same water depth. Wave breaking also starts at larger distance from the shoreline.

Also the dissipation due to bottom friction, $D_b$, is affected by the cut-off. Because of the larger depth offshore of the cut-off the energy dissipation due to bottom friction is smaller here. Along the slope of the cut-off the water depth decreases relatively fast. Together with larger wave heights this leads to an increased dissipation due to bottom friction onshore of the cut-off.

Bottom sediment transport

For bed-load transport computations the formula of Ribberink (see Van Rijn et al., 1995) is used in the UNIBEST-TC model.

Only a very small increase in wave energy dissipation occurs and therefore also the difference in bottom transport along both profiles is very small. Just onshore of the cut-off the onshore directed bottom transport tends to be slightly smaller in case of the cut profile.

Suspended sediment transport

Suspended transport is formulated with the velocity times concentration concept. Sediment concentrations are modelled following Van Rijn, 1993.

In case of the cut profile energy dissipation because of breaking waves is slightly higher than if the zero-alternative profile is applied. This yields a larger sediment concentration. Because of the higher waves also the offshore directed flow velocities increase. This results in an increased offshore directed suspended transport.
Differences in wave heights and energy dissipation are however small, so also the increase of the suspended transport is small.

Total sediment transport

Because of the smaller onshore directed bottom transport and the larger offshore directed suspended transport, the total sediment transport in case of a cut profile is more offshore directed. Even in this case, where hardly any wave breaking on the edge of the cut-off takes, the difference with the zero-alternative is relatively large.

Breaking waves on the edge of the cut-off

When waves break due to the sudden change of the depth at the edge of the cut-off, other effects occur than described in the previous section. In Figure 6 results are shown from computations with a cut profile where large wave breaking occurs at the edge of the cut-off ($H_{m0} = 2.75 \text{ m}$).

The wave height $H_{m0}$ distribution

Offshore of the cut-off the water depth is larger than at the same location in the zero-alternative profile. Because of smaller bottom influence, wave heights are here also slightly larger. At the edge of the cut-off the wave height suddenly decreases. In case of the cut profile the wave height at this location is significantly larger and wave breaking occurs. Onshore of the cut-off the wave height further decreases up to approximately 150 m from the waterline. Here wave heights are the same in both cases.

Energy dissipation

Where the wave height along the profile increases, the energy dissipation due to breaking, $D_w$, suddenly increases as well and $D_w$ is relatively high along the whole profile onshore of the cut-off. Along this part of the profile a large amount of breaking occurs and finally the wave height decreases to a height which is similar to the wave height distribution in case of the zero-alternative.

Offshore of the cut-off the water depth is still relatively large in relation to the wave height. Therefore also energy dissipation is much smaller in case of the cut profile. Along the slope of the cut-off the energy dissipation due to bottom friction, $D_f$, suddenly increases. Compared to the local water depth the waves are relatively high and this results in a large energy dissipation. Also onshore of the cut-off waves are higher than in the zero-alternative. This also results in larger $D_f$ values.

Bottom sediment transport

Along the profile the bottom transports are more or less similar in both cases. In case of the cut profile the onshore directed bottom transports are slightly smaller. Seaward of the cut-off this is because of smaller bottom friction (or larger water depth). At the edge of the cut-off large energy dissipation due to wave breaking causes a near bottom velocity which is offshore directed. Because of this, also the bottom transport becomes
Figure 6. Results of initial computations with large wave breaking on the edge of the cut-off.
offshore directed along the edge of the cut-off.

**Suspended sediment transport**

The effect of the sudden breaking of waves at the edge of the cut-off can also be seen in the suspended transport along the profile. At this point large turbulence because of breaking causes larger sediment concentrations and with a larger offshore directed flow this results in a larger offshore suspended transport.

**Total sediment transport**

Especially the suspended transport is largely influenced by the cut-off. This can also be seen in the total sediment transport distribution. Up to approximately 150 m from the waterline the difference in offshore directed transport is relatively large compared to the zero-alternative.

**Morphological effects of a cut profile**

In order to investigate the morphological effects of a cut profile close to the coast, computations were carried out over a period of 10 years. For these computations a wave scenario based on measured waves at the EURO-0 platform are used. Computations were performed for various cut-off depths and cut-off slopes and the results are again compared with the zero-alternative. As an example the profile changes of a cut profile with a cut-off at CD -6 m is shown in Figure 7.

![Figure 7](image)

Figure 7. Computed profile with $d_{cut} = CD -6$ m after 10 years.

As can be seen, large erosion occurs in the nearshore area and the waterline retreats.

If the cut-off is placed at larger depth, less waves break because of the sudden change of depth and therefore also the amount of erosion is smaller. In Figure 8 profile changes after 10 years are shown for a design profile with $d_{cut} = CD -14$ m. As can be seen, the profile is quite stable and there is even some accretion near the waterline.

In order to make a quantitative comparison between different cut profiles, the yearly averaged transports through depth contours is computed. This is discussed in the next sections.
As can be seen in the results of the initial computations especially the application of relatively high waves, which lead to wave breaking on the edge of the cut-off, results in a large effect on the sediment transports. It is obvious that the effect of the cut-off will decrease when the cut-off is applied at larger depth. Wave breaking on the edge of the cut-off then hardly occurs and therefore also differences in the sediment transports in comparison with the zero-alternative will be smaller. For investigating the influence of the cut-off depth on a morphological time scale, computations over a period of 10 years are made. The yearly average cross-shore transports are shown in Figure 9. In this figure the horizontal axis shows the depth contours along the profile and the vertical axis gives the yearly amount of sediment which is transported through that depth contour. This is done for cut-profiles with $d_{\text{cut}} = \text{CD} - 6 \text{ m}, -10 \text{ m} \text{ and } -14 \text{ m}$ Results are compared with the zero-alternative. As can be seen from this figure, a cut-off at CD -6 m results in large offshore directed transport up to large depth.

From Figure 9 it can also be seen that the initial cross-shore profile of the zero-alternative as applied is apparently not a fully stable (equilibrium) profile.
Influence of the cut-off slope $d_{cut}$

From the previous section it was seen that the cut-off depth has large influence on the yearly average transports along the profile. In Figure 9 however a very steep slope of 1:50 was used. A more gentle slope will result in a more gradual wave breaking. This will then result in smaller offshore directed transports. As an example results of morphological computations on a cut profile with $d_{cut} = CD - 8 \text{ m}$ are done for various cut-off slopes. Results are shown in Figure 10. As it can be seen from this figure, the cut-off slope indeed affects the yearly average transports in the nearshore section. However, even with a cut-off slope of 1:150 differences are still large compared to the zero-alternative.

![Figure 10. Influence of the cut-off slope on the yearly average transports.](image)

Conclusions

For a large scale land reclamation project as the ‘Plan Waterman’ a huge amount of material is needed, which makes a project like this very expensive. When applying a cut-profile instead of shifting the whole beach profile over the distance needed for the reclamation, a lot of material can be saved. Material savings up to 40% are possible.

During this study computations are made with the numerical model UNIBEST-TC, developed by DELFT HYDRAULICS. Especially the effects of a cut profile in cross-shore direction are investigated. Before computations on cut profiles were made, the model has been calibrated for the situation along the coast of between Hook of Holland and Scheveningen.

Computations have been subdivided in initial and morphological computations. From the initial computations it is concluded, that especially the location where waves break is of large influence on the energy dissipation and sediment transports. If waves start breaking onshore of the cut-off the processes are similar to the processes as occur on a profile without a cut-off. Relatively large waves start breaking due to the sudden
change of depth at the edge of the cut-off. This sudden breaking of waves results in large energy dissipation over a small distance which results in large offshore directed suspended transports.

From morphological computations it is concluded, that even a cut-off at large depth still has influence on the sediment transports in the nearshore section of the beach profile. During normal wave conditions differences in sediment transports along a cut profile are very small in comparison with a profile where no cut-off has been applied. When however looking at the yearly average cross-shore transports through specific depth contours, it can be seen that these small differences still have large influence on the coastal development in cross-shore direction. When applying a cut-off at relatively small depth (CD -8 m) a less steep cut-off slope can reduce the seaward directed transports. On the more gentle slope waves break more gradual and the more gradual energy dissipation leads to small offshore directed suspended transports.

In case of the Dutch policy for the coastline protection the coastline is not allowed to retreat due to erosion. In that case there are mainly two options:

- Placing the cut-off at large depth (at least CD -12 m) and do small extra maintenance nourishments;
- Placing the cut-off at small depth and do a lot of extra maintenance nourishments in order to prevent ongoing erosion.

Since the cross-shore profile will eventually develop to an equilibrium profile. At the end the volumes needed for the zero-alternative and the volumes, needed for a cut profile and maintenance nourishments together, are the same. In the first case this volume is already needed during construction. In the latter case the volume is spread over time. This might result in economical advantages.

Optimum Size of Distorted Ripple Train
for the Control of Cross-shore Sediment Transport

Satoshi Takewaka, Isao Irie, Masahiro Uchida,
Hirokazu Sakamoto and Nobuyuki Ono

Abstract

The Distorted Ripple Train System, which is aimed to control the cross-shore sediment transport, is proposed. The concept and basic functions of the artificial ripple system are introduced in this study and a detailed discussion is given on the determination of the optimum size of the individual ripple which enhance the effect of control.

Introduction

This study examines the basic function and determines the optimum size of the Distorted Ripple Train System (Fig. 1), which is developed to control the flow and sediment movement near the bottom. The form of the individual artificial ripple resembles a natural ripple, but its asymmetry is exaggerated and the steep side faces offshore. The difference of the scale and strength of the detached vortices which are formed behind the ripple crest during one wave cycle, being large when the water particle travels offshore, is the agency for the emergence of onshore directed steady flow and sediment transport.

One possible application of the Distorted Ripple Train System is its installation in front of a nourished beach which will endure the effect the nourishment (Fig. 2). Offshore directed sediment, which becomes active just after the nourishment, will be trapped and transported shorewards on the Distorted Ripple Train System.

5Research Assistant, Department of Civil Engineering, Kyushu Univ.
Part of this study is originated from the idea of Inman and Tunstall (1972) who have studied basic functions of asymmetrical ripple-like roughness element. No succeeding research, however, was reported to the author's knowledge.

While the general result obtained thus far by our research group is reported by Irie et al. (1998), this study concentrates on how the size of the individual ripple in the train system should be determined to maximize the performance of the sediment control. To this aim, results of laboratory experiments and numerical computations are presented in this paper.

**Laboratory tests**

The length $\lambda = 0.055m$ and height $\eta = 0.01m$ of the individual ripple in the train system were set as a trial equal to the length and height of a natural ripple formed in a movable bed experiment with water depth $h = 0.35m$, wave period $T = 1.5s$, wave height $H = 0.08m$ and sand diameter = $0.16mm$. The horizontal asymmetry is fixed tentatively to 1 : 3. Another train with ripples of same configuration but enlarged two times in dimensions ($\lambda = 0.11m$, $\eta = 0.02m$) was also prepared. The train of the distorted ripple was set in the bottom of the wave flume extending $6m$ in length.

Experiments were conducted by changing the wave condition ($0.05m < H < 0.09m$, $0.8s < T < 2.0s$). Vertical distributions of horizontal velocity $u$ above the ripple crest were measured with laser-doppler velocimeter. Fig.3 shows an example of the measurement, which indicates that the steady flow $U$
Figure 3 Velocity distribution above ripple crest. 

$u_a$: wave velocity amplitude, $u'_{rms}$: turbulent intensity, $U$: steady flow.

Experimental condition: $T=1.5\,s, \, h=0.08m, \, h=0.35m$.

Figure 4 Results of the experiment: 
(a) Shorewards mass flux $Q$, and (b) speed of the particle movement $V_c$, versus $d_o/\lambda$.

near the bottom is directed shorewards extending to the height $\delta$. The amount of the onshore directed steady flow = shorewards mass flux $Q = \int_0^\delta U$ varied
in accordance with the wave condition. This variation is depicted in Fig.4(a) with the horizontal axis being the ratio of water particle orbital diameter $d_0$ to ripple length $\lambda$. The flow becomes intense when $d_0/\lambda$ approaches 1.7, which is equivalent to the wave condition of the movable bed experiment mentioned before.

Movements of particles above the train were observed and their speed was measured. Three types of particles were used in the tests: glass bead (diameter: 0.08mm, specific gravity: 2.6), fine sand (0.16mm, 2.6) and synthetic particle (0.32mm, 1.6). Particles of 20g in weight were placed above the trough of the ripple at rest. Particles moved and scattered shorewards as a whole after the wave action in all experiments (Fig.5). On and offshore distributions of scattered particles were measured and the variation of their centroid position $X_c$ and dispersion width were recorded. Fig.4(b) shows the result of experiments, where the vertical axis is the variation of centroid in time $V_c=dx/c/dt$. The movement of particles shows a tendency to become intense when $d_0/\lambda$ approaches 1.7, which agrees well with the characteristics of steady bottom flow variation described before.

The result of the experiments suggests that an effective sediment control is achieved when the ratio of the orbital diameter of the wave motion to ripple length $d_0/\lambda$ approaches 1.7, which suggests that the size of the individual ripple in the train should be set identical to the size of the natural ripple. This finding will help the determination of the size of the ripple in practical application.

**Numerical computation**

System of equations for stream function $\psi$ and vorticity $\omega$ was solved numerically introducing turbulent diffusion coefficient. Curvilinear grid system and finite difference method were employed. There is a limitation in the nu-
Figure 6 Variation of $\psi$ during one oscillatory flow cycle

Figure 7 Variation of $Q$ versus $d_o/\lambda$

Numerical work: the computation is conducted under oscillatory flow condition, where the real phenomenon occurs under wave motion. This restricts the direct comparison between the experimental and computational results, however,
our primary concern in the computational work is to catch the change of vortex shedding pattern and shorewards mass flux according to the external flow condition variation.

**Figure 6** shows a typical result of the computation. The stream function distribution are depicted with contour lines. The vortex shedding from the ripple crest is observed, being asymmetric in one oscillatory flow cycle. The magnitude of the vortex can be estimated roughly by counting the number of isolines and it is evident that the vortex formed above the steep slope is more energetic.

A large number of computation was conducted by varying the oscillatory flow condition, the oscillatory period and excursion length. **Figure 7** shows the variation of the amount of shorewards mass flux according to external flow condition change. The steady mass flux reaches a maximum when $d_o/\lambda$ approaches 1.6, which is the same tendency with the experiment.

There remains some points to be refined in the computational work, however, the potential of the numerical approach have been demonstrated.

**Conclusion**

The performance of the Distorted Ripple Train System, which is aimed to control the bottom flow field and sediment transport, have been demonstrated through laboratory experiments and numerical computations. The optimum size of the individual ripple was determined from the experimental results. The flow and sediment control become effective when the wave condition approaches $d_o/\lambda \sim 1.7$, which suggests that the optimum size of the individual ripple should be set identical to the size of the natural ripple.

THE EFFECT OF SEDIMENT COMPOSITION
ON CROSS-SHORE BED PROFILES

Leo C. van Rijn

Abstract

This paper provides information on the effect of sediment (sand) composition on cross-shore sand transport and cross-shore bed profile evolution, based on computational results of a mathematical cross-shore profile model (CROSMOR) and data from flume and field experiments (Egmond beach, The Netherlands and Duck beach, USA). The model has also been applied to study longshore sand transport along a sand-gravel beach. Finally, the effect of sediment size on shoreface nourishment is discussed.

Introduction

The sediment bed of the coastal zone may exhibit a large variation of sediment sizes. Generally, cross-shore sorting due to selective transport processes will occur in nature, yielding coarser sediment just beyond the waterline (wave plunging zone) and fining of sediment size in seaward direction. These effects can only be represented by taking into account the full size composition of the bed material, which may vary across the profile. At present stage of research, mathematical modeling of sand transport and morphology generally is based on a single representative sediment fraction ($d=d_{50}$ and fraction size= 100%). A method is presented to compute the sand transport rate based on a multi-sediment fraction approach in cross-shore direction. The method is implemented as a submodule in a cross-shore model for wave propagation and wave-induced currents using a multi-wave (wave by wave) approach. The computational results of hydrodynamics and morphodynamics are compared to flume and field data. Model applications for sand-gravel beach and shoreface nourishment are given.

Model description

The details of the model (CROSMOR) are described by Van Rijn (1997b, 1998). Herein, a short summary is given.

The propagation, transformation (shoaling) and breaking of individual waves are described by a probabilistic model. The individual waves shoal until an empirical criterion for breaking is satisfied. Wave height decay due to bottom friction and breaking is modelled by an energy dissipation method. Wave-induced set-up and set-down and breaking-associated longshore and cross-shore currents are also modelled (Van Rijn and Wijnberg, 1996). The near-bed velocities of the high-frequency waves (low-frequency effects are neglected) are described by second order Stokes theory and by linear wave theory in combination with an empirical correction factor. The depth-averaged return current \( U_r \) under the wave trough of each individual wave (summation over wave classes) is derived from linear mass transport and the water depth \( h_t \) under the trough. Streaming in the wave boundary layer due to viscous and turbulent diffusion of fluid momentum is taken into account. The streaming \( u_b \) in the wave boundary layer is of the order of 5% of the peak orbital velocity and generally onshore-directed in deeper water (symmetric waves).

To show the performance of the probabilistic model with respect to the computation of wave height and longshore velocity, a recent laboratory experiment (Reniers and Battjes, 1997) was simulated. Measurements of wave height and longshore velocity across a barred beach profile in a laboratory basin were performed. Herein, the test (S0-014) with random waves is considered. The deep-water boundary conditions are: depth=0.55 m, \( H_{\text{rms}} = 0.07 \) m, \( T_p = 1.3 \) s and wave incidence angle = 30°. The bed roughness of the cement floor was \( k_s = 0.0005 \) m. Figure 1 shows computed and measured wave heights and longshore velocities. The breaking coefficient was taken to be 0.6. The horizontal mixing coefficient \( E \) was used as a fit parameter for the longshore current. Good results were obtained for \( E = 0.05 \) m\(^2\)/s in the surf zone (depth < 0.1 m).

Figure 1. Measured and computed wave height and longshore velocity for basin experiment
The sand transport rate of the model is determined for each wave (or wave class), based on the computed wave height, depth-averaged cross-shore and longshore velocities, orbital velocities, friction factors and sediment parameters. The net (averaged over the wave period) total sediment transport is obtained as the sum of the net bed load ($q_b$) and net suspended load ($q_s$) transport rates. The net bed-load transport rate is obtained by time-averaging (over the wave period) of the instantaneous transport rate using a formula-type of approach.

The net suspended load transport is obtained as the sum ($q_s = q_{sc} + q_{sw}$) of the current-related and the wave-related transport components (Van Rijn, 1993). The current-related suspended load transport ($q_{sc}$) is defined as the transport of sediment particles by the time-averaged (mean) current velocities (longshore currents, rip currents, undertow currents). The wave-related suspended sediment transport ($q_{sw}$) is defined as the transport of sediment particles by the oscillating fluid components (cross-shore orbital motion).

The oscillatory or wave-related suspended load transport ($q_{sw}$) has been implemented in the model, using the approach given by Houwman and Ruessink (1996). The method is described by Van Rijn (1997a). The modelling of the $q_{sw}$-component includes a calibration coefficient $\gamma$ in the range between 0.3 and 0.7. Computation of the wave-related and current-related suspended load transport components requires information of the time-averaged current velocity profile and sediment concentration profile.

The current velocity profile is represented as a two-layer system to account for the wave effects in the near-bed layer (Van Rijn, 1993). The convection-diffusion equation is applied to compute the equilibrium time-averaged sediment concentration profile for current-related and wave-related mixing. The effect of the local cross-shore bed slope on the transport rate is taken into account (Van Rijn, 1993, 1997a).

In the multi-fraction mode the bed material is divided in a number of size fractions and the sand transport rate of each size fraction is computed using an existing single fraction method (replacing the mean diameter of the bed material by the mean diameter of each fraction) with a correction factor to account for the non-uniformity effects (Van Rijn, 1993, 1997). This correction is necessary because the coarser particles are more exposed to the near-bed current and wave motion than the finer particles which are somewhat sheltered by the coarser particles (hiding effect). The interaction of the size fractions can be represented by increasing the critical shear stress of the finer particles and decreasing the critical shear stress of the coarser particles.

The total sand transport rate for all size fractions can be obtained by summation of the transport rates per fraction taking the probability of occurrence of each size fraction into account, as follows: $q_b = \Sigma p_i q_{bi}$ and $q_s = \Sigma p_i q_{si}$ in which: $p_i = \text{probability of occurrence of size fraction } i$, $N = \text{number of size fractions}$.

Bed level changes per fraction $i$ are described by: $\rho_s(1-e)\partial z_{bi}/\partial t + \partial (\rho_s\phi_i)/\partial x = 0$ with: $z_b = \text{bed level to datum}$, $q_{bi} = q_{b,i} + q_{si} = \text{volumetric total load (bed load plus suspended load) transport per fraction } i$, $p_i = \text{value of fraction } i$, $\rho_s = \text{sediment density}$, $e = \text{porosity factor}$. The total bed level change is obtained by summation of fractional bed level changes over all fractions. The bed material composition is computed in a thin surface mixing layer of thickness $\delta$ (order of 0.1 m) applying a one-layer approach. The thickness of the surface layer is assumed to be constant in space and time and is moving in vertical direction with the bed surface in response to bed level changes (deposition upwards and erosion downwards). Thus, the surface layer is always at the top layer of the bed. The mixing of sediment within the surface layer is assumed to be effected within each time step (instantaneous mixing) through small-scale bed form migration processes.
in the lower regime or by wave-induced vortices in the sheet flow regime. The bed material composition of the subsoil below the surface layer is assumed to be uniform (no layered structure) and equal to the initially specified fraction values.

**Model results of bar behaviour for Egmond, The Netherlands and Duck, USA**

Computations using the single and multi-sediment fraction methods have been made for a sloping coastal profile with multiple bars along microtidal (Duck beach, USA) and mesotidal coasts (Egmond beach, The Netherlands).

**Egmond beach, The Netherlands**

The model has been applied to simulate nearshore bar behaviour at Egmond in The Netherlands (Wolf, 1997). The case considered is an onshore, accretive event (15 October to 26 October 1992) during which accretive hydrodynamic conditions are present, resulting in significant bar growth and onshore bar migration. As no cross-shore distributions of the hydrodynamic and transport parameters are available, the model is mainly evaluated based on measured profile developments.

The field site is a coastal area of about 1 kilometre alongshore and about 1 kilometre offshore. It is situated south of the village of Egmond aan Zee along the Holland coast. Longshore differences in the offshore wave climate are small due to the relatively uniform orientation of this section of the Dutch coast. The wave climate is dominated by wind waves related to low pressure areas moving from west (Atlantic) to east (European Continent). The tidal range near Egmond varies between 1.2 m (neap tide) and 2.1 m (spring tide). At the site, the flood tide has a duration of 4 hours and the ebb tide of 8 hours. The horizontal tide runs ahead of the vertical tide by about 45 minutes. The semi-diurnal tide induces asymmetrical surface currents which may reach values of 0.6 to 1.0 m/s.

Because of the absence of man-made structures in the area, the coast can be characterised as a natural coast. The sequence of (usually) three bars in the cross-shore profile is representative for a large part of the central Dutch coastal region.

Wave data were collected at Pole 3 (Profile No. 39500), located 545 m offshore at a water depth of about 4 m. The available data comprises time series of water level, wave height, wave period and direction. A sea-sledge (Sub-Aquatic Profiler, SAP) was used to monitor the inner bar. The SAP is pulled back and forth through the surf zone by a capstan (attached to a tractor) and a cable in a closed loop between the capstan and two pulleys, one of which is attached to a beach pole and the other to a pole in the surfzone.

The boundary conditions (over 11 days) of the accretive event are: wave heights ($H_{rms}$) between 0.5 and 2.5 m, wave period between 4.5 and 10 s, wave angle between 50° and -50° to coast normal, water levels between 1.25 m and -1 m (to MSL).

As the wave model is based on a probabilistic approach, the number of wave classes has to be prescribed. Generally, three to five wave classes are sufficient to give accurate results. One base run was made using ten wave classes. The computed bed profiles were almost identical to those of the run with four wave classes.

The initial bed profile, the measured and computed bed profiles after 11 days for the base run (no oscillatory suspended transport or gamma = 0, median sand size $d_{50} = 0.3$ mm, bed roughness = 0.016 m) are given in Figure 2.
The computed profile shows offshore migration of the nearshore bar, whereas the measured profile shows weak onshore migration of the bar. The model produces minor bars in the swash zone near the beach, probably as a result of tide level variations modifying the location of the breaker zone.

The results of a series of sensitivity runs showed that the most sensitive parameters are: undertow velocity, bed roughness, oscillatory suspended transport (gamma-factor) and bed material composition.

The bed roughness was increased from 0.016 m to 0.05 m to better simulate the presence of vortex ripples on the bed, which may be present during accretive conditions. Increase of the bed roughness leads to reduced wave heights and reduced near-bed cross-shore velocities and hence to a relatively large decrease of offshore transport components.

Several gamma factors have been used to increase the onshore-directed suspended transport. Onshore bar migration was obtained for gamma values larger than about 0.3.

The undertow velocity (Ur) was by trial and error reduced to obtain reasonable agreement between computed and observed bar behaviour. The reduction factor was found to be 75%. Results are given in Fig. 2. The measured bed profile is reasonably well represented for x>775 m. The erosion is overpredicted for x between 740 and 775 m.

The effect of sand fractions was studied by a run using the multi-fraction method with 4 fractions; the d_{50} value of 0.29 mm was kept the same. The bed roughness was k_s=0.016 m in both runs.

The results are presented in Figure 3. The bed profile after 11 days shows a lower crest level without significant offshore migration of the crest. The undulations landward of the bar crest are somewhat larger. The cross-shore distribution of the d_{50} is changed after 11 days (constant value of d_{50}=0.29 mm at t=0). The nearshore sediment becomes coarser, because the fines are eroded in larger quantities and are carried in seaward direction.

The best agreement between measured and computed bed evolution (with onshore bar migration) was obtained by using four sand fractions, gamma= 0.3, k_s= 0.05 m, and a 20%-reduction of the undertow velocities. Results are shown in Figure 4.
Duck beach, USA

The CROSMOR profile model has been applied to the cross-shore profile data measured at the Duck beach (USA) during the year 1982 (Mason et al., 1984). The Duck site is exposed to waves coming from the Atlantic Ocean. The tidal range is about 1 m; the tidal currents are weak. The winter period is dominated by storm waves; offshore wave heights can be as high as 6 m. The summer period is dominated by long-period swell. The bed profile generally shows a single bar in the surf zone; sometimes a low outer bar is present. The swash zone near the shoreline consists of relatively coarse material (1 to 2
mm); the sediment is fining down in landward direction to about 0.5 mm on the upper beach and in seaward direction to about 0.2 mm in the outer surf zone (Richmond and Sallenger, 1984). Two cases are considered: storm event 9-12 Oct. 1982 (inner bar moved offshore) and calm event 24 Feb.-24 Aug. 1982 (outer bar moved onshore; beach profile accreted and gained about 50 m$^3$/m due to 3D effects).

Basic input data of Storm event, 9-12 Oct. 1982 : $H_s,0 = 2.4$ m (3 wave classes), $T = 11$ s, wave angle= 20°, time step= 300 s. The gamma-factor of the wave-related suspended transport was set to 0.35. The thickness of the mixing layer was set to 0.1 m. The bed roughness was set to 0.01 m.

Figure 5. Computed significant wave height, depth-averaged cross-shore undertow velocity (below wave trough), and depth-averaged longshore velocity for storm event 9-12 Oct. 1982, Duck beach, USA

Figure 6. Effect of particle size distribution on bed profile evolution for storm event 9-12 Oct, 1982, Duck beach, USA
The computed hydrodynamic parameters (wave heights and currents) along the profile are shown in Figure 5. The wave height at the bar crest is reduced to about 0.8 m. The longshore current is maximum (about 1.2 m/s) near the bar crest. The maximum cross-shore return current is about 0.15 m/s near the bar crest.

The effect of particle size distribution on bed profile evolution using the multi-fraction method (N=4) instead of the single-fraction method (N=1) is shown in Figure 6. The initial median particle size is assumed to vary between 0.2 mm at x=400 m and 0.35 mm at x=585 m for the run with N=4 fractions; the initial sediment size is taken constant along the profile for N=1 fraction. Using N=1 fraction instead of N=4 fractions results in a more seaward position of the bar after 3 days; thus the bar position is significantly affected taking selective transport processes into account.

Basic input data of Calm event, 24 Feb.-24 Aug. 1982 are: $H_s = 0.9$ m (3 wave classes), $T = 9$ s, wave angle= 10°, time step= 21600 s. The gamma-factor of the wave-related suspended transport was set to 0.7. The thickness of the mixing layer was set to 0.1 m. The bed roughness was set to 0.01 m. The computed hydrodynamic parameters (wave heights and currents) along the profile are shown in Figure 7. The wave height in deep water is 0.9 m, which increases to about 0.95 m at the bar crest due to shoaling. The depth-averaged longshore current is zero up to the bar crest, after which it increases to about 0.15 m/s near the shoreline due to oblique wave breaking. The maximum depth-averaged (below wave trough) cross-shore return current is about 0.05 m/s near the shoreline. The effect of particle size on bed profile evolution using the multi-fraction method (N=4 fractions) instead of the single-fraction method (N=1) is shown in Figure 8. The initial median particle size is assumed to vary between $d_{50}=0.14$ mm at x= 200 m and 0.35 mm at x= 635 m for N= 4 fractions; the median sediment size is constant ($d_{50}=0.2$ mm) for N= 1. The computed sand transport rates and bed profile evolutions for N=1 and N= 4 fractions are shown in Figure 8. Using N=1 fraction instead of N=4 fractions, results in a significant decrease of the onshore migration distance of the bar after 6 months (Figure 8); thus the bar position is significantly affected taking selective transport processes into account. Using N=1 fraction instead of N=4 fractions, results in a significant increase of the suspended transport close to the shore (x>600 m); this is an initial effect which hardly influences the bed level close to the shore after 6 months.

Figure 7. Computed significant wave height, cross-shore undertow velocity, and longshore velocity for calm event 24 Feb.-24 Aug. 1982, Duck, USA
The model has been used to compute the cross-shore distribution of the longshore transport rate for a sand-gravel beach. The (hypothetical) beach profile consists of: slope of 1 to 20 between -10 and -3 m, slope of 1 to 10 between -3 and -2 m and slope of 1 to 5 landward of -2 m (Fig. 9). The model has been calibrated for gravel (taking sizes of 5 and 20 mm), using the available data of Chadwick (1989) and Nicholls and Wright (1991). The cross-shore distributions of significant wave height, wave-induced longshore current and sediment transport (bed load and suspended load) for sand-gravel in the range between 0.2 and 5 mm due to storm waves ($H_{s0}=2.8$ m) are given in Figure 9. The profile consists of uniform sand ($d_{50}=0.2$ mm) seaward of $x=180$ m, uniform gravel ($d_{50}=5$ mm) landward of $x=190$ m and a bimodal sand-gravel mixture between 180 and 190 m, see Figure 9. Results for a pure gravel beach (no sand) are also shown. Suspended sand transport is dominant, if the bed seaward of the -3 m line consists of fine sand ($0.2$ mm). The width of the active littoral zone is about 100 m for a sand-gravel beach and about 50 m for a pure gravel beach.
Figure 9. Cross-shore distribution of wave, current and transport parameters

\( H_{s0} = 2.8 \text{ m}, \ T_p = 8 \text{ s}, \) wave angle = 30°

Top: Bed profile, wave height and longshore velocity
Middle: Grain size values (\( d_{50} \) and \( d_{90} \)) of sand-gravel mixture
Bottom: Longshore bed load and suspended load transport for uniform gravel (5 mm) and sand-gravel mixture (0.2-5 mm)

Results for a minor storm with \( H_{s0} = 1.4 \text{ m} \) are given in Fig. 10. The bed load transport is dominant in the gravel zone; the suspended load transport is dominant in the fine sand zone seaward of the -3 m line. The active sand zone has a width of about 30 m. The active gravel zone extends over about 10 m. Details are given by Van Rijn (1998).
Model results for shoreface nourishment

The model was applied to a hypothetical case consisting of shoreface nourishment on a sloping cross-shore profile. The cross-shore profile is assumed to be plane, consisting of four sections: slope of 1:200 up to -6 m, slope of 1:70 between -6 and -3 m, slope of 1:50 between -3 and 0 m and slope of 1:30 on the beach (see Figure 11). The bed material consists of uniform sand with $d_{50} = 0.3$ mm. Two types of sand ($d_{50} = 0.2$ mm and $d_{50} = 0.4$ mm) are assumed to be available for shoreface nourishment.
Figure 11. Effect of sediment size on shoreface nourishment for period of 100 days with low waves ($H_{s0}=1$ m)

Figure 12. Effect of sediment size on shoreface nourishment for period of 11 days with high waves ($H_{s0}=2$ and 3 m)
After nourishment the profile is assumed to be triangular with a slope of 1:50 over its seaward section of 150 m and a horizontal profile over its landward section of 150 m (see Figure 11). The water level is constant (no tide). Two wave scenarios are considered: calm period with $H_s = 1$ m during 100 days ($T=7$ s $\alpha=30^\circ$); storm period with $H_s = 2$ m during 10 days ($T=7$ s $\alpha=30^\circ$) and $H_s = 3$ m during 1 day ($T=7$ s $\alpha=30^\circ$).

The computed evolutions of the nourishment profiles with 0.2 and 0.4 mm sediment for the calm period (100 days) are shown in Figure 11. The bed profiles after 100 days are almost similar, showing no clear effect of particle size for low waves.

The computed evolutions of the nourishment profiles with 0.2 and 0.4 mm sediment for the storm period (10 days with $H_{s0}=2$ m and 1 day with $H_{s0}=3$ m) are shown in Figure 12. The nourishment profile of 0.2 mm sediment is moulded into a relatively large sand bar with a deep trough during conditions with $H_{s0}=3$ m (1 day). Furthermore, minor offshore sand transport can be observed for the case with 0.2 mm sediment; about 5% of the nourishment volume is carried offshore after 11 days of storm waves. The nourishment profile of 0.4 mm sediment shows considerably less variability and no offshore transport. The profile development landward of the nourishment is not much affected by the sediment size on the short term time scale of storms.

Conclusions

The most sensitive model parameters are: undertow velocity, bed roughness, wave-related suspended transport (velocity asymmetry) and sand composition. The presence of graded sand leads to flatter and wider bars; uniform sand leads to more peaked bars. The wave-related suspended transport due to velocity asymmetry can not be neglected; it is essential for onshore bar migration/growth.

The modelling of selective transport depends on hiding factor and effect of particle size on bed and suspended load transport. The model results show that: (1) coarser sediment is carried shorewards as bed load during calm periods, (2) finer sediment is carried seawards as suspended load and is deposited in bar trough zones and in offshore zone during periods with storm waves and (3) coarser sediment is eroded from outer bar and is carried landwards as bed load to swash/beach zone during periods with storm waves. Longshore suspended sand transport is dominant along sand-gravel beach under storm waves. The width of active littoral zone may be as large as 100 m for storm wave conditions.

Sand size between 0.2 and 0.4 mm has almost no effect on shoreface nourishment during periods with low waves (calm period). The use of fine sand of 0.2 mm for shoreface nourishment results in offshore loss (about 5% of nourishment volume) during storm conditions and more variability of the profile due to the generation of relatively large sand bars during storm waves.

THE BREACHING OF SAND INVESTIGATED IN LARGE-SCALE MODEL TESTS

Cees van Rhee* and Adam Bezuijen**

Abstract

The physical principles, which govern the breaching process, are analysed. It will be shown that this process involves both geotechnical and hydraulic phenomena. The stability of the surface of the slope and the internal stability are studied. The theories are compared with results from a large-scale experimental programme. Results show that the propagation velocity of the breach is influenced by the permeability and that the resulting slope is gentler as the breach height increases. The breaching process can even become unstable which can lead to failure of a slope over a very large distance.

Introduction

Suction of sand several metres below the original bottom will lead to breaching of sand. The sand will form a steep slope in front of the suction-mouth. The steep slope is not stable and will propagate from the suction-mouth, producing a sand water mixture that flows in the suction-mouth. Breaching of sand is an important process in the dredging industry. The steepness and propagation velocity of the slope determines the sand production that can be achieved. A research programme has been performed to investigate the mechanisms that govern the breaching of sand. This programme included large-scale model tests and theoretical modelling of the mechanism.

Theory

Erosion theories

When a suction pipe is moved forward with constant velocity $v_z$ in a two-dimensional situation, the so-called pit production $P$ follows from continuity:

$$ P = v_z B $$

The thickness of the sand layer or the physical limitations of the dredge mostly restrict the depth of the pit $B$, therefore the velocity $v_z$ determined the slope production. However, the forward velocity is limited by the behaviour of the soil body in front of the suction pipe.

The slope can be very steep due to the shear dilatancy effect of compacted sand. Dilatancy is the effect that the pore volumes of dense sand tend to increase during shear deformation as result from increased shear stresses. When the sand is saturated with water, this will lead to water under-pressure in the pores. The under-pressure will result in an increased effective pressure and hence increased shear resistance.

In the seventies, the behaviour in front of a dredger was studied at Delft Hydraulics using small-scale two-dimensional experiments. A suction tube was moved forward at the bottom of a flume and the developing slope in front of the suction mouth was studied. From a stability analysis of the surface of the slope the following relation between the forward velocity and slope angle $\beta$ was derived (Breusers, 1977):

\[
\frac{\cot \beta}{\cot \phi} = 1 - \frac{v_z}{v_w}
\]

(2)

In which $v_w$ was defined as the active wall velocity:

\[
v_w = \frac{k_r \cdot \Delta \cdot (1 - n_0) \cot \phi}{\Delta n}
\]

(3)

In which $\phi$, $\Delta n$, $n_0$, $\Delta$, and $k_r$ are the internal friction angle, relative porosity increase, initial porosity, relative grain density and permeability respectively. From Eq. (2) follows that at very low velocity the angle of the front slope will be equal to the internal friction angle. The limit speed follows from $v_z = v_w$. In that case the front slope will be vertical. The relative porosity increase is calculated with:

\[
\Delta n = \frac{n_1 - n_0}{1 - n_1}
\]

(4)

The active wall velocity ($v_w$) can be seen as the propagation speed of a vertical disturbance on the slope. By moving a suction mouth downwards a sudden disturbance is created in the soil. The initial steep slope will not be stable in the long term. Fig. 2 gives an impression of the development of a slope after some time. The vertical “wall" will move sideways. The sand from this collapsing front will flow towards the suction mouth. The slope angle below the producing wall is drawn rather steep in Fig. 2. Indeed at relative low production (i.e. small-scale test) this will be the case and a slope angle equal to the natural angle of repose will develop.

In practice however, it was experienced many times that the resulting slope angles were often more gentle. It was suggested that this was due to the erosion caused by a sand-water mixture (acting like a density current) running down the slope.
(Koning, 1981), although this hypothesis was not proven. Some years later the influence of the flowing sand-water mixture on the slope development (hydraulic filling) was studied in 1988 by Delft Hydraulics and Delft Geotechnics in the dredging flume of Delft Hydraulics. (Mastbergen and Bezuijen, 1988 and Bezuijen and Mastbergen 1988).

![Initial Disturbance](image1.png)  
![Slope Development](image2.png)

Figure 2: Slope development resulting after sudden disturbance.

It was found that at small production rate, the grain flow on the slope was laminar and slope angles were close to the natural angle of repose. When the sand production increased, the grain flow became turbulent and the slope angle decreased with increased sand flux $s\ [kg/(ms)]$. The other important factor was the grain diameter. Coarse sand resulted in steeper angles. The following empirical relation was found:

$$i = \tan(\beta) = 0.0049 \ D_{50}^{0.92} \ s^{-0.39} \quad (D_{50} \text{ in } [\mu m], \ s \text{ in } [kgm^{-1}s^{-1}]) \quad (5)$$

The sand production from the slope equals:

$$s = v_w B (1-n_0) \rho_s \quad (6)$$

The permeability can be calculated with the following equation:

$$k = \frac{g}{160v} d_{15}^2 \frac{n^3}{(1-n)^2} \quad (7)$$

Combining the equations above, the slope angle of an active wall at a certain depth can be calculated as a function of height. Since the production increases going down the slope, the slope angle will also decrease. Fig. 3 shows the results for two different dense sands. In this figure, it can be seen that at the lower end of a large breaching slope the slope angle will be small. In this example the slope is even gentler for the
coarser sand than for the fine sand because permeability (and therefore $v_w$ and $n_s$) dominates over the grain size.

Figure 3: Slope angle at toe of breach as function of breach height.

Figure 4: Stable and Unstable breaching.

When an active wall runs up an existing slope as sketched in Fig. 4, the breaching process can become unstable when the slope angle below the active wall is smaller than the existing slope. In that case, the active wall height and thus production will increase. This will lead to an even gentler slope at the toe, which again accelerates the growth of the breach height. This mechanism will go on until the bottom of the active wall reaches the sea bottom. It must be noted that this mechanism can be present in very dense sands. Therefore, it is very likely that this mechanism can be responsible for unexplained "slope liquefaction" in areas where sand was not in a loose state. The mechanism agrees with slope failures observed at the riverbanks of the Mississippi River (Torry, 1995).
Stability of slope

At large propagation velocity of the suction mouth and for a limited breach height, the slope of the breach will be steeper than the slope corresponding to the friction angle of the sand. A slope of saturated fine sand will be stable as long as the angle of the slope $\alpha_0$ is smaller than the friction angle $\phi$ of the sand. Above the water line capillary forces can lead to steeper slopes below the water line this is not possible. If therefore the slope is below the waterline and it is steeper then the friction angle, this will always lead to instability. This is not an instantaneous instability. The unstable slope will lead to plastic deformation of the sand and dilatancy (an increase in volume of the sand due to an increase of the pore volume, caused by a different arrangement of the grains, see Fig. 5). Such a dilatancy is only possible if water flows into the sand. Therefore a temporarily stable position is possible for slopes steeper than the friction angle of the sand. In such slopes, there will be dilatancy of the sand leading to a decrease in pore pressure and a water flow into the sand and to a temporarily stable slope. When maximum possible dilatancy is reached, there will be a collapse of the slope.

If the sand is in this temporarily stable situation, which means that the gradients generated by the dilatancy are just enough to stabilise the soil, the decrease in pore pressure can be calculated. A simplified calculation, neglecting the influence of the groundwater flow, is presented below. Assume that the sand mass within the triangle with a slope angle between $\phi$ and $\alpha_0$ (see Fig. 6) is just stable. In that case all particles in that sand mass should be just stable. With the notation presented in Fig. 6, this leads to the following equilibrium equation:

$$\tan \phi = \frac{\gamma' r \sin \alpha \partial \alpha \partial r + \partial p / \partial r r \partial \alpha \partial r}{\gamma' r \cos \alpha \partial \alpha \partial r + \partial p / \partial \alpha \partial \alpha \partial r}$$

(8)

Integration over the angle $\alpha$ and reworking leads to the equation:
\[ \frac{\partial p}{\partial r} - \frac{A}{r} = B \]  

(9)

with:

\[ A = \frac{\tan \phi}{\phi - \alpha_0} \quad \text{and} \quad B = \frac{\gamma}{\phi - \alpha_0} \left\{ \cos \phi - \sin \alpha_0 + \tan \phi \left( \sin \phi - \sin \alpha_0 \right) \right\} \]  

(10)

Integration over \( r \) leads to the minimum pressure \( (p) \) that can be expected in the breach:

\[ p = -\gamma r \left\{ \frac{(\cos \phi - \cos \alpha_0)}{\tan \phi} + \frac{\sin \phi - \sin \alpha_0}{1 + (\alpha_0 - \phi) / \tan \phi} \right\} \]  

(11)

The pressure drop increases with the slope angle and is linearly proportional with the height of the breach. This equation will be compared with the results of measurements in the section Results.

As long as dilatancy of the sand can provide this minimum pressure, the slope will be temporarily stable. When the maximum porosity of the sand is reached, instability will occur.

**Large scale model tests**

Two dimensional model tests have been performed in a flume of 32 m length, 1 m width and 2.5 m high at Delft Hydraulics. The flume was filled with fine (135\( \mu \)m) or medium fine (225\( \mu \)m) saturated sand. The density of the sand was controlled by a vibration procedure. In various tests the porosity varied between 38 and 47%. During the experiments a suction mouth was moved through the flume with a constant velocity, varying between 2 and 9 mm/s in the different tests. The suction mouth was moved forward over the bottom of the flume between 0.10 and 0.70 m above the bottom. The resulting breach height varied between 1.50 and 2.2 m

During a test the production, the density and discharge was measured using an EMF and radioactive concentration meter. The pore pressures in the sand and the porosity of the sand were measured by means of a measurement panel that was placed in one of the walls of the flume.

It was expected that during the tests a steep slope angle would develop and that the slope would move constantly forward. This complicated the measurements in the density current on
the slope. It was decided to place the instruments on a carriage that could move over the flume in the same direction as the suction mouth. Close to the instruments, a pressure sensor was placed and the carriage was moved forward automatically until the sensor "felt" the slope. At that moment the carriage stopped and started the measurements. If the process was stationary a concentration and velocity vertical could be obtained because the slope moved away from the instruments. Using this device, the thickness, concentration and velocity of the sand-water mixture could be measured. The process was monitored also by video, through the sidewalls of the flume. The set-up of the experiments is sketched in Fig. 7.

Measurements

Slope angles

Since the tests were two-dimensional, only the slope in front of the suction mouth could be investigated. From the video recordings, the development of the slope angle was followed. It became clear that the description of the active wall velocity according to eq. (3) was not valid at large breach height due to:

- The presence of a turbulent density current that eroded the sand surface at the toe of the breach leading to a gentler slope which was in accordance with the analysis of section Theory.
- Failure of lumps of sand that was noticed instead of raining of single grains, which occurred at small breach heights.

The effect of the density current on the slope angle

Fig. 8 shows one of the large numbers of concentration and velocity that were measured during the tests. Velocities up to 1 m/s were measured in the density current. It will be clear that this is sufficient to erode the surface of the slope. The influence of the density current on the slope can be investigated by varying

![Suction Mouth](image-url)
the slope height at a constant forward velocity of the suction mouth. As explained in the theoretical section, the sand-mixture flow must be turbulent to get sufficient erosion. This will only be the case above a certain production level and hence breach height. The sand level in the test flume was limited to 2.3 m.

To simulate the situation for a higher breach, a part of the mixture sucked from the toe of the breach was backfilled at the top of the slope, see Fig 8. The apparent extra height created with this method was approximately 1-1.5 m. During the test, the forward velocity of the suction mouth was 6 mm/s. At a breach height of 2.3 m the slope angle was between 52°-55°. During backfilling the apparent slope increased to 3.5 m and the slope angle decreased to below 40° as can be seen in the figure below.

![Graph showing production and slope angle over time](image)

**Figure 10: Influence of density current on slope angle**

In Fig. 10 it can be seen that at t=1500 s, backfilling at the top of the slope starts. From this moment the gross production increased (part of the mixture is circulating). The net production, which is the amount of soil being removed from the flume, maintains almost the same level. It can be seen clearly however that the large production fluctuations diminish soon after backfilling is started. This is a result from the eroding work of the current at the slope. Before backfilling started, the production was dominated by the sliding of sand lumps from the slope. This is a more irregular process than the erosion process. When the slope angle in Fig. 10 is compared with the theory (Fig. 3) it is clear that the slopes during the tests were steeper. This can be explained by the fact that the slope angles of Fig.3 are derived for a situation where sedimentation dominates, while at the experiments every part of the slope was eroding, due to the forward velocity of the suction mouth. However, both figures show the same tendency.
Porosity and pore pressures

Breaching of sand will lead to a reduction of the pore pressure in the remaining sand, as was explained in the chapter on theory. An example of this reduction is shown in Fig. 11. This figure shows the measured pore pressure and porosity changes on a horizontal plane. The surface of the slope was at that moment situated at x=15.1 m. At this location the reduction in pore pressure disappears. It appears from this figure that the pore pressure reduction is measured more than a metre from the suction mouth. This pore pressure reduction is caused by dilatancy in the sand before it runs.

Figure 11: Measured Porosity and porosity changes.

Figure 12: Pore pressure changes in front of suction mouth.
of the slope. However, the electrical density measurements show Fig. 11) that is only limited to a small layer of sand, as is also indicated in Fig. 12. Dilatancy is measured as a decrease of electrical resistance due to the increased porosity. The area indicated functions as a sink. Groundwater flow causes the reduction of pore pressures in the non-dilating part of the sand body. This corresponds with theory.

The measured maximum pore pressure reduction is compared with the results of Eq. (11) in Fig. 13. It appears that using the friction angle of the sand as measured in a triaxial test (35 degrees), Eq. (11) overestimates the pore pressure reduction. However, in densified sand the peak value is always larger than the residual value presented as result of a standard triaxial test. The peak value can be up to 45 degrees. Using this value there is good agreement between measurements and theory for slope angles up to 70 degrees. For larger slope angles the pore pressure reduction is overestimated by theory. This can be caused by density currents that are not taken into account for this model, but lead to an increase of pore pressure.

Figure 13: Measured pore pressure reduction compared with theory.

Conclusions

Measured pore pressure reduction in the sand is caused by groundwater flow to the limited zone of dilatant sand. The slope angle developing during the suction of sand and therefore the maximum forward velocity and hence production does not only depend on the sand characteristics. Also the height of the breach as well the effect of the density current are of importance. At a high breach this can lead to very small slope angles, and even to unstable breaching. This effect has been reported in literature from field experience and has now been proved by experiments and theory.

Chapter 22 in:
A Dimensionless Parameter Describing Sea Cliff Erosion

Akira Mano 1 and Shigenori Suzuki 2

Abstract

Macroscopic analysis based on the energy conservation on sea cliff erosion gives a dimensionless parameter including recession rate of the cliff, wave energy flux at the breaking point, Young’s modulus of rocks composing the cliff, and cliff height. This parameter was examined through field data on the Fukushima Coast where a series of soft rock cliffs extends about 50 km. The modulus was obtained by the measurement of the propagation velocity of elastic waves in the rocks and the energy flux was evaluated by the wave ray method. The long-term recession rate had been obtained from the aerial photographs. The recession rate is shown to be proportional to the wave energy flux and inversely proportional to Young’s modulus. These quantities prove that the dimensionless parameter has the constant value of 0.082.

1 Introduction

It is a common sense from the physical point of view that the rate of sea cliff erosion depends on both of the intensity of incoming waves and the strength of the rocks composing the cliff. However quantitative relationship to connect these parameters in the field was still unknown. This comes mainly from the difficulty of the observation. Significant cliff erosion occurs in the storm condition, often associated with massive collapse of the cliff. We cannot approach such site during the storm. Furthermore individual collapse may not represent the recession characteristics at the site, because the structural cracks would determine the position of the failure. Debris produced by the collapsed cliff would also affect the recession rate.

Thus we have only limited data on the sea cliff erosion in spite of the significant requirements on the protection works. To develop physical model on the recession characteristics at this stage, macroscopic approach using the energy conservation relationship would be appropriate.

2 Electric Power Development Co. Ltd., 6-15-1 Ginza, Tokyo, 104-0061, Japan
2 Energy Conservation Analysis

For the high cliffs made of soft rock, the erosion would take the following process: (1) erosion of the cliff base, (2) collapse of the overhanging, (3) successive fragmentation from large rocks into sands or mud, (4) longshore transport of the fine materials. However since the knowledge of (1) and (2) is unsatisfactory and the both process produce the debris, we will simplify them as one process. Let us consider a two dimensional configuration of the cliff erosion as illustrated in Fig. 1. Taking unit width in the longshore direction and denoting the cliff height and recession rate by \( L \) and \( q \) respectively, we have volume rate of the debris production from the continuity of the cliff material,

\[
\dot{V}_1 = Lq.
\]  

Furthermore steady state assumption gives the volume rate of the debris removal equal to the production rate.

![Fig. 1: Definition sketch.](image)

The energy conservation equation for the cliff erosion could be written as,

\[
F = \dot{W}_1 + \dot{W}_2 + \dot{W}_3 + \dot{R}.
\]  

Where \( F \) is the energy supply rate and represented by the onshore component of the wave energy flux in unit longshore length at the breaking point as,

\[
F = E_b C_{gb} \cos^2 \theta_b.
\]
Here subscript $b$ denoting the breaking point, $E_b$ is the wave energy density, $C_{gb}$ group velocity, and $\theta_b$ wave angle. The powers $\dot{W}_1$, $\dot{W}_2$, and $\dot{W}_3$ are the rate of the work to detach the large rocks from the cliff, to fragmentize the large rocks of debris into sand or mud, and to transport these fine sediments in the longshore direction. The power $\dot{R}$ is the remainder such as energy dissipation rate in the surf zone.

The first two terms of $\dot{W}_1, \dot{W}_2$ are modeled by the elastic theory. If external force is applied to compress the rock sample with unit length and unit cross section from zero to the yield stress, the work done by the force is given by

$$w = \frac{1}{2} \sigma_y \epsilon_y = \frac{1}{2} \frac{\sigma_y^2}{E}.$$  \hfill (4)

Where $\sigma$ and $\epsilon$ are the stress and strain respectively, $E$ is Young’s modulus, and the subscript $y$ indicates yield point. Among various kinds of metals, the yield stresses of the materials are directly proportional to their Young’s moduli as stated in Kobayashi (1993). This corresponds to the physical state that fracture occurs when the relative dislocation of atoms exceeds a certain time of the interatomic distance. Introducing this relationship also for rocks, we can rewrite the above equation as,

$$w \propto E.$$  \hfill (5)

Thus the maximum strain energy that the rock of unit volume can hold is proportional to its Young’s modulus. Then if cracks generate in the rock, a part of the strain energy transforms into the surface energy of the newly generated cracks. Therefore the energy consumed in the processes from the erosion to the fragmentation could be interpreted to change the surface energy. Thus, with coefficient $C_1$

$$\dot{W}_1 + \dot{W}_2 = C_1 L q E.$$  \hfill (6)

The third term is modeled by employing Komar and Inman(1970) with the coefficient $K$,

$$\dot{W}_3 = K F \tan \theta_b.$$  \hfill (7)

The last term is expressed by the efficiency factor $\beta$ as,

$$\dot{R} = (1 - \beta) F.$$  \hfill (8)

By substituting all these model into Eq.(2) and dividing by $F$, it follows,

$$1 = C_1 \Pi_c + K \tan \theta + (1 - \beta).$$  \hfill (9)

Where

$$\Pi_c \equiv \frac{q E L}{F}.$$  \hfill (10)

Equation (9) indicates the dimensionless parameter, $\Pi_c$ is constant if the wave angle $\theta_b$ is small and the efficiency coefficient $\beta$ is constant.

$$\Pi_c = \text{const.}$$  \hfill (11)

In the following sections, we will examine this parameter by collecting field data on the Fukushima Coast.
3 Outline of the Coast

The Fukushima Coast locates in the East of the main land of Japan and faces directly toward the Pacific Ocean as shown in Fig. 2. The coast extends about 50 km in the north direction and is composed of a series of cliffs and pocket beaches. The coast had suffered from serious erosion, reaching 10 m/y at most. The geographical situation that the coast is subject to high wave attack is one reason of the severe erosion.

![Fig. 2: Topography of the Fukushima Coast and sampling points.](image)

The other reason comes from geological condition. The coastal area together with the hinterland and offshore region is subject to the uplift, the rate of which is estimated by Oka et al. (1981) as 0.2 to 1.6 mm/y, varying temporarily and spatially. The bed layer of the cliff in the northern part of the coast is marine mudstone or sandstone, formed in the Upper Pliocene, while the southern part is widely covered with green tuff formed in the Miocene, the Tertiary. Weakly
consolidated rocks of geologically young age are easily eroded by wave attacks.

In the West of the coastline, Futaba Fracture zone parallels the coast. The West of the fracture zone uplifted about 200 m relative to the East in the Lower Pleistocene and is now called Abukuma Plateau. Many rivers originated in the plateau run east by eroding the Pliocene sediments on the bed layer and made pocket beaches at the coast. The submarine contour lines of 20 to 40 m are significantly winding in the northern part. It is also estimated that the submarine valleys were made by the fluvial erosion during the regression of seawater in the Pliocene. The valleys would affect the refraction of incident waves and then the distribution of wave energy.

Nine sampling points for the examinations of the rock and wave properties described in the next section were selected so as to cover the wide area of the coast and to include wide range of the recession rate. Fig. 2 illustrates also the points by the gray circles with numbers.

Figure 3 shows the cliff at No. 4 point. The headland is eroded vertically at the tip and has a hollow near the base at the side. In order to mitigate the erosion, numbers of concrete block were put at the shoreline and demonstrated to mitigate the erosion. The other places on the coast are also in the similar circumstances. To guard the railway, roads, and houses in the hinterland from the erosion, protection works were done in 1960s and 1970s. Now the protection works such as the block at the shoreline or detached breakwater has covered major part of the coast.

Figure 4 shows the cliff at No. 20. The cliff surface exhibits many layers stretching horizontally. At the base of the cliff, there scatter numerous large rocks of debris. The cliff height is about 18 m. Fig. 5 shows the cliff at point No. 36, which is formed by the hardest rocks in our study. The layers run nearly vertically. Thus, nine samples were taken from various conditions of cliff.

Fig. 3: Photograph at the cliff, No. 4.
Fig. 4: Photograph at the cliff, No.20.

Fig. 5: Photograph at the cliff, No.36.
4 Evaluation of the Parameters

Young's modulus \( E \) of the rock composing cliffs was evaluated by the measurement of the propagation velocity of the elastic wave. First, we collected rock samples of the size of about 30 cm by detaching them from cliffs near the sea water level. Then, after cutting them into the rectangular solids and drying them in the electric furnace at 200°C for 24 hours, we measured the propagation velocity of the elastic primary wave, \( V_p \) by attaching transducers on the surface of the formed samples. Young's modulus is given by the following equation,

\[
E = \rho V_p^2 \frac{(1 + \nu)(1 - 2\nu)}{1 - \nu}.
\]

(12)

Where \( \nu \) is Poisson's ratio and the standard value 0.25 was used. The obtained values of Young's modulus together with the other quantities are listed in Table 1.

Relative range \( S_d/\bar{z} \) 0.303 0.348 0.140

Energy flux was obtained by the wave ray method of Mano and Sawamoto (1997). That is, the wave ray equation of Mei (1983) and wave ray density equation of Munk and Arthur (1952) together with the dispersion relation are solved on the sea bottom topography approximated as a set of triangular panels. The breaking points are determined by Goda's criterion (1974).

Examples of wave rays are shown in Figs. 6 and 7 for respective wave directions ENE and ESE of wave period, 12.0 s. The numbers and vertical lines at the bottom of the figures indicate the sample numbers of cliffs specified in Fig. 2 and cliff extension respectively. Wave rays refract remarkably by the submarine valleys and then result in the periodic distribution of energy concentration and dispersion. In order to evaluate the wave energy flux from wave rays that include crossing, the
Fig. 6: Wave rays for the incident waves with the period, 12s, and direction, ENE.

Fig. 7: Wave rays for the incident waves with the period, 12s, and direction, ESE.
following definitions were adopted,

\[ F = \frac{1}{N} \sum_{j=1}^{N} \sum_{i=1}^{n_j} (E_b C_g \cos^2 \alpha_b)_i \]  

(13)

where \( N \) is the number of the data sets in a year, \( f_j = n_j \Delta S/\ell \), \( \Delta S \) is the ray ejection spacing in the offshore boundary, \( n_j \) is the number of wave rays approaching the cliff, \( \ell \) is the cliff extension projected to the offshore boundary. The coefficient \( f_j \) is introduced to take into account of the wave ray gathering. Here we adopted the data sets of daily mean values of the significant wave height, period and direction observed in 1991 off the Souma Harbor located at the north end of the coast with the total days, \( N = 364 \).

The Fukushima Prefecture (1993) had performed comprehensive research on the coastal erosion, including the recession rate evaluation of all cliffs on the Fukushima Coast and histories of the protection works. The aerial photographs taken in 1963 to 1991 were used for the evaluation. Thus the rate is the mean values in time span of 15 to 30 years. We took these values but modified them by assuming no recession after the protection works. The cliff height is obtained also in the same report.

5 Results and Discussion

Equation (11) for the dimensionless parameter \( \Pi_c \) constituted by four quantities deduces further several relations with the additional conditions that two quantities among four are chosen with keeping the other quantities constant;

\[ q \propto F, \]  

(14)

\[ q \propto 1/E, \]  

(15)

\[ q \propto 1/L. \]  

(16)

Before getting into the individual relationship, let us examine the characteristics of our data set in Table 1. The lowest three rows of the table indicate the mean values, standard deviation and relative range, which is defined by the standard deviation normalized by the mean value, among samples. In the three quantities, \( F, 1/E, \) and \( 1/L \), the first two quantities have wide range, while the last quantity narrow. In other words, our data set is appropriate to examine Eqs. (14) and (15), and is rather poor to Eq.(16).

Figure 8 examines the relationship between the recession rate \( q \) and the wave energy flux \( F \). The recession rate is linearly proportional to the energy flux as shown by the regression line but with a certain data scatter. This corresponds to Eq. (14). Similar relationship has been obtained by Gelinas and Quigley (1973) on the cliff erosion of the north shore of the Great Lake, Erie. As the parameter of wave intensity, they used the total energy flux, not the onshore component, however the difference is generally small, because waves approach perpendicularly to the shore. They made \( q - F \) plot and got the regression line but without passing the origin. If we ignore the intercept, which is not so unnatural judging from the scatter of their data, it also becomes Eq. (14).
Figure 8: Relationship between the recession rate and the wave energy flux.

Figure 9 examines the relationship between the recession rate and Young's modulus. The recession rate is inversely proportional to Young's modulus. Although there is also data scatter, referring to the previous figure, we could find some reasons for the scatter. For example, No 17 far above the regression line indicating excessive erosion for the strength of the rock is reasoned by the high energy flux shown in Fig.8. Therefore the data scatter of these figures does not always mean the poorness of the models (14) and (15). Fig. 9 is also supporting Eq.(15).

Sunamura (1992) examined the relationship between the recession rate and compressible yield stress, by collecting related data on the Fukushima Coast by
three researchers. He plotted these two parameters in the log-linear scale plane and got regression relationship by the logarithmic function. However, recalling the relationship used in Section 2 that the yield stresses are linearly proportional to Young's moduli, we can expect inversely linear relationship between the two quantities with the help of Eq. (15). Fig. 10 is the modification of Sunamura (1992)'s Fig. 5.13, by taking the linear scale for the inverse of the yield stress. Here the numbers by the circle indicate different sites. The expectation is realized with small data scatter in this figure.

![Graph showing relationship between recession rate and inverse of yield stress](image)

Fig. 10: Relationship between the recession rate and inverse of the yield stress, obtained by modifying Sunamura (1992)'s Fig. 5.13.

Figure 11 shows the correlation between the recession rate and cliff height. The largest data scatter would come from the narrowness of the relative range of $1/L$. We have shown the significant effects of the energy flux and Young's modulus on the recession rate, which was enabled by the wideness of the relative range of these parameters and the narrowness of the remaining parameter, because Eqs. (14) to (16) require the constancy of the other parameters when one parameter among $F, 1/E$ and $1/L$ is chosen.

As for the effect of the cliff height on the recession rate of the sea cliff, there have been conflicting arguments that high cliff is effective to retard the erosion in the short time span but ineffective in the long time span in Sunamura (1992). Detailed analysis on the effect of cliff height and discussions on the above arguments will appear in Mano and Suzuki.

Figure 12 shows the correlation between the recession rate and the combined parameter $F/EL$. The recession rate is proportional to the parameter with small data scatter. We have the regression line,

$$ q = 0.082 F/EL $$

identically,

$$ \Pi_e = 0.082 = \text{const.} $$

Thus, Eq. (11) is proofed.
Fig. 11: Relationship between the recession rate and the inverse of cliff height.

Fig. 12: Relationship between the recession rate and the combined parameter $F/EL$. 
6 Conclusions

The macroscopic analysis based on the energy conservation relation on the sea cliff erosion produces a dimensionless parameter $\Pi_c \equiv qEL/F$ and expects this parameter is constant in the first approximation. Four quantities constituting the dimensionless parameter were evaluated and collected on the Fukushima Coast which had been suffered from severe erosion through the dual reasons of the high wave attack and weakly consolidated rocks. Young's modulus was evaluated by the measurement of the propagation velocity of the elastic waves, while the energy flux through the wave ray analysis. The recession rate and the cliff height had been evaluated through the measurement by the aerial photographs and by the geographical maps, respectively, by Fukushima Prefecture.

Equation (11) on the constancy of the dimensionless parameter includes Eqs. (14) to (16) as special cases. Eq. (14) on the dependency of the recession rate on the energy flux and Eq. (15) on Young's modulus are satisfied by our data set and are shown to be consistent with the foregoing studies by Gelinas et al (1973) and Sunamura (1992). However for the last quantity, the cliff height, our data set is poor to proof Eq. (16), directly. Finally, as for the whole four quantities, our data set gives the relationship $q = 0.082F/EL$ with small data scatter. This is equivalent to $\Pi_c = 0.082$ and the constancy of the dimensionless parameter is proofed.

Acknowledgements

The authors are indebted to Professors Masaki Sawamoto, who introduced us this exciting subject, Tsuguo Sunamura, whose comprehensive review guided us to the important problems on this subject, Shigeru Niizeki, who allowed us to use the measurement system of the elastic wave, and Satoshi Kanisawa, who helped us to study the geological circumstance on the Fukushima Coast. Thanks are also due to Fukushima Prefecture for the permission to use the data and to the Ministry of Education, Science, Sports and Culture in Japan for the Grant-in-Aid.

The Sand Trapping Trench As A Countermeasure to Control Wind-Blown Sand on Beaches

Shintaro Hotta 1 Katsumori Hatanaka1, Hiroyoshi Tanaka 2 and Kiyoshi Horikawa 3

Abstract

The sand trapping trench for controlling wind-blown sand is proposed and general functioning, evaluation of sand trapping efficiency, process of trench development, and usage methods are described.

1 Introduction

One of the important problems in the beach stabilization and the effective utilization of beaches is how to control wind-blown sand. Different types of countermeasures are employed in different parts of the world depending on the local conditions at the beach, such as weather, sea, and geographical conditions as well as the economical importance of the region. At the latest ICCE (25th), Hotta and Horikawa (1996) proposed a new type of prevention work, a sand trapping trench, for controlling wind-blown sand. The trench is given a rectangular shape with a depth of more than 1 m and a width of around 5 or 6 m by excavating the backshore of the beach (see Fig. 1). However, the details of trench could not be described in the paper since the main focus of the paper was not to discuss the trench itself. The purpose of this paper is to report the design and use of the trench in more detail.

2 Procedure

2.1 Background and Process of Trench Development

The idea of a sand trapping trench for controlling wind-blown sand stems from the results of several previous studies. Inspiration to the trench came from an early paper that described a case where cultivated land close to a sandy beach was protected from wind-blown sand by excavating a stream upwind the beach, letting sand grains fall into the stream, and then returning the sand to the sea (Iwagaki, 1950).

Considering this case, Horikawa et al. (1983, 1984) tried to measure the sand transport rate in the field by using trenches those were 1 m deep and several meters wide. Figure 2 shows examples of the sand accumulation process in the

3Musashi Institute of Technology, Tokyo, Japan
trench and Photo 1 shows the trench (a) at the beginning of the observation, and (b) at the same location after 5 days. Figure 2 and Photo 1 show that the blown sand that fell into the trench was deposited at the upstream edge of trench with the deposition progressing in the downstream direction. The same level was maintained with respect to the beach surface and the rest angle of dry sand determined the downwind slope. This form of accumulation can be understood when we realize that a portion of the blown sand moves with the surface creep motion and that the flying distance of sand grains in saltation is rather short. Horikawa et al. (1983, 1984) also reported that no significant amount of sand was transported beyond the trench and they concluded that the trench could trap almost 100% of the blown sand.

Using a large wind tunnel, Hotta and Horikawa (1993) measured the flying distance of blown sand in saltation motion. Figure 3 shows examples of observed distributions of falling sand grains. The falling rate was measured by a horizontal distribution-type trap that was 1 m long in the wind direction.
At the downwind end of the trap, a stainless wire net with a mesh of 75 μm was stretched vertically to a height of 30 cm. In Fig. 3, the solid curves are predictions obtained from the modified equation of the vertical distribution of sand transport rate by wind derived by Kawamura (1951). A large amount of sand grains falls a distance of 20 cm downwind from the end of the sand bed. The falling rates at locations 80 cm and 90 cm somewhat increase compared to the value at location 70 cm and deviate upwards from the predicted curve when the shear velocity becomes larger. This was caused by the fact that the flying sand grains hit the end-net and fell into the trap. Sand grains associated with this increase in amount are probably those that would fly beyond 1 m in the horizontal direction if not trapped. Therefore, we must recognize the fact that some amount of sand grains fly beyond 1 m in the horizontal direction. However, considering the fact that over 90% of the total amount of wind-blown sand is transported below the elevation of 15 cm in a range of the shear velocity from 30 cm/s to 100 cm/s, we can safely assess that the flying distance for an amount of over 90% of the total transported sand will be smaller than 1 m.

Using a horizontal distribution-type trap similar to the trap used by Hotta and Horikawa (1993), but enlarged to be 50 cm wide and 2 m long, Shiozawa et al. (1993) measured the flying distance of blown sand at a real beach. The result of the measurements is shown in Fig. 4. Figure 4 shows that the theoretical curve of flying distance of blown sand grains modified from Kawamura’s equation can predict the observed data well and that the flying distance is smaller than 1 m in the horizontal direction for a shear velocity of about 29 cm/s. In the field measurements, a trench was used that was 1.5 m deep and 5.0 m wide. Shiozawa et al (1993) also reported that sand was transported beyond the trench for strong winds but the amount transported was negligible small compared to the amount trapped in the trench. The values of the transported and trapped sand and the wind speed were not given in the original paper.

![Fig. 3 Examples of horizontal distribution of falling sand grains. (copied from Hotta and Horikawa, 1993)](image1)

![Fig. 4 Flying distance of blown sand grains observed in the field. (redrawn from Shiozawa et al., 1993)](image2)
Based on the investigations discussed above, the present authors concluded that the trench could be employed as a prevention work for wind-blown sand and proposed to use the trench practically in the field.

2.2 Remaining Problems and Study Subject

It is highly probable that over 90% of blown sand will be trapped in the trench, if the trench has a length of about 2 m in the wind direction (hereafter we refer to the length as the width of trench), for shear velocities lower than 100 cm/s on sand surfaces with a grain size of around 0.3 mm. However, the field experiments carried out by Horikawa et al. (1983) also showed that the wind rushed onto the downwind edge of the trench and a violent disturbance of the flow field was generated in the case of a trench wider than 7 m. Thus, it was found that a trench too wide would not be good for stabilizing trapped sand. To solve this problem, the present authors carried out a wind tunnel experiments together with numerical simulations to determine a suitable width of the trench from the flow conditions in an open cavity (of similar shape). The main objective of this work was to find a suitable aspect ratio of the open cavity, where the aspect ratio is defined by the ratio of width to height of the open cavity. In the following sections, the wind tunnel and numerical experiments will be described.

3 Wind Tunnel Experiment

The wind tunnel experiments consisted of two parts, namely one part that was a tracer experiment to visualize the flow pattern inside the trench and an other part that encompassed measurements of wind speed to determine the wind speed field.

3.1 Facilities

The wind tunnel used in the experiments was a blow-off type with a test section having dimensions of 1.1 m high, 1.0 m wide, and 20 m long. To provide an open cavity (trench), the tunnel floor was fixed by wooden boards as shown in Fig. 5. An arbitrary aspect ratio could be selected by changing the width of the cavity.

Wind speed was measured with an array of hot-film anemometers consisting of twelve anemometers. The output from the amplifier unit of the anemometers was recorded and analyzed on a personal computer. The sampling interval of data was 1 Hz. The hot-film anemometer was omni-directional. Therefore, it was not possible to detect the wind direction.

For the tracer experiment, four 8 mm video cameras, including two digital-type and two high grade conventional-type cameras, were employed. The num-
The number of cameras used depended on the width of the cavity and the spatial range photographed by a camera varied from 20 cm to 60 cm.

Styrofoam particles with diameters ranging from 0.1 mm to 0.3 mm were employed as tracers. The specific gravity of the particles was about 0.02.

### 3.2 Experimental Procedures

The tracer experiment was carried out first. While blowing the wind and operating the cameras, the tracer was injected at different elevations through a pipe with an inner diameter of 25 mm that was lowered from the ceiling into the tunnel at a location 1 m upwind from the upwind edge of the cavity. The elevations of injection varied from the bottom to near the ceiling. A run continued until we could roughly sketch the flow pattern using visual observations. For one aspect ratio, tracer experiment was done for three reference wind speeds around 5 m/s, 10 m/s, and 15 m/s. The employed aspect ratios were 2, 4, 5, 6, 8, 10, and infinity (step down).

After finishing the tracer experiment, the vertical distribution of the wind speed was measured at locations where we judged that it was needed based on the tracer experiment. The measuring period of wind speed was 2 min at a location and data series encompassing 120 values was taken. The average of the wind speed at the point was then calculated. The complete wind field was also measured for three reference wind speeds.

### 3.3 Results and Discussions

Before discussing the results, we should keep in mind the limitations of this experiment.

The wind speeds employed, 5, 10, and 15 m/s, are prototype-scale. However, the floor surface consisted of a wooden board and the roughness of the surface

![Fig. 5 Floor configuration for experiments.](image)

![Fig. 6 Vertical distribution of wind speed.](image)
was smaller than that at real beaches. The length scale becomes 1/5 or smaller than 1/5 if we assume that a trench will be employed in the field that has a depth of 1 m or more. The model experiment was carried out at a distorted scale, making it difficult to define a characteristic Reynolds number for the experiment. If we choose the depth of the trench, 0.2 m, as the characteristic dimension, Reynolds number becomes about $6.7 \times 10^4$, $1.3 \times 10^5$, and $2.0 \times 10^5$, for wind speeds of 5, 10, and 15 m/s, respectively, where the kinematic viscosity is taken as $1.5 \times 10^{-5}$ m$^2$/s.

The tracer employed was light but still had some weight; therefore, the tracer tended to fall down to the floor. However, the flow patterns drawn from scattered tracers were almost the same for the three reference wind speeds, although the figures are not shown here because of space limitations.

The aim was to use a constant wind speed during the experiment. However, the wind speed fluctuated on the average about ±3.0 % due to the mechanical characteristics of the tunnel. Figure 6 shows the vertical distribution of the averaged wind speed above the wooden board floor. The logarithmic law is satisfied under an elevation of about 30 cm and the wind speed becomes constant at elevations higher than 30 cm. The reference wind speeds, 5, 10, 15 m/s are the wind speeds measured at the reference point (-2.0 m, +0.5 m) in Fig. 5 in the constant wind speed region. The wind speed measured was normalized by these reference speeds. The vertical distribution of the normalized wind speed at each location was the same for three of the reference wind speeds within the experimental error. Based on the above observations, the following discussion of the results is presented with reference to the flow patterns and the normalized wind speed field averaged for three of the reference wind speeds.

Figure 7 shows the flow patterns and the wind speed profiles. Allows showing the flow pattern are loci of tracers and do not mean wind velocity vectors. Attention is draw to Fig. 7 (b) showing the tests with aspect ratios of 6, 8, and 10 and the back step flow. The horizontal distance is reduced with a scale of 1/2 in these tests differentiating them from what is presented in Fig. 7 (a). In the back step flow the stagnation point appeared at a location of about 7.2H downwind the upwind edge of the cavity (from the origin). Many previous wind tunnel experiments or numerical simulations show that the stagnation point appears in a region about 7.0H to 7.5H. Therefore, it is considered that the present experiment provided reliable results in agreement with previous studies. The stagnation point shifts upwind to 6.8H for B/H = 10.0, to 5.8H for B/H = 8.0, and to 5.2H for B/H = 6 in the presence of a downstream wall so that an open cavity is formed. No stagnation point appears for B/H = 4.0, and for B/H = 5.0 it was difficult to establish the existence of a stagnation point in the visual observations during the experiment or on the video movie analysis. Considering these observation and looking closer at the flow patterns we can conclude that the main flow lowered downward due to the cavity touches
the bottom of the cavity and rushes onto the downwind wall of the cavity for aspect ratios larger than 6.0. The return flow from the downwind wall probably generates a violent disturbance in the cavity, and this result agrees with our field experience. A circulation cell exists for aspect ratios smaller than 5.0.

Fig. 7 Flow patterns and wind speed profiles. (SP : stagnation point)
At a first glance on the wind speed profiles it is difficult to directly find any particular features of the flow. However, careful investigations of the profiles together with the overall flow pattern allowed us to quantitatively establish the

Fig. 7 Flow patterns and wind speed profiles. (SP: stagnation point)
flow characteristics. Figure 8 shows curves of equal wind speed in the cavities. From Fig. 8 we can perceive that the wind speed inside the cavity becomes stronger when the aspect ratio increases. To evaluate the wind speed conditions, we focus on the curves that have a value of 0.5 for equal wind speed. It is seen that the lowering of the curve valued at 0.5 into the cavity becomes larger when the aspect ratio becomes larger than 5.0. Based on the above discussion of the results, the present authors conclude that the aspect ratio should be smaller than 5.0 to keep low-disturbance conditions inside the cavity.

Fig. 8 Equal wind speed curves in the cavities.
4 Numerical Experiment

4.1 Basic Equations

In order to theoretically examine the results obtained in the experiments, we performed numerical simulation of the air flow in the trench trap. Since the fluid under consideration can be treated as an incompressible viscous fluid and the flow is a fully developed turbulent flow, the time-dependent Reynolds-averaged Navier-Stokes equation were selected together with the $k-\varepsilon$ modeling equations as the basic equations of the simulation. The equations can be written in
the following form.

\[
\frac{\partial U_i}{\partial x_i} = 0
\]  

(1)

\[
\frac{\partial U_i}{\partial t} + U_j \frac{\partial U_i}{\partial x_j} = -\frac{1}{\rho} \frac{\partial P}{\partial x_i} + \frac{\partial}{\partial x_j} \left\{ \left( \nu + \nu_t \right) \left( \frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} \right) \right\}
\]  

(2)

\[
\frac{\partial k}{\partial t} + U_j \frac{\partial k}{\partial x_j} = \frac{\partial}{\partial x_j} \left\{ \left( \nu + \frac{\nu_t}{\sigma_k} \right) \frac{\partial k}{\partial x_j} \right\} + G - \varepsilon
\]  

(3)

\[
\frac{\partial \varepsilon}{\partial t} + U_j \frac{\partial \varepsilon}{\partial x_j} = \frac{\partial}{\partial x_j} \left\{ \left( \nu + \frac{\nu_t}{\sigma_\varepsilon} \right) \frac{\partial \varepsilon}{\partial x_j} \right\} + \frac{\varepsilon}{k} \left( C_{\varepsilon 1} G - C_{\varepsilon 2} \varepsilon \right)
\]  

(4)

\[
\nu_t = C_{\mu} \frac{k^2}{\varepsilon}
\]  

(5)

\[
G = \nu_t \left( \frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} \right) \frac{\partial U_i}{\partial x_j}
\]  

(6)

Here, \(U_i\) and \(U_j\) are the local time-averaged velocity components and \(P\) is the pressure, \(k\) and \(\varepsilon\) are the turbulent kinetic energy and its dissipation rate, respectively. \(\nu\) is the kinematic viscosity, \(\nu_t\) is the turbulent eddy viscosity, and \(G\) in the \(k\) and \(\varepsilon\) equations is the turbulence production term. The values of the constants \(C_{\mu}, C_{\varepsilon 1}, C_{\varepsilon 2}, \sigma_k, \sigma_\varepsilon\) used in the turbulence model are 0.09, 1.44, 1.92, 1.0, 1.3, respectively.

This formulation, however, is known to give poor predictions of turbulent characteristics when excessive generation of turbulent energy leads to a too high turbulent viscosity. To overcome this, Kato and Launder have presented a modified \(k - \varepsilon\) model. Let the dimensionless strain parameter \(S\) and vorticity parameter \(\Omega\) be defined according to :

\[
S = \sqrt{\frac{1}{2} \left( \frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} \right)^2}
\]  

(7)

\[
\Omega = \sqrt{\frac{1}{2} \left( \frac{\partial U_i}{\partial x_j} - \frac{\partial U_j}{\partial x_i} \right)^2}
\]  

(8)

From eq.(6), it is easily verified that the energy production term may be rewritten :

\[
G = \nu_t S^2
\]  

(9)

Near a stagnation point, the very high value of \(S\) leads to the excessive levels of \(G\). However, the vorticity parameter \(\Omega\) near a stagnation point becomes nearly equal to zero since the deformation is nearly irrotational. Thus the replacement,

\[
G = \nu_t S \Omega
\]  

(10)
gives a substantial reduction of $G$ in the region around the stagnation point. This method has been found to give satisfactory predictions in the computation of turbulent flows. The modification is no remedy for the weakness in the Boussinesq stress-strain hypothesis, but it does greatly improve the behavior in some flows.

The discretization strategy used in this study is the three-step Taylor/Galerkin method. The discretized formulations of the basic equations are omitted here due to the limited space. One can find more details about this strategy in the references Hatanaka et al. (1998) and Jiang, et al. (1993).

### 4.2 Results and Discussions

In the numerical simulations, the Reynolds number was fixed to $10^5$ and simulations for two aspect ratios, $B/H = 4$ and 6, were carried out. Figure 9 shows a definition sketch of the computational domain. The computational domain is discretized using bi-linear isotropic quadratic finite elements. The finite element mesh used in both cases had 8,365 nodes and 8,160 elements.

Figure 10 shows the streamlines of the flow field for the case $B/H = 4$ and for the case $B/H = 6$. In the case $B/H = 4$, one can see that the primary vortex in the trench is large and that the main stream does not flow into the trench. However, in the case $B/H = 6$, the primary vortex moves upstream in the trench and the main stream flows into the trench trap. Moreover, a stagnation point can be observed in the case $B/H = 6$ whereas no stagnation point can be observed in the case $B/H = 4$. These are the same results as were obtained in the experiments and therefore it can be said that the observations made in experiments were verified by the numerical model.

### 5 Concluding Remarks

The dimensions that the newly proposed sand trapping trench needs to function well as a controlling device for wind-blown sand are a width of 2 m (at
least in proto-type) and an aspect ratio of width to depth \((B/H)\) smaller than 5.0. However, for engineering use, when solving problems on real beaches, we must also consider the storage capacity for trapping sand and the removal of the trapped sand. The optimal width and depth of the trench depend on the maximum allowable volume of trapped sand and the frequency of removal of the trapped sand during the windy season. The sand volume that will be trapped can be calculated by using the Kawamura or Bagnold formulas with a reasonable accuracy for engineering purposes, if we can estimate the wind conditions at the site. Then, a suitable width and depth of trench can be chosen. In addition, we must consider the removal method of the trapped sand. It is reasonable to assume that trapped and stored sand will be removed by earthmoving construction machines such as power shovels and bulldozers. The dimensions and effectiveness of the earthmoving machines will be one of the factors that determines the width and depth of the trench. To preserve a safe environment for various activities on the beach, a cover made of screen or mesh plate should be placed on top of the trench. The opening ratio, defined as the ratio of the open space to the total project area of the plate, is also one of factors that determines the width of the trench; (this problem has not been studied yet). There are many problems to be solved in the practical use of trenches on beaches. The authors believe, however, that well-educated engineers can deal with them.

Coastal Sediment Transport: the COAST3D Project

R L Soulsby

Abstract
The MAST-III RTD project COAST3D started in October 1997. A consortium of 11 partners including hydraulic laboratories, universities and national regulatory authorities from five EU states (UK, Netherlands, France, Spain and Belgium) will undertake this three-and-a-half year project. The project will make field measurements of waves, currents, sediment transport and morphodynamics at two contrasting sites. The results will be used to valid existing morphodynamic computational models, and lead to coastal zone management tools.

Introduction
Coastal management and engineering decisions rely increasingly heavily on predictions made by computational numerical models of hydrodynamic and sediment-dynamic processes and the resulting morphodynamic changes to the coastline and sea bed. Yet such models are rarely tested adequately against real data from coastal field measurements. This is largely because the many field experiments made to date have been designed to elucidate the physical processes rather than to evaluate numerical models. In addition, the most detailed data-sets are from North American sites, which are fundamentally different to European conditions. Evaluation of numerical models makes special requirements of the data, such as detailed measurement at the boundaries, and a dense spatial coverage of measurements within the modelled area. At the same time, improvements to numerical models are mainly made through improved understanding of the processes, so it is important to measure and interpret these also. The knowledge and models also need to be taken beyond the domain of the scientist, and put into a framework of guidelines and methodologies to be of direct value for coastal zone management.

1 Manager, Marine Sediments Group
HR Wallingford, Howbery Park, Wallingford, OX10 8BA, UK

2548
Sandy coasts can be classified as 2-dimensional (uniform in the coastwise direction), 2.5-dimensional (as 2D, but with natural non-uniformities such as rip-channels), and 3-dimensional (with irregular features such as headlands and tidal inlets). One of the best ways of gaining insights into the complex 2- or 3-dimensional development and behaviour of sandy coastal systems is by simulating their structure, organisation and functioning by using numerical models. Nowadays, morphodynamic models especially have become important tools for coastal zone management to predict and evaluate the evolution in coastal morphology in response to environmental change and engineering works.

Numerical morphodynamic models are generally of two types: Coastal Profile (CP) Models, suitable for 2D coasts, and Coastal Area (CA) Models, suitable for 3D coasts, with certain variants of both being applicable to 2.5D coasts. The understanding and modelling of notionally 2D coasts is reasonably well advanced, but the question is being raised whether any natural coast is sufficiently uniform to enable 2D modelling techniques to make successful predictions. Hence the focus is now turning to understanding the three-dimensional aspects.

Objectives
The purpose of the COAST3D project is

- to improve understanding of the physics of coastal sand transport and morphodynamics

- to remedy the present lack of validation data of sand transport and morphology suitable for testing numerical models of coastal processes

- to test a representative sample of numerical models for predicting coastal sand transport and morphodynamics against this data

- to develop validated modelling tools, and methodologies for their use, in a form suitable for coastal zone management

This will be achieved by making field measurements purpose-designed for numerical model evaluation, with adequate boundary conditions and a dense horizontal array of measurement points, in conditions typical of the European coastline. Previous coastal experiments in Europe and elsewhere have placed their main emphasis on hydrodynamics; an innovative feature of the present project is that the emphasis throughout is on sand transport and morphodynamics.

Another distinctive feature is that the focus is on non-uniform (3D) coasts, rather than on the relatively well understood (but possibly unrealistic) uniform 2D case. Experiments will be performed at two contrasting sites: a quasi-uniform (2.5D) stretch of the Dutch coastline, and a fully 3D site on the UK coast. This phased
Figure 1. Schematic layout of instruments for Egmond experiment
approach will allow both the process information and the performance of the numerical models to be more easily interpreted.

Innovative techniques will be used in the experiments. Numerical modellers will work interactively with the experimenters, at the planning, experiment, and evaluation phases. Participants from national regulatory authorities will ensure that the project is focused on practical tools for coastal zone management.

Sites have been chosen in:

- the Netherlands for the 2.5D case, which is typical of the quasi-uniform sandy beaches dominated by breaker bars found on much of the coastlines of northeast France, Belgium, the Netherlands, western Germany, western Denmark, and eastern England.

- the UK for the 3D case, which is typical of the irregular coastlines featuring tidal inlets, river and estuary mouths, headlands, and coastal structures, often without breaker bars, found in western and southern Britain, Ireland, northern and western France, northern Spain, Portugal, and Norway.

A large proportion of the coastline of Europe falls into these two categories. The remainder comprise the micro-tidal coasts of the Mediterranean and the Baltic. These latter seas fall within the remit of the ongoing MAST-3 FANS project, based on an experiment in the Mediterranean to measure water, sediment and nutrient fluxes in three domains: the nearshore, the shelf and the continental slope. Another complementary MAST-3 project, INDIA, will study the morphodynamic behaviour of tidal inlet entrances and adjacent coastlines at a site in Portugal. Links will be forged between COAST3D, INDIA and FANS, through the presence of common partners, so that a wide variety of different European environments will be covered by these three projects.

Experiments

The first experiment will take place at Egmond on a quasi-uniform stretch of the Dutch coast (Fig.1), starting with a pilot experiment in spring 1998 followed by the main experiment in autumn 1998. Although the coastline and bathymetric contours appear on charts to be nearly straight, it is known from earlier work that the natural three-dimensionality produced by rip-channels intersecting a bar system has a major effect on the hydrodynamics and sediment dynamics of the coast. The site is regarded as "2.5-dimensional" as a result of these sedimentary non-uniformities, and the departures from 2-dimensionality are an important aspect of this experiment.

The second experiment, scheduled for 1999, will take place at Teignmouth on the south coast of England (Fig.2), where a rocky headland and a river mouth provide a
Figure 2. Schematic layout of instruments for Teignmouth experiment
strong three-dimensionality. A complicated re-curving spit is very active morphodynamically. This site, which additionally has a wide range of grain-sizes, will stretch the capabilities of present day coastal morphodynamic numerical models to their limits, and will provide a very exacting test of these and future models.

At each site a small number of permanent instruments will monitor conditions over at least 12 months. The main experimental work, however, will take place over an approximately 6 week period in the autumn (when beach conditions change most rapidly) at first the Dutch, and then the UK, site. The vast majority of the instruments are already owned by the partners, and will be deployed at both sites in succession, thereby making optimum use of the instruments, the logistics, the cooperative working practices, and the data management scheme. Instruments will be deployed in an array designed to meet the needs of numerical model evaluation, and to provide the more detailed process information. A pilot experiment of about two weeks duration will take place in the spring preceding each main experiment, to maximise the chances of success in the autumn.

The use of the innovative devices WESP and CRIS, which have been recently designed and constructed specifically for coastal experiments, is an important aspect of the implementation of the research programme. The WESP is a 10m high motorised tripod on wheels with a platform at the top supporting the engine and a cabin with facilities. Surveys can be conducted from the beach out to water depths of 6m in wave heights up to 2m (moderate storms). The WESP will tow a sledge (CRIS) carrying an intensive array of instruments wired in to the WESP cabin. This arrangement will ensure that the flow disturbance around the WESP does not influence the instruments.

The WESP is valuable for the collection of sand transport data, because it allows on-line measurements of short duration (30 min), and simultaneous collection of calibration samples by pumping systems. The availability of the WESP will allow a greater flexibility during the measurements by increasing the number of operational hours, by reducing ship time and the reaction time after an event and by deploying instruments at sites which are otherwise difficult to reach. The WESP will be used for measuring the 3-dimensional bathymetry of the nearshore zone, for placing and relocating instruments and for taking samples. The WESP can be dismantled to be able to carry it to various sites in Europe.

A crucial aspect of the experiments is the large number of instruments which will be deployed. In many ways this is what distinguishes COAST3D from previous field campaigns, and makes the resulting data-set of so much value for evaluating numerical models. Most of the instruments are already owned and used by the participants, and in many cases have been specially developed by them.
Modelling
A representative selection of numerical models of coastal hydrodynamics, sediment dynamics, and morphodynamics developed by the partners will be used at various stages throughout the project, most particularly for:

- preliminary runs to aid the design of the experiment. The models will be set up for the study area and run with representative inputs. Areas with strong spatial variations of the modelled parameters (waves, currents, sediment transport), and those areas where the models markedly disagree among themselves, will be identified for intensive instrumentation

- on-site modelling at a "modellers' week" midway through each experiment. Deficiencies in the experimental set-up can be remedied for the remainder of the experiment, and initial indications of the performance of the models obtained. The modellers' weeks will be open to modellers from outside the project to participate

- evaluation of the models after the full data validation, calibration and reduction. This will be the largest modelling effort, and will contribute towards the validation and accreditation of the models used.

The models used range from research models exploring the detailed physical processes (mainly at the universities) to fully operational models used routinely for consultancy applications (mainly at the hydraulic institutes).

Comparisons of the models with the data will be made in two distinct ways, by two distinct groups.

A diagnostic modelling group, made up of the university partners, will compare the measurements of individual physical processes with their representation by the models. It will identify: which models include the important processes, which of these give the best agreement with the data, how they can be improved, and how the improved algorithms can be included in the other models.

A practical modelling group, made up of the hydraulic institutes and regulatory authority partners, will test the overall capability of the models to reproduce the main trends in the data. They will address issues such as ease of setting up and driving the models, computational speed, stability and robustness, ease of plotting and interpreting results, as well as establishing an objective measure of "skill" in the models' performance against data. Best features will be further improved and included in all the models. Further, the group will decide on recommended procedures for the use of numerical models in coastal applications, and embody these in guidelines for use in coastal zone management.
Process Interpretation
The use of the data to further the understanding of the processes taking place in the coastal zone is every bit as important as the use for model validation. Accordingly, the experiments have been designed to accommodate both uses of the data.

For the 2.5D experiment one of the major questions which will be addressed is the growth, development and migration of nearshore bars in the surfzone and its impact on the behaviour of the coast, as well as the role of rip channels on bar behaviour. In many surfzones nearshore bars are the main morphological phenomena and their behaviour is still only partly understood and forms a good test case for the models. To measure the different processes and parameters a main cross-shore array of instruments will be installed covering the entire shoreface from a depth of about 20 m to the high tide levels on the beach. A number of instruments will be mounted to one side of the main line, to quantify the effects of rip channels on longshore nonuniformity (Figure 1).

For the 3D experiment the main emphasis is on the variations in the measured parameters in the two horizontal dimensions, particularly identifying horizontal circulation patterns of currents and sediments. A wide range of depths is necessary to identify the differing processes which re-distribute sediment in offshore areas and in the surf-zone. Some emphasis on the vertical distributions is also necessary. To measure the different processes and parameters a main array of instruments will be installed along intersecting cross-shore and longshore transects as shown schematically in Figure 2. Instruments will be located at the offshore and lateral boundaries of the studied region, to provide boundary conditions for the numerical models.

In both cases, it must be emphasised that the layout of instruments in the figures are schematic, and the exact layout will be determined by consultation between all the partners at an early stage of the project, after initial runs of the numerical models have been made.

Data Management and Availability
Good data management is a vital part of the project. A Data Management Group will oversee and specify:

- the synchronisation, record lengths and file formats of the logged data,
- the validation, calibration and basic analysis of the data,
- the design of a suitable data-base system,
- the storing of the data in the data-base,
- the public dissemination of the data through the Internet and CD-ROMs.

This will ensure uniformity of procedures between partners.
The data will be publicly available six months after the end of the project in two distinct forms:

(a) the complete data-set for study of physical processes,
(b) a condensed data-set of the basic variables for running and evaluating numerical models.

Coastal Zone Management

One of the most important products of the project is a set of tools and guidelines for practical coastal zone management (CZM). The production of these CZM tools will be guided particularly by the Rijkswaterstaat and Environment Agency partners, having regard to the following considerations.

Tools available to the coastal zone manager for solving problems are:

- data analysis
- measurement and monitoring
- (numerical) modelling.

Guidelines for using these tools should answer the following basic questions:

- WHEN to use,
- WHAT tools, and
- HOW to use these.

Answering the WHEN question first of all, requires an analysis of the CZM problem(s), leading to the definition of measurable:

- CZM objective(s), [eg maintenance of the coastline over a well defined length and for a well defined period of time],
- CZM parameter(s), [eg sand content of a well defined control volume],

and on this basis the definition of the most important

- temporal and spatial scale(s), and
- physical parameters.

Then, the answer to the question WHAT tools to use is depending on

- the availability of data,
- the possibilities for monitoring and measurements,
- the availability and (more important) the validity of numerical models, considering the spatial and temporal scales of interest.
Finally, the question HOW to use the tools may lead to guidelines for each individual tool, eg

- statistical analysis techniques (minimum data demands etc),
- monitoring and measurement schemes (parameters, instrumentation, frequency and spatial distribution, accuracy etc),
- methodology and procedures for applying individual numerical models.

For practical use however, it is just as important to develop guidelines on the combined use of the tools, answering:

- how to interpret measurement data,
- how to interpret model results, and
- how to draw conclusions in relation to the CZM problems.

**Conclusions**

The COAST3D project will

- make measurements at two contrasting sites, one typical of 2.5D and one of 3D conditions
• store the data in a properly managed data-base, and make them publicly available in two forms:

(a) the complete data-set for study of physical processes, and

(b) a condensed data-set of the basic variables needed for running numerical models, to provide definitive test-cases against which present and future models can be evaluated

• interpret the data to provide an increased understanding of the physical processes operating in the coastal zone

• make an evaluation of a representative sample of present-day European morphodynamic numerical models, in terms of both their ability to represent individual processes (diagnostic), and their overall usability and performance (practical)

• present the models and methods in a form suitable for coastal zone management, for example by providing a series of guidelines.

Acknowledgements

The COAST3D project is funded partly by the European Commission's research programme MAST under Contract Number MAS3-CT97-0086, and partly through national funding from the UK Ministry of Agriculture, Fisheries and Food under research project FD0803, the UK Environment Agency’s Research and Development programme, the UK Natural Environment Research Council, and the Netherlands Rijkswaterstaat. This paper is written on behalf of all the partners in the project. Much of the material in the paper was published previously by the European Commission, DG XII, Third European Marine Science and Technology Conference, Project Synopses Vol.II, 1998.
MODELLING OF A THREE-LAYER SEDIMENT TRANSPORT SYSTEM
IN OSCILLATORY FLOW

Leszek M. Kaczmarek & Rafał Ostrowski

Abstract

An extension of the bedload model of Kaczmarek & Ostrowski (1996), taking account of suspended sediment, is proposed for the calculation of sediment transport features, such as the transport rate and thickness. The paper is focused on the transition region (named as a contact load layer) between the outer region (suspension layer) and the bedload layer within the proposed three-layer sediment transport model.

Theoretical background

Formulation of the problem

A typical vertical distribution of velocity at a rough bed is supposed to be characterised by a sub-bottom flow and a main or outer flow, as shown in Fig. 1. The figure provides an explanatory drawing with velocities and concentrations. The collision-dominated granular-fluid region stretches below the nominal static bed while the wall-bounded turbulent fluid region extends above it. The outer region of pure suspension is characterised by very small concentration, where the process of sediment distribution may be considered as a convective and (or) diffusive process. In contrast, the granular-fluid region below the nominal bed is characterised by very high concentrations, where the intergranular resistance is predominant.

Since both water and grains are assumed to move in both regions, there must be a certain transition zone between these two regions, in which the velocity and stress profiles merge and preserve continuity of shape. The transition zone, called a contact load layer, is a central topic of the present study. The velocity profile in the contact load layer is assumed to be continuous. Its intersection with nominal seabed is the

---

apparent slip velocity $u_b$ which can be identified as a characteristic velocity of sediment moving in the form of bedload. The downward extension of the velocity distribution in the outer zone of the main flow yields a fictitious slip velocity $u_0$ of the fluid at the nominal static bed level. Clearly, the fluid velocity $u_0$ is greater than the sediment velocity $u_b$.

![Fig. 1. Definition sketch](image)

The above three-layer system of the momentum exchange has recently been observed in the measurements of concentrations carried out by Ribberink & Al-Salem (1995).

**Physical bases**

It is traditionally assumed, see for instance Wilson (1987), that the contact load layer consists of several layers of grains in motion, and in these layers the applied shear stress $\tau$ is resisted by the sum of a granular component $\tau_s$ and a fluid component $\tau_f$. As demonstrated by Bagnold (1956), $\tau_s$ is associated with the intergranular stresses due to particle collisions. The sheared layer extends down to a certain level (say nominal bed) at which the intergranular resistance $\tau_s$ equals the applied shear stress $\tau$. Further down towards the non-moving bed the intergranular resistance is predominant and it can be assumed that the particle interactions in the bedload layer produce two distinct types of behaviour. The particle collisions give rise to viscous-type stresses, while further down towards the non-moving bed, Coulomb friction between particles (which remain in contact with each other) give rise to plastic-type stresses.

Because the intergranular resistance is predominant in the bedload layer, it is postulated that the weight of moving sediment is transferred to the grain skeleton in the non-moving bed.

In contrast, the sediment in the contact load layer is transported partially as a bedload and partially as a suspended load. This means that the sediment is carried both by the dispersive stresses and by the fluid. When the suspended sediment is carried by
the fluid, its weight causes an increase in the pressure above the hydrostatic. Hence, it can not be assumed that the stress transferred to the bedload layer from the contact load layer corresponds exactly to the weight of the load. This was illustrated by Deigaard (1993) who considered a grain jumping in fluid.

Grain-grain-water interactions in the contact load layer are assumed to produce three distinct types of behaviour. The random motion of the sediment grains, which is the basis for the diffusion process, is caused by a combination of turbulence and the collisions between the grains in the contact load layer. These two effects give rise to skin friction $\tau'$. Aside from the skin friction, a particle exposed to a turbulent flow will additionally feel a drag due to a pressure difference on the up- and downstream sides of the grain because of flow separation. Thus, the residual part of the total shear stress $\tau - \tau'$ is carried as a drag on the moving bed particles. This drag gives rise to a convective sediment exchange rather than to turbulent diffusion.

The above shows that the two layers, e.g. bedload and contact load, differ considerably in momentum exchange. Hence, the interface between them, i.e. the level at which the intergranular resistance equals the applied total shear stress, can be expected as a very distinct one. This is supported by the recent measurements of concentration carried out by Ribberink & Al-Salem (1995). The detailed concentration measurements showed a three-layer system with a lower and upper sheet flow layer and a suspension layer. The lower and upper sheet flow layer can be identified as bedload and contact load layers, respectively. Sediment was picked up from the lower sheet flow layer at the two phases of maximum velocity during the wave cycle, resulting in two concentration dips in the lower sheet flow layer and two concentration peaks in the upper sheet flow layer.

Solution procedure

It is next proposed that the downward extension of the velocity distribution from the suspension layer to the bedload layer is described by the logarithmic distribution and is controlled by effective bed roughness $k_e$. The logarithmic velocity profile extrapolated from the suspension region is positioned at $z_0 = k_e/30$, the height where the velocity profile approaches zero. Further, the flow at the top of the contact load layer is assumed to be unaffected by the transition phenomena.

These assumptions allow to solve the problem of nearbed sediment motion within two steps, schematically shown in Fig. 2. Within the first step, the problem is reduced to bedload transport (Fig. 2a) the solution of which was proposed in a series of papers by Kaczmarek et al. (1994), Kaczmarek et al. (1995) and Kaczmarek & Ostrowski (1996), who used a theoretical approach based on grain-grain interaction ideas in analogy to the flow of dry, cohesionless materials. The iterative procedure was employed to match the velocity and shear stress profiles in both regions (Fig. 2a) using a theoretical bed level for the outer wave-induced flow of $\delta_0$, which was taken as an arbitrary fraction of the thickness of the moving, collision-dominated bed layer $\delta_n$.

The motion of sediment inside the contact load layer is proposed to be solved within the second step (Fig. 2b). In this case the problem is focused on finding of skin effective roughness $k_e'$ with determination of the thickness $\delta_c$ of the contact load layer. As a boundary condition it is proposed to use the instantaneous (during wave period) sediment velocity $u_b(t)$ and concentration $c_b$ (assumed to be constant and equal to 0.32) at the top of bedload layer, found from the bedload model with $\delta_{bd}/\delta_n = 0.50$. 

Two step solution

(I) Bedload model

(a) iteration procedure for finding matching point $A$ with determination of $\delta_r$ and $k_c$

(b) finding skin effective roughness $k_c'$ with determination of $\delta_r$ using $u_b$ as boundary condition, found from step (I)

Fig. 2. Solution procedure

Basic equations and solution

Bedload layer

The bedload sediment transport model is based on a collision-dominant drag concept and uses a single parameter, $\delta_{ss}$, to define the theoretical level of the top of the moving bedload layer in relation to the effective roughness height, $k_e$, of the above-bed wave-induced flow.

Previous comparison of model results with experimental data for sediment transport rates and thicknesses, presented by Kaczmarek et al. (1995) and Kaczmarek & Ostrowski (1996), had suggested a value of $\delta_{ss}/\delta_r=0.5$. The use of the single constant parameter $\delta_{ss}/\delta_r=0.5$ yields the effective roughness height decreasing with the increase of the grain roughness Shields parameter $\theta_{2.5}$, the definition of which is given by Nielsen (1992). This decreasing trend is related to the constant value of $\delta_{ss}/\delta_r$ ratio kept for the entire range of $\theta_{2.5}$, see Fig. 3.

It is possible, however, to determine the variation of $\delta_{ss}/\delta_r$ with $\theta_{2.5}$ (see Fig. 4) so that the model reproduces the variation in apparent roughness $k_a$ observed by Nielsen (1992) for (artificially) flat beds, see Fig. 3.

Next, using the variable $\delta_{ss}/\delta_r$ values, calculations were made to find bedload properties such as bedload thickness and transport rate. These calculations have been
carried out for a wide range of wave heights and for two sets of depth and period values, i.e. $h=5 \text{ m}$, $T=3.6 \text{ s}$ and $h=10 \text{ m}$, $T=8.39 \text{ s}$, with grain diameter $d=0.2 \text{ mm}$ for both sets of parameters and additionally $d=0.7 \text{ mm}$ for the long-period data set. The results of computations shown in Fig. 5 reveal that the present approach with the fitting parameter $k_e$ given by Nielsen (1992) provides a good approximation of bedload thickness $L_{B,\text{max}}$ for (artificially) flat beds at low flow intensities ($\theta_{2,5} < 0.4$). In the range of relative effective roughness values with $\theta_{2,5} > 0.4$ the theoretical results overestimate the experimental data. It seems that, for this range of $\theta_{2,5}$, the present approach with the fitting parameter $k_e$ resulting from constant ratio $\delta_{sl}/\delta_n=0.5$, provides a better estimation of bedload thickness. The same conclusions can be drawn from the calculations of bedload rate carried out for both fixed and variable values of $\delta_{sl}/\delta_n$.

Fig. 3. Comparison of an apparent roughness found from friction and dissipation lab. data ($k_a$) with computed effective roughness ($k_e$) for $\delta_{sl}/\delta_n=0.5$ (solid line) and for variable $\delta_{sl}/\delta_n$ (dashed line)

Fig. 4. Variation of sensitivity parameter $\delta_{sl}/\delta_n$ with $\theta_{2,5}$
Contact load layer

Following Fernández Luque’s, after Fredsøe & Deigaard (1992), and Engelund & Fredsøe’s (1976) ideas, the momentum transfer in the contact load layer can be described by the equation:

\[ \tau = \tau_f + \tau_s + nF_D \]  

(1)

where \( F_D \) is the average drag on a single moving particle, while \( n \) is the number of moving particles per unit area.

It is assumed that the moving particles in the contact load layer reduce the fluid shear stress \( \tau_f \) by exerting an average reaction force on the surrounding fluid. This reduction, however, is not so drastic as it is inside the bedload layer, where the intergranular resistance is predominant. Further, it is proposed that the velocity gradient inside the contact load layer is affected by the presence of sediment.

A new formulation for skin friction, which is considered as a combination of turbulence and the collisions between the grains, is proposed. A new model of sheet flow is developed, incorporating the diffusion concept presented by Deigaard (1993).

By assuming that the settling of sediment balances the vertical exchange, and that the momentum exchange balances the shear stress, Deigaard (1993) proposed two coupled differential equations to determine the mean concentration profile and the velocity profile:
in which \( w \) denotes settling velocity of grains, \( s \) is a relative sediment density, \( c_m \) and \( c_d \) are the added mass and drag coefficients, respectively, and \( l \) is a mixing length defined as \( l = \kappa z \).

In general, two coefficients \( \alpha \) and \( \beta \) have to be determined, e.g. by calibration. For simplicity, equal values of \( \alpha \) and \( \beta \) have been assumed in further considerations. The boundary conditions for these equations are that the sediment velocity \( u \) and concentration \( c \) are given at the top of bedload layer positioned in the model at \( k_0/30 \). In the calculations the sediment concentration at \( z = k_0/30 \) was assumed as 0.32 (in agreement with the bedload model). It was further assumed that \( (s+c_m)=3.0 \) and \( c_d=1.0 \).

It is still unclear how to evaluate the drag due to moving sand particles. It is possible, however, to overcome these difficulties making an additional assumption that the sediment velocity distribution in the contact load layer is controlled by the effective skin roughness \( k_e' \) and that the sediment velocity profile attains a logarithmic shape at a certain distance from the nominal bed. Making use of the above, sediment motion in the contact load layer is determined by Eqs. (2) and (3) and by the following relationship:

\[
\tau' = \tau - nF_D = \rho u_f'^2
\]

in which \( u_f' \) is the skin friction velocity, proposed to be found using Fredsøe's (1984) integral momentum model with \( k_e' \) specified as a fixed constant value. Following Nielsen (1992) a value of 2.5\( d \) was adopted for the effective skin roughness \( k_e' \) of the moveable flat bed.

Knowing the instantaneous (during the wave period) skin shear stress \( \rho u_f'^2(t) \) it is possible to calculate sediment concentration \( c(z,t) \) and velocity \( u(z,t) \) in the contact load layer using Eqs. (2) and (3) with the boundary conditions \( u_b(t) \) and \( c_b \) given at \( z = k_0/30 \) from the bedload solution with \( \delta_b/\delta_i = 0.50 \). The proposed solution depends on the coefficient \( \alpha (=\beta) \). Making use of the fact that the velocity attains a logarithmic shape at a certain distance from the bed and that the roughness corresponding to this logarithmic profile depends on \( \alpha \), an iterative procedure is postulated to find \( \alpha (=\beta) \). The sought value of \( \alpha (=\beta) \) must provide the match of velocity profile yielded by Eqs. (2) and (3) with the logarithmic profile described by the skin friction parameters \( k_e' \) and \( u_f' \). The match is found at the moment corresponding to the maximum skin shear stress.

The model solution is restricted by a number of simplifying assumptions. Therefore, the determination of the layer thickness \( \delta_i \) identified as the solution validity limit plays a very important role. The selection criterion for \( \delta_i \) can be based on the degree of fit to experimental data comprising sediment concentrations and transport rate within the contact load layer. In the next section, two values for the upper limit of the contact load layer are tested against laboratory data, namely \( \delta_i/4 \) and \( \delta_i/2 \), where \( \delta_i \) is the thickness of the bed boundary layer \( \delta(t) \) calculated from Fredsøe's (1984)
model at the moment corresponding to maximum free stream velocity. The quantity $\delta_l/2$ can be identified as the conventional bottom boundary layer thickness while $\delta_l/4$ denotes upper limit of the region where the logarithmic velocity profile is observed.

Finally, it is worthwhile noting that the turbulence damping by the suspended particles is represented in the model by the following relationships:

$$e_s = \beta_1 \cdot \varepsilon = \beta_1 \cdot \kappa \cdot u_f \cdot z$$  \hspace{1cm} (5)

$$e_s = \kappa \cdot z \cdot (\beta \cdot u_f) = \kappa \cdot z \cdot u_f'$$ \hspace{1cm} (6)

in which $e_s$ is the mixing coefficient for solid material, $\kappa$ is von Karman’s constant ($=0.4$) and $\beta_1$ is a factor which, according to Deigaard, after Fredsøe & Deigaard (1992), is always smaller than the turbulent momentum exchange coefficient $\varepsilon$, with difference proportional to $\omega/\omega_f$.

Comparison with experimental data

Reference concentration and sheet flow layer thickness

The model has been run for two sets of water depth and wave period ($h=10$ m, $T=8.39$ s and $h=5$ m, $T=3.6$ s) and for the grain diameter $d=0.2$ mm. In addition, the first set of depth and period values has been run for the grain diameter $d=0.7$ mm. The wave height has been changed in each run so that a wide range of sediment transport intensities has been analysed. The model results for concentration at $z=1.5d$ have been compared with the experimental data of Guy et al., as interpreted by Zyserman & Fredsøe (1994). The comparison, shown in Fig. 6, yields quite good agreement.

Fig. 6. Reference concentration $c_0$: model results vs. experimental data of Guy et al. as interpreted by Zyserman & Fredsøe (1994)
The same sets of computational parameters have been used in the modelling of the sheet flow layer thickness $\delta$. The upper limit of this layer has been interpreted as the level at which the model result for velocity at the moment corresponding to the maximum skin shear stress attains the logarithmic velocity distribution with the accuracy of 99%. The distance between the above defined level and $z=k_e/30$, summed up with the bedload layer thickness, yields the sheet flow layer thickness and is shown in Fig. 7 as a function of dimensionless maximum skin shear stress, i.e. $\theta'=u_f^2/[g(s-1)d]$. It can be seen that the sheet flow layer thickness, even in very severe storm conditions, does not exceed 20 grain diameters. Good agreement between theoretical findings for the sheet flow layer thickness from the present model and the experimental data of Sumer et al. (1996) has also been found, see Fig. 7.

![Graph showing sheet flow layer thickness](image)

**Fig. 7. Sheet flow layer thickness: model results vs. experimental data of Sumer et al. (1996)**

**Time-dependent and mean concentration**

The data used in the present comparisons were obtained by Ribberink & Al-Salem (1994, 1995) for regular symmetric and asymmetric waves. The experiments were carried out in the Large Oscillating Water Tunnel (LOFT) at Delft Hydraulics. All the data were obtained above plane sand beds, corresponding to very vigorous conditions in nature, with median grain diameter $d=d_w=0.2\,\text{mm}$. Suspended sediment concentrations were measured principally with an optical concentration meter (OPCON) while concentrations in the sheet flow layer were measured using a conductivity concentration meter (CCM), see Al-Salem (1993) for details.

In the comparisons discussed below the aim has been to compare the model predictions with emphasis on time-variation in sediment concentration $c(z,t)$ at different heights ($z$) above the bed. The data sets used for this purpose are the series "C" experiments: Conditions 1 and 2 for asymmetric waves, with $U_{rms}=0.6\,\text{m/s}$, $T=6.5\,\text{s}$ and $U_{rms}=0.6\,\text{m/s}$ and $T=9.1\,\text{s}$, respectively, and Condition 3 for sinusoidal wave, with $U_{rms}=1.2\,\text{m/s}$ and $T=7.2\,\text{s}$. 
In Fig. 8 the exemplary model predictions for Condition 2 are compared with time-varying sediment concentrations \( c(z,t) \) measured at two representative ordinates with respect to the original bed level \( z=0 \) (i.e. the undisturbed bed level prior to the start of the experiment, identified as \( z=k_e/30 \) in the model). The curve for \( z=-1 \) mm has been produced (for the time sectors in which the sediment movement occurs) using the bedload model while for \( z=+1 \) mm the concentration has been computed by the present contact load model. At both levels the prediction shows satisfactory agreement with the data. The concentration at \( z=0 \) is assumed as \( c_b=0.32=848 \) g/l (with grain density of 2650 kg/m\(^3\)).

At higher levels, however, the measured time series of \( c(z,t) \) develops a more complicated structure, and agreement in phase between the model and the data is lost. The reason for the failure of the model to predict the phase angle of the time-dependent concentration is the appearance, at around the time of flow reversal in the free stream between wave crest and trough, of an additional peak in sediment concentration, identified by Davies et al. (1997) as a convection peak. Near the bed (roughly up to \( z=\delta/4 \)) this peak is very small and the time series of concentration is dominated by the main diffusion peak associated with the maximum velocity, and hence maximum bed shear stress, during the wave cycle. With increasing height, the additional peak grows in relative importance, becoming larger than the diffusion peak and dominating the concentration time series.

Hence, the ordinate of \( \delta/4 \) (which corresponds to \( z=0.5 \) cm for Condition 2) determines the upper limit of the region where the phase agreement exists between the model and data concentrations. This value can be recommended as the upper boundary of the contact load layer for the purpose of net sediment transport calculations.

The model also provides reasonably accurate vertical profile of time-averaged concentration \( <c> \) up to the level of \( \delta/2 \), as shown in Fig. 9 for Condition 2 of Al-Salem's (1993) laboratory experiments.

Further evidence of good model predictions in the context of time-averaged concentration is depicted in Fig. 10 where the model results for \( z=1 \) cm are compared with experimental data of 10 wave series B and 3 series C of measurements of Ribberink & Al-Salem (1994, 1995).
Fig. 9. Time-averaged concentration profiles: model results (solid line) vs. measurements of Condition 2 (symbols), experimental data after Al-Salem (1993)

Fig. 10. Time-averaged concentrations at z=1 cm: model results ("+") and "×" for series B and C, respectively) vs. measurements ("o" and "•" for series B and C, respectively) of Ribberink & Al-Salem (1994, 1995)

**Half-period averaged and net sediment transport**

The same sets of computational parameters as used for determination of the sheet flow layer thickness have been assumed as the model input in the computations of sediment transport rate averaged over half wave period. In accordance to the discussion of the contact load layer thickness, the computations comprise the layer up to \( \delta_{1}/2 \). The model results can be presented as a function of \( \Theta_{2.5} \), the definition of which has been given by Nielsen (1992).

The model results are successfully compared in Fig. 11 with laboratory half-period sediment transport measurements. As one could have expected, for low shear stresses sediment transport consists mainly of bedload while for higher shear stresses it is dominated by suspended load. The contribution of suspended load is obviously bigger for fine sediments. It has been found out that this contribution at low shear stresses is a bit more pronounced for short wave period while at high shear stresses...
suspended load is slightly bigger for long wave period. The above results from bigger values of maximum shear stress and - on the other hand - smaller values of $\delta_i$ for short periods. The value of $\delta_i$ plays more important role in the regime of suspended load, thus bigger suspended load contribution is achieved at high $\theta_{25}$ for long wave periods. Since the differences between long and short wave period results are not very significant, one approximation for long and short wave period, for $d=0.2$ mm, is given in Fig. 11.

Fig. 11. Sediment transport rate averaged over half wave period model results vs. laboratory data of Sawamoto & Yamashita and Horikawa et al., definition of $\Phi_{\text{T1/2}}$ and experimental data as given by Nielsen (1992), and IBW PAN laboratory data.

Finally, the comparison between predicted and observed net sediment transport rates for Ribberink & Al-Salem's (1994) experiments is presented in Fig. 12. Here, following the discussion on the upper validity limit for net transport determination, the computations have been carried out up to the level of $z=\delta_i/4$ only. Except for one experiment, the compliance between calculated and measured values is good.

Conclusions

The contact load layer model, being an extension of the bedload model, is proposed for the calculation of sediment transport features, such as sheet flow layer thickness, sediment concentration and velocity distributions under sinusoidal and asymmetric waves. The bedload model is a basis of the proposed approach as it provides the boundary conditions for the solution of the contact load layer which makes use of the equations proposed by Deigaard (1993). The iterative procedure has been developed to determine two calibration coefficients, basically unknown in the Deigaard’s (1993) proposal.

The comparisons made between the model results and available laboratory data in all analysed cases yield at least satisfactory agreement. Significant discrepancies between the model results and the experimental data, in the context of time-dependent concentrations, are found at higher levels of the contact load layer. They are most probably linked to convective events in flow reversal. Now, there is a need to carry out further studies in order to include the description of convective terms in the present model.

Analytical model for wave-related transport

Judith Bosboom\textsuperscript{1,2}, Gert Klopman\textsuperscript{3,2}, Ad Reniers\textsuperscript{1,2}, Marcel J.F. Stive\textsuperscript{1,2}

Abstract

A computationally efficient, analytical model to determine net sediment transport rates in oscillatory flow is presented. The model is based on (approximate) analytical solutions to the 1DV momentum and advection-diffusion equations and on the subsequent analytical integration of the sediment flux over time and depth. The model is validated against measurements of sediment concentrations and net transport rates performed in WL|DELFT HYDRAULICS' Large Oscillating Water Tunnel (LOWT). Further, comparisons are made with the predictions of numerical 1DV models and sediment transport formulae. The model gives accurate estimates of the net transport rates for medium sand. For finer sand, although qualitatively correct, the model fails to predict the strong offshore sediment transport rates at higher velocities, mainly due to limitations of the diffusion approach for the upward transport of sediment.

Introduction

A variety of concepts is used in morphodynamic models to describe the wave-related transport, i.e. the transport related to the correlation between sediment concentration and long wave motions as well as to wave asymmetry and time lag effects between wave orbital velocity and concentration within the wave cycle.

In quasi-steady models, instantaneous adaptation of the concentration to the time-varying near-bed velocity (or bed shear stress) is assumed such that the total load is directly related to some power of the instantaneous velocity. Assuming in addition that the velocity profile is reasonably uniform over the vertical, the vertically integrated flux can be schematised as the product of the velocity at some reference level and the total load, typically resulting in a formula in which the transport is proportional to some power of the instantaneous velocity, e.g. the Bagnold model (Bowen, 1980; Bailard, 1981). Although the neglect of phase-lag effects between velocity and concentration is potentially inaccurate, quasi-steady formulae are popular amongst morphodynamic modellers thanks to their simplicity and possibility to combine processes acting on different time-scales.

Experiments of Ribberink and Chen (1993) and Janssen et al. (1996) demonstrate that in asymmetric oscillatory sheet flow conditions, the net transport rates for fine sand decrease for increasing oscillatory velocities and ultimately even reverse. In contrast with the Bailard formula, the semi-unsteady formulation according to Dibajnia and Watanabe (1992)

\end{thebibliography}
qualitatively reproduces these unsteady effects (Janssen et al., 1996). The latter formulation combines an essentially quasi-steady approach with a schematised time lag effect. It was found that for coarse sand the results obtained with both formulae are almost identical.

A more general modelling approach requires the intra-wave-period modelling of the velocity and concentration fields using for instance 1DV models (e.g. Fredsøe et al., 1985; Davies et al., 1997). The direct use of such a detailed intra-wave transport model in a morphodynamic model is time-consuming from a computational point of view, especially when used to study the effects of irregularity of the waves and wave groups. This disadvantage is partly removed by making an initial effort of tabulating the results of the intra-wave model for a specific situation, after which the morphodynamic model is run at relatively low costs (Rakha et al., 1997). An alternative way to reduce the computational costs is to apply (semi-) analytical methods to account for the intra-wave effects on the net transport rates while still capturing the essential features of the unsteady transport, i.e. the strong vertical gradients in the near-bottom time-varying flow and concentration including the non-instantaneous response of the sediment.

The purpose of this work is to present an analytical model based on the equations underlying the 1DV unsteady models. By finding (approximate) analytical solutions for the oscillatory velocity $\bar{u}(z,t)$ and the oscillatory concentration $\bar{c}(z,t)$ in the near-bed wave boundary layer and analytically integrating over time and depth, the net transport rate

$$I_{\text{wave}} = \int_{-h}^{h} \bar{u} \bar{c} \, dz \, dt$$

as a function of the depth is obtained. A similar approach has been taken by Nielsen (1988), who however assumes a depth-invariant oscillatory velocity, therewith neglecting one of the essential features, viz. the strong vertical variation of the oscillatory velocity close to the bed.

The oscillatory boundary layer structure is taken into account by using an (approximate) analytical solution to the wave boundary layer momentum equation using a time-invariant eddy viscosity approach. For the computation of the bed shear stress, the time-variation of the eddy viscosity is accounted for. The time- and depth-dependency of the concentration field is resolved by analytically solving the advection-diffusion equation using a time-invariant sediment diffusivity and a bottom boundary condition which is a function of the instantaneous bed shear stress. In this way we expect to account for the majority of the transport near the bed; the bed load transport is assumed to be small as compared to the suspended load contribution.

Although in principle the model can be applied for an arbitrary input series of the oscillatory near-bed velocity, the validation of the model as presented in this paper focuses on second order Stokes conditions in the absence of a mean current. Measurements in WURDELF HYDRAULICS' Large Oscillating Water Tunnel (LOWT) by Ribberink and Al-Salem (1994) and Ribberink and Chen (1993) are used for model validation. In addition, comparisons are made with 1DV numerical models and the transport formulae of Bailard (1981) and Dibajnia and Watanabe (1992).

**Oscillatory boundary layer model**

**Equation of motion and boundary conditions**

After Reynolds-averaging, the wave boundary layer approximation to the momentum equation, for a rough, fully turbulent wave boundary layer flow, reads:

$$\frac{\partial \bar{u} - u_\infty}{\partial t} = \frac{\partial u_d}{\partial t} = - \frac{\partial (u'w')}{{\partial z}},$$

in which $u = u(z,t)$ is the Reynolds-averaged horizontal velocity, $\bar{u}_\infty = u_\infty(t)$ the free stream velocity outside the boundary layer and $u_d = u - u_\infty$ the deficit velocity. Note that only a
purely oscillatory motion is considered in this paper. Further, $-\langle u'w' \rangle = \tau_{z}/\rho$ is the Reynolds shear stress representing the vertical flux of fluid momentum. Here $\rho$ is the fluid density, $u'$ and $w'$ are the instantaneous velocity fluctuations in horizontal and vertical direction respectively, and the brackets denote averaging over the turbulence time-scale.

The turbulence fluxes are modelled according to the Boussinesq hypothesis as:

$$-\langle u'w' \rangle = v_{i,j} \frac{\partial u}{\partial z},$$

(2)

where $v_{i,j}$ is the eddy viscosity or turbulence eddy diffusivity of fluid momentum which we assume is not influenced by the presence of suspended sediment.

The wave boundary layer equation (1) is solved subject to the no-slip boundary condition and the boundary condition of the wave velocity approaching the quasi-constant ($\partial u/\partial z = 0$) velocity prescribed by e.g. an irrotational theory at the edge of the wave boundary layer:

$$u = 0 \text{ at } z = z_n = \frac{k_n}{30},$$

(3)

$$u \rightarrow u_\infty \text{ for } z \rightarrow \infty,$$

where $z_n$ is the effective position of the bottom depending on the equivalent Nikuradse sand grain roughness $k_n$ and where $\infty$ implies a distance far from the bed compared to the boundary layer thickness, but close to the bed compared to the water depth.

**Eddy viscosity model**

Using the Prandtl mixing-length hypothesis and assuming that in the immediate vicinity of the bed the mixing length $l$ is proportional to the distance above the bottom, $l = k_n z$, yields for the bed shear stress:

$$\tau_b(t) = \lim_{z \to 0} \left( \rho(k_n)^2 \frac{\partial u}{\partial z} \frac{\partial u}{\partial z} \right)$$

(4)

Using the Boussinesq hypothesis and realising that $\tau_b(t) = \rho|u_e(t)|u_e(t)$ gives for the eddy viscosity close to the bed $v_{t,\rho} = k|u_e|z$. Trowbridge and Madsen (1984) demonstrated that the solution to the wave boundary layer equation (1) depends only slightly on time variation in the eddy viscosity and is more sensitive to a proper treatment of the vertical distribution; the third harmonic of the velocity, present in the velocity field due the time-varying nature of the eddy viscosity, was found to be only a few percent of the first harmonic. In order to avoid the complex mathematics involved when using a time-varying eddy viscosity, the eddy viscosity close to the bed can be simplified by replacing $|u_e|$ by a characteristic constant $u_{e,\text{char}}$.

On the contrary, the third harmonic of the bed shear stress was found to be 20-25% of the first harmonic. The lack of higher harmonics in the predictions of a linear model with time-invariant eddy viscosity may significantly underestimate the asymmetry of the bed shear stress and therewith the asymmetry in sediment concentrations and transport. For that reason, in the determination of the bed shear stress a time-variant eddy viscosity will be used as will be addressed later.

Based on the above considerations, for the determination of analytical solutions to Equation (1), the viscosity close to the bed is often taken to increase linearly away from the
Grant and Madsen (1979) used $v_{t,f} = \kappa u_{e,max} z$ over the entire wave boundary layer thickness where $\kappa = 0.4$ is the von Karman's constant and $u_{e,max}$ is the maximum bed friction velocity which is related to the maximum bed shear stress $\tau_{b,max}$ via $u_{e,max} = \sqrt{\tau_{b,max}/\rho}$. A two layer model was used by Brevik (1981) who combined the Grant and Madsen model close to the bed with a constant eddy viscosity in the outer layer. The two-layer concept is adopted here since it provides the best compromise between accuracy and simplicity; the constant eddy viscosity in the outer layer is not only more realistic than a linearly increasing eddy viscosity but results in simple analytical solutions as well, whereas close to the bed the linearly increasing eddy viscosity is essential for a good representation of velocity and shear stress. The following two-layer model is used:

$$v_{t,f} = \kappa u_{e,\text{char}} z, \quad z_0 < z \leq \delta,$$
$$v_{t,f} = \kappa u_{e,\text{char}} \delta, \quad \delta < z,$$  \hspace{1cm} (5)

in which the transition level $\delta$ between the two profiles is modelled as:

$$\delta = m \frac{\kappa u_{e,\text{char}}}{\omega},$$  \hspace{1cm} (6)

where $\omega$ is the wave cyclic frequency and $u_{e,\text{char}}$ is a characteristic time-invariant shear velocity representing the time-variant turbulence level in the flow. The choices for the characteristic shear velocity and the coefficient $m$ are discussed later. Note that $\delta$ directly determines the magnitude of the eddy viscosity in the relatively large outer layer.

**Oscillatory velocity solution**

Analytical solutions to (1) using the above specified two-layer eddy viscosity profile (5) are in terms of simple exponential functions of $z$ in the outer layer where a height-invariant viscosity is assumed. In the lower layer however, the linearly varying viscosity results in an analytical solution in terms of Kelvin function of zeroth order (e.g. Grant and Madsen, 1979; Brevik, 1981), which are not only time-consuming from a computational point of view but complicate the depth-integration of the sediment fluxes. For small values of $z_0\omega/\kappa u_{e,\text{char}}$ and $z_0\omega/\kappa u_{e,\text{char}}$ or equivalently close to the bottom and for large values of $u_{e}/k_b$, asymptotic expressions for the zeroth order Kelvin functions may be used to simplify the velocity profile. These assumptions result in a logarithmic velocity profile and a depth-invariant shear stress and were seen to be valid up to $z = \gamma_0 k_b u_{e,\text{char}}/\omega$. Here we use the equivalent assumption that the shear stress is constant to obtain the velocity profile in the lower layer.

Inserting Equation (2) in (1), using the constant stress assumption in the lower layer and the viscosity profile defined by (5), results in the following set of equations:

$$\frac{\partial}{\partial z} \kappa u_{e,\text{char}} z \frac{\partial u}{\partial z} = 0, \quad z_0 < z \leq \delta,$$
$$\frac{\partial u - u_{e}}{\partial t} = \kappa u_{e,\text{char}} \delta \frac{\partial^2 u}{\partial z^2}, \quad \delta < z,$$  \hspace{1cm} (7)

In addition to the two boundary conditions (3), we require the velocity and the velocity gradient to be continuous at the transition level $\delta$ between lower and outer layer.

Solving the momentum equations (7) proceeds assuming a harmonic time-dependent wave motion specified by its near-bottom velocity:
\[ u_n(t) = \sum_{n=1}^{N} U_n e^{i\omega_n t} + c.c., \]  

where \( \omega_n = 2\pi/T_n \) is the angular frequency, \( T_n \) the harmonic period, \( N \) the number of components under consideration, and \( i = \sqrt{-1} \). Note that the coefficients \( U_n \) are complex which means that phase differences may exist between the various harmonics in the near-bottom velocity and that \( c.c. \) denotes the complex conjugates to the terms in the series since the resulting quantities must be real-valued.

The complete solution for the velocity profile in the wave boundary layer as a function of time becomes in the lower layer \( (z_0 < z < \delta) \):

\[ u(z,t) = \frac{\ln \frac{z}{z_0}}{\ln \frac{\delta}{z_0}} \sum_{n=1}^{N} U_n(\delta) e^{i\omega_n t} + c.c. = \ln \frac{z}{z_0} \sum_{n=1}^{N} \frac{2U_n}{2 \ln \frac{\delta}{z_0} + \delta_n(1-i)} e^{i\omega_n t} + c.c \]  

and in the outer layer \( (z < \delta) \):

\[ u(z,t) = \sum_{n=1}^{N} \left[ U_n(\delta) - U_n(\delta) \right] e^{-\frac{1}{2} \frac{z-\delta}{\delta_n} \omega_n t} + c.c. \]  

where:

\[ \delta_n = \sqrt{\frac{2Ku_{char} \delta}{\omega_n}} \]  

Comparison of velocity predictions of analytical and numerical model

The velocity predictions were compared with the results of the IDV NEREUS wave boundary layer model (Klopman, see Ribberink and Al-Salem, 1995) in which a mixing length approach (see previous section) is used to derive a time-varying eddy viscosity. For the coefficient \( m \) and the characteristic shear velocity \( u_{char} \) in Equation (11) we used \( m = \frac{1}{2} \) and \( u_{char} = u_{mean} \) based on representation of the mean bed shear stress. For a purely sinusoidal shear velocity, we would have \( u_{mean} = \sqrt{2} u_{max} \). Generally, the characteristic shear velocity \( u_{char} \) is chosen to represent the maximum bed shear stress \( (u_{char} = u_{max}) \) in order to avoid underestimation of the eddy viscosity during the high-velocity portion of the wave cycle when most of the turbulence is generated (Grant and Madsen, 1979). For the predictions of the maximum velocity profile however, we found that \( u_{char} = u_{mean} \) gave the best results in the analytical model. The coefficient \( m \) can be expected to be in the range of \( \frac{1}{2} \) to \( \frac{1}{4} \). The value of \( \frac{1}{2} \) corresponds to Kajiju's (1964) transition level to the outer layer, whereas the value of \( \frac{1}{4} \) corresponds to the optimal level as found by Brevik (1981) which is half the boundary thickness as defined by Jonsson and Carlsen (1976). The latter value of \( m = \frac{1}{4} \) is adopted here as the standard value for \( m \) and has been applied in all computations shown in this paper. Somewhat better velocity predictions can be obtained using a smaller...
value for $m$. Note that the assumption of constant shear stress can formally not be expected to be valid up above $z = \sqrt{\frac{\nu}{\kappa u_{rms}}}$.

A second order Stokes condition is used in the comparison corresponding to the conditions of LOWT test Cl (see Table 1). We determine $u_{rms} = \sqrt{\frac{1}{2} \hat{u}_1}$ using Swart’s (1974) explicit approximation for the wave friction factor to Jonsson’s implicit, semi-empirical formula. The influence of the use of $\hat{u}_1$, the amplitude of the first harmonic, rather than the root-mean-square velocity was negligible and more appropriate in the wave tunnel situation used in the net transport model validation.

Figure 1 shows the velocity at different phases with zero phase corresponding to the maximum ‘onshore’ velocity as well as the amplitudes of the two harmonic components and the root-mean-square velocity. It can be seen that the predictions of the velocity amplitudes by the analytical model are somewhat smaller than the NEREUS predictions. The velocity predictions with the analytical model are quite reasonable, especially when considering the use of this velocity profile for sediment transport predictions.

\[ \tau_{b,1} = \lim_{z \to 0} \left( \rho \kappa u_{rms} \frac{\partial u}{\partial z} \right) = \rho \kappa u_{rms} \left( \frac{1}{\ln \frac{z}{z_0}} \sum_{n=1}^{N} U_n(\delta) e^{i \omega t} + c.c. \right) \]
from which it can be seen that a linear model with a time-invariant eddy viscosity is obviously not able to predict any higher harmonics in the shear stress field. By choosing $u_{\text{char}} = u_{\text{max}}$ in a time-invariant model, the maximum bed shear stress can be predicted quite accurately. Trowbridge and Madsen (1984) suggested that a simple way to reproduce in a theoretical model the potentially important third harmonic of the bed shear stress while ignoring the small third harmonic of the velocity would be to compute the velocity field by using a time-invariant eddy viscosity and then compute the bed shear stress by combining the velocity prediction with a time-varying eddy viscosity proportional to a shear velocity based on the instantaneous bed shear stress predicted by the time-invariant model.

This concept is adopted by using the bed shear stress definition (4) which corresponds to a time-variant eddy viscosity model:

$$
\tau_{h,2} \equiv \lim_{z \to 0} \left( \rho \kappa (\kappa') \frac{\partial u}{\partial z} \right) = \lim_{z \to 0} \left( \rho (\kappa') \frac{\partial u}{\partial z} \right) = \rho \kappa^2 \left( \frac{\ln \delta}{z_0} \right) u(\delta, t)|u| u(\delta, t),
$$

(13)
in which the velocity field is obtained using the time-invariant eddy viscosity model (see Equation (9)).

**Comparison of shear stress predictions of analytical and numerical model**

Figure 2 shows the bed shear stress for both the time-variant and time-invariant eddy viscosity model using $\delta = \kappa u_{\text{mean}} / \omega$ as well as $\delta = \kappa u_{\text{max}} / \omega$ in comparison with the bed shear stress as computed by NEREUS.

![Figure 2](image-url)
From Figure 2, it can be seen that for the predictions of the linear model with the time-invariant eddy viscosity, the maximum shear velocity must be used to adequately predict the shear stress amplitude. This could be expected since the shear stress in the linear model is directly proportional to the characteristic shear velocity $u_{char}$, whereas the velocity gradient is less sensitive to the value of $u_{char}$. The predictions using the time-variant model, which are governed by the velocity gradient, are relatively insensitive to $u_{char}$. The most important feature in the predictions of the time-invariant model, is the presence of third and higher harmonics such that the asymmetry of the bed shear stress is in better accordance with NEREUS than the relatively symmetrical bed shear stress as predicted using the time-invariant model. This was found to be extremely important to predict the asymmetry in the sediment concentration at the bed.

Sediment concentration model

Advection-diffusion equation

Conservation of mass is applied to the sediment and the resulting equation is Reynolds averaged. Assuming that the Reynolds averaged vertical water velocity is negligible compared to the fall velocity of the sediment, using the boundary layer approximation and introducing the mass balance for the fluid, yields:

$$\frac{\partial c}{\partial t} + w_s \frac{\partial c}{\partial z} + \frac{\partial \langle c'w' \rangle}{\partial z} = 0,$$

in which $c$ denotes the turbulence averaged concentration, $w_s$ the particle fall velocity (assumed constant) and $\langle c'w' \rangle$ the turbulence upward sediment flux, where the brackets denote averaging over the turbulence time-scale. In order to model the turbulence sediment flux, we make the assumption of upward transport due to turbulence diffusion as for the fluid, see Equation (2):

$$-\langle c'w' \rangle = \rho v_{t,s} \frac{\partial c}{\partial z},$$

in which $v_{t,s}$ is the turbulence diffusivity of sediment mass.

The solution to Equation (14) requires two boundary conditions in $z$. At the water surface the vertical flux is zero which due to the limited extent of the wave boundary layer is normally equivalent to $c \to 0$ for $z \to \infty$. The second boundary condition is related to the bed concentration of the suspended sediment taken at a specified level above the mean bed level. Here we use the reference concentration of Zyserman and Fredsoe (1994) which has the advantage of an upper cut-off for the sediment concentration at large values of the bed shear stress. The sediment concentration is prescribed at a reference level $z_a = 2D_{50}$:

$$c(z_a, t) = c_0(t),$$

Besides, we apply the above boundary condition as a pick-up type boundary condition in which it is the upward diffusive flux from the bed $-v_{t,s} \frac{\partial c}{\partial z}$ and therefore the concentration gradient rather than the concentration itself which is prescribed:
Diffusivity model

The diffusivity of sediment mass is in principle assumed to follow the same distribution as the diffusivity of fluid momentum, Equations (5). The exact solution in case of a linearly varying diffusivity in the lower layer is in terms of higher order Kelvin functions (Smith, 1977) which are time-consuming to compute and not easily approximated. Therefore, a representative constant diffusivity in the lower layer is used which is determined by requiring the mean concentration at \( z = \delta \) to be equal to the mean concentration when using the linearly varying diffusivity. We now have:

\[
\begin{aligned}
    v_{i,s} &= v_{i,s,1} = \beta k u_{r,\text{char}} \delta \\
    v_{i,s} &= v_{i,s,2} = k u_{r,\text{char}} \delta
\end{aligned}
\]

in which \( \beta \) follows from the above requirement.

In addition, we allow the settling velocity to be different in the two layers. In the lower layer we have \( w_s = w_{s,1} \), which is taken as the settling velocity corresponding to the \( D_{50} \) of the bed material. In the outer layer, the settling velocity \( w_s = w_{s,2} \) can be expected to be smaller, corresponding to \( 0.7D_{50} - 0.9D_{50} \).

Solution

Solving the advection-diffusion equation (14) proceeds assuming a harmonic time-dependent wave motion specified and using complex variables. The general solution in case of a constant diffusivity reads:

\[
c(z, t) = \sum_{m=-M}^{n=M} C_m \exp \left( -\alpha_m \frac{w_s}{v_{i,s}} z \right) e^{i\omega_m t},
\]

with

\[
\alpha_m = \frac{1}{2} + \sqrt{\frac{1}{4} + i \omega_m \frac{v_{i,s}}{w_s}},
\]

and \( M > N \) is the number of harmonic components in the bed concentration. The complex coefficients \( C_m \) are determined by the bed boundary condition. With \( c_b(z, t) = \sum_{m=-M}^{n=M} C_{b,m} e^{i\omega_m t} \), we find \( C_m = C_{b,m} \) and \( C_m = C_{b,m}/\alpha_m \) for the concentration-type and gradient-type boundary condition, respectively. At the transition of the lower and outer layer, the concentration is required to be continuous.

Wave-related sediment transport model

Writing the previously found expressions for oscillatory velocity and concentration as \( \tilde{u}(z, t) = \sum_{n=1}^{m=n} \zeta_{\nu,\rho}(z) e^{i\omega_d t} + cc. \) and \( \tilde{c}(z, t) = \sum_{m=-M}^{n=M} \xi_{c,\omega_m}(z) e^{i\omega_d t} + cc. \), integration of the
The instantaneous flux \( \varphi(z,t) = uc \) over time and depth yields for the net wave-related sediment transport:

\[
q_{\text{net}} = \frac{1}{t_2 - t_1} \int_{z_2}^{z_1} \varphi(z,t) \, dz \, dt = \int_{z_2}^{z_1} \left( \varphi(z) - c \right) \, dz = \int_{z_2}^{z_1} \sum_n \zeta_{n,a}(z) \zeta_{c,n}(z) + cc \, dz
\]

(22)

In the outer layer with a constant diffusivity of fluid momentum and sediment mass, the solutions \( \zeta_{n,a}(z) \) and \( \zeta_{c,n}(z) \) are in terms of exponential functions such that the integration of the time-averaged flux \( \langle \varphi(z) \rangle \) over depth is easily carried out analytically. The linearly increasing diffusivity close to the bed yields a logarithmic profile for \( \zeta_{n,a}(z) \) which complicates the analytical integration of \( \langle \varphi(z) \rangle \). Therefore a polynomial approximation valid for small values of \( z \) is used to approximate the integral.

Hence we have arrived at a computationally efficient method to account for the wave-related suspended sediment transport taking into account the strong vertical variations in the near-bottom time-varying flow and concentration including the non-instantaneous response of the sediment. With the present time-domain formulation of the bed boundary condition for the sediment, the determination of the net transport rate requires a transformation from frequency to time-domain and vice versa. Compared to using a numerical finite difference scheme however, we have at least a two orders of magnitude reduction in the computational effort.

Comparison with LOWT experiments and results of various models

Description of LOWT experiments

The data used for model validation were obtained by Ribberink and Al-Salem (1994) for dune sand with \( D_{50} = 210 \mu m \) and by Ribberink and Chen (1993) for finer sand with a \( D_{50} = 130 \mu m \). The experiments were carried out in the Large Oscillating Water Tunnel. The experiments used here were performed above a plane sand bed for regular asymmetric (2nd order Stokes) waves in the absence of a mean current. The set of experiments covered a range of wave periods, flow velocity and asymmetry (see Table 1). For C1 and D13 (bold in Table 1) detailed time-dependent measurements were performed. For all tests net transport rates were derived using a mass-conservation technique. Time-averaged concentration were measured using a suction system, whereas time-dependent concentrations were measured using a conductivity concentration meter (CCM) in the sheet flow layer and an optical concentration meter (OPCON) in the suspension layer.

The comparison with the experiments was carried out on sediment concentration and time-averaged sediment fluxes for the tests C1 and D13 and on net transport rates for all tests in the respective series. For all tests, the model was run using the standard settings of \( \delta = 0.25u_{\text{mean}}/\omega \) and \( k_n = 3D_{50} \) and with a fall velocity in the outer layer corresponding to a grain diameter of \( 0.75D_{50} \) based on grain-size data collected during the experiments. Both the concentration-type and pick-up type concentration boundary conditions were used. Only for D13, a significant difference could be observed in the results of the two boundary conditions.

Series B and C (\( D_{50} = 210 \mu m \))

In Figure 3, the prediction of the analytical model is compared with the time-varying sediment concentrations at four heights above the original bed level and with the time-
Table 1 Test conditions for B- and C-series (Ribberink and Al-Salem, 1994) and D-series (Ribberink and Chen, 1993).

Figure 3 Comparison of measured (drawn) and computed (dashed) sediment concentrations for C1 averaged sediment concentration profile. At the lower levels the predictions are in good agreement regarding amplitude and phase. With distance from the bed especially the phase between the model and data increases. Further, the data show a single-peaked concentration, whereas a second peak is still present in the model predictions. The time-averaged concentration profile is reasonably well predicted. Qualitatively, these features are in agreement with model predictions discussed in a MAST2 G8-M intercomparison study comparing four numerical 1DV models with LOWT data (Davies et al., 1997). In Figure 4 (upper left plot), the predicted time-averaged flux profiles are compared with the data and the
predictions of the Danish STP model based on an eddy viscosity approach (Fredsøe et al., 1985) and a turbulent kinetic energy model (Davies, 1995). The results of the latter two models were taken from the aforementioned paper and were obtained without any fine-tuning of the respective models. Note that for the lower five points measured values for the concentration were combined with estimated values of the velocity, since no velocity measurements were available here. All models and the data show an 'onshore' transport in the near-bed layer and an 'offshore' transport in the outer suspension layer. All models give comparable results and significantly overestimate the height of zero flux and is a direct result of the underestimation of the phase differences between velocity and concentration in the models which are all based on a diffusion approach for the upward transport of sediment.

**Figure 4** Comparison of measured and computed time-averaged fluxes (upper left plot, STP: dashed, t.k.e.: dashed-dot; analytical: drawn) and comparison of measured and computed net transport rates for various models for the B- and C-series.

The net sediment transport is dominated by the flux in the near-bed layer such that the mismatch between model and data further from the bed can be expected to be relatively unimportant for the net transport predictions. This can be seen in Figure 4, which compares the net transport predictions of the analytical model with the data. Besides, the performance of the Bailard (1981) and Dibajnia and Watanabe (1992) is shown. The latter model results are taken from Janssen et al. (1996). In this figure, perfect agreement corresponds with the 45° line. Also shown are the lines indicating a factor 1.5 and 2 around the line of perfect
agreement. It can be seen that the predictions of the analytical model, the Bailard model and the Dibajnia and Watanabe model are within a factor 2 from the data for 100%, 90% and 100% of the tests considered, respectively. Within the band of factor 1.5 we have 100%, 60% and 50% respectively. Also compared to the predictions in Davies et al. (1997), the analytical model gives favourable results.

**Series D** \((D_{50} = 130\mu m)\)

A comparison of the predicted and measured time-varying and time-averaged sediment concentrations, not shown here for brevity, showed many of the features as reported above for test C1. An important difference is the relatively large concentration in the outer layer, such that the predictions in the outer layer are more important to the net sediment transport rate predictions than for the coarser sand.

In Figure 5, these net transport rate predictions are compared with the data, together with the predictions of the Bailard and the Dibajnia and Watanabe model (from Janssen et al., 1996). The data show a decreasing and eventually reversing transport rate for increasing root-mean-square velocities. Due to its assumption of quasi-steadiness, the Bailard model cannot follow this trend. Both the analytical model and the Dibajnia and Watanabe model qualitatively follow the observed behaviour, although neither of them predicts the right order of magnitude of the transport rates. The Dibajnia and Watanabe model gives somewhat better results.

**Conclusions**

The sediment fluxes and net transport rates predicted by the analytical model are comparable to results of numerical IDV models. However, a considerable reduction of computational effort is obtained. The model gives accurate estimates of the net transport rates for medium sand. For finer sand, although qualitatively correct, the model fails to predict the strong offshore sediment transport rates at higher velocities, mainly due to the diffusion approach.

Vertical Length Scales of Nearshore Suspension Events

D. L. Foster, A. J. Bowen, and A.E. Hay

Abstract

Most commonly, nearshore suspended sediment time series are characterized by distinct high concentration events. These events are coherent structures which should have lengths scales that are dependent on the length scale of the near bed turbulence. Possible generation mechanisms for coherent turbulent structures include bed shear, vortex shedding from bed forms, shear instabilities of oscillatory boundary layers, and surficial wave breaking. For turbulence mechanisms other than wave breaking, the characteristic length scale should be governed by the thickness of the bottom boundary layer. The objective of this investigation is to characterize the observed vertical length scales of suspended sediment plumes over the course of a single evolving storm and to compare these length scale estimates with the thickness of the displacement WBBL.

Field observations were made at Queensland Beach on the east coast of Nova Scotia in 1995. This steep planar beach faces a restricted opening, with incoming waves approaching normal to the shore and has a 1 m tidal range. The instruments were located in an intermediate water depth of 3.2 m where the median grain size was 0.02 cm. Sediment suspension was measured with a 2.25 MHz acoustic sounder looking downward and the bed geometry was measured with a rotary sonar.

Over the course of a relatively short lived storm event within a 24 hour period, the wave height ranged from .35 m to 1.4 m and the bed geometry underwent multiple transitions. During this event, the sediment suspension observations showed that while the relatively infrequent large suspension events increase with increasing storm intensity, the mean suspension event length scale shows little variability. The suspended sediment length scales were compared with an estimate of the displacement thickness of the wave bottom boundary layer. Although the two estimates showed an order of magnitude agreement, the displacement thickness estimates increased slightly with increasing storm intensity. The rms deviation between the estimated boundary layer thickness and the mean length scale of the suspended sediment vertical excursion was 1.2 cm.

1Department of Oceanography, Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4J1.
Introduction

Nearshore suspended sediment observation time series are dominated by distinct high concentration events. Recent observations have shown these events to be spatially-discrete coherent structures (Hay and Bowen, 1994) with horizontal lengths scales ranging two orders of magnitude from 5 cm to 1 m. The length scale of the coherent plumes should be dependent on the length scale of the near bed turbulence, indicating the near bed turbulence also exhibits a coherent, spatially discrete structure. Possible generation mechanisms for these turbulent structures include bed shear, vortex shedding from bed forms, shear instabilities of the oscillatory boundary layers, and surficial wave breaking. The turbulence length scale should be governed by the wave bottom boundary layer (WBBL) thickness for these mechanisms, other than wave breaking.

The objective of this investigation is to characterize the observed vertical length scales of suspended sediment plumes over the course of a single evolving storm. Furthermore, we will compare these length scale estimates of the suspended sediment with an estimate thickness of the displacement WBBL.

Figure 1: Sea surface elevation, $\eta$, as a function of time (top) and suspended sediment concentration, $c$, as a function of time and elevation (bottom). The solid black line indicates the elevation of the 1 g/l contour line and the circles indicate the elevation of individual suspension events.
Observations

Field observations were made at Queensland Beach on the southeast coast of Nova Scotia in 1995. This steep planar beach faces a restricted opening, with incoming waves approaching normal to the shore and has a 1 m tidal range. The instruments were located 80 m offshore in an intermediate water depth of 3.2 m. The median grain size was 0.02 cm.

Figure 2: Significant wave height (top), $H_s$, peak wave period (middle), $T_p$, and bed form geometry (bottom) over consecutive 500 second runs during year-day 260-261.

For this investigation, sediment suspension and bed elevation were measured with an acoustic sounder operating at 2.25 MHz. The backscatter profile from the sounder spanned a vertical range of about 1 m divided into 0.6 cm range bins and was acquired at 8 Hz. Surface elevation was measured with an upward looking acoustic sounder. A sample time series of sea surface elevation and suspended sediment concentration is given in Figure 1. The concentration and sea surface elevation observations were recorded for 500 seconds every 30 minutes. Bed form geometry was determined over a 5 m radius at each 30 minute interval with a rotary sidescan and rotary pencil beam sonar.

This investigation will focus on the evolving storm during year-days 260 and 261. During the course of this storm the significant wave height, $H_s$, varied from .35 m to 1.4
m, and the peak wave period, $T_p$, varied from 2.5 s to 8.3 s. The bed varied between rippled and flat bed, Figure 2.

Results and Discussion

This section is divided into three parts. First, we determine the vertical distribution of suspension excursion. Secondly, we estimate the displacement boundary layer thickness with an empirical model. Finally, we compare the boundary layer thickness estimate with the vertical excursion length scale of the suspended sediment.

Figure 3: Histogram of the 1 g/l contour elevation of the 2.25 MHz sounder (top panel) and the offset mean profile of observations contained within each histogram bin (bottom panel). The frequency of occurrence in each bin are given directly above each bar.

The upper boundary of the sediment laden water was defined with the 1 g/l elevation computed over consecutive 30 second windows, Figure 1. This example shows the 1 g/l contour elevation mostly remains on the bed and has occasional short duration excursions to elevations ranging from 2 to 7 cm. The histogram of the 1 g/l contour elevation time series for this record (Figure 3) shows that 84% of the elevations are less than 2 range bins (1.2 cm) from the bed but there are occasional occurrences where the elevation reaches 15 to 20 cm above the bed. The histogram can be used isolate the mean profile of the suspension events by conditionally sampling the observations based on the elevation of the 1 g/l contour elevation. This is accomplished by calculating the mean vertical profile
Figure 4: The significant wave height (top), and $\log_{10}$ of the fraction of events in each histogram bin. Note that an intensity corresponding to a value of 1 would indicate 100% of the events would be in the single bin and an intensity corresponding to a value of .5 indicates 50% of the events would be contained in the single histogram bin.

of the observations for the set of observations within each histogram bin. The confidence of each profile will be directly dependent on the number of samples in each histogram bin. The sample shows a significant deviation between the complete record mean profile and the mean profile within the individual bins at the higher contour elevations (see the mean profiles for the histogram bins greater than 5 cm from the bed). This sample shows the mean concentration profile of the record is strongly biased towards the large percentage of occurrences when insignificant levels of sediment are in suspension.

The histogram for each of the records over the 24 hour period are shown in Figure 4. In general, as the significant wave height increases larger suspension excursions are reached. Under the storm peak, the sediment suspension reaches elevations of at least 25 cm above the bed.

For this investigation, a displacement thickness was chosen as the characteristic length scale of the WBBL. The displacement WBBL thickness, $\delta$, was estimated following an empirical formulation outlined in Nielsen (1992),

$$\delta_w = c_d A$$  (1)
where \( A = \frac{u_o}{\omega} \) is the wave orbital excursion amplitude and the drag coefficient, \( c_d \), is defined with (Swart, 1974)

\[
c_d = 0.5e^{5.2^{0.2-6.0}}.
\]  

(2)

This formulation is based on numerous laboratory experiments and relies on an accurate estimate of the bed geometry. For these observations on a restricted opening beach with normally incident waves, the excursion amplitude is dominated by onshore and offshore motions. The relative roughness, \( r \), was assumed to be a function of the bed geometry and grain roughness (Nielsen, 1992)

\[
r = \frac{8\eta_b^2 + 170(\theta_{2.5} - 0.05)^{0.5}}{A}
\]  

(3)

where \( \eta_b \) is the bed form amplitude, \( \lambda_b \) is the bed form wavelength, and \( \theta_{2.5} \) is the grain roughness Shields parameter. The bed form amplitude and wave length were quantified with a rotary pencil beam sonar (Hay and Mudge, in preparation). The grain roughness shields parameter is defined with

\[
\theta_{2.5} = c_d_{2.5} \psi
\]  

(4)

where \( c_d_{2.5} \) is the grain roughness drag coefficient and \( \psi \) is sediment mobility number (Swart, 1974). The grain roughness drag coefficient is defined with

\[
c_d_{2.5} = \frac{1}{2}e^{5.213(\frac{2.5d_{50}}{A})^{0.194} - 5.977}
\]  

(5)

and the mobility number is defined with

\[
\psi = \frac{(A\omega)^2}{(s - 1)gd_{50}}
\]  

(6)

where \( d_{50} \) is the median grain size diameter, \( \omega \) is the peak frequency, \( s \) is the relative sediment density, and \( g \) is gravity.

The relative roughness varies over an order of magnitude throughout the experiment, Table 1. There also exists a significant variation in the drag coefficient over the 24 hour period, Figure 5. Prior to the storm, the existing bed geometry and low excursion amplitude yields a large relative roughness. As the wave height increases and wave period decreases, the orbital excursion amplitude increases and the bed begins to plane off resulting in a significant decrease in the drag coefficient. The resulting boundary layer thickness increases by a factor of 2 as the storm intensity increases.

The mean vertical length-scale, \( L_z \), was estimated by calculating the mean of the individual event vertical intrusion heights in each record. Individual events were identified by searching for local maxima greater than 2 range bins (1.2 cm) away from the bed of the 1 g/l contour elevation sampled at 8 Hz and smoothed with a 1/2 second boxcar win-
Figure 5: The significant wave height (top), mean vertical excursion length scale, $L_z$, (middle panel), estimated displacement WBBL thickness, $\delta$, (middle panel), and the drag coefficient, $c_d$, (bottom) as a function of time.

dow. The darkened circles in Figure 1 show the time and elevation of the defined events for this example. The mean vertical intrusion height is compared with the estimated displacement WBBL thickness in Figure 5. Unlike the extreme event envelope (Figure 4), the mean vertical excursion length scale remains remarkably uniform over the period. The mean vertical length scale remains relatively uniform because the statistic is dominated by the relatively high number of small events. The rms deviation between the mean vertical length scale and estimated displacement WBBL thickness is 1.2 cm over the 24 hour record.

Summary

These results showed that while the relatively infrequent large suspension events increase with increasing storm intensity, the mean suspension event length scale shows little variability. The estimated displacement WBBL thickness increased with increasing storm intensity. The rms deviation between the estimated boundary layer thickness and the mean
length scale of the suspended sediment vertical excursion was 1.2 cm. Further investigations of these observations will include similar evaluations of the horizontal length-scales and temporal evolution of events. Also, vertical lengths scales as measured by 2 other sounders will be compared.

Sediment Resuspension under Non-Breaking Waves.
Predicting Sediment "Pulses" as a Function of Groupiness

José A. Jiménez, Agustín Sánchez-Arcilla (M.ASCE) and German Rodríguez

Abstract

Near-bottom sediment suspension reacts to non-breaking random wave-induced velocity field showing a pulsating structure (high concentration discrete events) lagged with respect to the actual velocity field. A coefficient of variation, $G_{F_{cpb}}$, has been applied to low pass filtered concentration time series to characterise these pulses. The use of simple parameters based on the actual velocity field such as the shear stress (e.g. using the velocity squared) is not enough to fully explain the sediment response. To take into account the apparent relationship between groups and sediment pulses, several parameters characterising groupiness have been analysed: (i) the groupiness factor, $G_F$, derived from SIWKEH; (ii) the mean run length, $j_1$, and mean total run, $j_2$, based on the use of the envelope; and (iii) the spectral correlation coefficient between successive waves, $\rho$. The best predictor for the pulsating structure of the sediment response was found to be $G_F$, with a linear relationship for similar energetic wave states ($u_{*\text{im}}/u_{*\text{ir}} > 1$), i.e. the larger the $G_F$ is, the larger $G_{F_{cpb}}$ the will be. When the time lag in the sediment response is analysed, the parameters retaining information about the temporal structure of the groups such as $j_1$ or $\rho$ are the only able to predict it. Thus, a linear relationship was found between the time lag and the mean run length and $\rho$, i.e. the longer the group is, the longer the lag in the sediment response will be.

1. Introduction

It is reasonably well known that in natural conditions, sediment resuspension from the bottom is a more or less intermittent process, in which large sediment concentrations are picked-up from the bed and released to the water column as "pulses" (e.g. Hanes, 1990). These pulses are generally related with the presence of wave groups and their associated long waves (e.g. Shi and Larsen, 1984; Sato, 1992) (figure 1).

1 Laboratori d'Enginyeria Marítima, ETSECCPB, Catalonia University of Technology, c/Jordi Girona 1-3, Campus Nord, Ed. D1, 08034 Barcelona, Spain (e-mail: jimenez@etseccpb.upc.es).
2 Department of Physics, Universidad de Las Palmas de Gran Canaria, Campus Universitario de Tafira, 35017 Las Palmas, Spain.

2595
However, although conceptually this is generally accepted, there is no model able to predict this sediment pulsing structure as a function of the level of groupiness of a determined wave-energetic state. Most of existing studies recognise the influence of groupiness (e.g. Shi and Larsen, 1984; Hanes, 1990, Shibayama et al. 1992) or estimate the increase in the integrated suspended sediment concentration within a wave state (Sato, 1992, Lee et al. 1994) but without details on how to predict frequency and magnitude of sediment pulses.

It is the aim of this paper to analyse the relationship between wave groups and induced suspended sediment pulses and to find wave groups related parameters able to predict/characterise the pulsing structure.

2. Field data

Data used in this study were acquired in the inner shelf (8.5 m depth) of the Ebro delta (Spanish Mediterranean coast). The data were obtained by using an instrumented tripod supporting 3 ECM's, 3 OBS's, 1 pressure sensor and 1 compass. The system worked in burst mode, with a burst duration of 20 min every 3 hours and with a data acquisition frequency of 1 Hz. All the data were taken under non-breaking wave conditions. A description in depth about the governing conditions during the survey period can be seen in Jiménez et al. (1998).

All the data analysed in this work correspond to the measurements taken at the lowest position, 10 cm above the bottom.

3. Sediment resuspension and incident velocity field

Since sediment resuspension depends on the characteristics of the near-bottom flow, a first approach is to directly relate sediment suspension with near-bottom velocity. Following earlier works of Smith (1977) and Smith and McLean (1977), suspended sediment concentration, $C$, can be expressed as a function of the excess of shear stress, $\tau_b$, above a critical value $\tau_{cr}$, as...
\[ C = C_b \gamma \frac{s'}{(1 + \gamma s')} \quad s' = \frac{\tau_{b}}{\tau_{cr}} - 1 \]  

(1)

where \( C_b \) is the reference concentration at the bottom and \( \gamma \) is the resuspension factor. Eq. (1) can be simplified assuming that the actual shear stress is much higher than the critical one as

\[ C(t) \propto \frac{\tau_{b}(t)}{\tau_{cr}} \propto U(t)^2 \]  

(2)

Following this approach figure 2 shows the relationship between near-bottom sediment concentration and velocity squared in the time and frequency domains. As it can be seen, although cross-correlation gives a different from zero value (indicating the existence of a relationship between them), the calculated coefficient of correlation is relatively low.

Figure 2. Relationship between near-bottom sediment concentration and near-bottom velocity squared. Left: cross-correlation (lines show limits for different from zero correlation). Right: squared coherence from cross-spectral analysis using both variables.

If this is done in the frequency domain through cross-spectral analysis similar results are found. Thus, results show that the squared coherency at low frequencies is much higher than the calculated for at high frequencies (peak frequency -0.19 Hz- corresponding to \( u \) or first harmonic -0.38 Hz- corresponding to \( u^2 \), figure 2). This should indicate that a large part of the sediment suspension would be related to the existence of low frequency motions such as those induced by the presence of wave groups.

Figure 2 also shows the existence of a time lag between the sediment response (suspension) and the incident velocity field as it has been demonstrated in earlier works (e.g. Jaffe et al. 1994). Two dimensionless parameters have been selected to look for a simple relationship between the lag in the sediment response and the incident velocity field. These dimensionless parameters retain both velocity field and sediment characteristics and they are (i) a kind of excess of bottom shear stress, \((u_{*}\text{rms})^2\) above the critical shear stress for initiation of sediment motion, \((u_{*,cr})^2\), i.e. \((u_{*}\text{rms}/u_{*,cr})^2\) and (ii) the shear velocity adimensional ised with the fall velocity of the sediment, \( w_r \), i.e. \( u_{*}\text{rms}/w_r \). The first parameter gives an idea about the capacity of sediment mobilisation of the incident velocity field, the larger this parameter is, the larger the mobilisation will be. On the other hand, the second one gives an idea about
and the ability of the sediment to be in suspension in the water column. Thus, assuming that the suspended sediment concentration is a function of the \(-w/u_{*\text{rms}}\) power (e.g. Nielsen, 1992), this would imply that the larger the \(u_{*\text{rms}}/w_s\) is, the longer the "resident" time of the sediment in the water column will be.

Figure 3 shows the time lag adimensionalised with the actual peak period versus both parameters. As it can be seen no simple relationship can be found. The only aspect arising from the figures is that velocity fields with a relatively low capacity of mobilisation - \((u_{*\text{rms}}/u_{*,Cr})^2 \approx 0.5\) - show a trend to present longer time lags.

On the other hand, for velocity fields with a relatively high capacity of mobilisation - \((u_{*\text{rms}}/u_{*,Cr})^2 > 1\) - and inducing a relatively long residence time, there seems to exist a trend for longer time lags as both parameters increase. However, this trend is not uniform since there are some cases not showing this behaviour.

As a summary, although the near-bottom velocity squared and related parameters are able to qualitatively predict some aspects of the near-bottom suspended sediment concentration, their predictability skill is relatively low as it has been pointed out by Jaffe et al. (1994) among others, i.e. some hydrodynamic aspects are missed.

4. Sediment resuspension and groupiness

To account the apparent effect of wave groups in sediment resuspension (figure 1), the incident velocity field was manipulated to characterise its degree of groupiness. To do this several methods have been investigated: two in the time domain -SIWEH and the run length (derived from the envelope)- and one in the frequency domain -the spectral correlation coefficient between successive waves-. In all the cases, the selected parameter is related to the suspended sediment time series to analyse its ability to characterise the pulsing structure and the observed time lag between velocity and concentration.

The SIWEH method (Funke and Mansard, 1979) was applied to near-bottom velocities projected on the mean wave direction (SIWKEH, where K means kinetic) to characterise velocity groupiness (eq. 3). Moreover, to remark the sediment pulsing
behaviour, suspended sediment concentration time series were also filtered using a Barlett window similar to SIWEH but with a linear gain (eq. 4). Figure 4 shows the effect of applying such technique on the original time series.

\[ E_u(t) = \frac{1}{T_p} \int_{-\infty}^{\infty} u^2(t+\tau)Q(\tau)d\tau \]  

(3)

\[ C_{fi}(t) = \frac{1}{T_p} \int_{-\infty}^{\infty} c(t+\tau)Q(\tau)d\tau \]  

(4)

where \( Q(\tau) \) is a Barlett filter given by

\[ Q(\tau) = \begin{cases} 
1 - \frac{|\tau|}{T_p} & |\tau| < T_p \\ 
0 & |\tau| \geq T_p 
\end{cases} \]  

(5)

Figure 4. Bottom: original time series of velocity (left) and concentration (right). Upper: filtered time series -SIWKEH (left)- and concentration (right).

Figure 5 shows the results of a cross-correlation analysis between SIWKEH and the bottom filtered concentration, where a significantly different from zero correlation at the 95\% level was found. This correlation amounts to 0.65 which is larger to the obtained with \( u^2 \), and it should imply that when groupiness is taking into account, the suspended sediment response can be better explained. As in the previous analysis, a time lag between velocity and suspended sediment concentration was also found with the same value (figure 5). In a simple manner, with regards the “magnitude”, the larger the SIWKEH is, the stronger the sediment pulse will be and, with respect to the temporal structure, sediment pulses appear to be retarded with respect to the group.
To characterize wave groupiness, the groupiness factor $GF$ (Funke and Mansard, 1979) was used, which in essence is a coefficient of variation given by

$$GF = \frac{1}{E_u} \sqrt{\frac{1}{T_n} \int_0^{T_n} (E_u(t) - \bar{E}_u)^2 \, dt}$$  \hspace{1cm} (6)$$

$$\bar{E}_u = \frac{1}{T_n} \int_0^{T_n} E_u(t) \, dt$$  \hspace{1cm} (7)$$

This $GF$ was also applied to the filtered suspended sediment time series, $C_{fil}$, to obtain a measure of the pulsing structure, $GF_{Cfil}$. Large values of $GF_{Cfil}$ would imply a strong pulsing structure.

Figure 6 shows $GF_{Cfil}$ versus the wave groupiness factor, $GF$. As it can be seen, the larger the wave groupiness factor is, the stronger the pulsing structure will be. In numerical terms, this linear relationship is highly significant with a coefficient of determination, $r^2 = 0.7$. However, there exist some cases with similar $GF_{Cfil}$ values for different $GF$ ones. These cases correspond to wave states with very different energetic contents. Thus, points in the shadow area of figure 6 were taken under relatively low energetic conditions, i.e. $(u_{*_{rm}}/u_{*_{cr}}) < 0.5$, and as $GF$ is a measure of the variance of the SIWKEH, a large $GF$ can be obtained for small waves but grouped. On the other hand, as $GF_{Cfil}$ is a coefficient of variation, relatively high values can be obtained for time series with a low mean value (see figure 6 right). Thus, similar $GF_{Cfil}$ values for different energetic conditions have different implications. For low energy conditions, few pulses give a larger than expected $GF_{Cfil}$ value due to the actual low mean concentration.

All of this indicates that although $GF$ obtained from SIWKEH is a good "predictor" of the pulsing structure, a $GF$ larger than others will not necessarily imply a larger sediment pulsing, $GF_{Cfil}$, unless wave states with similar energetic contents are compared. In this sense, it is recommended restricting the comparative analysis to wave states with $(u_{*_{rm}}/u_{*_{cr}})^2 \geq 1$. 

Figure 6. Relationship between filtered concentration time series and SIWKEH (same case than in figure 3). Left: cross-correlation. Right: zoom of time series illustrating the time lag.
Figure 6. Suspended sediment pulsing structure, $GF_{\text{Cfl}}$, versus wave groupiness factor, $GF$. Cases in the shadow area correspond to time series with $(u^*/u^*_{\text{rms}})^2 \approx 0.5$. Right: selected filtered suspended sediment concentration time series.

Figure 7 shows the time lag in the sediment response adimensionalised with the peak period of the incident waves versus the groupiness factor, $GF$. As it can be seen, there is no relationship between both, i.e. $GF$ is not a good parameter to predict such lag.

The different behaviour of $GF$ to measure pulsing and time lag can be explained taking into account that SIWKEH gives a measure of the variability of the energy packets within a wave state but it does not measure the temporal distribution of the groups. A large $GF$ indicates that many packets exist (and in consequence the probability to have sediment pulses will be larger) but it does not include any information about the energy content, so only wave states with similar contents can be compared.

Figure 7. Normalised time lag versus wave groupiness factor, $GF$. 
The run length method (Goda, 1970) was applied to near-bottom velocities projected on the mean wave direction using the envelope method. Thus, the envelope of the incident velocity field was calculated by using the Hilbert transform. Once the envelope was obtained, the groups were defined using a threshold value characteristic of the analysed problem. Since we are studying the sediment response, the threshold value was selected to be the critical velocity for initiation of motion, obtained by assuming the Shields criterion to be valid for oscillatory flow. Once this value was obtained, the run length of each group is calculated in a continuous manner, i.e. the time during which the envelope exceeds the threshold, with a minimum duration of the peak period (see figure 8).

Figure 8. Run length and total run definition using the envelope method (line is the threshold velocity for initiation of sediment motion calculated by using Shields criterion).

Figure 9 shows the sediment pulsing intensity, $GF_{C_{th}}$, and the normalised time lag versus dimensionless mean run length, $j/T_p$, and dimensionless mean total run, $j_2/T_p$. As it can be seen, no relationship between $GF_{C_{th}}$ and mean run length or mean total run was found. On the other hand, a linear relationship between normalised time lag and normalised mean run lengths and mean total run was found. In the case of the use of the run length, if low energetic wave states are removed, i.e. $(u_{*cn}/u_{*cr})^2 \approx 0.5-1.0$, the larger the duration of the group (run length) is the longer the time lag will be. Similarly, a linear relationship between time lag and mean total run was also found with about the same coefficient of correlation and also taking out the low energetic states (figure 9). This implies that for similar energetic states and for the same threshold, the longer the time between groups is, the longer the time lag will be.

This different behaviour of $j/T_p$ and $j_2/T_p$ to measure pulsing and time lag can be explained taking into account that in opposite to SIWKEH, these parameters give a measure of the temporal structure of the groups. However, they do not give too much information about the energy content (only that each group exceeds the selected threshold). A possible improve of its predictive skill could be the application of an approach similar to the proposed by Medina et al. (1990), the envelope exceedance coefficient, in which not only the duration of the group is considered but also its energy content.
Kimura (1980) proposed the correlation coefficient between successive waves as a way to predict the mean and standard deviation of the run lengths and the total runs of a wave state. This method was originally derived to work in the time domain (i.e. using the zero crossing analysis) and, in consequence, it does not include not too much advantage in comparison with the direct determination as presented above (see e.g. Mansard and Sand, 1994).

However, Battjes and van Vledder (1984) derived such correlation parameter directly from the spectral density of the waves, which implies that most information on wave groups is contained in the spectrum itself. In this work, an improved correlation coefficient in the way proposed by van Vledder (1992) is used to characterise wave groupiness. This correlation coefficient is given by

$$\rho_f = \frac{\rho_f \left(\frac{1}{2} \bar{T} \right) + 2 \rho_f \left(\bar{T} \right) + \rho_f \left(\frac{3}{2} \bar{T} \right)}{2 + 2 \rho_f \left(\frac{1}{2} \bar{T} \right)}$$

where
\[ T = \frac{1}{2} T_{m02} (1 - \frac{1}{2} V^2) \]  

(9)

Figure 10 shows the sediment pulsing intensity, \( GF_{CI} \), and the normalised time lag versus the spectral correlation coefficient between successive waves. As expected, since this coefficient is related to the mean run length, it presents a similar behaviour than \( j_i \). Thus, no relationship between \( GF_{CI} \) and \( \rho \) was found. On the other hand, a linear relationship between normalised time lag and \( \rho \) was also found, with a similar coefficient of correlation, \( r=0.84 \), although there is no need to consider the energetic content of each cases (as it was done with the mean run length).

The different behaviour to measure pulsing and time lag can be explained in the same way that was done in the case of the mean run length, since they are related. The advantage of this method is that can be applied directly to the recorded spectra without identifying the groups in the time series.

\[ \begin{align*}
GF_{CI} & \quad \rho \quad \beta \\
0.1 & \quad 0.2 & 0.0 & \quad 0.8 & 0.7 & 0.6 & 0.5 & 0.4 & 0.3 & 0.2 & 0.1 \\
0.2 & \quad 0.4 & 0.6 & 0.8 & 0.8 & 0.8 & 0.8 & 0.8 & 0.8 & 0.8 & 0.8 \\

\end{align*} \]

Figure 10. Sediment pulsing intensity, \( GF_{CI} \) (left) and normalised time lag (right) versus spectral correlation coefficient between successive waves.

**Summary and discussion**

Near-bottom sediment suspension reacts to non-breaking random wave-induced velocity field showing a pulsating structure, i.e. high concentration discrete events, that it is lagged with respect to the actual velocity field. This pulsating structure was characterised via a coefficient of variation similar to the groupiness factor, \( GF_{CI} \), applied to a low pass filtered concentration time series (eq. 4).

The use of a simple parameter based on the actual velocity field such as the shear stress (e.g. using the velocity squared) is not enough to fully explain the sediment response. To solve this and taking into account the apparent relationship between groups and sediment pulses, several parameters characterising groupiness have been analysed: (i) the groupiness factor derived from SIWKEH (using the actual velocity instead of the wave height), \( GF \); (ii) the mean run length, \( j_1 \), and mean total run, \( j_2 \), based on the use of the envelope; and (iii) the spectral correlation coefficient between successive waves, \( \rho \).

When the **pulsating structure** of the sediment response, \( GF_{CI} \), is analysed, the best predictor of the tested parameter was found to be the groupiness factor derived from SIWKEH, \( GF \). Thus, for similar energetic wave states (with \( \left( \frac{u_{*\text{rms}}}{u_{*\text{er}}} \right)^2 > 1 \)), a linear
relationship was found, i.e. the larger the $GF$ is, the larger $GF_{_{CFI}}$ the will be. The other two tested parameters are not useful to predict the pulsating structure, i.e. no relationship was found.

When the time lag in the sediment response is analysed, the parameters retaining information about the temporal structure of the groups such as $j_i$ or $\rho$ are the only able to predict it. Thus, a linear relationship was found between the time lag and the mean run length and $\rho$, i.e. the longer the group is, the longer the lag in the sediment response will be. From both parameters, that directly obtained from the spectrum, $\rho$, is recommended because there is no need to account its energetic content as it is the case of the use of $j_i$. In this last case, the groups have been defined using a threshold selected as a function of the analysed problem, the critical velocity for initiation of sediment motion.

These results seem to suggest that instantaneous sediment transport models have to account grouping-induced sediment response (sediment pulses and time lags) to make realistic predictions.

Present on-going analysis is being directed to include an intensity-oriented parameter (to take into account the magnitude of the pulse) and to analyse the possibility of the existence of a relationship between the time lag and the wave group-induced bound long wave.

Coherent Doppler Sonar: Sediment Flux and Turbulent Velocities in a Wave Flume

Len Zedel¹ and Alex Hay²

1 ABSTRACT

Observations of vertical sediment flux and velocity structure are made under prototype scale waves in the Wave Research Flume at the National Research Council (NRC) in Ottawa. Observations were made under regular waves of 3.5 s period with heights ranging from 20 to 70 cm. Direct measurement of sediment flux is made possible using 1.7 MHz pulse-to-pulse coherent sonar which determines concentration from acoustic backscatter levels and velocity using acoustic Doppler. Operating over a 0.8 m range, velocity profiles with 1.4 cm range resolution and a 0.5 cm s⁻¹ vertical velocity accuracy can be made at a rate of 30 profiles per second. We find that there is an apparent balance between the mean downward flux of sediment and the upward flux due to turbulent motions. The component of (upward) vertical flux caused by wave action is small compared to the turbulent and mean components. Profiles of turbulence intensity are provided by the vertical velocity fluctuations, these profiles show a rapid rise to a peak value within 5 cm of the bottom and then a subsequent decrease. The (near bottom) peak value of root-mean-square vertical velocity fluctuations are equal to the friction velocity characteristic of the bottom boundary layer. The decrease in turbulence with height above the bottom shows behavior consistent with the decrease in grid generated turbulence but appears sensitive to the length scales of the bed-forms rather than sand grain roughness.

2 INTRODUCTION

Knowledge of the vertical distribution of suspended sediment is required to model the transport of sediment due to wave action. In order to better understand the contributions of turbulent motions to the sediment suspension process coincident measurements of suspended particle concentration and velocity must be made. Such observations are lacking and are particularly needed for comparison with model predictions.

We present acoustic measurements of vertical velocity and suspended sediment concentration using a coherent Doppler sonar (Zedel et al. 1996). The 1.7 MHz, Dopbeam system was configured to provide velocity profiles with 1.4 cm range resolution and a 0.5 cm s\(^{-1}\) vertical velocity accuracy at a rate of 30 profiles per second. Concentration measurements are acquired at the same time and location through calibration of the acoustic backscatter levels to absolute concentrations for the sediment samples used. The Dopbeam system has been calibrated using a sediment laden turbulent jet as described by (Hay 1991).

The measurements were made in the Wave Research Flume at the National Research Council (Ottawa), Canada. This facility has a length of 100 m, a width of 2.0 m and was filled to a water depth of 1.8 m. A 10 cm thick layer of 150 μm (sorted) sand was deposited through a 20 m long test section. Observations were made with regular and irregular waves with nominal heights of 20 to 70 cm.

3 VERTICAL FLUX

The vertical flux of sediment can be expressed as:

\[
F = <\tilde{w}c + \tilde{w}'c' + w'c'>
\]  

where \(w\) is the vertical component of velocity, \(c\) is the concentration, the tilde and prime refer to wave and turbulent components respectively, \(<>\) indicates a time average. The three terms on the right hand side of Equation (1) represent mean, wave induced, and turbulent vertical flux respectively: each of these terms are evaluated from the amplitude and Doppler shift of the backscattered signal as a function of height above the bed.

The mean component of flux results from the mean settling velocity and the concentration structure. In general, the mean flux component will depend on changes in concentration and velocity. One approach to modeling this component is to assume that the mean velocity is fixed at the free descent velocity of the particles (Nielsen 1992). For the present observations, where the particles have uniform size, we might expect mean velocities to be constant with height. Fig. 1 shows concentration profiles (Fig. 1a) and mean vertical velocities (Fig. 1b) for the present observations. The concentration profiles show the expected logarithmic form decreasing with height above the bottom. The velocities however are notable in that the mean downward velocity is not constant with height. In particular, there is a consistent trend for the mean velocity to decrease with proximity to the bottom in a region extending to within 5 cm of the bottom. Based on these observations, the assumption of a uniform mean velocity is not appropriate.

Wave components were isolated by selectively averaging data according to the wave phase, the turbulent components were then determined as the residual after mean and wave components were removed. We find that the sum of these flux terms is approximately balanced as is shown by the example in Fig. 2. The averaged mean flux is downward (settling) with the wave and turbulent flux being in an upward direction. The wave component of flux is relatively small and thus an approximate balance exists between the turbulent upward flux and the mean downward settling flux.

4 TURBULENCE INTENSITY

The energy driving sediment upward from the bottom is derived from turbulent fluid motions. This energy can be parameterized in terms of the friction velocity $u_\ast$. A parametric estimate of friction velocity can be determined from sand grain roughness, wave amplitude and frequency (Nielson 1992),

$$u_\ast = \frac{\sqrt{f_w}}{2 A \omega}$$  \hspace{1cm} (2)

where $\omega = 2\pi/T$, $T = 3.5$ s is the wave period, $A$ is the wave orbital excursion and $f_w$ is the friction factor computed as,

$$f_w = \exp(5.5(r/A)^2 - 6.3)$$  \hspace{1cm} (3)

with $r = 150$ $\mu$m the sand particle diameter. Values for this parametric estimate of friction velocity are listed under $u_\ast$ in Table 1 along with bed form characteristics and wave heights.
Figure 2: Profiles of mean, wave, turbulent and total sediment flux. Profiles are based on a 6 minute data sample under regular, 3.5 s period waves of 60 cm height.

Table 1: Summary of trials under 3.5 s period waves with heights indicated as H; $u_*$ is the friction velocity computed from parameterizations of wave height, $u_*(\text{sediment})$ is based on the near bottom profile of suspended sediment (Sheng and Hay, 1995), $w'_{\text{max}}$ refers to the maximum observed variance in vertical velocity observations. Bedforms are indicated by $R_l, R_s, X$, and $F$ for long crested, short crested, cross ripples, and flat bed respectively, $b(\text{parametric})$ and $b(\text{observed})$ are the predicted (see 5) and observed slope in $1/ <w'_{\text{rms}}>$ profiles.

Values of $u_*$ can also be estimated from the observations through the slope of the suspended sediment concentration following the approach used by Sheng and Hay (1995). Table 1 compares the values of $u_*$ derived from this technique ($u_*(\text{sediment})$ in Table 1) with parameterizations based on the waves
and grain roughness (Nielsen, 1992) ($u_*$ in Table 1).

An independent indicator of the turbulence characteristics of the boundary layer is provided in the present observations by profiles of $<w'_{rms}>$: example profiles are shown in Fig. 3a. Nielsen (1992, p. 72) reports that peak values of $<w'_{rms}> = 0.5u_*$ occurring at a height approximately equal to the top of the roughness elements. Similar relations are also seen in unidirectional boundary layer flow (Tennekes and Lumley, 1972 p. 162). The peak values of $<w'_{rms}>$ in the present observations are very close to the parametric estimates of friction velocity as well as those based on concentration profiles (see the values listed as $w'_{max}$ in Table 1).

![Figure 3: a) Profiles of $<w'_{rms}>$ and b) $1/<w'_{rms}>$ as observed under 3.5 s period waves of height 20, 40, 60 and 70 cm indicated by ○, ×, +, and * respectively.](image)

An important aspect of the data summarized in Table 1 is the apparent response to changing bedforms. In particular, the decrease in the observed indicators of friction velocity ($u_*$ (sediment), and $w'_{max}$ in Table 1), that occurs between 60 and 70 cm wave heights coincides with the disappearance of small scale bedforms. The associated change in roughness is not accounted for in the
parametric estimate of friction velocity but it is clearly important to regulating
the turbulent contribution to sediment flux.

5 TURBULENCE DECAY

Sleath (1991) suggests that oscillatory boundary layers can be modeled
after the turbulence generated by an oscillating grid. Such a model is qualita-
tively consistent with the present observations where $< u'_{rms} >$ decreases with
height beyond a point of maximum value near the bottom. Following Sleath’s
model, the turbulent intensity should decrease with distance from the bottom
according to the relation (Sleath, 1991),

$$1/ < u'_{rms} > = b z$$

with

$$b = KA^{-3/2}r^{-1/2}T$$

where $A$ is the wave orbital excursion, $r$ is the bottom roughness (here we
have set $r = \lambda_r$ because use of the sand grain roughness gave extremely in-
consistent results), and $K \approx 6.29$ is a constant. Values for the expected slopes
from (5) are indicated as b(parametric) in Table 1. Figure 3b shows observed
values of $1/ < u'_{rms} >$ plotted as a function of height above the bottom for
trials under wave heights of 20, 40, 60 and 70 cm. There is a well defined
section where a straight line fit to the data is achieved. The slope from lin-
ear regression fits to this region (indicated by straight line segments in Fig.
3b), are identified in Table 1 as b(observed). Approximate agreement between
predictions of (5) and the observations is seen for some of the trials, but in
general, there are significant differences. In particular, at low wave energies,
the value of $b$ predicted by (5) is larger than the observations by a factor of
3 indicating that turbulence does not decay with height as rapidly as expected
based on the grid turbulence model.

6 DISCUSSION

Doppler velocity estimates represent a backscatter strength weighted aver-
age over the velocity of any scatterers present in the sample volume. When
Doppler sonar is used to measure water velocities, it is necessary to assume
that the motion of the scattering particles is representative of the water mo-
tion as a whole. For the present application, the velocities observed will be
those of the uniformly sized (150 $\mu$m diameter) sand particles added to the
tank. Only when the concentration of these particles is extremely low will the
small bubbles and dust particles in the tank provide an estimate of the water
velocity itself. As a result, the mean vertical velocities shown in Fig. 1 are a
direct measure of the in-situ settling velocity of the suspended sand particles.

The settling velocity for spherical particles can be calculated using Stokes
law,

$$w_s = \frac{(s - 1)gd^2}{18\nu}$$

where $s = 2.7$ is the relative density of the particle, $d$ is the particle diameter
($d = 150 \mu$m for the present sand particles), $g$ is the acceleration of gravity and
$\nu$ is the viscosity ($\nu = 1.0 \times 10^{-6}$ m$^2$s$^{-1}$). For the present $d = 150 \mu$m sand
particles, $w_s \approx 2.0$ cm s$^{-1}$. 

Settling velocities of 2 to 3 cm s\(^{-1}\) were observed at heights of between 10 and 20 cm for the 60 and 70 cm height wave runs (Fig. 1b). These values are consistent with the prediction of the Stokes settling velocity given by (6). The low velocities seen in this depth range for lower wave heights are most likely caused by the low particle concentrations (\(\approx 10^{-2} \text{ g l}^{-1}\)) that occur (see Fig. 1). Under such circumstances, the backscatter from small contaminants in the water would provide an adequate signal such that the true water velocity would be obtained.

In all cases, the mean velocity goes to zero as the bottom is approached. These decreased settling velocities clearly have a significant impact on the concentration profiles. The cause of the reduced velocities is not obvious but some disturbance is expected due to the presence of bedforms. These bedforms could not however account for the gradual transition to zero velocity that is observed. It is very likely that these near bottom reduced settling velocities are related to the presence of turbulence as described by Murray (1970).

Profiles of mean turbulent intensities based on values of \(< w'_{\text{rms}} >\) demonstrate a rapid increase from 0 at the bottom to a peak value within 5 cm of the bottom and then an asymptotic decrease with greater height. In the present observations, \(\max(< w'_{\text{rms}} >)\) is clearly proportional to friction velocity, but it appears to vary as an equality; that is \(\max(< w'_{\text{rms}} >) = u_*\) (see Table 1). It is possible that the present observations do not resolve velocities close enough to the bottom to recover the true peak values. If this were the case, one would expect that the proportion of the fluctuations seen would change with the bed-form dimensions. No such dependence is seen and so we feel that we are sampling a consistent maximum in velocity fluctuations. It is also possible that the sonar system does not resolve the total turbulent spectrum. We consider this explanation unlikely as well because the ‘red’ nature of turbulent spectra places most of the energy at lower frequencies, (and larger scale structures) which the Dopbeam system does resolve.

7 CONCLUSIONS

Through the use of combined Doppler sonar and acoustic backscatter measurements it has been possible to make simultaneous estimates of particle velocity and concentration. This combination of measurements allows for direct observation of particle flux. Phase averaging under regular waves (possible in the tow tank test facility) allows the discrimination of both turbulent and wave components of flux \((w'c' + \bar{w}\bar{c})\) in addition to the mean (downward) flux.

The assumption of a balance between the upward wave and turbulence induced flux with the mean downward flux is fundamental to most models of vertical sediment transport (see for example Lee and Hanes, 1996). We have demonstrated that such a balance does exist in the present data. Previous estimates of the downward flux term have been made from independent measurements of particle descent rate and concentration: a common assumption is that the particle descent rate is given by the free descent rate of the particles (Sheng and Hay, 1995). This assumption appears to hold for most of the water column but breaks down within 5 cm of the bottom in the present observations.

The turbulent velocity represented by \(< w'_{\text{rms}} >\) peaks a small distance above the bed (within 5 cm in the present observations). At heights above the peak value, \(< w'_{\text{rms}} >\) decays as 1/height, consistent with Sleath (1991).
The near bottom peak values of $<w'_{rms}>$ are equal to the friction velocity characteristic of the bottom boundary layer (as estimated parametrically and from the concentration profile). We conclude that the direct observation of $<w'_{rms}>$ possible with the coherent Doppler system is an effective means of estimating friction velocity.

The three separate estimates of friction velocity (based on the sediment diffusivity, the wave parameters, and the $<w'_{rms}>$ measurements) are all consistent. The slight decrease in friction velocity occurring in the diffusivity and $<w'_{rms}>$ based estimates when going from the 60 cm to 70 cm wave height at first appears inconsistent. However, the fact that both of these direct observations show the same behavior supports their accuracy. The bed-form observations for these two wave conditions show that they correspond to the transition from cross ripples to 'mega-ripples'. The 'mega-ripples' result in a much reduced mean bottom slope and associated with this reduced bottom slope we would expect a reduced efficiency in turbulence generation. While the data is clearly limited, we believe that the reduced friction velocity is accurately being observed and is associated with the changing bed-forms. The parametric estimate of friction velocity (which ignores bed-forms) matches the observations reasonably well. This close agreement indicates that (in the present case), while bedforms effect the turbulence generation they do not account for a large contribution to turbulence important to sediment suspension.

Eddy Viscosity Models for Wave Boundary Layers

Ole Secher Madsen¹, M. ASCE, and Paulo Salles²

Abstract

Motivated by recent experimental results on wave, current and combined wave-current flows over an artificially rippled bed, the boundary resistance experienced by waves over two-dimensional bottom roughness elements is formulated in terms of a drag law. The resulting empirical relationship for the drag coefficient suggests a flow resistance that is similar in nature to one obtained from a constant, pseudo-laminar eddy viscosity model for the wave boundary layer flow. Analysis of available experimental data on energy dissipation for oscillatory flow over movable rippled beds leads to a constant eddy viscosity model for wave boundary layers above naturally rippled beds. The constant eddy viscosity model is modified to include a near-bottom linear transition to make it zero at the bed. This hybrid eddy viscosity model is shown to capture the essential features of wave boundary layer flows for the full range of bottom roughnesses encountered, i.e. from sand grains to ripples. Application of the hybrid model requires knowledge of the equivalent bottom roughness for which empirical expressions are derived. The implication of the results, obtained here for waves, for combined wave-current boundary layer flows suggests modifications of the Grant-Madsen model that greatly improve this model’s ability to predict observed current velocity profiles over rippled bottoms in the presence of waves.

Introduction

In recent papers Mathisen and Madsen (1996a and b, hereafter referred to as MM) reported results from laboratory experiments on currents and waves, separately as well as combined, over a bottom covered by fixed equally spaced 1.5-cm-high triangular two-dimensional roughness elements. The major result of their study was that waves and

¹ Professor and ² Graduate Student, R. M. Parsons Laboratory, Department of Civil and Environmental Engineering, Massachusetts Institute of Technology, Cambridge, MA 02139, USA
currents perpendicular to the axes of their artificial ripples experience the same equivalent bottom roughness, i.e., the equivalent bottom roughness, \( k_N \), was shown to be a function of the bottom roughness characteristics only and independent of the flow. Besides being limited to the particular flow conditions of their experiments, i.e. wave, current and combined co-directional wave-current flows perpendicular to fixed two-dimensional roughness elements, their conclusion of \( k_N \)'s single-valuedness is limited to analyses of these flows based on a modified version of the Grant-Madsen model (Grant and Madsen, 1979 and 1986; hereafter referred to as GM) since this model was used by MM in their analysis of experimental data.

To make this latter limitation more explicit, and also to introduce concepts and notation to be used in subsequent sections, MM obtained experimental values for the average rate of energy dissipation per unit bottom area, \( D \), from measurements of wave attenuation and expressed \( D \) in terms of turbulent wave bottom boundary layer theory,

\[
D = \frac{1}{4 \rho} f_w \cos \phi \frac{u_m^3}{\tau_{m0}} = \frac{1}{4 \rho} f_e \frac{u_m^3}{\tau_{m0}}
\]

in which \( \rho \) denotes the fluid density; \( f_w \) is the wave friction factor defined by

\[
\frac{\tau_{m0}}{\rho} = u_m^2 = \frac{1}{2} f_w \frac{u_m^2}{\tau_{m0}}
\]

where \( \tau_{m0} \) is the maximum bottom shear stress; and \( \phi \) is the phase lead of the bottom shear stress relative to the periodic near-bottom wave orbital velocity

\[
u_b = u_m \cos \omega t
\]

Thus, from their experiments MM obtained values for the energy dissipation factor, \( f_e = f_w \cos \phi \), which, in turn, may be related to the relative bottom roughness, \( u_m/(k_N \omega) \), through the use of a theoretical model for turbulent wave boundary layer flows over a rough bottom. In taking this last step, which leads to the determination of the equivalent bottom roughness, \( k_N \), MM found it necessary to modify the GM model in order to obtain the \( k_N \)-values that were in agreement with the values obtained from analysis of measured current velocity profiles over the same bottom roughness configuration. This modified version of the original GM-model has been presented by Madsen (1994) and consists of the determination of the wave friction factor, \( f_w \), and the phase lead, \( \phi \), by evaluating the bottom shear stress at \( z = z_0 = k_N /30 \), where \( z \) is the vertical distance above the theoretical bed level, instead of in the limit \( z \rightarrow 0 \).

However, when the modified GM-model is used to predict the structure of the wave orbital velocity profile within the wave boundary layer this is found to be in poor agreement with measurements. In particular, the GM-model’s prediction of the wave boundary layer thickness

\[
\delta_w = A \frac{k_N u_m}{\omega}
\]
in which $\kappa$ is von Karman's constant ($=0.4$) and $A$ is a scaling factor given the value of 1 to 2 by GM, is found to be too small by a factor of 2 to 3 when compared with measurements. This disturbing observation has profound implications for the GM-model's ability to predict the velocity profile of currents in the presence of waves, since $z=\delta_w$ is the location where the eddy viscosity is assumed to change from being scaled by the wave-current shear velocity, $u_{rm}$, to being scaled by the generally much smaller current shear velocity, $u_c$. Thus, in order to obtain a reasonable agreement between predicted and observed current velocity profiles in the presence of waves, MM found it necessary to introduce an artificially "enhanced" wave boundary layer thickness. This apparent inability of the GM-model to predict the velocity structure as well as the thickness of the wave boundary layer for flows over a rippled bottom motivated the present study.

**Drag Law Formulation and its Implications**

In an attempt to break with the conventional treatment of wave boundary layer flows based on an eddy viscosity formulation, we express the flow resistance experienced by an oscillatory flow over a bottom covered by two-dimensional ripples in terms of the drag force exerted on the flow by the individual roughness elements. Formally, we may write this drag force per unit length

$$F_D = \frac{1}{2} \rho C_D \eta |u_b|^3$$

in which $\eta$ is the height of the ripple, $u_b$ is the wave orbital velocity given by (3), and $C_D$ is a drag coefficient. Assuming this drag force to dominate the flow resistance, i.e. neglecting the contribution of skin friction shear stress acting directly on the bottom between roughness elements (ripple crests), the rate of energy dissipation associated with this drag force is given by $F_D u_b$. Since this represents the rate of energy dissipation per roughness element, we obtain the time average rate of energy dissipation per unit area

$$D = \frac{\bar{F}_D u_b}{\lambda} = \frac{2}{3\pi} \rho C_D \frac{\eta}{\lambda} |u_{km}|^3$$

where "overbar" denotes time-averaging and $\lambda$ the ripple spacing (length). In passing it is noted that the neglect of a potential inertia force has no effect on the calculated average energy dissipation rate since this force would be proportional to $\partial u_b / \partial t$ and hence time-average to zero.

Comparison of the expressions obtained from conventional boundary layer theory, (1), and drag law formulation, (6), shows that

$$C_D = \frac{3\pi}{8} (\lambda/\eta)f_e$$

Thus, the experiments on wave attenuation performed by MM, which provide values of $f_e$ for given $\lambda$ (10 or 20 cm) and $\eta$ (1.5 cm), may be used directly in (7) to obtain
experimental values for the drag coefficient, $C_D$, for waves over the artificially rippled bed. In analogy with drag coefficients for circular cylinders, e.g. Sarpkaya and Isaacson (1981), one would expect the drag coefficient to be a function of a Reynolds number, $Re$, and a Keulegan-Carpenter number, $KC$. Recognizing that the roughness elements in the experiments performed by MM were 90° angle iron bars placed on the glass bottom of a flume, i.e. effectively corresponding to half cylinders, the equivalent “diameters” of their two-dimensional roughness elements is $2\eta$. Therefore, one would be seeking an empirical expression of the form

$$
C_D = C_D \left( Re = \frac{2\eta u_{bm}}{v}, KC = \frac{u_{bm} T}{2\eta} = \pi \frac{A_b}{\eta} \right)
$$

where $v$ is the kinematic viscosity of water and $A_b = u_{bm}/\omega = u_{bm} T/(2\pi)$ is the near-bottom wave orbital excursion amplitude.

For the experiments performed by MM the range of Reynolds Numbers is $(3$ to $6).10^3$, i.e. a range for which $Re$-dependency is expected to be weak. As seen from the values of $C_D$ plotted against $\eta/A_b$ in Figure 1, the excellent correlation supports this anticipation and results in the empirical drag coefficient relationship given by

$$
C_D = C_{Do} \frac{\eta}{A_b} = 9.0 \frac{\eta}{A_b}
$$

For the experiments performed by MM the range of Reynolds Numbers is $(3$ to $6).10^3$, i.e. a range for which $Re$-dependency is expected to be weak. As seen from the values of $C_D$ plotted against $\eta/A_b$ in Figure 1, the excellent correlation supports this anticipation and results in the empirical drag coefficient relationship given by

$$
C_D = C_{Do} \frac{\eta}{A_b} = 9.0 \frac{\eta}{A_b}
$$

---

Figure 1: Ratio of the ripple height over the bottom excursion amplitude, $\eta/A_b$, as a function of the drag coefficient, $C_D$. Experimental values (stars) and linear fitting (solid line). The coefficient of determination is $r^2 = 0.87$. 
The limitation of this relationship to the experimental range of $\eta/\lambda_b$ values from which it is obtained should be kept in mind. Extension beyond this range leads to obvious errors, e.g. $C_D \to 0$ or $\infty$ as $\eta/\lambda_b \to 0$ or $\infty$. However, for the range covered by (9) the dependency of $C_D$ on $\eta/\lambda_b$ is similar to the dependency on Keulegan-Carpenter number for circular cylinders and $Re = 10^4$ (Sarpkaya and Isaacson, 1981, Figure 3.15; Salles, 1997).

A Pseudo-Laminar Eddy Viscosity Model

When the empirical drag coefficient relationship, (9), is introduced in the drag law expression for the rate of energy dissipation, (6), and $u_{bm} = \lambda_b \omega$ is utilized one obtains

$$D = \rho \left( \frac{2}{3\pi} C_{D_0} \frac{\eta^2}{\lambda} \right) \omega u_{bm}^2 \quad (10)$$

This form of the average dissipation rate, in particular, its proportionality to the square of the wave orbital velocity, resembles the expression obtained from a laminar or constant eddy viscosity model of oscillatory boundary layers, e.g. Jonsson (1966)

$$D = \rho \left( \frac{1}{4} \sqrt{2\nu_c / \omega} \right) \omega u_{bm}^2 \quad (11)$$

in which $\nu_c$ denotes the value of the constant viscosity.

Equating (10) and (11) leads to a functional relationship for an equivalent constant, pseudo-laminar eddy viscosity

$$\nu_c = \left( \frac{8}{3\pi} C_{D_0} \right)^2 \frac{\eta^4}{\lambda^2 T} \equiv 180 \frac{\eta^4}{\lambda^2 T}$$

$$\quad (12)$$

where $C_{D_0} = 9.0$, obtained from MM’s experiments, was introduced. With a constant eddy viscosity, the classical solution of Stokes gives the wave orbital velocity profile as the real part of the complex expression ($i^2 = -1$)

$$u_w = (1 - e^{-\delta/\delta}) u_{bm} e^{i\omega t} \quad (13)$$

with

$$\delta = \sqrt{2\nu_c / \omega}$$

$$\quad (14)$$

denoting the boundary layer scale.

The wave boundary layer thickness, $\delta_w$, is obtained by requiring the orbital velocity to approach the free stream velocity to within a small, but finite, fraction, $\varepsilon$, of the free stream velocity. Defining $\delta_w$ in this manner and making use of (13) and (14) results in

$$\delta_w = (-\ln \varepsilon) \delta = \begin{cases} 3.0 & \text{for } \varepsilon = 5\% \\ 4.6 & \text{for } \varepsilon = 1\% \end{cases}$$

$$\quad (15)$$
Figure 2 demonstrates that the pseudo-laminar wave orbital velocity profile obtained from (13) and (14) with $v_c$ given by (12) is in excellent agreement with the measurements obtained in MM's experiment "a". This agreement includes the prediction of the wave boundary layer thickness, the scale of which is obtained from (14) with $v_c$ given by (12) ($\delta = 7.6 \eta^2/\lambda = 1.7$ cm). From (15) it follows that $\delta_n$ is of the order of 5.1 to 7.8 cm for the $\lambda = 10$ cm spacing of the individual roughness elements, in agreement with MM's "enhanced" wave boundary layer thickness of 6.0 cm.

![Velocity Amplitude Profiles](image)

Thus, the pseudo-laminar model is capable of not only predicting the observed wave attenuation – an ability that is, of course, assured since $v_c$ was derived to produce exactly this result – but also the detailed velocity structure within and the thickness of the wave boundary layer.

Mathisen and Madsen (1996a and b) chose the geometry of their artificial ripples, $\eta = 1.5$ cm and $\lambda = 10$ cm, in accordance with observed ripple geometry for similar wave conditions to those in their experiments. Differences between the detailed geometry of natural and MM's artificial ripples may, however, prevent the success of the pseudo-
laminar model to be transferred to naturally rippled beds. Guided by our results from analysis of MM's data, equating the expressions for the rate of energy dissipation given by (1) and (11), with \( v_c \) depending on ripple geometry as suggested by (12), we obtain

\[
v_c = v_{co} \frac{\eta^4}{\lambda^2 T} = \frac{1}{4\pi} T \left( \frac{\lambda}{\eta} \right)^2 u_{hm}^2
\]

(16)

Following the suggestion of (16) we plot experimental values of ripple geometry and energy dissipation for experiments with waves over naturally rippled beds in Figure 3, from which we obtain a best fit value of the constant \( v_{co} = 95 \) in (16), with a standard deviation of 53. Not surprisingly, the eddy viscosity for naturally rippled beds is not as well defined as the one obtained for the artificial ripples. Nevertheless, the result that \( v_{co} \) is smaller for natural ripples than for artificial ripples is statistically significant and does make physical sense since one would expect the more rounded crests of the natural ripples to result in a smaller rate of energy dissipation and hence a smaller eddy viscosity.

Figure 3: Eddy viscosity \( \nu' = (8/3\pi^2)v_c \) as a function of \( \eta^4/(\lambda^2 T) \). Both quantities are in \( (cm^2.s^{-1}) \). Experimental data from Carstens et al. (1969) (pluses), Lofquist (1986) (circles), Rosengaus (1987) and Mathisen (1989) (crosses). The linear fitting (solid line) has a coefficient of determination \( R^2 = 0.70 \).

From a practical point of view, the difference between the values of \( v_c \) for artificial and natural ripples may be less significant, when one considers the fact that the data plotted in
Figure 3 used observed ripple geometry. For application, one would have to use predicted values of \( \eta \) and \( \lambda \) in the empirical expression for \( v_c \), (16). Our current ability to predict geometry of wave generated ripples is unfortunately such that a potential factor of 2 variability in \( v_{co} \) in (16) is overshadowed by the uncertainty associated with the prediction of \( \eta^4/\lambda^2 \).

Detailed velocity profile measurements are not available within the wave boundary layers over naturally rippled beds. The similarity of the expressions obtained for \( v_c \) suggests, however, that one may expect the pseudo-laminar eddy viscosity model to afford reasonably accurate predictions of the velocity structure within the wave boundary layer over naturally rippled beds.

**A Hybrid Eddy Viscosity Model**

The constant eddy viscosity model presented in the preceding section can be considered valid only for the very large bottom roughness values corresponding to rippled beds. It will neither predict a phase lead of the bottom shear stress different from \( \pi/4 \) or a near-bottom logarithmic wave orbital velocity profile, both of which are experimentally observed features for wave boundary layer flows for smaller values of the relative roughness. These features are, however, predicted by simple wave boundary layer models that employ an eddy viscosity that, near the bottom, increases linearly with distance above the theoretical bottom, e.g. Hsu and Jan (1998).

A hybrid eddy viscosity model that captures the observed features of wave boundary layer flows for small as well as large relative bottom roughness values is chosen as

\[
\nu_t = \begin{cases} 
\kappa\mu_{sm}(z + z_0), & 0 \leq z \leq z_m \\
\kappa\mu_{sm}(z_m + z_0), & z > z_m
\end{cases}
\]

(17)

in which \( z_0 = k_N/30 \) is the hydraulic bottom roughness, and \( \mu_{sm} \) is defined by (2). In (17) the value of \( z_m \), the elevation above which the eddy viscosity is considered constant, is chosen as

\[
z_m = 0.5 \frac{\kappa\mu_{sm}}{\omega}
\]

(18)

For this choice of \( z_m \) the constant value of the eddy viscosity given by (17) is roughly the same as the pseudo-laminar viscosity given by (12) for the experiments of MM. Furthermore, this value of \( z_m \) coincides with value chosen by Madsen and Wikramanayake (1991) who showed this choice to lead to acceptable agreement between predicted and observed velocity structures within the wave boundary layer for relative roughness, \( k_N/A_b \), smaller than \( O(10^{-1}) \).

Solving the linearized boundary layer equation with the eddy viscosity prescribed by (17) and evaluating the maximum bottom shear stress at \( z = 0 \) determines the relationship between wave friction factor and the relative bottom roughness. Approximating this
relationship in a manner analogous to that utilized by Madsen (1994) we obtain explicit expressions for the wave friction factor $f_w$ and the phase angle $\varphi$ (in degrees)

$$f_w = \exp\left\{8.89\left(\frac{A_b}{k_N}\right)^{-0.059} - 10.68\right\}$$

$$\varphi = 38 - 8.3\log\frac{A_b}{k_N}$$

(valid for the range $0.2 < A_b/k_N < 10^2$. For larger values of $A_b/k_N$ the formulas given by Madsen (1994) may be used.

From the experimental value of $f_e = f_w \cos \varphi$ obtained by MM the equivalent bottom roughness, $k_N$, is obtained from (19). The predicted wave orbital velocity profile obtained from the hybrid eddy viscosity model, given by (17) is shown in Figure 2, and is virtually indistinguishable from the velocity profile predicted by the pseudo-laminar model.

The hybrid eddy viscosity model requires knowledge of the equivalent bottom roughness in order to be applied. Thus, to make the model applicable for the prediction of wave boundary layer flows over naturally rippled beds, an empirical relationship for $k_N$ is required. Such a relationship is obtained by assuming it to be of the form

$$k_N = \left\{ \begin{array}{ll}
\frac{\alpha \eta}{\beta (\eta/\lambda) \eta} & \\
\end{array} \right.$$

and determine the best fit values of $\alpha$ and $\beta$ by fitting the experimental data on rate of energy dissipation over naturally rippled beds using the experimentally measured ripple characteristics. This exercise results in values of $\alpha = 12$ and $\beta = 78$, with both formulations providing a fit of equal goodness to the data used.

The experimentally obtained values for $f_e$ are plotted against $A_b/k_N$, with $k_N = 12 \eta$, in Figure 4. The relationship, $f_e(A_b/k_N)$, obtained from (19) is shown for comparison, and represents the experimental data with a coefficient of variation of 28%. This accuracy of the hybrid eddy viscosity model is similar to that of the pseudo-laminar model. For the pseudo-laminar model we obtained a coefficient of variation for $v_c$ of $53/95 = 0.56$ which is roughly twice the coefficient of variation for the prediction of $f_e$ since $f_e \propto \sqrt{v_c}$ for the pseudo-laminar model. Again, it is emphasized that the accuracy of 28% for the prediction of the energy dissipation factor when $k_N$ is obtained from (20) is likely to be an optimistic value when $\eta$ is predicted rather than measured. Finally, it should be pointed out that the seemingly very large value of $\alpha = 12$ is obtained as a result of using (19), which is the friction factor relationship obtained by evaluation of the bottom shear stress at $z + z_0 = \zeta_0$. For a model that uses a near-bottom eddy viscosity proportional to $z$ instead of $(z + z_0)$ this corresponds to evaluation of the shear stress at $z = \zeta_0$ instead of in the limit $z \rightarrow 0$. The original GM-model, if applied to the data shown in Figure 4 would therefore lead to different best fit constants in (20). In fact, for the GM-model with the shear stress evaluated in the limit $z \rightarrow 0$, one obtains values of $\alpha = 4$ and $\beta = 25$, i.e. roughly a factor of three lower than the best fit values obtained for the hybrid eddy viscosity model.
Figure 4: Measured and predicted energy dissipation factors, $f_e$, as a function of relative roughness, $A_b/k_N$. Theoretical values using (19) with $k_N = 12 \eta$ (solid line); data from Carstens et al. (1969) (pluses), Lofquist (1986) (circles), Rosengaas (1987) and Mathisen (1989) (crosses).

**Modified Grant-Madsen Wave-Current Interaction Model**

If one is willing to sacrifice a little accuracy in the prediction of the velocity structure within the wave boundary layer for the sake of simplicity, one may adopt a linearly increasing eddy viscosity throughout the wave boundary layer. In this case the eddy viscosity reduces to the first expression given by (17) and the wave orbital velocity within the wave boundary layer is simply that predicted by Madsen (1994) with the origin of $z$ taken a distance $z_0$ below his theoretical bed elevation. This effectively changes Madsen’s (1994) eddy viscosity length scale from his “z” to the value $z+z_0$ used in (17). Except for this change, all formulas obtained by Madsen (1994) are still valid. To achieve a measure of the accuracy one sacrifices if adopting this simplification, the predicted wave orbital velocity profile of this modified GM-model is show in Figure 2. Obviously, either the pseudo-laminar or the hybrid eddy viscosity models provide a better fit to the experimental data shown in Figure 2 than does the modified GM-model. However, the GM-model does provide a reasonably accurate (better than 10% error) representation of observations for this large bottom roughness,
Given the modified GM-model’s ability to represent the velocity structure within the wave boundary layer, it is extremely surprising that the model’s prediction of the wave boundary layer thickness is as poor as it is for the experiments by MM involving artificial ripples. This inability of the modified GM-model was discussed in the Introduction, where it was mentioned that the GM-model estimated the wave boundary layer thickness from (4) with a scaling factor $A$ between 1 and 2, which for MM’s experiment “a” shown in Figure 2 gives $\delta_w = 2.5$ cm – clearly a value much lower than the wave boundary layer thickness suggested by the data.

This inability of the GM-model to afford an accurate estimate of $\delta_w$ and hence, for combined wave-current flows, the elevation at which the current profile exhibits a discontinuous slope in the presence of waves, is actually not an inability of the model but the result of an unfortunate oversight on the part of the model’s authors. The estimate of the scaling factor $A$ in (4) being of the order of 1 to 2 was originally derived by Grant and Madsen by considering the elevation above the bottom where the wave orbital velocity had reached the free stream velocity within a relative error of roughly 5%. This, of course, is a completely legitimate criterion to use for the definition of a wave boundary layer thickness. However, GM failed to recognize that their value of $A$, which they obtained for a relative roughness $k_	heta / A_b \approx 0.01$, should be considered a function of the relative roughness and not be treated as a generally valid constant. When one corrects this oversight by defining the wave boundary layer thickness as the value of $z$ for which the velocity magnitude is within 5% of the free stream velocity, the resulting value of the scaling factor in (4) may be expressed as

$$A = \exp\left\{2.96\left(A_b/k_N\right)^{-0.071} - 1.45\right\} \quad (21)$$

For $A_b/k_N = 100$ this formula gives $A = 2.0$ in agreement with the original GM-value. However, for $A_b/k_N = 0.35$, which is representative of the relative roughness values in the MM experiments over artificially rippled beds, $A = 5.7$ is obtained from (21), i.e. an increase by a factor of roughly 2.8 over the value obtained if $A = 2.0$ is assumed independent of the relative roughness.

Use of (21) in conjunction with (4) to obtain the wave boundary layer thickness and modifying the GM-model’s prediction of current velocity profiles in the presence of waves accordingly completely removes the need for the artificially “enhanced” wave boundary layer thickness introduced by Mathisen and Madsen. The modified GM-model can be used directly to explain and analyze observations for combined co-directional wave-current flows over a rippled bed so long as it is corrected to account for the wave boundary layer scaling factor’s dependency on relative roughness.

**Conclusions**

From a drag law formulation of the boundary resistance experienced by waves over an artificially rippled bottom, we were led to the establishment of a constant pseudo-laminar eddy viscosity formulation for wave boundary layer flows over rippled bottoms. For naturally rippled bottom, analysis of available experimental data suggests the adoption of a pseudo-laminar eddy viscosity given by
\[ v_c = v_{co} \frac{\eta^4}{\lambda^2 T} \]  \hspace{1cm} (22)

in which \( v_{co} = O(100) \), \( \eta \) and \( \lambda \) are the ripple height and length, respectively, and \( T \) is the wave period.

The pseudo-laminar model should be considered limited to the flow conditions corresponding to the existence of two dimensional wave-generated ripples covering the bottom. To establish a model that could be considered generally valid for the range of bottom roughness encountered by waves over a movable bottom, a hybrid eddy viscosity model was developed. For this model, given by (17), the constant eddy viscosity was reduced towards zero through a linear transition immediately above the bottom. The velocity structure within the wave boundary layer predicted by the hybrid eddy viscosity model was shown to be virtually identical to the predictions of the pseudo-laminar model for rippled beds. However, the hybrid model is, in contrast to the pseudo-laminar model, capable of predicting observed velocity features for small values of the bottom roughness. For wave boundary layer flows over naturally rippled bottoms, the bottom roughness, \( k_N \), needed to apply the hybrid eddy viscosity model was found, from laboratory experiments with simple periodic wave motions, to be related to the ripple height through

\[ k_N = 12\eta \]  \hspace{1cm} (23)

Both the pseudo-laminar and the hybrid eddy viscosity models gave estimates of the wave boundary layer thickness that were in good agreement with observations for artificially rippled beds. An unfortunate oversight in the development and application of the Grant-Madsen model for combined wave-current flows over very rough bottoms was corrected by introducing a roughness-dependent scaling factor, \( A \), given by (21). Following this correction, the artificially “enhanced” wave boundary layer thickness introduced by Mathisen and Madsen (1996b) to explain and analyze their experimental results for combined co-directional wave-current flows over artificially rippled bottoms, was found to be entirely unnecessary. Thus, the applicability of the corrected Grant-Madsen wave-current interaction model to the prediction of current profiles in the presence of waves over very rough, rippled, bottoms was established. For a rippled bed, it is emphasized, however, that application of the modified GM-model is limited to co-directional wave-current flows. The reason for this limitation is that the bottom roughness has been shown to be the same for waves and currents only for this type of combined flows over two-dimensional roughness elements.

Measurement of Shear Stress on a Moveable Bed

Kelly L. Rankin¹, Michael S. Bruno², member ASCE, Richard I. Hires³

Abstract

A shear plate has been developed to obtain direct measurements of bottom shear stress under non-breaking surface gravity waves on a movable sand bed. The shear plate provides a direct measurement of the bottom shear stress on a sand bend under complex flow conditions particularly over bottom roughnesses. It was designed for use under laboratory oscillatory flow conditions where the periods of motion range from 1.5 to 6 seconds and the range of shear forces are from 0.08 Nm² to 84 Nm². The spatially averaged bottom shear stress was determined and the quadratic drag law was used to convert measurements of bottom shear stress to values of wave friction factor. The apparent roughness of the bed was specified using four times the sum of the mean and standard deviation of the sediment profile on the shear plate. Values of wave friction factor compared well with both theory and data obtained through previous laboratory studies.

Introduction

The accurate measurement of bottom shear stress over moveable sand beds is critical to our understanding of nearshore processes, including sediment transport and

shallow water wave attenuation. Although indirect techniques for estimating bottom shear stress including the use of bottom boundary layer velocity profiles, wave energy dissipation, and the measurement of Reynolds stresses have been used successfully in previous experiments, these techniques can be problematic in complex flow regimes particularly in the presence of bedforms. A shear plate, designed using the same principles as those employed in the field of naval architecture for measurement of the resisting force on a towed vessel, avoids these problems. The shear plate provides a non-intrusive, direct measurement of the tangential force on the sand bed and can resolve temporal changes in the bottom stress caused by variable wave-generated bedforms.

As part of a development effort pointed at designing a shear plate for use in the open ocean environment, a shear plate has been constructed for use in a laboratory wave tank. This enabled the evaluation of a number of design issues pertinent to long-term deployments in the field. It also permitted the testing of the apparatus under carefully controlled conditions, and the comparison of results to previous theoretical and experimental investigations of moveable bed dynamics.

Shear Plate Design and Tests

The shear plate design and experimental methodology are outlined in Rankin and Hires (submitted to J. Geophys. Res., 1998). The original experimental design was modified slightly during the present study. These modifications included the use of an aluminum plate mounted on top of an existing drag balance and the reduction of the gaps between the shear plate and the false bottom from 1.5 cm to 0.6 cm.

The shear plate was designed for use under laboratory oscillatory flow conditions where the periods of motion range from 1.5 to 6 seconds and the range of shear forces are from 0.08 Nm\(^2\) to 84 Nm\(^2\). The shear plate was 0.875 m long by 0.620 m wide (0.543 m\(^2\) area) and was constructed by mounting a 0.63 cm thick aluminum plate on top of a drag balance (fig. 1). The drag balance was instrumented with a waterproofed linear variable differential transformer (LVDT) which produced linearly increasing voltage with the horizontal deflection of the plate. Resolution was to ± 0.08 Nm\(^2\).

The shear plate was tested for moveable bed conditions under waves in Davidson Laboratory’s Large Wave Tank. The wave tank is 95m long, 3.7 m wide and can accommodate water depths up to 1.8 m. It is equipped with a double flap wavemaker that is designed to simulate both regular and irregular waves. It can produce wave heights to 46 cm and wave periods to 6 seconds.
The shear plate was bolted to the concrete floor of the wave tank (fig. 2). A false bottom was constructed to surround the plate. The gap between the shear plate and the false bottom was fixed conservatively at 0.6 cm to ensure that sediment grains would not become trapped or wedged in the gap. A 1.0 to 2.5 cm thick layer of cohesionless quartz sand \( (d_{50} = 0.23\text{mm}) \) was placed on top of the shear plate and the surrounding false bottom. The shear stress on the sand bed was measured under waves ranging in height from 11 to 38 cm and periods from 1.75 to 6 seconds.

Surface elevation records were obtained using three resistance-type gauges mounted on the sill of the wave tank. The gauges were installed 17.50 m, 28.17 m (over the center of the shear plate) and 38.84 m from the wavemaker, respectively. The gauges
resolve ± 1 mm changes in the surface elevation and were calibrated over a range of 15.24 cm.

Profiles of the sediment bed were taken according to the procedure outlined in Rankin and Hires (submitted to J. Geophys. Res., 1998). Table 1 summarizes the test matrix.

Results

Figure 3 represents sample time histories for the resistance on the shear plate with sand, resistance on the shear plate without sand, and the surface elevation.

The time history for the resistance on the shear plate without sand contains a conspicuous departure from a sine wave due to a relatively large second order harmonic signal. What is not immediately apparent is that this signal is also present in the time history for the resistance on the shear plate with sand; in this case the amplitude of the first order harmonic is over two orders of magnitude larger than the amplitude for the second order harmonic and therefore the non-linearity is not easily discerned.
Harmonic analysis was performed on the resistance and surface elevation time histories to determine the amplitude and phase of the harmonic components of the signal. The analysis program reads the input file and determines the fundamental period by counting the number of zero crossings. Next, it estimates the amplitude and phase of the signal by using a least squares method. The analysis assumes that the signal is of the form

$$y_i(t) = A_{i0} + \sum_{n=1}^{NH} A_{in} \cos\left(\frac{2\pi}{T} t \right) + \sum_{n=1}^{NH} B_{in} \sin\left(\frac{2\pi}{T} t \right)$$

where

- $n = 1, 2, 3, \ldots$
- $A_{i0}$: mean of the time series
- $A_{in}$: harmonic coefficient
- $B_{in}$: harmonic coefficient
- $T$: fundamental period
- $NH$: order of harmonics

The program calculates the harmonic coefficients, $A_{in}$ and $B_{in}$, to minimize the sum of the squares of the difference between the recorded value and the estimate. The cosine and sine coefficients, $A_{in}$ and $B_{in}$, are changed to the amplitude and phase as,

$$y_i(t) = C_{i0} + \sum_{n=1}^{NH} C_{in} \cos\left(\frac{2\pi}{T} t - \phi_{in}\right)$$

where

- $C_{i0}$: mean of the time series
- $C_{in}$: amplitude of the $n^{th}$ harmonic of the time series
- $\phi_{in}$: phase of the $n^{th}$ harmonic of the time series

Amplitudes of the first order harmonics are reported in Table 1. The amplitudes of the second order harmonics were nearly identical for runs with sand and without sand and had relatively small magnitudes that ranged from 0.05 to 0.20 N. It is believed that the second harmonics are related to the mechanical properties of the instrumentation.

The elimination of secondary forces to obtain the force on the shear plate due to the resistance associated with the sand bed alone, $F_{res}$, through the subtraction of the first order amplitude of the resistance on the shear plate without sand from the first order amplitude of the resistance on the shear plate with sand, and the calculation of the spatially averaged bottom shear stress, $\overline{\tau_{bm}}$, are reviewed in Rankin and Hires (submitted to J. Geophys. Res., 1998). These data are summarized in Table 1.

Analysis

apparent roughness

The apparent roughness, $k_n$, was specified initially as $k_n = 4 * \eta$ as suggested by Wikramanayake and Madsen (1994). After their extensive review and analysis of field and laboratory studies, they suggest that the ripple length does not appear to have a significant
influence on the apparent bottom roughness. It has been concluded by Wiberg and Harris (1994) that for wave dominated environments, the ripple length scales with wave excursion amplitude \( \lambda \approx 0.75A_b \) where \( A_b \) is the bottom excursion amplitude and the ripple steepness, \( \eta / \lambda \), is nearly constant between 0.15 and 0.17 for equilibrium conditions. The results presented here are in close agreement with Wiberg and Harris (1994) with ripple steepnesses between 0.11 and 0.15 and an average wave steepness of 0.13 indicating that equilibrium conditions were achieved (Table 1).

Figure 4 illustrates the profile of the rippled sand bed and represents a general example of the bottom roughness.

Since the excursion amplitude of a section of the flow extended from the false bottom, across the gap and onto the shear plate, the ripple height alone was not sufficient to specify the apparent roughness (fig. 5).
The thickness of the sand bed itself made a significant contribution to the bottom roughness. The sand bed on the plate was therefore treated as a large ripple ($\eta \approx 2.5\text{cm}$ and $\lambda \approx 91.5\text{cm}$ where $\eta$ is the ripple height and $\lambda$ is the ripple length) with smaller surface ripples superimposed ($\eta \approx 0.3\text{cm}$ and $\lambda \approx 10.0\text{cm}$). The apparent roughness was finally specified using the mean and standard deviation of the sand bed profile by $k_n = 4 \times (\text{mean} + \text{s.d.})$ (Table 1; fig. 6).

**friction factor**

The quadratic drag law was used to convert measurements of bottom shear stress to values of wave friction factor using a spatially integrated version of Jonsson's (1966) equation

$$\tau_{bm} = \frac{1}{2} f_w \rho \overline{u_{bm}^2}$$

where $\tau_{bm}$ is the maximum spatially integrated shear stress on the bed over the area of the shear plate, $f_w$ is a wave friction factor to be experimentally determined, $\rho$ is the density of the water and $\overline{u_{bm}^2}$ is the spatially integrated maximum of the squared near-bottom velocities on the plate at one instant in time.

Figure 5. Sediment Profile from the False Bottom, across Gap and onto Shear Plate
Figure 6. Specification of the Apparent Roughness of the Bed using the Mean and Std. Dev. of the sediment profile

Our values of wave friction factor were compared with Jonsson's (1966) semi-empirical theory,

$$\frac{1}{4 \sqrt{f_w}} + \log_{10}\left[ \frac{1}{4 \sqrt{f_w}} \right] = \log_{10}\left[ \frac{A_b}{k_n} \right] - 0.08$$

(4)

(where $k_n / A_b$ is a measure of relative roughness), and Grant and Madsen's (1979) theory,

$$f_w = \frac{0.08}{k e r^2 2 \sqrt{\xi_o} + i k e i^2 2 \sqrt{\xi_o}}$$

(5)

(where $\xi_o$ is a non-dimensional distance from the boundary) (figs. 7 and 8). Our values were also compared to values of wave energy dissipation factor, $f_e$, from previous studies using moveable beds, assuming that $f_w = f_e$. 

These data compared well with those obtained from previous studies; values of the wave friction factor derived from the shear plate were as accurate as those derived from the energy dissipation method. The data also suggest that the value for the wave friction factor may be predicted using Jonsson's (1966) theory (fig. 8) for values of relative roughness greater than unity. Simons et al. (1996) also found agreement for this range of relative roughness.
Conclusions

A shear plate has been designed and constructed for use in the laboratory measurement of bottom shear stress over moveable beds. The device has been tested in a large wave tank under a range of wave conditions that offers the opportunity of comparing the results to the findings of previous investigators. The values of wave friction factor obtained here compare well with both theory and the data obtained through former laboratory experiments. These comparisons have proven the utility of the device. Discretion must be exercised in the specification of the apparent bottom roughness; for this study, the bed thickness as well as the ripple height significantly contributed to the bottom roughness. The wave friction factor does not reach a constant value for values of relative roughness exceeding unity. Instead, data in this region were in reasonable agreement with Jonsson's (1966) theory. A new configuration of the shear plate will include an attempt to eliminate the gap between the plate and the false bottom by introducing a layer of latex between the plate and the sand bed. In addition, the dimensions of the shear plate will be greatly reduced.

Evaluation of Longshore Sediment Transport Models on Coarse Grained Beaches Using Field Data: A Preliminary Investigation

Erik Van Wellen¹, Andrew J. Chadwick¹, Mark Lee², Brian Baily³ and John Morfett⁴

Abstract

This paper evaluates a number of widely used predictive transport equations and the use of tracers and GPS in the measurement of longshore transport for the validation of such equations. It also addresses the inconsistencies which can sometimes be introduced as a result of these techniques. The analysis shows that most of the equations examined tend to over-predict the expected transport by a factor of 1.5 to 4. The use of tracers on macro-tidal coarse grained beaches is found to be a viable method for obtaining reliable transport rate measurements of which the confidence levels are expected to increase as present day calculation techniques are adapted for use on macro-tidal shingle and mixed beaches. DGPS appears to be an economical way of data collection but needs to be used with the highest possible accuracy level settings if it is to be used in quantifiable sediment transport calculations.

Introduction

The management of beaches has become an important and effective engineering tool for protecting coastal areas. Increasing research efforts in this field have been aimed mostly at trying to understand and quantify the elements which govern the morphodynamics of beaches over both long- and short-term time scales. One of the key elements in improving the engineer's understanding of beach morphodynamics and sediment budgeting along a coastline is the search for a better determination of the net longshore movement of the sediment. The formulation of a reliable estimate of the total longshore transport (TLT) rate is paramount in coastal engineering problems such as feasibility studies of port extensions, derivation of

COASTAL ENGINEERING 1998

sediment budgets for coastal areas and the appraisal of long term beach stability. Such estimates should be based only on the use of reliable sediment transport models underpinned by accurate transport measurements. To date, sand beaches have received the bulk of the attention. The number of documented studies and available data on sand beaches is, therefore, considerable and ranges from analytical/numerical models and laboratory tests to large scale field experiments. In strong contrast is the moderate attention which coarser grained (i.e. shingle) beaches have received. Studies of the processes governing shingle beaches have been limited mainly to empirical models based on laboratory studies, such as those by Pilarczyk and den Boer (1983) and Powell (1990). The prediction of longshore transport rates on shingle beaches has been mainly limited to the use of variations of the CERC formula from the US Army Corps of Engineers (1984), combined with laboratory studies.

Approximately one third of the UK's coastline is protected by shingle and mixed beaches (Fuller and Randall, 1988). Some of the areas protected by these beaches have a considerable economic importance attached to them. Coarser grained (i.e. shingle) beaches therefore warrant the attention of British researchers. The Shingle Beach Project (Van Wellen et al., 1997) funded by the UK Ministry of Agriculture, Fisheries and Food (MAFF) and the Environment Agency (EA) was designed to go some way towards this. To date, two large scale field deployments have been carried out by the authors and their institutions in partnership with HR Wallingford. The 1996 deployment concentrated upon shingle transport on an open section of beach at Shoreham-by-Sea whilst the 1997 work was carried out on an adjacent groyned beach at Lancing. These two major field deployments have produced an extensive database of high quality field data. The present paper concentrates on the longshore transport rates as measured during the 1996 Shoreham open beach experiments and the evaluation of existing TLT equations using this field data.

Field Site

The field site at Shoreham-by-Sea, West Sussex, is an open stretch of beach consisting predominately of shingle. The beach is open towards the West and is in a natural state over an alongshore distance of 1500m. To the East, the beach is confined by a long harbour breakwater which extends approximately 200m. The prevailing wave direction is from the SW and SSW and the site is exposed fully to storm waves generated within the English Channel. A more detailed description of the field site is given in Van Wellen et al. (1997).

Historical Analysis of Net Longshore Transport and Annual Wave Climate

The Southern Water Authority (SWA) has been carrying out annual aerial surveys of the coastline in the area since 1973. The records also contain a statistical analysis of the trends of beach line movements and the changes in cross sectional area. In his analysis of this data, Chadwick (1989) assumed no longshore transport moving past the harbour breakwater. This assumption appears to be reasonable since the most seaward cross shore position of the toe of the shingle beach extends only half way along the breakwater. Chadwick estimated a mean sediment volume accretion of 14,539m$^3$ per year. This figure is supported by the volumes obtained from sediment
bypassing around the harbour breakwater which suggest that sediment accumulates against the breakwater at a mean rate of 15,000-20,000m\(^3\)/a (Wilson, 1996).

The mean annual hydrodynamic conditions \textit{i.e.} wave height, period, direction and frequency of occurrence within a representative year were obtained using hindcast offshore wave data based on a wind data set covering a four year period between May 1980 and August 1984 (Chadwick, 1991). This period is also covered by the SWA beach surveys, which increases the level of confidence with regards to the comparison of the predicted and measured transport rates.

**Data Collection and Methods**

One of the key objectives during the 1996 field work was to undertake a comprehensive series of field measurements of hydrodynamic conditions and concurrent sediment transport. This data has been used to evaluate the performance of existing analytical TLT equations and to make an intercomparison between independent techniques for measuring the longshore transport.

The first method of measuring the sediment transport at the field site was the use of tracers. Three types of shingle tracer were used within the project as a whole: painted indigenous pebbles (Caldwell, 1981); aluminium tracers (Wright \textit{et al.}, 1978) and electronic tracers (Workman \textit{et al.}, 1994). The comparatively low cost of the painted and aluminium tracers made them ideal for use in pilot studies in the early stages of the two deployments, when the least was known about the behaviour of the indigenous material and tracer losses were likely to be at a maximum. The highest quality tracer data \textit{i.e.} those studies with the highest recovery rates, the most frequent searches and the most complete supporting wave, current and sedimentological data) were those using the electronic tracer system. The main advantage of the electronic system was the ability to detect buried tracers at depths of up to 100cm as compared to 35-40cm with the aluminium system and 0-10cm with the painted tracers.

A wide range of tracer sizes and shapes were used within the study; the sieve diameters of the electronic tracers ranged from 23.9mm to 66.8mm and the shapes from 0.93 Maximum Projection Sphericity (MPS) to 0.621 MPS. These electronic tracers represent between 9.5 and 44.5% of the size range of the indigenous material. This is an advantage over the standard aluminium tracers which represented a smaller size and shape range throughout the majority of the study. The number of tracers deployed was relatively small (60-147) due to the labour intensive nature of tracer recovery and the logistical limitations of the study.

Tracer injection was at three cross-shore sites, chosen according to the expected active beach width at the time of deployment. Between 1 and 3 layers of tracers were placed at each cross-shore site to ensure that possible variations in tracer movement with depth were represented. The depths chosen were governed by the expected hydrodynamic conditions. The individually identifiable tracers were located by means of specially designed detectors and their depth and position surveyed in. Each of the electronic tracer studies lasted for four low waters in total. Tracer injection was carried out on the first low water, tracers were located but left in position during the two following low waters and were recovered on the fourth low water. Recovery rates of the electronic tracers lay usually around 90%.
From the tracer experiments, drift rates \( (Q_h) \) were calculated using the method of Nicholls and Wright (1991) which has its basis in the work of Komar and Inman (1970). Three parameters are needed for this calculation: the velocity of movement of the tracer centroid (centre of mass) \( (U_s) \), the width of the active beach \( (m) \) and the thickness of the moving sediment layer (depth of disturbance) \( (n) \).

\[
Q_h = U_s m n
\]  

(1)

The recorded co-ordinates of the pebbles in the horizontal plane were used to calculate the tracer centroid (centre of mass) position on the beach. The velocity of the tracer centroid was given by the average longshore distance travelled by the moving tracers and the average duration of coverage. The average duration of tidal inundation of each tracer was determined by means of the height at which it was found on the beach and by using the measured beach profile data and Admiralty tidal predictions for the site. The thickness of the moving sediment layer was taken as the depth of the boundary between moving and non-moving tracers (Voulgaris et al., 1998). If an event occurred in which more than 90% of the tracers were in transport, then the thickness of the moving sediment layer was taken as the depth above which 95% of the moving tracers were present. Active beach width was taken from the measured topographic profile at the site \( i.e. \) the distance between the high water mark and the sand/shingle border.

The second method of obtaining measurements of the transport rate is by means of calculating the volume changes of the beach based on topographic surveys in the vicinity of a structure (for example the harbour breakwater) which is assumed to stop all longshore transport. Traditional surveying allows constant high accuracy surveys to be carried out. However, using traditional surveying techniques, relatively few points can be captured over large areas within a short time period. Whilst the collection of a large number of points may not be relevant on simple topographic features, on more complex morphological surfaces there is a need for a system that can capture large amounts of data in relatively short time intervals. One answer to this problem is the use of DGPS (Differential Global Positioning Systems) to monitor beach morphological changes and the use of GPS technology is becoming more widespread by those concerned with obtaining and recording geographic information (Cornelius et al., 1994). The most important features of GPS are its high positional accuracy and velocity determination in three dimensions, all weather capability, accurate timing capacity and global coverage (Leick, 1995). Importantly, from the point of view of the coastal geomorphologist, the ability of GPS kinematic surveying to record measurements rapidly and accurately over relatively large areas can be seen to be potentially invaluable in such a dynamic environment. Morton et al. (1993), discuss the use of GPS surveying techniques to monitor beach changes and state that GPS beach monitoring provides a way of understanding beach dynamics and the factors that influence volumetric gains and losses.

Typical surveys recorded between 3,500 and 5,000 points in a four hour time interval. These data points are then used as the input for a topographic modelling system to create a DEM (Digital Elevation Model) from the irregularly spaced data. This in turn allows subsequent volumetric analysis of the GPS data. For this purpose, individual blanking files for five different areas were set up (blanking files allow a particular section of the beach to be separated from a larger grid file). The volumetric differences were then fed into a finite difference scheme which allows calculation of
Sediment size distribution data were obtained from extensive sampling during the tracer experiments. Concurrently with each tracer experiment, sediment samples of approximately 70kg each were collected at each low water during a tracer study. Samples were taken at three cross shore positions close to the original injection sites for the tracers. The samples were then subjected to sieve analysis at half φ intervals.

**Analytical Models Used**

Numerous analytical expressions have been developed for the prediction of the TLT rate. A selection of seven equations representing the current approaches to longshore transport calculation is used here. They have been selected based on either their long standing use, their new approach to the analytical prediction of the TLT or the fact that they have been developed specifically for the transport of coarse grain material. The selected equations are:

- The energetics based CERC formula (CERC, 1984) calibrated for shingle size sediment comparable to that found during the field experiments (Chadwick, 1989)

  \[
  Q_{ls} = K \left( \frac{1 + e}{\rho_s - \rho} \right) \left( \frac{1}{16} \rho g H_{sb}^2 C_{nb} \sin 2\theta_b \right)
  \]  
  \(Q_{ls}\) is the TLT rate tracer at the location where the tracer experiments took place (\(x\) on Figure 1).

  Figure 1 Schematic of finite difference scheme for the volumetric survey data.

  The nearshore waves were recorded using the Inshore Wave Climate Monitor (IWCM; Chadwick et al., 1995). This device consists of a star array of four 6m resistive sensors mounted on a 6m sided triangular aluminium tubular frame. This device measures the waves acting on the beach directly rather than measuring them offshore and having to refract them in by computational means at a later stage.

  \[
  \Delta V = Q_{in} - Q_{out}
  \]  
  for any section.

- A physics based analytical equation for the longshore bedload transport \(Q_{b,ls}\) of shingle (Damgaard and Soulsby, 1996)

  \[
  Q_{b,ls} = \text{sign}\{\theta_b\} \max\{|Q_{z1}|,|Q_{z2}|\}
  \]  

  where \(K\) is a proportionality coefficient equal to 0.0527, \(e\) is the void ratio, \(\rho\) is the fluid density, \(\rho_s\) is the sediment density, \(g\) is the gravitational acceleration, \(H_{sb}\) is the significant wave height at breaking, \(C_{nb}\) is the wave group velocity at breaking and \(\theta_b\) is the angle of the breaker line relative to the shoreline.
where $Q_{x1}$ is the longshore transport under current dominated conditions and $Q_{x2}$ is the sediment transport under wave dominated conditions. Expressions for both of these can be found in Damgaard and Soulsby (1996). This equation explores a new path in analytical TLT prediction by means of using a force-balance approach to quantify the TLT rate.

- Two empirical formulae developed by Kamphuis (Kamphuis et al., 1986 and Kamphuis 1991)

\[
Q_{x1} = \frac{1.28}{(1-n)(\rho_s - \rho)} \tan \alpha \frac{H_{sb}^{7/2}}{D} \sin 2\theta_b \tag{4}
\]

where $\tan \alpha$ is the representative bed slope, $D$ is the representative grain diameter and $n$ is the porosity. With additional laboratory study and further data analysis Kamphuis (1991) modified Equation (4) and included the influence of the peak wave period, $T_p$:

\[
Q_{x1} = \frac{2.27}{(1-n)(\rho_s - \rho)} H_{sb}^2 T_p^{1.5} \tan \alpha^{0.75} D^{-0.25} \sin 0.6 2\theta_b \tag{5}
\]

This equation has been found to be the most accurate transport equation (Schoonees and Theron, 1996).

- Two improved versions of the Kamphuis 1991 equation as suggested by Schoonees and Theron (1996)

\[
Q = \frac{63433}{365 \cdot 24 \cdot 60 \cdot 60} x_{Kamphuis} \tag{6}
\]

recommended for use on exposed sites where the sediment is of a finer nature; and

\[
Q = \frac{50000}{365 \cdot 24 \cdot 60 \cdot 60} x_{Kamphuis} \tag{7}
\]

recommended for use at sites where calm conditions prevail and/or where the sediment is coarser.

\[
x_{Kamphuis} = \frac{1}{(1-n)\rho_s} \frac{L_0}{T_p} t_{1.25} H_{sb}^2 (\tan \alpha)^{0.75} \left( \frac{1}{D_s} \right)^{0.25} (\sin 2\theta_b)^{0.6} \tag{8}
\]

where $L_0$ is the deep water wave length.

- An empirical formula developed specifically for the transport of coarse grain material by van der Meer (1990)

\[
Q_{x1} = 0.0012 g D_{50} T_p H_{sb} \sqrt{\cos \theta_b} \left( \frac{H_{sb} \sqrt{\cos \theta_b}}{D_{50}} - 11 \right) \sin \theta_b \tag{9}
\]

Evaluation and Findings

Using the long term average wave climate as input, the predicted TLT was calculated using the seven analytical models and compared to the expected net annual longshore transport. From Figure 2 it can be seen that CERCF and DS96 give the most accurate prediction for the sediment transport in the study area. This was not altogether unexpected since both of these equations have been calibrated against transport measurements for sediment of similar size to that at Shoreham beach. VDM90 scores rather poorly by giving the highest estimate of all despite being derived specifically for coarse gained sediment. KAM86 scores reasonably well and even out-performs the KAM91, which gives an estimate that is nearly three times as high as the one from KAM86. The improved versions of KAM91 (SCHA and SCHB)
give estimates which are closer to the one initially put forward by the KAM86 equation. Most equations appear to have a tendency to over-predict the TLT.

As part of the analysis, an extensive sensitivity analysis of the equations to the different parameters was undertaken. From this analysis two interesting plots are shown in Figure 3 and Figure 4. The TLT rates \( Q \) predicted by each equation have been divided by a reference TLT rate \( Q_{ref} \) obtained using that same equation with a fixed set of input parameters.

**Figure 2** Expected (grey band) and predicted TLT at Shoreham.

**Figure 3** Sensitivity analysis for \( H_{sb} \).
Figure 3 illustrates the power-law-like growth in predicted transport rate with an increase in wave height for each of the transport equations. The main difference is the magnitude with which the transport rate is increased. This is to be expected since all formulae incorporate the influence of the wave height on the transport by raising the wave height to a certain power larger than unity e.g. CERC-like equations have $H^2$. Apart from KAM 86 which does not take wave period into account, different transport rates are predicted for different wave periods. In general, all equations predict a larger TLT rate for larger wave periods. This appears to be a logical trend in transitional water depths were larger periods mean larger orbital velocities. Conversely, DS 96 shows an opposite trend, predicting larger transport rates for smaller wave periods. Since this equation assumes shallow water conditions the TLT becomes independent of the wave period but increases with wave steepness.

When looking at the influence of the $D_{50}$ on the predicted transport rate (Figure 4) a similar anomaly is shown. Apart from the CERC equation (which does not take grain size into account) all equations predict lower transport rates for larger grain sizes. Again the exception is DS 96 which, under wave dominating conditions, predicts larger TLT rates for coarser sediment. This property of the DS 96 equation can be explained by the underlying assumptions of the model where an increase in $D_{50}$ means an increase in the roughness influencing the wave boundary-layer and an increase in the wave related bottom shear stress resulting, in turn, in an increase in TLT (Damgaard and Soulsby, 1996).

![Figure 4 Sensitivity analysis for $D_{50}$](image)
With regard to sensitivity to $\theta_b$, all the equations included in this paper showed a similar trend differing only in magnitude. Shoreham is characterised by a fairly stable wave climate with waves breaking at about 2 to 3° relative to the beach orthogonal and hence any variation in $\theta_b$ is unlikely to be an important factor in the comparison of measured and predicted TLT. Nevertheless, the sensitivity analysis showed the importance of an accurate determination of $\theta_b$ when predicting TLT.

![Figure 5](image) Measured (filled symbols) and modelled (open symbols) TLT for the 1996 fieldwork.

Using the wave data as recorded at the field site, Figure 5 shows a temporal plot of both the measured and the modelled TLT rates. It can be seen that there is a significant difference between the measured and the predicted transport rates.

To quantify the discrepancy between the measured and the predicted transport rates, a discrepancy ratio equal to $Q_{\text{predicted}}/Q_{\text{measured}}$ was introduced. Figure 6 and Figure 7 are histograms giving the percentage of occurrence that the discrepancy ratio from a certain formula can be placed in a preset interval. Combining these two figures with Figure 5, shows that for the tracer data most transport predictions made by the equations are characterised by a discrepancy ratio lower than 4 whilst for the GPS measurements nearly all fall in the bin for discrepancy ratios larger than 10. Since Figure 2 suggested that most models were likely to over-predict the transport measurements made during the experiment these discrepancy ratio's are likely to be underestimates. Calculation of the Relative Standard Error of Estimate (RSEE) for the GPS data suggests an average RSEE of about 1.4. This is a very high value and can be
only partially explained by the relatively small sample size. Kamphuis (1986) and Schoonees and Theron (1996) using large samples, found RSEE values of below 0.4.

**Figure 6** Discrepancy ratio of the predicted over the TLT rates measured by tracers.

**Figure 7** Discrepancy ratio of the predicted over the TLT rates measured by GPS.
One of the most widely accepted assumptions is that the TLT rate is proportional to the alongshore energy flux, $P$. The validity of this assumption has been underpinned by several studies and data sets (Kamphuis et al., 1986, Kamphuis 1991 and Wang et al., 1998). It is fair to say that this assumption holds true for shingle transport, although the importance of a threshold of motion criteria for sediment transport to occur is far greater than for sand. However, there is no consistent proportionality between the alongshore energy flux and the TLT rates measured by the tracers and GPS (Figure 8). The graph shows a significant amount of scatter and a particularly low correlation coefficient ($r^2 = 52\%$) for the GPS measurements.

![Figure 8: Correlation between the measured TLT rates (using Tracers & GPS) and the alongshore energy flux ($P$).](image)

The significant difference in measured transport rates between the two systems was not expected, neither was the low correlation between the predicted transport rates and those obtained from the GPS measurements. The latter discrepancy is potentially more significant since GPS technology is starting to take over from the more classical surveying techniques in coastal management applications. Bodge and Kraus (1991) found their TLT estimates obtained from sediment impoundment combined with classic survey techniques to be more accurate than those obtained from tracer experiments. They stated that spurious trapping unrelated to the TLT and survey inaccuracies could each account for up to 100\% of the TLT. Most of the erratic TLT measurements obtained from the GPS measurements are probably a result of the poor vertical accuracy accepted on the measurements made using the GPS when operating in kinematic mode in this study.
Some of the scatter in the data obtained from the tracers can be explained by the limitations of present day tracer theory. Often the main uncertainty lies in how representative the tracer is of the resident sediment, both in size distribution and quantity of the tracers. Bodge and Kraus (1991) stated that TLT estimates derived from tracers can be in error by a factor of 4 due purely to limitations in sampling methodology (or recovery rate, when dealing with individually identifiable tracers). However, problems such as recovery rates needed for reliable TLT measurements and differences in cross-shore distribution of the TLT have been minimised in this study by means of high recovery rates and by simultaneous injection of the tracer at different cross-shore locations. It is believed that the main uncertainty in the measured transport rate using the tracers is introduced through the calculation technique, which was originally developed for fine grain sediment on beaches characterised by a small tidal range.

Conclusions and Recommendations

This paper has examined a selection of today's most widely used predictive total longshore transport equations and two commonly used methods of obtaining estimates of the longshore transport under field conditions.

The CERC equation and Damgaard and Soulsby (1996) equation, calibrated for shingle of similar size to those found on Shoreham beach, appear to produce good estimates of the average annual TLT rate in the study area. The other equations tend to over-predict the expected annual TLT by a factor ranging from 1.5 to 4. This is perhaps not surprising since the Kamphuis equations and the Schoonees and Theron equations have been developed as general purpose transport equations rather than being specifically aimed at shingle and mixed sediment transport. The fact that they give predictions which are of the right order of magnitude gives a very encouraging signal for their future development to incorporate the coarser spectrum of the grain size scale, whilst maintaining their robustness by means of using only a limited number of environmental input parameters. The Damgaard and Soulsby equation shows promise in that it is based on the physically meaningful principle of force-balance. Unfortunately the resultant expression is significantly more complex. However, the sensitivity analysis has shown that it predicts opposite trends to all the other equations suggesting that further research is required. The van der Meer (1990) equation which was specifically developed for the prediction of TLT on gravel beaches did not perform well against the Shoreham long term transport data.

The use of tracers on macro-tidal shingle and mixed beaches shows promise in producing reliable transport rates. Care needs to be taken, however, since it appears that the present calculation techniques for obtaining sediment transport rates from the raw tracer data (i.e. the methods traditionally used for sand beaches and beaches with a small tidal range) may not be valid for the field conditions as described here. In general, the tracers appear to give higher transport rates than would be expected over the duration of a tracer experiment. This needs to be taken into account when extrapolating the results from tracer experiments to annual TLT values. Work is presently being undertaken within the MAFF Shingle Beach Project to improve the techniques for extracting transport rates from tracer data. It is expected that this will lead to an increase in confidence level on the measured values.
The method of obtaining estimates of the TLT rate from the volumetric change between topographic surveys using GPS was proven to be a fast and relatively inexpensive way of data collection. However, the potential error introduced by a low preset level in acceptable accuracy means that although more data points are collected, these do not necessarily give an accurate representation of the true beach volume. Ideally, real-time DGPS with a preset accuracy of 1cm in the vertical should be used if the data are to be used for construction of accurate morphological DEMs. This, in turn, will lead to a higher degree of confidence in the transport rates inferred from the changes in volume. This is especially important if the resultant transport rates are used by shoreline managers as part of a predictive tool over a wider range of time scales. Volumetric surveys, either from DGPS or more traditional methods using a Total Station or Level form a proven technique which should work irrespective of the type of beach or sediment. The fact that both short and long times between surveys can potentially smooth out the individual link between specific hydrodynamic conditions and the corresponding TLT but may lead to more stable predictions for the TLT.

Acknowledgements

The authors wish to acknowledge the financial support of the UK MAFF and EA. J. Damgaard and T. Mason are thanked for their invaluable discussions. The authors also extend special thanks to L. van Rijn, W. Kamphuis and J. Schoonees for their positive encouragement and comments after the presentation at the conference. We also thank C. Walker of Shoreham Port Authority for his assistance.

MOTIONS OF PEBBLES ON PEBBLE BEACH

Ichiro Deguchi\textsuperscript{1}, Masanobu ONO\textsuperscript{1}, Susumu ARAKI\textsuperscript{1} and Toru SAWARAGI\textsuperscript{2}

ABSTRACT

Motions of pebbles on an artificial pebble beach were measured by tracking tracers. After the beach profile reached equilibrium, pebbles moved mainly in the longshore direction parallel to the shore line under the condition of oblique wave incidence. Intensive motions of pebbles were observed in the swash zone and the maximum displacement reached 30m during one week. The authors proposed a numerical procedure for analyzing pebble motion. The motion of pebble up to the maximum wave set-up point can be predicted numerically when the time and spatial variation of water particle velocity and fluid force on pebbles are given.

INTRODUCTION

The authors have been carrying out series of field studies on an artificial pebble beach constructed as a seawall of the reclamation. The sea wall was originally designed as a usual vertical seawall with wave energy absorbing blocks in front of it. However it was altered to be a permeable gentle slope seawall constructed by using pebbles of marble. The reason was that the mild slope permeable seawalls has little influence on the surrounding coast. The accessibility to the shoreline is also greatly improved when compared with the impermeable seawalls with armor blocks.

A gentle slope seawall is usually constructed by using rubble stones with a cover layer. Therefore any significant deformation of the cover layer is not permitted in the design because the deformation may cause fatal destruction of the seawall. The artificial pebble beach was constructed without cover layer and the deformation in the profile is permitted as far as it maintains the initially designed hydraulic function as is the case of the artificial sandy beach. Therefore it is necessary to know the deformation pattern of the beach and the change in the hydraulic function caused by the deformation. Although a number of research has already been done about the deformation of sandy beach, only a few have been done on the pebble beach.

In this paper movement of pebbles on the artificial pebble beach is investigated through field measurement of the motion of pebbles. Numerical model for analyzing the movement of pebbles is constructed to know the influence of the geometry of the beach, diameter of the pebble and characteristics of incident waves on the pebble motion.

FIELD MEASUREMENT OF PEBBLE MOTION

Figure 1 shows the location and plane view of the artificial pebble beach. The total length of the beach is about 3 km and the slope of the beach is 1/15. A representative cross section of the beach is schematically illustrated in Fig.2. The beach was constructed by rubbles of a mean diameter about 6 cm and covered by the pebble of marble of the diameter 4 to 8 cm. The thickness of marble layer is about 1 m. The beach is divided into some portions by groins of the length about 80 m. The length of the beach of one portion is 300 m.

Figure 3 is the bottom topography of the objective beach measured on November 1996. The predominant wave direction is found to be vary from season to season but waves from north and northwest predominant all through the year. The cross-shore profile reached equilibrium relatively shortly after the completion and longshore movement of the pebble from SW to NE. As a result, contour lines advanced more than 15 m around measuring lines Nos. 13 and 15. (Deguchi et al, 1996)
Until 1997 we carried out four times measurements of the pebble motion on the beach. Here the results of the first two measurements are analyzed. In the measurement, pebble motions were measured by tracking pebbles to which running number were given. 10 to 20 numbered pebbles were placed at four locations at the distance of 2 m along the three measuring lines perpendicular to the initial shoreline. The displacements of pebbles were measured one week after the placements.

The first measurement was conducted during 21st and 28th of November 1996. Tracers were placed along the measuring lines Nos.3, 10 and 13 as shown in Fig.3. The south groin shades a region around the measuring line No.3 from the predominant incident waves. The longshore pebble transport due to the predominant incident waves becomes the maximum around measuring lines Nos.9 to 10 and the measuring line No.13 locates in the accretion area by the longshore pebble transport (Deguchi et al. 1996).

Figure 4 is the cross-section along the measuring line Nos.3, 10 and 13 where the tracers were placed at the first measurement. The most of tracers were placed above the MWL.

The second measurement was carried out during 28th February and 7th March, 1997 just after finishing the maintenance reshape of the beach. The beach profile was reshaped to be an almost initial profile. Tracers were place along the measuring line Nos.5, 9 and 13.
The most of tracers except for the measuring line No.5 were placed between HWL and MWL as shown in Fig. 5.

CHARACTERISTICS OF INCIDENT WAVES AND MEASURED PEBBLE MOTIONS

First measurement:

Along the measuring line No.3 any movement of tracers could not be found and the tracers placed in the region higher than 2.8m along the measuring lines Nos.9 and 13 did not move. Figure 6 shows the measure displacements of tracer pebbles. More than 60% of the tracers placed along the measuring line No.9 were found.

Fig. 5 Cross section of tracer placement (Second measurement)

Fig. 6 Measured displacement of tracers along measuring line Nos.10 and 13 (first measurement)
All tracers moved in the longshore direction toward NE and the maximum longshore displacement is more than 30m. While the cross shore displacement was 4m at the maximum. As was already explained, the longshore pebble movement became the maximum around the measuring line Nos. 9 and 10.

Only a few tracers placed along the measuring line No. 13 were found. They also moved in the longshore direction toward NE with the offshore displacement. The bottom profile was almost equilibrium around measuring line No. 13 and the longshore pebble transport decreased to a large extent. It seemed that the a large part of tracers were covered by the pebbles transported in a steady stream from SW.

![Graph showing incident waves and tidal level during the first measurement](image)

**Fig. 7 Incident waves and tidal level during the first measurement**

Figure 7 is the time history of the incident waves and tidal level during the first measurement. A so-called $E_a$ parameter that is usually used to relate incident waves and longshore sediment transport rate and is calculated from Eq. (1) are also shown.

$$E_a = \frac{1}{8} \rho g H^2 C_g \sin \theta \cos \theta$$  

(1)

Just after the placement of the tracers, height of incident waves increased rapidly and finally it became more than 1 m. The direction of incident wave energy flux was from SW to NE. Active motion of tracers were observed under these waves. Another high waves of significant wave height more than 0.5m were measured in 25, 27 and 28 of November. Especially, during 27 and 28 high waves continued for more than 24 hrs and direction of incident wave energy in the period changed from NE to SW. In average incident wave energy flux from SW to NE was predominant in this period.

Second measurement:

In the second measurement, tracers placed in the deeper region along the measuring line No. 5 did not move. Someone threw tracers in the shallower region. So, we could not judge whether the tracers were moved by waves or not.

Figure 8 is the measured displacements of the tracers along measuring lines Nos. 9 and 13. Tracers placed in the deeper region than MWL moved longshore direction from NE to SW. However, the displacement was only 2m at the maximum. Tracers in the shallower region along measuring line No. 9 moved little and tracers in shallower region along No. 13 moved toward NE. The maximum displacement was 1m. More than 80% of the tracers were collected.
Fig. 8 Measured displacement of tracers along measuring line No.9 and 13 (Second measurement)

Fig. 9 Incident waves and tidal level during the second measurement

Figure 9 is the time variation of significant incident waves, tidal level and value of $E_a$ parameter. Large waves of wave height higher than 1m appeared only once when the tide was low. The energy flux was in the direction of SW. The movements of pebbles in the deeper region along Nos.9 and 13 were caused by these waves. Pebble motion in the shallower region might be caused by the waves of wave height higher than 0.5m and tide was high, i.e. 1 March and 6 March.
ANALYSIS OF PEBBLE MOTION

Modeling of pebble motion:

Currently there are two methods for analyzing pebble motion. One is a so-called discrete element method where the motions of all pebbles in an objected region are solved simultaneously (for example Araki et al., 1997). The other is the usual way to solve equations of motion for sliding and rotation of projected pebbles on the bottom. In this paper, the motion of pebble is analyzed by the latter method.

Here we focus on the motion of the projected pebble on the bottom. Figure 10 is the rough flow of our procedure for calculating motion of pebbles on the pebble beach. First of all we have to evaluate spatial and temporal variation of fluid motion in the objective region. This is done by calculating wave transformation and wave-induced current. Then fluid force on the projected pebble is estimated to determine the mode of motion and displacement of pebble. The loop is iterated during the desired time. The mode of the pebble motion and displacement of the pebble is determined by the equations of motion for rotation and sliding of pebble.

Spatial and temporal variation of fluid motion

Evaluation of fluid force on pebble

Determination of mode of pebble motion

Calculation of pebble displacement

Determination of mode of pebble motion

Calculation of pebble displacement

Fig. 10 Flow of calculation

Definition of the forces on the model pebble C whose diameter is a, mass in the air is W is shown in Fig. 11 where X and Z are the displacements in the cross-shore and upward directions, v is the speed of the motion and $\phi$ is the mean bottom slope.

Fig. 11 Definition of the forces on projected pebble
Horizontal and vertical fluid forces are expressed by $R_T$ and $R_L$ and reactive forces from pebble A and B of diameter $b$ are $N_A$ and $N_B$. These forces are expressed by the following equations.

$$N_A = \frac{\left(W_g - R_L\right) \tan \beta + R_T}{\sin \alpha + \tan \beta \cos \alpha}$$

$$N_B = \frac{\left(W_g - R_L\right) \tan \beta + R_T}{\sin \beta + \tan \alpha \cos \beta}$$

When both $N_A$ and $N_B$ are positive, C does not move. When $N_A$ is positive and $N_B$ is less than or equal to zero, pebble C moves toward the left hand side and so on.

When the pebble moves toward the left hand side as shown in Fig. 12, the equations of motion are expressed by Eqs. (4)-(6).

![Fig. 12 Motion of pebble to left hand side caused by rotation and sliding](image)

Equation of motion in the horizontal direction:

$$M \frac{dv}{dt} = R_T \cos (\alpha - \theta_A) + \left(R_L - W_g\right) \sin (\alpha - \theta_A) + k_2 F_S$$

Equation of motion in the upward direction:

$$M \frac{v^2}{a + b} = -R_T \sin (\alpha - \theta_A) + \left(R_L - W_g\right) \cos (\alpha - \theta_A) + N_A$$

Equation of motion of rotation:

$$I \frac{d\theta}{dt} = k_1 F \cos \alpha - k_2 F_S a$$

where $I = \frac{2}{5} Ma^2$, $M$ is the immersed mass of pebble C, $\theta_A$ is the displacement angle defined in Fig. 12 and the values of $k_1$ and $k_2$ are determined according to the direction of pebble motion as follows:
\[ w \geq 0: k_1 = 1, w \leq 0: k_1 = -1 \]  
\[ v \geq 0: k_2 = -1, v \leq 0: k_2 = 1 \]  

In this case, the speed of pebble motion \( v \) is expressed by Eq.(9)

\[ v = (a + b) \frac{d\theta_A}{dt} \]  

Using Eq. (9), Eqs.(4) to (6) are rewritten as follows:

\[
M(a + b) \frac{d^2 \theta_A}{dt^2} = R_T \cos(\alpha - \theta_A) + (R_L - W_g) \sin(\alpha - \theta_A) + k_2 F_S
\]  

\[
M(a + b) \left( \frac{d\theta_A}{dt} \right)^2 = -R_T \sin(\alpha - \theta_A) + (R_L - W_g) \cos(\alpha - \theta_A) + N_A
\]  

\[
\frac{2}{5} Ma \frac{d^2 w}{dt^2} = k_1 F^* a - k_2 F_S a
\]  

There are six unknowns in these equations, i.e., \( N_A, \theta_A, v, F_S, F^* \) and \( w \). However, there are only five equations, i.e., Eqs.(2), (9), (10), (11) and (12). Another one equation is determined through the mode of the pebble motion.

**Motion caused by rotation**

When the motion is caused by purely rotation, then Eq.(13) relating \( \theta_A \) and \( w \) is used.

\[
(a + b) \frac{d\theta_A}{dt} = aw
\]  

Equations (10) to (12) are also simplified as follows:

\[
\frac{2}{5} M(a + b) \frac{d^2 \theta_A}{dt^2} = k_1 F^* - k_2 F_S
\]  

\[
\frac{d^2 \theta_A}{dt^2} = \frac{5}{7M(a + b)} \left( R_T \cos(\alpha - \theta_A) + (R_L - W_g) \sin(\alpha - \theta_A) + k_1 F^* \right)
\]  

\[
k_2 F_S = k_1 F^* - \frac{2}{5} M(a + b) \frac{d^2 \theta_A}{dt^2}
\]

When \( F_S \) is smaller than \( \mu N_A \), the motion due to rotation takes place. This condition is expressed by Eq.(17).

\[
F_S \leq \mu N_A
\]  

**Motion caused by rotation and sliding**

When the pebble moves by rotation and sliding, \( F_S \) is expressed by Eq.(18).

\[
F_S = \mu N_A
\]

where \( \mu \) is the friction factor in motion.
In this case, equations of motion in horizontal and vertical direction are rewritten as follows:

\[
\frac{d^2 \theta_A}{dt^2} = \frac{1}{M(a + b)} \left\{ R_T \cos(\alpha - \theta_A) + (R_L - Wg) \sin(\alpha - \theta_A) + k_2 \mu' N_A \right\}
\] (19)

\[
N_A = M(a + b) \left( \frac{d\theta_A}{dt} \right)^2 + R_T \sin(\alpha - \theta_A) - (R_L - Wg) \cos(\alpha - \theta_A)
\] (20)

The condition for the occurrence of motion due to rotation and sliding to take place is expressed as shown here.

\[
F_s \leq \mu N_A, \quad (a + b) \frac{d\theta_A}{dt} = aw
\] (21)

When \( N_A \) becomes less than 0, the pebble leaps out.

These equations of motion are solved step by step by 4th-order Runge-Kutta method to obtain \( \theta_A, v, w \) and so on. Before calculating these values, the mode of the motion are judged. In this case, there are 5 modes of the motion. That is, motion to left hand side and to right hand side, and the motion caused by purely rotation and that caused by rotation and sliding and no movement.

Using calculated values of \( \theta_A \) and so on, variables concerning the pebble motion such as the horizontal displacement \( X \), speed of displacement \( v \) and angular velocity \( \omega \) are calculated according to the mode of motion.

Displacement caused by rotation:

\[
X = (a + b) \left\{ \sin \alpha - \sin(\alpha - \theta_A) \right\}
\] (22)

\[
w = \frac{a + b}{a} \frac{d\theta_A}{dt}
\] (23)

\[
v = (a + b) \frac{d\theta_A}{dt}
\] (24)

Displacement caused by rotation and sliding:

\[
X = (a + b) \left\{ \sin \alpha - \sin(\alpha - \theta_A) \right\}
\] (25)

\[
w_n = \frac{5[k_1 \mu' + k_2 \mu']}{2Ma} N_A h + w_{n-1}
\] (25)

\[
v = (a + b) \frac{d\theta_A}{dt}
\] (25)

where subscript \( n \) and \( n-1 \) are the time steps of calculation.

When the pebble moves to the right hand side, the same modeling as shown above is done.

Evaluation of fluid force:

Figure 13 is the procedure for evaluating fluid force on the projective pebble. At first, wave field is determined by solving an equation of wave energy conservation, where
the effect of bottom permeability is taken into account. Then the wave-induced current is calculated by solving depth and time averaged shallow water equations. Spatial and temporal variation of fluid motion caused by waves is assumed to be sinusoidal.

Calculation of Waves on Pebble Beach
- Energy Conservation

Calculation of Wave-Induced Current

Determination of Spatial and Time Variation of Fluid motion: \( \exp\{i(\kappa x - \alpha t)\} \)

Determination of Fluid Force

Fig. 13 Flow for determining fluid force

Finally the spatial and temporal variation of fluid force on pebble are determined by Eq.(26) where \( C_D \) is the drag coefficient and is evaluated by Eq.(27), \( C_M \) is the added mass coefficient and \( \mathbf{u}_f \) is the velocity vector due to waves and wave-induced current.

\[
R_f = \frac{\rho_f C_D \pi D^2}{2} \left( u_f - u_s \right) \left( u_f - u_s \right) + \frac{\rho_f C_M \pi D^3}{6} \frac{d}{dt} \left( u_f - u_s \right) 
\]

\( C_D = 2 + 24/R_c, R_c = |u_f - u_s|D/\nu \) (27)

In the following calculation, the vertical force is assumed to be negligibly small.

CALCULATED PEBBLE MOTION ON INITIAL PROFILE

These equations are extended to three-dimensional motion. In the actual beach, there are various arrangement of projected pebble. For simplicity, we assume the situation where the pebble is on uniformly arranged pebble layer. Then there are two initial arrangements of projected pebble as shown in Fig.14. We carried out calculations of the motion on these two initial conditions.

Fig. 14 Initial arrangement of projected pebble
As the first step of the application of these procedure, we calculated pebble motion on the initial beach with the straight parallel bottom contours. Figure 15 is an example of calculated wave field and wave-induced current under the condition of incident wave height is 1.2m, period is 4.5s and wave direction is 150°.

Figure 16 is the examples of the calculated displacement of pebbles of diameter 6 cm during one wave period under the condition of fluid motion shown in Fig.15. The results shown by the thick line thin line correspond to the initial condition of the cases(a) and (b), respectively. Figure 17 is the result calculated under the small wave incidence.

Calculated results shown in Fig.16 indicates that the pebbles of diameter 6cm moves in the longshore direction toward NE. The maximum displacement takes place around the midpoint between shoreline and wave breaking point at the depth between 40cm and 60cm regardless of the initial condition. The maximum speed is 8cm/1cycle. When this
waves continue for one half hour, the displacement of the pebble reaches almost 30m. The order of the displacement corresponds to the measured maximum displacement.

![Graph showing displacement of pebbles](image)

Fig. 14 Calculated displacement of pebbles during one period

(a) $H_i=1.2\text{m}, T=4.5\text{s}, \theta=150^\circ$

(b) $H_i=0.8\text{m}, T=4.5\text{s}, \theta=150^\circ$

The calculated speed of the same pebble at the same depth under the incident wave condition of wave height 80cm, period 4.5s and incident angle 150° decreases significantly to 1cm/1cycle at the maximum. Any significant residual displacement is not calculated when wave height is 50cm.

By carrying out series of calculations of the movement of pebbles, we evaluated the rate of longshore pebble transport. It is found that the longshore pebble transport rate is not directly proportional to the longshore component of the incident wave energy flux at wave breaking point as is the case of the longshore sediment transport rate. The reason is explained by the difference of the characteristics of the movements of sand and pebble. The pebble usually moves intermittently during one wave period even under the condition of large wave incidence. While sand moves constantly over a whole wave period and is easily transported by wave-induced current when it is brought into suspension.

The movement of pebbles in the swash zone can not be reproduced by the numerical model because the model is based on the linear wave theory.

CONCLUSIONS

The main results obtained in this study are summarized as follows:

Pebbles on the surface of the beach of almost equilibrium profile move mainly in the longshore direction under obliquely incident waves.
The motion of pebble up to the maximum wave set-up point can be predicted numerically when the time and spatial variation of water particle velocity and fluid force on pebbles are given.

To evaluate the motion of pebbles in the swash zone, we have to solve a nonlinear wave equation including swash oscillation exactly.

REFERENCE
Abstract

This paper describes the latest revision of the Queen's University coastal morphology model ONELINE. The model provides practical and reliable full, time-dependent simulations of shoreline change for coasts controlled by structures and complex boundary conditions. ONELINE calculates shoreline change due to longshore sediment differentials as well as on-offshore sediment movements. Model tests and case studies from around the world were conducted to test ONELINE's capabilities. Two case studies for Sea Isle City beach, New Jersey, and along the Nile Delta Coast in Egypt are discussed in this paper. Results are compared with observed field measurements to examine the model capabilities.

Introduction

The increasing development of coastal areas is faced with persisting erosion and flooding problems. Almost two-thirds of the world's population reside within 200 km of the coast, and continuous engineering activities are needed to safeguard coastal areas from erosion and flooding. Comprehensive coastal zone management and erosion/flood control requires a reliable and practical tool for predicting shoreline evolution to optimize shore protection measures.

One-dimensional coastal morphology models (one-line models) have demonstrated practical capability in predicting long-term shoreline change. However, most one-line models suffer from various constraints that limit their wide applicability. Work is currently in progress at Queen's University on upgrading ONELINE, a shoreline morphology model developed earlier, to create a practical shoreline change model with wide applicability for complex beach system configurations. The main objective is to provide accurate predictions that match the quality of available input data and knowledge of sediment transport processes.

ONELINE is based on the one-line theory of shoreline change, but does not make any small angle assumption with respect to the incident wave angle and the shoreline
direction. The work on ONELINE was started in 1988 and was followed by several refinements to improve the model’s capabilities. The latest upgrades include the cross-shore sediment transport contribution to shoreline change, the capability to simulate shoreline response to any combination of off-shore or shore-connected structures, improved formulation of the lateral boundary conditions, and provision of a Windows-based user interface that renders a user-friendly environment.

This paper provides a brief description of the ONELINE modeling system and demonstrates its capabilities through model tests and case studies. Two case studies are described in which complex beach system configurations are simulated. The first one features a groin field at Sea Isle City, New Jersey along the East Coast of the United States. The second is along the Nile Delta Coast in Egypt and includes detached breakwaters, groins, seawall, and a river mouth boundary. Simulation results are compared with measured shorelines to examine the model’s capability of predicting shoreline change.

Model Description

Following the one-line assumption that the beach profile moves parallel to itself out to a limiting depth of closure ($d_c$), conservation of sediment for an infinitely small length of shoreline, $\Delta x$, can be expressed as follows (Figure 1):

$$\frac{\partial y}{\partial t} = -\frac{1}{d_p} \left( \frac{\partial Q}{\partial x} + q \right)$$ (1)

where $y$ is the shoreline position, $x$ is the longshore coordinate, $t$ is the time, $Q$ is the longshore sediment transport, $q$ represents the average on-offshore transport rate, and $d_p$ is the profile depth which equals the closure depth $d_c$ plus the beach berm height $d_B$. The present model uses the Kamphuis formula (Kamphuis, 1991) modified to include transport by wave height gradient (Hanson and Kraus, 1989) to calculate longshore sediment transport (Equation 2).

$$Q = CKH_0^2T^{1.5} \beta^{0.75}D^{-0.25} \left[ \sin^{0.6} (2\alpha_b) - \frac{2}{\beta} \cos \alpha_b \frac{\partial H_b}{\partial x} \right]$$ (2)

where $Q$ is the alongshore sediment transport rate, $C$ is a constant that is 7.3 when $Q$ is expressed in $m^3/hr.$, $K$ is the ratio of actual over potential sediment transport rate (used as
an empirical factor for model calibration), $H_b$ is the breaking wave height, $T$ is the wave period, $\beta$ is the beach slope in the breaking zone, $\alpha_b$ is the breaking wave angle, and $D$ is the nominal grain size. Cross-shore sediment transport is calculated using Bailard's 1982 model (Equation 3).

$$q = k_s \frac{\rho C_f u_b^*}{(\rho_s - \rho)g} \left\{ \varepsilon_B \left( \psi_1 + \frac{2}{3} \delta u - \frac{\tan \beta}{\tan \phi} u_3^* \right) + \frac{u_b \varepsilon_s}{\omega_s} \left[ \psi_2 + \varepsilon_a u_3^* - \frac{u_s}{\omega_s} \varepsilon_c \tan \beta u_5^* \right] \right\}$$

In which $\delta$, $\psi_1$, $\psi_2$, $u_3^*$, and $u_5^*$ are cross-shore velocity moments defined by Bailard (1982) as functions of wave height; $\phi$ is the angle of internal friction; $\varepsilon_B$ and $\varepsilon_S$ are the coefficients of bed load and suspended load efficiency; $C_f$ is the drag coefficient, $u_b$ is the fluid bottom velocity, $\rho$ and $\rho_s$ are the fluid and sediment densities respectively, $p$ is the sediment concentration, $\omega_s$ is the fall velocity, and $k_s$ is an empirical factor used for calibration.

The basic ONELINE model structure is illustrated in Figure 2. The modeled shoreline is discretized into a finite grid and the simulation time is divided into time steps. For each time step wave shoaling, refraction, diffraction and the resulting sediment transport are calculated at each grid point. Then, the governing equations are solved simultaneously in the form of a matrix to determine the new shoreline.

The updated version of ONELINE includes improved mathematical formulation of boundary conditions and internal constraints. The new lateral boundary conditions give the modeler greater control in defining complex conditions near the boundaries. User-specified inflow and outflow factors at each boundary are used to define the sediment transport gradients at the boundaries. Boundary conditions can be properly formulated through sensitivity analysis and model calibration with observed shorelines. These highly adaptable boundary conditions provide the capability to simulate a wide range of complex beach system configurations with various sources or sinks near the boundaries. For example, sources such as river sediment discharges, updrift feeder beaches where nourishment occurs outside the modeled area, and sinks such as tidal inlets, or submarines canyons can all be modeled. Likewise, the representation of internal constraints such as groins or breakwaters was significantly improved to provide accurate response of shoreline to nearshore structures. The mathematical formulation of the influence of various structures on wave transformation and morphological changes was
refined, tested, and calibrated with various model runs and case studies from around the world.

Figure 3b. Shoreline response and longshore transport patterns near breakwaters

Figure 3c. Shoreline response and cross-shore transport pattern near breakwaters

Figure 3. Model test results
Several model tests were performed to examine ONELINE's new formulations. Figure 3a shows the result of a 5-year simulation on a straight beach with various coastal structures subjected to an annual wave time series with 4-hour time step. Figure 3b shows simulation results of the net longshore transport rate distribution near a series of detached breakwaters subjected to measured wave time series. Figure 3c indicates simulated crossshore transport patterns near breakwaters subjected to big waves. The breakwaters reduce wave heights behind them yielding on-shore sediment movement unlike the open coast areas where larger waves produce net offshore sediment losses. The results reflect ONELINE's realistic simulation of the influence of coastal structures on wave transformation, sediment transport and shoreline change.

Two cases are discussed in this paper to demonstrate the capability of ONELINE. The cases were selected along Sea Isle City beach, New Jersey, USA, and the Nile delta coastline in Egypt.

Sea Isle City Model

The first case study is a 15-year simulation of a groin field at Sea Isle City, New Jersey. Sea Isle City faces the Atlantic and is located at the south end of Ludlam Island, a barrier island in southern New Jersey, USA (Figure 4).

Background

Sea Isle City coastline is a fine sandy beach backed by sand dunes. The predominant waves come from northeast direction producing an average net longshore transport of about 300,000 m$^3$/yr to the south (Everts 1979). To stabilize the beach and reduce erosion rates along Ludlam Island, several groins have been constructed to form a groin field. Early groins were built at the northern part of the Ludlam Island by the turn of this century. The groins were low in profile and relatively short so that they would not produce large shoreline offset across them. The groin system along with periodic nourishment maintained a wider, more stable beach within the groin compartments. However, erosion was shifted to the beach downdrift of the southermost groin. Thus, over the years, the groin field was extended southward to cover most of the island shoreline.

Figure 4. Sea Isle City location
Model Setup

The Sea Isle City model covers 2.6 km between a groin field at the northern boundary and a tidal inlet at the southern boundary (Figure 5). ONELINE modeled this shoreline reach by 75 grid cells 35 m long each. The input wave data were determined from measured wave gauges near Sea Isle City. The simulations were carried out in two phases for the period between November 1980 and March 1995 with a 4-hour time step, generating a total of 11,406 time steps. The first simulation phase from 1980 to 1986 was used for model calibration. During that simulation period 4 groins were added in 1983. Calibration involved the determination of the sediment transport calibration constants, and appropriate representation of the lateral boundary conditions and internal constraints. The fast execution time of ONELINE simulations allowed sensitivity analyses for each of those controlling parameters. Thus, several runs were performed: first to estimate the sediment transport factors to give average transport rates close to the estimated or measured rates; then the lateral boundaries were adjusted so that the observed sediment losses or gains for the area were correct, and finally, the internal
constraints (structures on the grid) were adjusted by changing groin permeability to provide good agreement between predicted and measured shorelines near the structures.

Figure 6 shows the calibration results. The averaged prediction error ($E_p$) for the calibration phase was 10%, where $E_p$ is the average of all the absolute values of the error of calculated shoreline change at each grid point. Following calibration, the second simulation phase from January 1986 to March 1995 verified the calibrated model. During that period two more groins and two major beach fills were added and still verification showed close agreement of measured and predicted shorelines of 1995 with $E_p = 9\%$ (Figure 7).

The Simulation of Sea Isle City beach showed the effectiveness of ONELINE’s improved features. Of particular concern was the simulation of the southern boundary formed by the tidal inlet. The beach morphology close to that inlet is greatly affected by the inlet processes and realistic simulation of the sand influx across the boundary was crucial to the reliability of the predictions. The adaptable formulation of the lateral boundary conditions in ONELINE enabled a reasonable presentation of that complex boundary condition. The improved formulation of internal groins also provided accurate shoreline response within the groin field of Sea Isle city over a 15 year simulation period as shown in Figure 7. The top part of Figure 7 shows the net shoreline change along the modeled area where 6 groins and half a million cubic meters of sand were added over a period of 15 years. ONELINE succeeded in identifying locations and magnitudes of erosion and accretion along the modeled region.

![Figure 7. Sea Isle City model verification and final results](image-url)
Ras-El-Bar Model

The second case study is of a rather complex beach system along the Nile Delta Coast in Egypt. The Nile Delta was formed by the Nile river sediment discharges into the Mediterranean Sea over thousands of year. Human intervention with the natural system of the Nile has profoundly modified the geological processes in the northern delta. Since completion of the Aswan High Dam in 1964, fluvial sediments are no longer transported to the coast, and the balance between fluvial and marine processes has been completely modified. The Nile Delta is not an active delta anymore, but an entirely wave-dominated coastal plain. Widespread erosion along the Nile delta coastline became a persisting problem and large-scale coastal projects have been implemented to combat coastal erosion. Ras-El-Bar is a site along the Nile delta west of the Damietta Nile branch (Figure 8). The Nile Delta coastline runs generally west to east, while local orientation of Ras-El-Bar shore is southwest to northeast. Thus only waves coming from west to northeast can reach the nearshore zone of Ras-El-Bar. The predominant wind directions offshore of Ras-El-Bar are from NW and WNW (Delft, 1987). Wave records from 1985 to 1990 near Ras-El-bar indicate that the maximum and average offshore wave heights were 4.5m and 0.6 m respectively (Coastal Research Institute Alexandria, 1996).

Ras-El-Bar beach is composed of very fine sand with average median diameter of about 0.12 millimeters. Several studies along the Egyptian coast provide sufficient description of sediment transport at Ras-El-Bar (Inman and Jenkins, 1984; Frihy and Komar, 1991). The general net longshore transport is eastward, but due to local shoreline orientation near the Damietta mouth, the local net transport is to the west. Although Ras-El-Bar represents a littoral-drift convergence zone, the accretion is small and secondary to offshore losses caused by cross-shore transport. Longshore transport at Ras El Bar is small in both directions and the net transport is minimal. Cross-shore transport plays a significant role in the shoreline change at Ras-El-Bar. Shoreline recession due to cross-shore transport was estimated in Delft Hydraulics (1987) to be about 3 to 5 m/year.

Several erosion control measures have been taken to stabilize the beaches of Ras-El-Bar (Figure 9) after the construction of the Aswan Dam. Three groins were constructed in 1970 in an attempt to eliminate the erosion of Ras-El-Bar peninsula. The groin system was not successful because the cross-shore sediment transport dominates. A dolos and riprap revetment was placed within the groin field to protect a nearby highway. Erosion was maximum at the western end-groin and diminished to the west. The erosion threatened Ras-El-Bar resort community, and further shore protection was needed to
restore its eroding beach. A system of detached breakwaters was constructed in 1990, west of the groin field. The breakwaters were placed 400 meters offshore such that they would restore the recreational beach while being far enough offshore to prevent tombolo formation. In 1994, the beach area east of the breakwaters was nourished with two hundred thousands cubic meter of sand.

Model Setup

A complete time dependent simulation of shoreline changes over a 9-year period for Ras-El-Bar beach was carried out using ONELINE. The modeled area embodied a number of coastal protection works and rather complex boundary conditions. The modeled region covers 4 kilometers of beach west from the Damietta Nile mouth. This shoreline reach was modeled in ONELINE by 200 grid cells 20 m long each. The focal point of the model is the four detached breakwaters built in 1991. The breakwater system covers 1.4 km of beach; however the modeled region was extended far enough to include all the nearby littoral barriers affecting the hydro-sedimentological regime in the area. Figure 9 shows the model location and coordinate system and Figure 10 shows the modeled region schematically. Measured shorelines of 1986, 1993, and 1995 were digitized from the surveying and contour maps and transformed to the model coordinate system. Input wave data were generated using measured time series at Ras El Bar (Coastal Research Institute Alexandria, 1996). The wave gauge was located at the eastern side of Damietta promontory at 7-meter depth of water. The simulation runs covered the period from June 1986 to September 1995 on two phases. Phase one was from 1986 to 1993 during which
the 4 breakwaters where built in 1991, while phase two was from 1993 to 1995. A time step of 2 hours was used in all simulations, yielding a total of 40,500 time steps.

Model Calibration and Verification

Figure 11. Ras-El-Bar model calibration results

The model was calibrated and verified with measured shorelines of 1993 and 1995 respectively. During the calibration process, first the calibration coefficient for longshore and cross-shore transports were adjusted to provide values within reasonable ranges of measurements and observations; then the lateral boundaries were set to match the inflow and outflow of sediment through both boundaries with the prototype

Figure 12. Ras-El-Bar model verification and final results
conditions; and finally the internal constraints such as the properties of the jetty, groins, and breakwaters were set to fine tune the calculated shoreline to match the measured shoreline.

Figure 11 shows the model calibration results. The averaged prediction error ($E_p$) on calibration was 13%, while for the verification was $E_p = 12\%$. Figure 12 shows the model verification and final results. A plot of the net shoreline change over the nine-year simulation period is also shown in Figure 12. ONELINE has successfully calculated the shoreline buildup behind the breakwaters due to the combined effect of longshore and cross-shore sediment transport. The results also indicate success in calculating sand bypassing and buildup seaward of the revetment in the westerly groin compartment.

**Model Results**

Figures 13 to 16 show samples of Ras-El-Bar model results and demonstrate the realistic simulations of coastal processes in the vicinity of various coastal structures.

![Figure 13. Wave transformation patterns](image)

![Figure 14. Net annual longshore transport rates along the modeled area](image)
event. The spatial change in wave heights and directions along the modeled region reflects clearly the diffraction patterns from different structures. The calculated longshore and cross-shore transport rates are shown in Figures 14 and 15 respectively. The model results correspond well with the field measurements and observations. The model results show how the breakwaters reduce the wave energy and consequently the sediment transport in the shadow zones. The smaller waves in the shadow zones move sediment on-shore, unlike outside the breakwater protected area where the cross-shore transport produces substantial offshore losses.

**Sediment Budget**

Sediment budget analyses based on model results were conducted before and after the placement of the breakwaters. Figure 16 demonstrates the effects of the breakwater system on the sediment regime at Ras-El-Bar. The sediment transport rate entering the region from western boundary was around 100,000 m³/yr. while only 16,000 m³/yr. bypass the terminal jetty at the eastern boundary. The breakwater system reduced the offshore losses from 167,000 m³/yr. to 42,000 m³/yr. The sediment budget analyses indicate that before the construction of the breakwaters, a net loss of 83,000 m³/yr (equivalent to shoreline erosion of an average 2.3m/yr) while after the construction a gain of 42,000 m³/yr. is attained (equivalent to a shoreline gain of an average 1.4m/yr.).
Conclusion

This paper describes, ONELINE, a shoreline change modeling system, and demonstrates its capabilities through model tests and case studies. ONELINE's recent improvements boosted its practical applicability to simulate more complex beach system configurations. Model tests indicated ONELINE's credible predictions of sediment transport and shoreline response to various combinations of coastal structures. Two case studies were simulated to verify the model capabilities. A 15-year simulation of a 2.6-km shoreline reach at the southern part of Sea Isle City, New Jersey, proved the effectiveness of ONELINE to simulate shoreline response to permeable groins and complex boundary conditions. The refined formulation of lateral boundary conditions enabled reasonable presentation of the tidal inlet boundary of Sea Isle City model. ONELINE was also used to model Ras-El-Bar, a beach resort area along the rapidly eroding Nile delta. Several erosion control measures were built over the years such as breakwaters, groins, seawall, and river mouth jetties. A 9-year simulation of a 4 km-long beach at Ras-El-Bar was successful. The adaptable boundary conditions of ONELINE enabled simulation of the sediment flow patterns at the jettied river mouth of the eastern boundary as well as longshore transport gradients at the western boundary. Cross-shore sediment transport plays a large role in the shoreline change at Ras-El-Bar. ONELINE's ability to simulate cross-shore sediment transport as well as longshore transport in the vicinity of different coastal structures allowed a successful modeling of these complex beach systems. The model results corresponded with the field measurements and hence provided quantitative results and a well-verified prediction capability of the region. The consistently small prediction error on calibration and verification of these widely varying cases demonstrates the robustness of ONELINE. The modeling system, ONELINE, is still under development. Future improvements include upgrading ONELINE to contour lines model to enable predictions of profile changes as well.

Acknowledgments

This study is supported by the Natural Science and Engineering Research Council of Canada, and by funds from the School of Graduate Studies, Queen's University. Thanks to Dr. J. Richard Weggel for providing us with necessary data for the Sea Isle City beaches, and to the Egyptian Shore Protection Authority for the Ras-El-Bar data.

ABSTRACT: An algorithm for representing seasonal variations in shoreline position as caused by on-offshore sediment transport in a one-line model is presented. The study was based on an analysis of an 11-year long time series of waves and shoreline location obtained at Duck, North Carolina. Two different approaches were used: one was based on wave steepness and dimensionless fall speed and the other on ratio of the maximum near-bottom orbital velocity to the critical velocity required to initiate sediment movement. Both applications showed that it is possible to reproduce the overall spatial and temporal behavior of seasonal cross-shore transport related shoreline variation using two simple one-line model compatible approaches. Preliminary calculations show that the method may be used for analyzing the seasonal behavior of a beach. At the same time, the impact of individual storms are not represented to any significant degree.

INTRODUCTION

One-line models of shoreline response have demonstrated their predictive capabilities in numerous projects (Hanson et al. 1988). This class of models calculates shoreline position changes that occur over a period of years to decades. Changes in shoreline position are assumed to be produced by spatial and temporal differences in the longshore sand transport rate (Hanson 1989, Hanson and Kraus 1989). Thus, this type of model is best suited to situations where there is a systematic trend in long-term change in shoreline position, such as recession down-drift of a groin. Cross-shore transport effects, such as storm-induced erosion and cyclical movement of shoreline position associated with seasonal variation in wave climate, are assumed to cancel over a long enough simulation period or are accounted for through external calculation.

Hans Hanson and Magnus Larson

Cross-shore models, on the other hand, typically predict beach change as a result of cross-shore transport produced by storms (Larson and Kraus 1989). This type of models is simplified by omitting longshore transport processes. Although these models have been relatively successful in reproducing short-term profile response to individual storm, they have been less suitable for long-term predictions. In principle, the two types of models could be combined to obtain both long- and short-time changes in shoreline position. Such attempts have been done (e.g. Bakker 1969, Perlin and Dean 1979, Larson et al. 1990), but these approaches have not yet found their way into engineering practice.

Nevertheless, it is recognized that seasonal variations can play a significant role in the long-term evolution of the shoreline. Therefore, it would be a significant step forward if, at least in a schematic way, the main features of cross-shore related seasonal shoreline variations could be represented in one-line shoreline response models. If successful, it would constitute a model for simulating long-term cross-shore related coastal evolution for engineering use and at the same time eliminate one of the main constraints of the use of one-line models.

An important criterion for the formulation of the cross-shore contribution was that it should be compatible with the one-line formulation in terms of independent variables and level of sophistication. This may seem like a paradox because numerous studies (e.g. Larson and Kraus 1989) have shown that the profile shape is a key parameter for the cross-shore transport magnitude and direction. At the same time, it is recognized that one-line models does not provide any information about the profile shape. Thus, the relatively simple one-line model cannot be expected to represent the complex impact of individual storms, but rather to capture the more long-term effects. Consequently, the objective of this study was to represent seasonal variation due to cross-shore transport using a one-line model.

PROCEDURE

Transport Magnitude

Because the one-line model does not require or provide any information about the actual shape of the bottom profile, the cross-shore transport magnitude must be calculated using a relation that is independent of the profile shape. Numerous formulae for the cross-shore sand transport rate may be found in the literature (Horikawa 1988, p. 196 ff.). Many of these may be written in the generic form

$$\frac{q_o}{wd} = K_q (\Psi - \Psi_c)\eta$$

where $q_o =$ cross-shore sediment transport rate per unit width, $w =$ sediment fall speed, $d =$ median grain size, $K_q =$ transport coefficient, $(\Psi_c)$ $\Psi =$ (critical) Shields parameter, and $\eta =$ exponent. The value of the exponent $\eta$ varies from 1 to 3 in the different proposed
relationships. In the present study a value of 1.5 was selected in accordance with Watanabe (1982). For simplicity, the value of the critical Shields parameter was set to zero. Thus the expression may be written:

\[
\frac{q_o}{wd} = K_q \Psi^{1.5}
\]  

(2)

Recognizing that the Shields parameter may be expressed in the form (using shallow water approximations),

\[
\Psi = \frac{f_w u_{b,m}^2}{2 s g d} = K_m \frac{u_{b,m}^2}{g d} = K_m \frac{g H}{g d} = K_m \frac{H}{d}
\]

(3)

where \(f_w\) = Jonsson's (1966) wave friction factor, \(u_{b,m}\) = the maximum horizontal near-bottom orbital fluid velocity, \(s\) = sediment specific density in water, \(g\) = acceleration due to gravity, \(K_m\) = coefficient, \(H\) = the local wave height. In order to be consistent with the one-line theory, it is presumed that the conditions at the break point may be used to compute the overall cross-shore sediment transport, i.e., a fixed transport distribution is assumed that scales with the breaker height. Thus, the cross-shore sediment transport rate per unit length alongshore, \(q_o\), here regarded as a potential rate, may be calculated, with \(K = K_m K_q^{1.5}\):

\[
q_o = wd K_q \left( K_m \frac{H_b}{d} \right)^{1.5} = w K \left( \frac{H_b}{d} \right)^{0.5}
\]

(4)

where \(H_b\) is the breaking wave height. This relationship will be used in the following application of a numerical model with \(K\) used as a calibration parameter. However, because this relation does not give a transport direction, this will have to be resolved separately.

**Transport Direction using Fall Speed**

Kraus et al. (1991) presented several criteria for discriminating between erosive and accretive conditions on the basis of a classification of profile response to breaking waves in large wave tank (LWT) model tests as well as from the field. The LWT data consisted of two data sets. One was from US Army Corps of Engineers, compiled by Kraus and Larson (1988) and referred to in the following as the CERC data. The other set was from the Central Research Institute for Electric Power Industry (CRIEPI) in Japan (Kajima et al. 1982) and referred to here as the CRIEPI data. The field data set (Kraus and Mason 1991) consisted of observations of well-documented responses to small and large storms.

In the present study, on the basis of shoreline (MSL) movement alone, the results from the LWT and field tests were re-evaluated in terms of erosion and accretion. Figure 1 shows
Figure 1. Discriminating erosive and accretive shoreline conditions on the basis of wave steepness and dimensionless fall speed (modified from Kraus et al. 1991).

The data plotted on wave steepness $H_o/L_o$ versus dimensionless wave steepness $H_o/wT$, where $H_o$ = deep-water wave height, $L_o$ = deep-water wavelength, $w$ = fall speed, and $T$ = wave period. The proposed criteria,

$$\frac{H_o}{L_o} = M_1 \left( \frac{H_o}{wT} \right)^3 = 0.00054 \left( \frac{H_o}{wT} \right)^3$$

where $M_1$ = discriminator coefficient, discriminates between erosion and accretion with a skill of 0.92, defined as the ratio of correct predictions to total observations (Seymour and Castel 1989).

By assuming a Rayleigh probability distribution function (pdf) for the wave height, the smallest (critical) erosional deep-water wave height $H_{oc}$ may be derived from Eq. (5) as (Larson 1996):

$$H_{oc} = \sqrt{\frac{1}{M_1} \left( \frac{wT}{L_o} \right)^3}$$
At a location $x$, a certain portion $\delta_e$ of the broken waves will be erosional:

$$\delta_e = e^{-\frac{(H_{\infty})^2}{H_{r-max}^2}}$$  \hspace{1cm} (7)

Thus, if evaluated at the shoreline where $H_{bo} = 0$, the portion will be

$$\delta_e = e^{-\frac{(H_{\infty})^2}{H_{r-max}^2}}$$  \hspace{1cm} (8)

By substituting Eq. (6) into Eq. (8) we obtain

$$\delta_e = e^{-\frac{1}{M} \left( \frac{H_{r-max}}{L_o} \right)^2 \left( \frac{H_{r-max}}{H_{r-max}} \right)^3}$$  \hspace{1cm} (9)

If a portion $\delta_e$ of the broken waves are erosional the rest $\delta_a=1-\delta_e$ of the waves must be accretionary. Giving each single wave equal weight when summing up to determine the net direction yields,

$$\xi = \delta_a - \delta_e = 1 - 2\delta_e \quad -1 \leq \xi \leq 1$$  \hspace{1cm} (10)

where $\xi$ gives the net direction and a weight that includes the variability in wave height defined by the Rayleigh pdf. Substituting Eq. (9) into Eq. (10) gives the net transport direction as:

$$\xi = 1 - 2e^{-\frac{1}{M} \left( \frac{H_{r-max}}{L_o} \right)^2 \left( \frac{H_{r-max}}{H_{r-max}} \right)^3} \quad -1 \leq \xi \leq 1$$  \hspace{1cm} (11)

**Transport Direction using Velocity Ratios**

Based on the same field data as above, Ahrens and Hands (1998) parameterizes beach erosion and accretion processes on the basis of the ratio of the maximum near-bottom orbital fluid velocity $u_{b,m}$ to the critical velocity $u_{cr}$ required to initiate sediment movement under the wave. Whereas Ahrens and Hands (1998) use stream function wave theory, the present study will focus on linear wave theory, again to be consistent with traditional one-line modeling procedures. The critical velocity $u_{cr}$ was defined as (Hallermeier 1980),

$$u_{crit} = \sqrt{8\Delta g d}$$  \hspace{1cm} (12)

where $\Delta = (\rho_s - \rho)/\rho$, $\rho_s$ ($\rho$) is the density of the sediment (water).
Figure 2 shows the data plotted on wave steepness $H_s/L_o$ versus relative velocity $u_{bm}/u_{crit}$. The horizontal full line is given by $u_{bm}/u_{crit} = 9.85$ and represents the criterion that separates most of the accretion and erosion events. Thus, in this analysis the discriminating criterion may be written as

$$u_{bm} = M_2 u_{crit} = 9.85 u_{crit}$$  \hspace{1cm} (13)

where $M_2$ = discriminator coefficient, that discriminates with a skill of 0.92 if only field data are considered and 0.85 if all data are considered. The application of the random wave concept leads to relationships quite similar to Eqs. (6) to (11) in the previous section and will not be discussed here.

**Slope Effects**

Because the proposed Eq. (4) gives the transport magnitude for a horizontal bottom, it has to be corrected for slope effects on an inclined bottom. Madsen (1993) presents a relationship,
\[ q_\beta = q \frac{1}{1 + \frac{\tan\beta}{\tan\theta_m}} = q \, k_\beta \]  

(14)

where \( \beta \) = bottom slope (positive for upward slope in transport direction), \( \theta_m \) = angle of moving friction (here set to 30° according to King (1991)), and \( k_\beta \) = slope coefficient.

**Actual Transport Rate**

With the transport potential \( q_\alpha \), the net direction and magnitude of transport \( \xi \), and the slope coefficient \( k_\beta \) all determined, the actual transport rate \( q \) is given by:

\[ q = q_\alpha \, \xi \, k_\beta \]  

(15)

**Shoreline Change**

Following the one-line theory, the shoreline location \( y \) is calculated based on the continuity equation:

\[ \frac{\partial y}{\partial t} + \frac{1}{D_c} \left( \frac{\partial Q}{\partial x} - q \right) = 0 \]  

(16)

where \( y \) = shoreline position, \( t \) = time, \( D_c \) = vertical extension of the active profile, \( Q \) = the longshore sediment transport rate, and \( x \) = the alongshore coordinate. By assuming no longshore transport gradients (\( \partial Q/\partial x = 0 \)), the shoreline change \( \Delta y \) during a time step \( \Delta t \) is given by:

\[ \Delta y = \pm \frac{q \, \Delta t}{D_c} \]  

(17)

where a positive sign corresponds to onshore transport.

**FIELD APPLICATION**

**Field Data**

As an application of the proposed procedure, simultaneously collected data on waves and beach profiles from the US Army Field Research Facility at Duck, North Carolina (Figure 3) (Howd and Birkemeier 1987, Lee and Birkemeier 1993) were analyzed to investigate the relationship between the incident waves and the seasonal shoreline variations over a longer...
The data set comprised shoreline positions extracted from surveys taken bi-weekly in profile line 188 during 11 years (Figure 4). Spectral wave properties (significant height and peak period), recorded at least every 6 hours, were available for the same period.

The beach at Duck is one of the most well-documented field sites in the world with collected time series on waves and profiles that are unique in their length and quality. Thus, it was a natural choice to employ data from Duck in the development and validation of the cross-shore transport algorithm. However, coarse material is often found around the shoreline at Duck (Larson 1991) creating a steep beach face and an armoring effect that could significantly reduce the shoreline response to changes in the wave conditions. Because of this the beach response at Duck might not be as well-behaved as on other beaches. In spite of this, the Duck data was chosen. The long-term variation of different contour lines was extracted by linear interpolation from the measured profiles. For this study, the MSL (+0.08 m NGVD) of profile line 188 was analyzed.

In order to investigate the temporal scale in the shoreline (defined as MSL) variation, an FFT analysis was performed on the data series after a linear trend was removed. Figure 5 (solid line) shows that there is a strong annual variation with a frequency of 1 year, that most likely is associated with seasonal variations in the wave climate. The long-term trend in the shoreline signal was assumed to be associated with alongshore processes and was, therefore, removed from the continued analysis. For simplicity, the long-term trend was assumed to be linear, although the FFT analysis indicates that there are other low-frequency oscillations in the signal.

Model Simulation using Fall Speed

Based on the wave time series, the cross-shore sediment transport rate was calculated at each time step according to Eq. (15). In the calibration procedure, a best fit value of the discriminator coefficient $M_r$ that separates onshore from offshore transport, was determined to minimize the difference between measured and calculated shoreline positions on the basis of visual evaluation. The shoreline change and the corresponding shoreline location associated with the cross-shore sediment transport was calculated based on Eq. (17). A best fit
Figure 4: Temporal variation of MSL in profile line 188.

Figure 5: FFT analysis of periodicity in shoreline fluctuations.
value of $M_1 = 0.00056$ was obtained (Figure 6), which is only marginally greater than the value obtained from the comparison with laboratory model tests (Figure 1). As for the actual shoreline change, the calculated shoreline variation was analyzed by FFT. The temporal behavior of the oscillations is shown in Figure 5 (dashed line). Similar to the measured variations the calculated ones show a strong annual signal indicating that there is a pronounced seasonal variation in addition to a low-frequency variation associated with interannual changes in the wave climate. It is also worth noticing that there are virtually no higher frequencies represented. Thus, the calculations show that, although the seasonal behavior of the shoreline is clearly expressed, the impact of individual storms are not represented to any significant degree. In addition, a comparison between measured and calculated shoreline changes (Figure 6) indicates that he excursion around the mean value is of the right order of magnitude. Hence, the overall temporal and spatial properties seem to be well represented in the model. However, there does not seem to be a coherent instantaneous behavior of the two signals. The phase difference is generally quite significant.

Model Simulation using Relative Velocities

Using the same data as in the above section, the shoreline change was determined using the criterion based on the velocity ratio. Figure 7 shows the result of a simulation with a best fit value of $M_2 = 8.0$, which is somewhat smaller than the value obtained from the comparison with the LWT and field data sets (Figure 2), but still with a skill of 0.85, i.e., as
Figure 7. Comparison between calculated and measured temporal variation of MSL.

good as the proposed value of 9.85. A visual evaluation seems to suggest that this method reproduces the actual shoreline change slightly better than the previous method based on fall speed. Like in the previous application, the seasonal behavior is quite well represented.

CONCLUSIONS

The present analysis showed that it is possible to reproduce the overall spatial and temporal behavior of seasonal cross-shore transport related shoreline variation using two simple one-line model compatible approaches. Similar to measured shoreline changes at Duck, N.C., model calculations over 20 years showed clear seasonal variations. FFT analysis of measured and calculated shoreline changes also showed strong similarities for more long-term variations. As expected, the impact of individual storms that are present in the measurements, are not represented in the simulated shoreline behavior to any significant degree. More work is still needed to represent the instantaneous changes correctly with the proposed methods.

The reason for the limited success of the proposed methods could be that the selected parameters are more related to bar behavior than to shoreline behavior and that the lag represents an intrinsic phase shift between the shoreline response and the bar movement as documented in Hanson et al. (1997). Another, more pessimistic, explanation could be that
the approach is too simplified to be able to represent such a complex process as cross-shore transport under breaking waves. It is not totally clear, at present, which of the two hypothetical reasons is true even though the former is our working hypothesis.

The predictive capability of the proposed method is still not demonstrated. In this respect, it will have to be shown that the criteria cannot only be used to determine the direction of the transport but also the magnitude. For this reason, further applications will be made with field data from other well-documented sites.

COASTLINE EVOLUTION IN RESPONSE TO A MAJOR MINE SEDIMENT DISCHARGE ON THE NAMIBIAN COASTLINE

G G Smith and G P Mocke

Abstract
The measurement, monitoring and modelling of the impacts of a major sedimentary discharge to the highly dynamic coastline of southern Namibia is described. Some 27 million m$^3$ of sediment will be discharged over a 5 year period as a result of a novel diamond mining technique employing an inland dredger. The study demonstrates that mathematical modelling, supported by comprehensive monitoring information, constitutes an important tool for mining optimization and impact prediction and management.

Introduction
A major diamond mining operation at Oranjemund in Namibia (Figure 1) which commenced in April 1997 involves the dredging and processing of overburden material (CSIR, 1996; Smith et al, 1996). This overburden sediment overlays rich diamond deposits located primarily in gravel layers on the bedrock. Typical overburden thicknesses are from 5 to 20 m. As an alternative to historical “dry” mining techniques, calling for massive dewatering operations, the present mining uses a dredger floating in excavated ponds. Water-levels in the ponds are controlled by a balance between seepage from the sea, a wellfield on the beach, and extraction pumping.

The sediment resulting from the dredging process is then discharged onto the beach (Figure 2 and Figure 3) on a highly dynamic coastline (median wave height $\approx$ 1.9 m). A total of some 27 million m$^3$ is to be discharged onto the beach over a period of about 5 years. This massive amount of sediment is comparable with the total quantities supplied for beach nourishment in some European countries (Hamm et al, 1998). The shoreline accretion which results from the discharge will have a significant effect on the safety of mining operations and in the protection of beach wellfield installations from wave action. In addition, the shoreline behaviour affects the rate of water seepage to the inland dredge pond, and accordingly affects pumping requirements to maintain the required water-level.

Furthermore, accretion of the shoreline will facilitate land reclamation and consequent additional

exploitation of mining terrain. Thus, accurate predictions of the shoreline evolution, both in the short-term and long-term, are essential for the mine to plan these aspects.

Figure 2: Dredger tailings discharge

A delicate balance exists, with regard to water seepage, as is schematically illustrated in Figure 4. In Figure 4 (top) the situation at the start of dredging is shown. At this stage the dredger was situated on an existing pond created from a previously mined-out area. By means of pumping from a wellfield close to the shoreline, the water-level was maintained just above mean sea level (MSL). As dredging progresses, the pond water-level is progressively lowered, as indicated in Figure 4 (bottom). The advantage of this is that the bedrock, which is inclined towards the sea, will be accordingly exposed, thus allowing mining to continue. As the water-level drops, seepage will tend to increase. However, by optimising the beach accretion the seepage during the later stages of dredging can be minimised. This optimisation of accretion was evaluated at the feasibility stage of the project by adapting the sediment discharge locations.

Figure 3: Aerial oblique view of the study site
An interesting aspect is that the coast in the project region is already in an extremely accreted condition. This is due to the discharge in the region of some 80 million m$^3$ of sand onto the beach between 1971 and 1997. About 60% of this quantity was in the form of hydraulically discharged mine tailings, while 40% was in the form of direct nourishment of overburden sand to massive sand seawalls used for protection from wave action and in some cases for land reclamation (Smith et al., 1996). This sand input to the shoreline caused accretion of up to about 250 m in places (Figure 5). With the use of survey data in regions relatively unaffected by sand input, the assumed beach profile of 1971 was reconstructed, and is plotted together with the pre-dredging profile of 1996 in Figure 6. It may be noted that the recently measured profile is steeper on average. Utilising profile information together with shoreline data, the total volume of accretion between 1971 and 1997 could be estimated. Taking into account losses of sediment as a result of longshore transport, it was estimated that some 6% of material comprised fines lost offshore.
In sum, both the massive quantity of sediment to be discharged on a high-energy coastline during the dredging project and the extremely accreted condition of the beach result in a unique shoreline evolution study. In order to attain quality shoreline predictions, the long-term (months/years) shoreline behaviour is assessed by means of monitoring data analyses in combination with employment of a one-dimensional shoreline model. Superimposed on these results, short-term (hours/days) shoreline fluctuations are investigated by means of data analyses and cross-shore profile modelling.

Monitoring Data Analysis
The comprehensive monitoring programme at the study site incorporates wave measurements, sediment measurements, measurement of beach topography and nearshore bathymetry, photography and debris-line recordings.

Waves

Directional wave measurements were conducted offshore of the project site in 16 m to 20 m water depth. In the first few months of measurement, two SEAPAC current meters, utilising an electromagnetic current meter and a pressure sensor to resolve directional waves, were situated 4 km offshore. A directional wave buoy operating on a dual-frequency differential GPS system (CSIR, 1997) was situated 2 km offshore. The measurement by three instruments allows some comparison and data quality checks. In Figure 7(a) it may be noted that the time series of significant wave height for SEAPACs and the GPS buoy are remarkably similar, despite being some 2 km apart. Directions are also reasonably similar (Figure 7(b)) considering instrument accuracy and the separation between the instruments. More recently, only a single instrument has been deployed. A total of 14 months of measurements has been recorded since October 1996. It is intended to obtain a further 10 months of measurements.

An energetic wave climate is reflected in the exceedance plot (Figure 8) which indicates a median significant wave height of 1.9 m and significant wave heights of up to 6 m. The nearshore waves (in 20 m depth) approach the project site from a fairly narrow band of directions, with waves approaching from the south-westerly and south-south-westerly sectors 89% of the time (Figure 9). Since the coastline extends from south-east to north-west, this results in a net northerly-directed longshore sediment transport, varying from
0.4 to 1.6 million m$^3$/year. Wave periods are relatively long, with 80% of these being between 8 and 14 seconds.

Figure 7: A comparison of wave heights (top) and wave direction recordings by 3 different instruments

Figure 8: Wave height exceedence graph

Figure 9: Histogram of wave directions (measured in 20 m depth)
Sediment

The beach sediment at the project site is fairly coarse, a composite median grain size of 611 \( \mu \text{m} \) being recorded prior to the commencement of dredging in April 1997. Extensive sampling of the beach 4 months after dredging had commenced indicated a somewhat finer composite median grain size of 447 \( \mu \text{m} \), seemingly in response to the discharge of material of median grain size 495 \( \mu \text{m} \). This occurred despite the winnowing effect of winter waves on a steep beach. It is recognized, however, that as the sampling is limited to the intertidal beach (spring tidal range\( \approx 1.6 \text{ m} \)) the sediment sizes are not representative of the entire cross-shore profile.

Morphology

An analysis of surveyed beach topography and nearshore bathymetry reveal a dynamic hydro-sedimentary regime at the study site. Vertical variations in the profile of up to 4 m over a period of a few months are also not uncommon, with a profile closure depth of up to 18 m.

Figure 5 illustrates the shoreline evolution since commencement of the dredging project in April 97. The details of quantities discharged are as indicated in Table 1. A total of 3.766 million m\(^3\) of dredger tailings was discharged in a period of 16 months. During this period, a quantity of 0.832 million m\(^3\) (in the form of a finer tailings discharge from a mine processing plant) was discharged via positions M1 and M2. This slightly finer sediment seems to have a limited impact on shoreline evolution (Figure 5). However, the effect of the dredge discharge, which shifts (for the most part) from position D1 to D2 to D3, on the shoreline evolution is clearly evident. By July 1998, the maximum measured seaward shoreline excursion (as represented by the MSL+2m contour) relative to the pre-dredging shoreline of 12 March 1997 is about 130 m.

A survey of the beach topography and nearshore bathymetry was conducted in September 1997, after 1.107 million m$^3$ had been discharged onto the beach from discharge point D1. With the use of GIS overlay techniques whereby the September 1997 survey is superimposed on a pre-dredging survey, the fate of this material could be assessed. At that stage material was evenly distributed, with 0.57 million m$^3$ calculated to have accumulated to the north-west of D1, while 0.55 million m$^3$ was deposited to the south-east. The slightly higher accretion to the north-west is likely due to the discharge of finer mine tailings at positions M1 and M2, although the morphology suggested that most of this material is transported north-westwards away from the dredge discharge region.

The surveys also revealed that at that stage about half of the accreted material was situated above MSL, while some 45% of the material accumulated between the MSL-6m and MSL.

The above information provides valuable insights for shoreline modelling to estimate the long-term shoreline evolution. Superimposed on this, an understanding of the short-term variability of the shoreline is also required. Figure 10 shows the on/offshore excursions of the MSL+2m contour, relative to the situation as measured in November 1995. In some cases a classical summer/winter variability occurs, such as 1200 m south of the discharge location, where a shoreward shift is seen around and after July, while a seaward shift is seen around January. This trend does not always occur, however. For example, the data from 2100 m north (Figure 10) indicate a retreat of the MSL+2m contour in January 1997. Such deviations from seasonal trends are likely due to the formation of localised giant cusps, as observed frequently on the study coastline. Also evident in Figure 10 is the accretion as a result of dredge discharge. A steady build-out of the shoreline is evident from about April 1997 at the dredge discharge position (D1), while 750 m to the north, the response of the shoreline is delayed but extremely rapid. This is likely the result of relatively rapid distribution of sand by longshore transport.

Also evident in Figure 10 is a rapid retreat of the shoreline just prior to July 1996 (except for the 2100 m north case, since data was not available). This retreat occurred as a result
of a major storm (of estimated recurrence interval of 2 years) during which significant wave heights of up to 5.9 m were recorded, while high waves (mostly over 4 m) persisted for four days. The result of this storm was an average retreat along the 9 km study coastline of 5 m, while a maximum retreat of 20 m was recorded.

Figure 11: Average widths of cusp embayment. The number of samples are shown as well as the standard deviation (error bars)

A detailed analysis of the variability of the shoreline was conducted, utilizing 9 surveys of 38 beach profiles along some 9 km along the study site. These indicated a maximum shoreline (MSL+2m) accretion (relative to the average of the shorelines) of 29 m, while a maximum shoreline retreat of 35 m was measured. Since the major variations of the shoreline are the result of giant cusp formations, a study was focussed on these. A coastal section of some 20 km at the study site was investigated, with the use of photographs taken prior to the commencement of any significant mine sediment discharges (i.e. in 1943 and 1964) as well as later (1976, 1978 and 1993). In Figure 11, the average width of cusp (i.e. shore perpendicular extent) are indicated, while numbers indicate total cusps recorded in the study region and the error bars provide the standard deviation of the width. A definite increase in cusp width is evident after the commencement of discharge of mine sediment onto the beach in the early '70's. The pre-mining cusps average about 30 m width, while the later cusps average about 40 m width. The number of cusps observed also increases. The average cusp length for all the measurements is 383 m, with a standard deviation of 115 m.

Additional measurements

The "more conventional" measurements of waves, sediments and bathymetry/topography are supplemented with regular photographs and measurements (from a series of fixed beacons) of the debris line. The photographs provide a useful qualitative assessment of cusps, beach slopes and wave conditions, while the debris-line measurements provide an indication of the maximum extent of wave runup. The latter is useful for verifying wave runup calculations and for assessing safe setback distances.

Trials are in progress to improve measurement techniques. A system of digital video recording is being tested. Analysis of the digital images will ultimately provide more comprehensive data on intertidal topography, wave runup, and some indication of nearshore bathymetry. In addition, it is intended to improve measurement of bathymetry through the surf zone through the deployment of a helicopter-borne survey. This method
is the obvious choice in a region to which rapid access is difficult, calm days are limited, and where a mine helicopter is readily available. Referring to trial surveys conducted in 1990 (Coppoolse et al, 1992) and the technique of Pollock (1994) improved survey techniques have been explored. In Figure 12(a), the method involving deployment of a stand is illustrated. Using ranging rods or a differential geographical positioning system (DGPS) with a graphical display, the helicopter is positioned. The 5 m high stand is lowered onto the sea bed. The elevation and distance to the prism cluster are obtained by means of a shore-based total station. This method is practical provided conditions are reasonably calm. Preliminary tests indicate that the method is functional in wave heights of over 1 m.

![Diagram of Helicopter Survey Techniques](image)

*Figure 12: Helicopter survey techniques for (a) the near-beach region and (b) further offshore*

Although not yet tested, figure 12(b) provides a possible method for surveying in deeper water. As for the above, the helicopter would be positioned by means of ranging rods or DGPS. The weight at the end of the steel cable is then lowered and carefully observed by the flight engineer. At the instant that the weight touches the sea bed, the flight engineer depresses a light switch. Until this time a prism triangle would have been tracked from the shore-station, from which the position of the helicopter prism is logged as the light is switched on. Since the line has a predetermined length, the position of the bed can be recorded.

**Predictive Modelling**

*Shoreline model predictions*

The measured wave data were synthesized into 7 offshore swell conditions (representing 94% of the measured swell conditions) and 5 offshore sea conditions (representing 80% of the sea conditions). Wave refraction for these conditions was computed with the HISWA model. With the use of the resulting nearshore wave data, an extensive set of survey data (incorporating 17 measured shorelines) and historical records of sediment
inputs to the beach (from mine plant tailings discharges and from nourishment of sand seawalls), the shoreline model UNIBEST was set up over a coastal extent of 16 km. The relatively featureless coastline is ideal for a shoreline model application, and the "fixed sediment transport" boundaries were situated far enough from the region of interest to have any impact. Figure 13 illustrates the result of the shoreline model validation. As can be seen measured shorelines, which display on/offshore excursions of up to some 200 m over a 21 year period, are well predicted.

![Figure 13: Shoreline model predictions against measured data (pre-dredging)](image)

This validation of the shoreline model provided a firm basis for the prediction of shoreline evolution as a result of dredger tailings discharge along part of the shoreline. Extensive data on discharges and shorelines (6 surveys extending up to 9 km along the study coast) available since commencement of dredging in April 1997 allowed an updated validation of the model, some of the results of which are depicted in Figure 14. Here the model generally predicts the shoreline evolution well within 20 m of measured shorelines, while at isolated points the accuracy is within 30 m. This accuracy margin is within the limits of short-term shoreline changes, such as due to cusps and storms.
Although the shoreline model is well verified, a considerable degree of uncertainty exists for predictions of shoreline evolution as a result of the massive sediment input proposed for the next few years. A key question in this regard is how longshore transport and offshore loss of finer material will be affected by the rapid steepening of the beach and corresponding increase in wave breaking intensity. Violent plunging breakers observed on site will certainly be extremely effective in suspending and transporting sediment. An additional uncertainty is the exact rate and volume of sediment to be discharged from the dredging operation. These uncertainties were accommodated by simulating several scenarios which test the sensitivity to wave conditions, grain size, sediment discharge rates and sediment discharge volumes. For example, Figure 15 illustrates shoreline model sensitivity to the volume of sediment discharged. A standard case was run, with the model based on the boundary conditions as for the model verification, and the volume of sediment as is anticipated at present. The result at the end of dredging in January 2004 is depicted in the figure. If the total volume discharged is 25% more, but at the same rate of discharge, the coastline is predicted to be some 30 m to 40 m seaward (in July 2005). On the other hand, 25% less material results in a predicted shoreline of some 40 m to 50 m shoreward of the standard case.

![Figure 14: Shoreline model predictions against measured data (during dredger discharge)](image-url)
Figure 15: Predicted shoreline evolution sensitivity to the volume of material discharged

A notable feature of the predicted shorelines is that the accretion occurs opposite the dredging area. This has been carefully planned to ensure that seepage to the area, which will have a lowered water level near the end of dredging, is limited. This facilitates minimal pumping to maintain an area of exposed bedrock to be mined (as in Figure 4(b)).

Table 2 indicates the results of further sensitivity tests. In each case, the condition of the shoreline at the end of dredging is compared to the standard case, and the maximum shoreline variation relative to the standard case is indicated. In general the scenarios tested were "pessimistic", in order to explore worst cases for the mine.

As may be noted, considerable variations in the wave, grain size and sediment discharge conditions cause variations in the shoreline of the same order of magnitude (i.e. approximately 50 m).
Cross-shore profile model predictions

In order to obtain comprehensive shoreline predictions, short-term shoreline variations must be superimposed on the long-term shoreline model predictions. In addition to the insights obtained from empirical data, cross-shore profile modelling provides an assessment of erosion during episodic events such as storms. Figure 16(a) shows a validation of the SBEACH profile model predictions against beach profile measurements made over a storm event (i.e. the 1 in 2 years storm as described above). Unfortunately nearshore data were not available for a full calibration of the profile. Nevertheless, the "dry" beach profile behaves approximately as would be expected, i.e. material is eroded from the upper beach and deposited on the lower profile. Based on this calibration, the response to more severe storm action can be explored. Figures 16(b) and 16(c) depict predicted profile changes under storms of return periods 1:10 and 1:50 years respectively. The effect of these storms on the shoreline (MSL+2m contour) are recorded in Table 3.

</tbody>
</table>
Based on these results, together with results of cusp analysis and wave runup calculations, a safe setback of 90 m was recommended for mining operations. This is however provided that protection against waves overtopping the beach berm is in place, and does not take account of longer-term erosion due to longshore transport. A maximum erosion of 40 m, and intrusion of wave runup by a further 30 m, was recorded prior to dredging. As short-term erosion of a temporarily accreted shoreline is likely to be more extreme, the above-mentioned setback estimate is considered reasonable.

**Conclusion**

The accreted condition of over shoreline in combination with the massive quantity of sediment to be discharged some 5 years set the scene for a totally unique project. An open, relatively straight coast, together with large sediment inputs and significant coastline changes, provide ideal conditions for the application of a one-dimensional shoreline model. With the availability of extensive data, a reliable validation of the model was possible. Together with model sensitivity tests, reasonable predictions of future long-term shoreline evolution scenarios were made.

Further analyses of survey and aerial photograph data facilitated, together with the application of a cross-shore profile model, an understanding of the short-term shoreline fluctuations. Combining these with the long-term predictions results in the provision of essential input to mining operations.

LONGSHORE PATTERNS OF
THE SEA BOTTOM MORPHOLOGY

Giovanna Vittori¹, Huib de Swart², Paolo Blondeaux³

Abstract

It is shown that the two-dimensional flow field and the bottom configuration induced by a wave of small amplitude normally approaching a straight beach may be unstable with respect to infinitesimal perturbations. The time development of the bottom perturbation leads to the formation of crescentic forms periodic in the longshore direction. The growth of the perturbation is due to a positive feedback mechanism, involving the incoming wave, synchronous edge waves and the bedforms. In particular the growth is related to the presence of steady currents caused by the interaction of the incoming wave with synchronous edge waves which in turn are excited by the incoming wave moving over the wavy bed. For natural beaches the model predicts two maxima in the amplification rate; the former is related to incoming waves of low-frequency, the latter to wind waves. Thus two bedforms of different wavelengths can co-exist in the nearshore region, the longshore spacing of which is few hundreds and few decades of metres respectively. To illustrate the potential validity of the model, its results are compared with field data.

1 INTRODUCTION

Field surveys of the morphology of the coastal region show the existence of periodic longshore patterns. These patterns are characterized by different length scales in the range between 1 meter to 1 kilometer. Previous studies on the process originating these coastal forms assume that edge waves are the driving mechanism. However in these models bottom topography does not enter in the mechanism originating bottom forms since the dynamics of the sea bottom is not considered and sediment motion is assumed to be passively driven by the water flow.

Recently Vittori et al. (1998) have shown that rhythmic longshore patterns may be due to a feedback between water flow and the erodible bottom. In their paper it is demonstrated that crescentic forms in the coastal area, far away from the breaker line, can be produced by the time development of

¹Assistant Professor, Hydraulic Institute, University of Genoa, via Montallegro, 1 - 16145 Genova, Italy

³Professor, Hydraulic Institute, University of Genoa, Via Montallegro, 1 - 16145 Genoa, Italy
small random perturbations both of the sea bottom and of the water motion which interact with a monochromatic wave which approaches the beach. The basic mechanism is that the incoming wave interacts with a small bottom perturbation (periodic in the longshore direction) and produces a synchronous edge wave. This wave subsequently interacts with the incoming wave and leads to the generation of steady currents. These currents induce a net sediment transport, the convergence pattern of which is in phase with the bedforms. Hence there is a positive feedback between the water motion and the erodible bottom which gives rise to an exponential growth of both the free surface and bottom morphology perturbations.

In the present paper the analysis of Vittori et al. (1998) is briefly outlined and their results are summarized. Then a comparison is performed between their theoretical results and field data. In particular the observations of Homma & Sonu (1963) and Pruszak et al. (1997) are considered.

2 THE THEORETICAL MODEL

In the theoretical model of Vittori et al. (1998) a simplified beach profile is used (see figure 1) which consists of two regions. In the outer region \( x^* > x^*_w \) the local water depth increases in the offshore direction with a constant slope \( \beta \), starting from a finite value \( h_0^* \) at \( x^* = x^*_w \). The inner region \( x^*_s < x^* < x^*_w \) is characterized by a slope which rapidly increases when moving towards the beach. The variables \( x^*, y^*, z^* \) denote an orthogonal coordinate system with the \( x^* \) and \( y^* \) axes lying on the still water level. The \( x^* \)-axis points offshore, while the \( y^* \)-axis is parallel to the straight beach and the \( z^* \)-axis is vertical.

The water motion in the outer region is described by the shallow water
The equations which read

\[
\frac{\partial (h^* + \eta^*)}{\partial t^*} + \frac{\partial [h^* + \eta^*]u^*}{\partial x^*} + \frac{\partial [(h^* + \eta^*)v^*]}{\partial y^*} = 0
\]  

(1)

\[
\frac{\partial u^*}{\partial t^*} + u^* \frac{\partial u^*}{\partial x^*} + v^* \frac{\partial u^*}{\partial y^*} = -g^* \frac{\partial \eta^*}{\partial x^*}
\]  

(2)

\[
\frac{\partial v^*}{\partial t^*} + u^* \frac{\partial v^*}{\partial x^*} + v^* \frac{\partial v^*}{\partial y^*} = -g^* \frac{\partial \eta^*}{\partial y^*}
\]  

(3)

The forcing is due to a prescribed surface gravity wave which normally approaches the straight beach and is partially reflected. This yields the matching condition (see Mei, 1989)

\[
\lim_{x^* \to \infty} \eta^* = \lim_{h^* \to 0} \frac{a^*_x(x)}{2} \left[ \exp(i \int \ell^* dx^*) + \hat{K} \exp(-i \int \ell^* dx^*) \right] e^{iu^*t^*} + \text{c.c.}
\]  

(4)

In (1), (4) \( h^* \) is the water depth, \( \eta^* \) is the water surface displacement, \( (u^*, v^*) \) are the depth-averaged velocity components in the cross- and long-shore directions respectively. Furthermore \( a^*_x, \ell^* \) and \( \omega^* \) are the amplitude, the wavenumber and the angular frequency of the incoming wave and \( \hat{K} \) is the complex reflection coefficient of the beach. Finally c.c. denotes the complex conjugate of a complex quantity.

By assuming that \( x^*_w - x^*_e \) is much smaller than the horizontal length scale of the problem, the dynamics of the flow in the inner region is neglected and all the phenomena which take place between \( x^*_e \) and \( x^*_w \) are described by means of an appropriate boundary condition at \( x^*_w \):

\[
u^*(h^* + \eta^*) = \chi^* \eta^*
\]  

(5)

Relationship (5) simply forces a mass balance within the inner region and the constant \( \chi^* \) depends on the reflection coefficient of the beach and the characteristics of the wave.

The problem is then closed by Exner equation, which forces the sediment balance, and by a constitutive relationship relating the sediment transport rate per unit width \( (q^*_x, q^*_y) \) and the water motion

\[
\frac{\partial h^*}{\partial t^*} = \frac{1}{(1 - p)} \left[ \frac{\partial q^*_x}{\partial x^*} + \frac{\partial q^*_y}{\partial y^*} \right]
\]  

(6)

\[
(q^*_x, q^*_y) = h_0^3 \hat{Q} \alpha(x)(\bar{u}^*, \bar{v}^*) \quad \alpha = \left| \frac{u^*_w}{\sqrt{gh_0^*}} \right|^{b-1}
\]  

(7)

In (5), (6) \( p \) is sediment porosity, an overbar denotes the time average over a wave cycle, \( \alpha \) is a wave stirring coefficient which depends on the dimensionless
periodic component \( u_w^* / \sqrt{g' h_0^*} \) of the wave field, \( Q \) is a dimensionless constant which depends on sediment characteristics and \( b \) is assumed to be equal to 4.

The basic wave field, which is uniform in the longshore direction, can be easily determined by expanding the solution in terms of the small parameter \( a = a^*/h_0^* \) (\( a^* \) denotes the wave amplitude at \( x^* = x_w^* \))

\[
\begin{align*}
  u &= \frac{u^*}{\sqrt{g' h_0^*}} = a U_1 + O(a^2) \\
  \eta &= \frac{\eta^*}{h_0^*} = a E_1 + O(a^2) \\
  h &= \frac{h^*}{h_0^*} = \frac{x}{x_w} + O(a^2)
\end{align*}
\]

In (10) \( x \) is the dimensionless cross-shore coordinate \( (x = x^* \omega^*/\sqrt{g'h_0^*}) \) and \( x_w = x_w^* \omega^*/\sqrt{g'h_0^*} \) is a dimensionless frequency parameter. Moreover because of the matching (4) with the deep water solution, the wave amplitude \( a^* \) is related to the wave amplitude \( a^*_{\infty} \) of the incoming wave far from the coast \( (a^* = a^*_\infty \sqrt{2\pi/\beta}) \). Both the dimensionless free surface \( E_1 \) and the velocity \( U_1 \) turn out to be periodic in time with angular frequency \( \omega^* \) and characterized by a cross-shore structure described by Hankel functions.

\[
\begin{align*}
  E_1(x,t) &= \frac{1}{2} \left\{ H_0^{(1)}(2\sqrt{g' x_{\omega}}) + \dot{K} H_0^{(2)}(2\sqrt{g' x_{\omega}}) \right\} \cos(\Omega^* t) + c.c. \\
  U_1(x,t) &= \frac{1}{2\sqrt{g' x_{\omega}}} \left\{ H_1^{(1)}(2\sqrt{g' x_{\omega}}) + \dot{K} H_1^{(2)}(2\sqrt{g' x_{\omega}}) \right\} \cos(\Omega^* t) + c.c.
\end{align*}
\]

where \( t = \omega^* t^* \) is the dimensionless time.

Then small perturbations of the free surface and of the bottom configuration are considered

\[
\begin{align*}
  \eta^* &= a E_1 + \epsilon \left\{ A^\pm(\tau) \hat{\eta}_0(x) e^{i(k^* y^* \pm \sigma^* t^*)} + c.c. + O(a) \right\} \\
  h^* &= \frac{x}{x_w} + \epsilon \left\{ B^\pm(\tau) \hat{h}_0(x) e^{i k^* y^*} + c.c. + O(a) \right\}
\end{align*}
\]

where \( \epsilon \) is a parameter much smaller than one (strictly infinitesimal) and \( \tau \) a slow time scale defined by \( \tau = a \omega^* t^* \). Of course perturbations of similar form are induced in the velocity field.

At order \( \epsilon \) equations (1), (3) provide the structure of \( \hat{\eta}_0(x) \)

\[
\hat{\eta}_0(x) = e^{-k^* x^*} U(d, 1; 2k^* x^*)
\]

where \( d \) is equal to \( (k^* - \sigma^2 x_w^*/(g' h_0^*)) / 2k^* \) and \( U \) indicates one of the Kummer functions (Abramowitz & Stegun, 1964). Then the boundary condition (5)
yields the dispersion relation

\[ d = -\frac{U(d, 1, 2k^*x_w^*)}{2U(d + 1, 2, 2k^*x_w^*)} \] (16)

which shows that different modes are possible. Moreover at order \( \epsilon \), \( \hat{h}_0^\pm(x) \) turns out to be arbitrary as well as \( A^\pm(\tau) \) and \( B^\pm(\tau) \).

In order to determine \( \hat{h}_0 \) and the time behaviour of \( A^\pm \) and \( B^\pm \), it is necessary to study the interaction between the perturbations and the incoming wave which is described by the problem at order \( \epsilon a \). In nonresonant cases a solution of the problem forced by the interactions of the perturbation with the basic wave field can be found and it gives rise to a slight modification of the original perturbation. However, as discussed by Guza \& Davis (1974) who considered only perturbations in the water motion, many resonanting cases exist and in particular resonance is present when the interaction between subharmonic edge waves (frequency \( \sigma^* \) equal to \( \omega^*/2 \)) and the incoming wave is considered.

When bottom perturbations are included, it can be seen that their presence induces extra forcing terms. These terms can give rise to a secular growth of the solution if \( h^* \) is characterized by a periodic longshore dependence characterized by a wavenumber \( k^* \) equal to that of a synchronous edge wave.

In order to prevent the solution from growing unbounded on the fast time scale, a solvability condition must be imposed which leads to

\[ \frac{dA^\pm}{d\tau} = \gamma_1^\pm B^+ + \gamma_2^\pm B^- \] (17)

where the coefficients \( \gamma_1^\pm, \gamma_2^\pm \) depend on the characteristics of the incoming wave. These equations describe the growth of the amplitude of synchronous edge waves due to their interaction with the incoming wave propagating on a wavy bottom. A further link between \( A^\pm \) and \( B^\pm \) is found by considering the bottom time development forced by the steady part of the \( O(\epsilon a) \) flow. This is because the interaction of synchronous edge waves with the incoming wave generates steady currents, which cause the movement of sediment and thereby result in the formation of bedforms. Sediment continuity equation and the sediment transport rate relationship yield

\[ \dot{h}_0^\pm(x) = \frac{d}{dx} \left[ \overline{|U_1|^{b-1}u_1^\pm} \right] + ik|U_1|^{b-1}v_1^\pm \] (18)

\[ \frac{dB^\pm}{d\tau} = QA^\pm \] (19)

where the steady velocity field described by \( u_1^\pm, v_1^\pm \) can be derived by means of the variation of the parameter method and the constant \( Q \), which turns out to be \( \dot{Q}a^{b-1}/(1 - p) \), is much smaller than one.
The solution of the amplitude equations is of exponential type

\[ B^\pm \sim \exp(a(t^{0+1/2} \tilde{t})) \] (20)

where

\[ \tilde{t} = t^* \sqrt{\frac{Qh_0^*}{(1 - p)(x_w^*)^2}} \] (21)

is a dimensionless time coordinate obtained using a morphodynamic time scale which does not depend on wave characteristics. Of course the amplification rate \( \tilde{\Omega} \) appearing in (20) depends on the parameters of the problem, i.e. \( x_w = x_w^* \omega^*/\sqrt{\Omega h_0^*} \) and \( \tilde{K} \).

3 THE RESULTS

The theoretical analysis, briefly summarized in the previous section, shows that crescentic forms may appear when \( A \) and \( B \) tend to grow. Figure 2 shows the maximum value of amplification rate \( \tilde{\Omega} \) versus the frequency parameter \( x_w \) for different values of \( |\tilde{K}| \) and for the first mode \( (n = 1) \). Note that \( |\tilde{K}| \) indicates the modulus of the reflection coefficient of the beach and its phase \( \tilde{\theta} \) is determined by means of the simple model described in (Vittori & al., 1998). The results indicate that bedforms periodic in the longshore direction tend to form when the incoming wave has an angular frequency \( \omega^* \) such that \( x_w \) takes values close to 4.5. However the first mode is not always the most unstable as...
Figure 3: Maximum value of the growth rate $\hat{\Omega}$ plotted versus $x_w$ for different mode numbers $n$ and $|\hat{K}| = 0.8$.

It can be seen from figure 3, where $\hat{\Omega}$ is plotted versus $x_w$ for $|\hat{K}| = 0.8$ and different mode numbers. In this case the second mode is the most unstable and crescentic forms appear when forced by incoming waves characterized by an angular frequency such that $x_w \approx 4.75$. By considering the behaviour of $\hat{\Omega}$ for different values of $n$, $x_w$ and $\hat{K}$ it is possible to single out the most unstable conditions, i.e. to evaluate the frequency $\omega^*$ of the incoming wave triggering the instability of the bottom configuration and the wavelength of the most unstable mode.

Let us now compare the theoretical findings with some field data. First of all this requires the determination of the values of $x^*_w$ and $h^*_0$ which are representative for the actual beach profiles. Figure 4 shows one of the bottom

Figure 4: Bottom profile measured along Niigata beach in 1958 (Homma & Sonu, 1963) and the model beach geometry.
profiles measured by Hom-ma & Sonu (1963) at Niigata beach during 1958 along with our simplified beach profile in such a way that the differences between the two geometries are minimized in a least square sense. In this case our best fitting procedure yields $x^*_w = 260 \text{ m}$ and $h^*_0 = 2.1 \text{ m}$. However it turns out that $x^*_w$ and $h^*_0$ depend on the longshore coordinate as it follows from figure 5 where the beach profiles detected at different longshore locations along the Niigata coast during 1958 are shown together with the values of $x^*_w$ and $h^*_0$. Hence in order to apply the theory, it is necessary to average $x^*_w$ and $h^*_0$ along the longshore coordinate. The data described in the paper by Hom-ma & Sonu (1963) provide the beach profiles at Niigata site at 6 longshore locations only and the average values of $x^*_w$ and $h^*_0$ can be determined with some uncertainty. It turns out that $x^*_w$ and $h^*_0$ fall within a small range around 280 m and 2.2 m respectively. The same procedure applied to the data obtained by Hom-ma & Sonu (1963) in August 1957 at Tokai beach provides values of $x^*_w$ and $h^*_0$ which are somewhat larger, i.e. 310 m and 2.9 m respectively. However it is necessary to point out that different wave climates make $x^*_w$ and $h^*_0$ to change. Indeed
Figure 6 shows that beach profiles detected at the same longshore location but at different times are characterized by large differences. The changes observed in the values of $x^*$ and $h^*$ are significant and hence the theoretical analysis should be used to indicate the range of wavelengths of possible crescentic forms rather than to predict an exact value.

Because the maximum value of the amplification rate $\tilde{\Omega}$ is around $x_w = 4.75$, the incoming waves which are most likely to give rise to the appearance of crescentic forms are those characterized by a period equal to about 80 s and 85 s for the Niigata and Tokai sites, respectively. Then the dispersion relation yields a value of the longshore wavelength of the bottom forms. For Niigata site the predicted length is around 600 m while for Tokai beach it appears that the most unstable crescentic forms are characterized by a wavelength of about 700 m. If a comparison is performed with the observed values a fair agreement is found taking into account that, at this stage, the analysis is linear and that a highly idealized model has been used. From figure 7, which shows bottom morphology measured in front of Niigata beach in 1958, it can be seen that bottom forms periodic in the longshore direction are present, which have wavelengths larger than 500 m. Likewise figure 8 clearly shows a longshore periodic pattern in the offshore bar at Tokai beach, with a wavelength which ranges between 1000 and 1500 m depending on the wave climate. The field surveys show also the presence of much shorter crescentic forms, with wavelengths of about 50 m. These bottom forms are also predicted by the theory since the total
amplification rate of the bottom perturbations (see (20)) is characterized by two maxima. The former is due to the maximum of $\Omega$, the latter is caused by maximum of the amplitude $a$ of the incoming wave which of course depends on the frequency parameter $x_w$. The prediction of the smaller bottom forms would require accurate measurements of the spectrum of the incoming wave field outside the breaker zone. These data are not available for Niigata and Tokai beaches. However it can be certainly assumed that the wave spectrum is characterized by a maximum for wind waves which have periods around 10 s. With these data, the theory predicts bedforms with a longshore wavelength of about 50 m, a value which is very close to the observed one. Good agreement is also found when comparing the theoretical findings with the field survey performed at Lubiatowa (Poland) by Pruszak et al. (1997). The presence of longshore crescentic forms can be seen in figure 9 which is an adaptation of the data described in Pruszak et al.’s (1997) paper. The wavelength of these crescentic forms is approximately 800 m even though the presence of only two bars and three pools does not allow a precise evaluation. By analysing the beach profile measured by Pruszak et al. (1997) during august 1996 it turns out that the values of $x^*_w$ and $h^*_0$ are 370 m and 2.1 m respectively. Using these input values in the theoretical model, the predicted wavelength is close to 850 m. In determining this value it has been assumed that it is caused by the maximum in the growth rate induced by the curve $\Omega$ versus the frequency parameter $x_w$. The bottom forms induced by wind waves which give rise to a maximum in $a(x_w)$ have not been observed by Pruszak et al. (1997). This may be due to the reflection coefficient of the beach. Indeed the theory predicts the appearance of crescentic forms only when the incoming waves are somewhat reflected by the beach. At Lubiatowa site the presence of a system
of longshore parallel bars induces the breaking of short waves and makes the reflection coefficient of the beach very small.

4 CONCLUSIONS

The comparison between the theoretical findings and field data described in the previous section seems to indicate that the main ingredients of the process leading to the formation of crescentic forms are captured by the simplified model formulated by Vittori et al. (1998). Of course in order to obtain more refined predictions of the characteristics of the bottom forms it would be necessary to improve the model by removing some of the assumptions introduced to work out the solution by analytical means. In particular the geometry of the beach should allow for the presence of bars and the wave model should include the description of breaking, since quite often the surf zone is not small when compared with the length of the incoming wave. Such a refined model would require a numerical approach to determine both the basic wave field and the time development of bottom perturbations.

SIMPLE MODELS FOR EQUILIBRIUM PROFILES UNDER BREAKING AND NON-BREAKING WAVES

Magnus Larson\textsuperscript{1} and Randall A. Wise\textsuperscript{2}

ABSTRACT: Simple theoretical models are presented to calculate the equilibrium profile shape under breaking and non-breaking waves. For the case of breaking waves the seaward transport in the undertow at equilibrium is locally balanced by a net vertical sedimentation so that no bottom changes occur. The parameterization of the water and sediment flux in the surf zone yields a power curve for the equilibrium profile with a power of 2/3. Three different models are developed to derive the profile shape under non-breaking waves, namely (1) a variational formulation where the wave energy dissipation in the bottom boundary layer is minimized over the part of the profile affected by non-breaking waves, (2) an integration of a small-scale sediment transport formula over a wave period where the slope conditions that yield zero net transport determine equilibrium, and (3) a conceptual formulation of mechanisms for onshore and offshore sediment transport where a balance between the mechanisms defines equilibrium conditions. All three models produce equilibrium profile shapes of power-type with the power typically in the range 0.15-0.30. Comparisons with laboratory and field data support the results obtained indicating different powers for the equilibrium profile shape in the surf zone and offshore zone.

INTRODUCTION

The concept of an equilibrium profile (EP) is of central importance to coastal engineers because it provides a basis for assessing a characteristic shape to a beach in design and analysis situations. A beach of a specific grain size, if exposed to constant forcing conditions (monochromatic waves or random waves with constant statistical properties), normally assumed to be short-period breaking waves, will develop a profile shape that displays no net change in time, although sediment will be in motion. The validity of this concept has been verified through a large number of laboratory

\textsuperscript{2}Coastal and Hydraulics Laboratory, U.S. Army Corps of Engineers, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199, USA.
experiments on beach-profile change (e.g., Saville 1957, Kajima et al. 1982, Kraus and Smith 1994, Dette et al. 1998). On a natural beach, however, the forcing conditions are never constant and changes in the beach topography occur at all times. In spite of this, the beach profile in the field exhibits a remarkably persistent concave shape (Bruun 1954, Dean 1977), where changes may be taken as perturbations upon the main profile configuration. Such changes in beach profile shape can be regarded as adjustment of the profile from the course of one equilibrium state to another as the forcing conditions change (for example, during a storm). With this view the equilibrium concept is valid not only for the long-term average forcing conditions but for varying forcing conditions over different time scales.

The conditions for equilibrium on a beach and associated slopes and profile shapes have been a topic of research since the 1950's. Bruun (1954) proposed a power law to describe the profile depth as a function of distance from the shoreline based on field data from the Danish West coast and from California (a power of 2/3 provided the best fit). Dean (1977) analyzed an extensive data set consisting of beach profiles measured along the Atlantic and Gulf coasts of United States. He also found that a power law with a power of 2/3 provided the best overall fit to the measured profile shapes. Furthermore, Dean (1977) theoretically motivated this power law by assuming that equilibrium occurred for constant wave energy dissipation per unit water volume along the profile. This constant is known as the equilibrium energy dissipation and has been shown to be a function of grain size (Moore 1982) or fall speed (Dean 1987).

Bowen (1980) derived EP shapes by analysis of the sediment transport formulas proposed by Bagnold (1963). Analytical expressions for the profile shape were obtained for the cases of a steady drift due to wave mass transport in the boundary layer and wave asymmetry, producing powers of 2/3 and 2/5, respectively. Larson and Kraus (1989) generalized the derivation by Dean (1977) to include the effect of gravity leading to a planar beach slope at the shoreline. Inman et al. (1993) divided the profile into two portions, an inner and outer region, which corresponded to the regions with breaking and non-breaking waves, respectively. Both portions were successfully approximated with power curves matched at the break point and the optimum values of the power was 0.4 for both curves. In fitting the power curve to the inner portion of the profile the height of the berm was employed as the base elevation; this differs from previous studies where typically the mean sea level was used as vertical datum.

Although a number of studies have been carried out regarding EPs, as indicated above, there are presently no general, physically based theories to derive the EP shape under both breaking and non-breaking waves that produce a realistic EP shape over the entire active profile. Thus, the main objective of this study is to develop theories for the EP shape under breaking and non-breaking waves. It is assumed that the region where wave breaking prevails may be treated separately from the offshore zone where mainly non-breaking waves control the profile shape. This separation is conceptually justified because intense turbulence exists in the surf zone, making both bedload and suspended load significant, whereas bottom-boundary layer processes and bedload transport are
expected to be dominant in the deeper and less turbulent water offshore under non-breaking waves. First, the EP shape in the surf zone will be discussed, where wave breaking controls the profile development. Then, the EP under non-breaking waves is treated where oscillatory waves determine the profile shape. The derived EP formulas were validated through comparisons with laboratory and field data.

THEORETICAL CONSIDERATIONS

EP Shape Under Breaking Waves (Surf Zone)

Although the theoretical model proposed by Dean (1977) for EPs produces a shape that is in agreement with field data, the physical justification for the equilibrium condition is not clear and the assumptions made are rather ad hoc. Also, a profile that is close to equilibrium may still produce a significant net sediment transport in the undertow that is difficult to explain within the framework of the Dean model. Here, an alternative model is derived that relies on certain assumptions about the circulation of water and sediment in the surf zone. In this sense the model is non-local as opposed to the Dean model where the equilibrium conditions are established from a local criterion of zero transport. A beach subject to waves experiences a return flow across the profile that carries sediment stirred up by the waves offshore in the undertow. Even at equilibrium conditions, when no net change in the profile shape occurs, this transport should take place implying that material has to come onshore above the undertow layer to compensate for the offshore transport. When the undertow reaches the break point the transported sediment has to be resuspended up into the water column and pushed onshore to ensure an equilibrium situation where no material goes offshore. Thus, such a simplified picture yields a surf zone with sediment moving, but with no net changes in time of the profile depths, and the break point acts almost as a singularity. Fig. 1 schematically illustrates the water and sediment flow in the surf zone at equilibrium conditions (note that the size of the arrows is exaggerated in the figure).

To arrive at an EP shape it is assumed that the change in the sediment transport in the undertow is balanced by sedimentation through the water column. This sedimentation represents the net effect from sediment being resuspended locally by the waves and the settling of the material. If it is assumed that the transport in the undertow is the product between the flow $q$ and a characteristic bottom concentration $c$, and that the gradient in this transport is balanced by a net sedimentation ($\mu wc$), the following equation for the EP profile may be derived (Larson et al. 1998),

$$\frac{d}{dx} \left( \lambda_u \sqrt{gh^2} \right) = \mu wh$$  \hspace{1cm} (1)$$

where $h$ is the water depth, $w$ the sediment fall speed, $g$ the acceleration of gravity, and $\lambda_u$, $\gamma$, and $\mu$ constants (referring to the undertow flow, wave height-depth ratio, and net sedimentation, respectively). The undertow flow was set proportional to the mass transport in the breaking waves, $c$ was derived from a balance between the work needed
to keep grains in suspension in the bottom layer and the energy dissipation in the bottom boundary layer (Larson et al. 1998), and the vertical sediment transport was parameterized in terms of $c$. Integrating the above equation with $h=0$ when $x=0$ yields:

$$h = \left( \frac{3}{5} \frac{\mu w}{\lambda_0 \sqrt{g' \gamma}} \right)^{2/3} x^{2/3}$$

(2)

This is the same EP shape as Dean derived with a similar functional dependence on $w$ for the constant in front of $x^{2/3}$ as what Kriebel et al. (1991) obtained (c.f., Bowen 1980).

Figure 1. Schematic picture of assumed sediment transport pattern in the surf zone for deriving an EP shape.

**EP Shape Under Non-Breaking Waves (Offshore Zone)**

Three different approaches were employed to derive the EP shape under non-breaking waves. The first approach was based on the heuristic assumption that the profile shape seaward of the break point at equilibrium is such that the waves dissipate a minimum of energy when traveling across the profile. In the second approach a detailed sediment transport formula proposed by Madsen (1991) was integrated over a wave period, and an equilibrium slope is determined that produces zero net transport. Finally, a conceptual model was formulated that assumed a balance at equilibrium between onshore transport due to wave asymmetry and offshore transport due to gravity.
Variational Formulation

Many systems in nature strive towards equilibrium in such a way that some energy quantity attains a minimum. Thus, it seems reasonable to assume that a beach profile is in equilibrium with the forcing conditions when an appropriate energy quantity reaches its minimum value. The basic assumption employed in the present formulation is that the total wave energy dissipation per unit beach width and time along the profile exposed to non-breaking waves attains a minimum at equilibrium. This implies that the waves lose minimum energy as they propagate across the profile, experiencing the least reduction in wave height for all possible profile shapes. Using the Euler-Lagrange approach from variational calculus to determine the optimal profile shape that minimizes the integral expressing the total wave energy dissipation gives the following equation to solve for the EP shape,

$$C_l h^{9/4} \sqrt{1 + (dh/dx)^2} = -1$$

where $C_l$ is a constant. However, this equation does not have a general solution that satisfies the boundary conditions $h=h_b$ for $x=x_b$ and $h=h_c$ for $x=x_c$, where subscripts $b$ and $c$ denote break point and closure depth, respectively (dissipation is assumed to occur between $x_b$ and $x_c$). Instead, by assuming a general power shape for the EP, that is, $h=(h_b/n+(h_c/n-h_b/n)(x-x_b)/(x_c-x_b))^n$, the following integral should be minimized to obtain the optimal power $n$,

$$J = \int \frac{1}{(1 + (Z^{1/n} - 1)\xi)^{n/4} \left(1 + (Z^{1/n} - 1)\xi\right)^{(n-1)/4}} \, d\xi$$

where $Z=h_c/h_b$, $W=(x_c-x_b)/h_b$, and $\xi=(x-x_b)/(x_c-x_b)$. The optimal value of $n$ ($n_o$) is a function of $h_c/h_b$ and $(x_c-x_b)/h_b$ and may be found from solving the equation $dl/dn=0$. Thus, the EP shape depends on the location of the boundaries and these have to be specified before the shape can be predicted. The breakpoint location can be calculated from the incident wave height, whereas the seaward limit of the profile experiencing significant dissipation is more difficult to estimate. Fig. 2 displays how $n_o$ varies with $h_c/h_b$ and the mean offshore slope $\tan \beta = (h_c-h_b)/(x_c-x_b)$. In all cases with realistic values on these parameters, $n_o$ is markedly lower than the value 2/3 that is often found for the surf zone. Thus, the predicted EP shape under non-breaking waves has a lower curvature than the EP shape under breaking waves.

Microscale Formulation

Madsen (1991) derived a formula for the instantaneous bedload sediment transport rate based on a detailed description of the physical processes controlling the transport in the offshore zone. Under certain conditions this formula will produce zero net transport
over a wave period which implies that the beach does not experience any changes because of the transport. Only the wave motion will be considered here and there will be no attempt to include a steady current, although it is possible if the current speed can be specified. The Madsen formula always produces offshore transport for a sloping bed under purely sinusoidal waves (gravity promotes down-slope transport); thus, it is necessary to include the asymmetry of the velocity field so that a realistic balance is obtained between the tendency of onshore transport in shoaling waves and offshore transport due to gravity. The local condition for equilibrium may be expressed as (Larson et al. 1998),

\[ \int_{I_p}^I h \frac{I_p + I_n}{I_p - I_n} \, dh = \tan \phi_m (x - x_p) \]  

(5)

where \( I \) is an integral over the bottom shear stress, \( \phi_m \) the friction angle for a moving grain, and subscripts \( p \) and \( n \) denote the periods when the shear stress is positive and negative, respectively. The EP shape can only be obtained if the shear stress integrals \( I_p \) and \( I_n \) are calculated which require a detailed solution of the flow in the bottom boundary layer. However, using a number of approximations a simple analytical solution can be derived from the above exact equation.

![Figure 2. Dependence of the optimal power in the EP equation for the offshore on the geometric parameters.](image)
Cnoidal wave theory was used to describe the asymmetric properties of the waves and an empirical equation was fitted to the theory to allow straightforward calculation of these properties. Furthermore, the effect of the initiation of motion was neglected and the asymmetric waves were schematized using two sinusoidals to describe the periods when the shear stress is positive and negative. These assumptions together with a nonlinear shoaling law for the wave height yield the following EP shape for larger values of \( h/h_b \) (Larson et al. 1998),

\[
\frac{h}{h_b} = \left( 1 + \frac{1}{K_1} \frac{\tan \theta_m x - x_b}{h_b} \right)^{\frac{1}{1+(2-p)m}}
\]

where \( K_1 \) is a constant, \( p \) the power in the nonlinear shoaling law, and \( m \) an empirical power (about 7/5) originating from the empirical fit to cnoidal wave theory. Realistic values on \( p \) and \( m \) yields a power in the EP equation of about 0.25.

**Conceptual Formulation**

Instead of starting from a detailed sediment transport formula (e.g., Madsen) a conceptual approach was taken to derive the EP shape. It is assumed that the two main mechanisms that govern the profile shape in the offshore are the onshore transport due to the shoaling waves and the offshore transport due to gravity (compare Niedoroda et al. 1995). At equilibrium these two mechanisms produce equal amounts of transport and there will be no local net transport. The mean cross-shore transport rate \( q_c \) is often related to the bottom Shields stress \( \psi_b \) to a power \( k \). To include the effect of wave asymmetry on the transport rate, a dependence on the Ursell number \( U_r \) was introduced,

\[
\frac{q_c}{w_d} = C \psi_b^k U_r^m
\]

where \( d \) is the grain size and \( C \) a constant. The \( U_r \)-dependence (including the power \( m \)) is the same as was used in the previous section. The transport \( q_c \) should be balanced by the offshore transport due to gravity, which is estimated from a sediment layer with a characteristic concentration \( c \) moving offshore at the speed \( w_d h/\partial x \) (\( c \) is estimated in a similar manner to what was done in the surf zone; see Larson et al. 1998). Equating the two types of transport and introducing shallow-water approximations yields the following EP shape,

\[
\frac{h}{h_b} = \left( 1 + r K_2 \frac{x - x_b}{h_b} \right)^{U_r}
\]

where \( r = 1 + 3/2k + 9/4(m-1) \) and \( K_2 \) is a constant. Again, an EP shape is derived that follows a power law. The coefficient \( k \) is typically in the range 3/2 to 3, and \( m = 7/5 \).
provided a good fit to cnoidal wave theory. Thus, for \( k=3/2 \) the equation gives the power a value of 0.24, whereas \( k=3 \) produces a value of 0.15.

**COMPARISONS WITH LABORATORY AND FIELD DATA**

In summary, the previously derived EP shapes under breaking and non-breaking waves may be written, respectively,

\[
\begin{align*}
  h &= Ax^n, & 0 \leq x \leq x_b \\
  h &= \left( h_b^{1/n} + B(x - x_b) \right)^n, & x \geq x_b
\end{align*}
\]

where \( A \) and \( B \) are shape parameters, and subscript \( b \) denotes the break point. The values of the powers were determined to be \( m=2/3 \) (compare Bruun 1954 and Dean 1977), whereas \( n \) was in the range 0.15-0.30, depending on the mechanisms assumed to control profile equilibrium. The shape parameter \( A \) has been related to grain size (or fall speed), whereas \( B \) is a function of the sediment characteristics as well as the offshore wave conditions (in the general case). Descriptions of beach profiles that involve regions governed by different predictive relationships have previously been proposed by Everts (1978) and Inman et al. (1993).

Eqs. 9 and 10 were least-square fitted towards measured profiles in the laboratory and the field to evaluate how well they are able to characterize the profile shape in the surf zone and offshore zone. The distinction between these two zones was typically made based on the presence of a nearshore bar (compare Inman et al. 1993). Only the shape parameters \( A \) and \( B \) were optimized in the fitting procedure, whereas \( x_b \) and \( h_b \) were visually determined based on the observed profiles introducing an element of subjectivity in the calculations. The value of the power \( n \) was also varied, but \( n=0.3 \) provided the best overall fit. This value is somewhat larger than what was typically found from the theoretical analysis, although it still within the range of realistic values. The theoretical EP models were essentially based on monochromatic (or representative) wave conditions and the effects of wave randomness were not explicitly addressed. In the following, the least-square fit was carried out some distance away from the bar region, where the effects of randomness are expected to be most pronounced. Thus, seaward of the bar mostly non-breaking waves prevail and shoreward of the bar fully broken waves dominate, implying that a monochromatic wave description should be appropriate as a first approximation.

**Laboratory Data**

Data obtained in the German Large Wave Tank were employed to evaluate how well the derived EPs could describe measured profile shapes at near-equilibrium conditions (Dette et al. 1998). The tests used here for comparison involved random waves according to a TMA spectrum with an \( H_{\text{mo}}=1.2 \) m and \( T_{\text{m}}=5 \) sec. In total data from three tests were used and the experimental conditions were similar in all tests except for the foreshore slope. In all cases, both in the surf zone and offshore zone, it
was possible to obtain a close fit between the equations and the data (one example given in Fig. 3). The estimated A-value in the surf zone \( A=0.12 \, \text{m}^{1/3} \) was in good agreement with what is to be expected for the grain size employed (median grain size 0.33 mm). The B-values varied somewhat more \( (0.44-0.78 \, \text{m}^{7/3}) \), which partly depended on the amount of material deposited in the bar area. A larger amount implied a steeper seaward bar face and the need for a larger B-value to properly fit both the steep bar face and the more gently sloping profile seaward of the bar.

![Figure 3. Comparison between theoretical and measured EPs from Test B2 in the German Large Wave Tank.](image-url)

**Field Data**

Profile measurements from several locations around the United States were employed to test the derived EP shapes for field conditions. Data sets from Ocean City, Long Island (Fire Island, Westhampton Beach, and Ponds), Cocoa Beach, and Silver Strand were employed in this comparison representing a wide variety of wave and beach conditions. In most cases a more or less clear breakpoint bar was present along the profiles that provided a natural separation point between the surf zone and offshore zone. As an example, Fig. 4 displays a fit towards a profile measured at Silver Strand (Larson and Kraus 1992), where the estimated parameter values were \( A=0.21 \, \text{m}^{1/3} \) and \( B=12.3 \, \text{m}^{7/3} \). The obtained A-parameter value is somewhat high considering the grain size at the site; however, the profile shape near the shoreline reveals a feature indicative of accretion that complicates the picture.
In Fig. 4 the bar feature was quite suppressed and the two EPs could be joined at a matching point without too much deviation from the measured profile around this point. This was not always the case, but frequently a pronounced bar feature appeared that produced a region where it was not possible to obtain an acceptable fit. Fig. 5 illustrates one such example from Ocean City (Stauble et al. 1993), where a large bar was present creating a region where the composite EPs fail to describe the shape. On the contrary, extrapolating the EPs so that they intersect at a match point could be a useful way of defining the bar feature. The shape parameters for the fit described in Fig. 5 were $A=0.14 \, m^{1/3}$ and $B=3.7 \, m^{1/3}$.

![Figure 4. Comparison between theoretical and measured EPs from Silver Strand, USA.](image)

As indicated by the profile fits presented in Figs. 3-5 the optimal value of the shape parameter $B$ varied substantially between the studied surveys. In order to usefully employ the composite EP for predictive purposes, a formula is needed that will yield $B$ as a function of the governing factors ($A$ is predicted from grain size according to Moore (1982) or Dean (1987)). A closer examination revealed a distinct correlation between $h_b$ and $B$ (see Fig. 6), implying that knowledge of the depth at the location where wave breaking typically occurs can be used to compute $B$. Several different empirical relationships were developed, encompassing both linear and power-type functions (see Fig. 6), each explaining about 70% of the variation in the data (in total 41 profiles from the above-mentioned sites were used in the fit). The following equation is dimensionally consistent and results if the EPs (Eqs. 9 and 10) are scaled with $h_b$: 
The rational between Eq. 11 is that the typical breaking wave height (and, thus, water depth at breaking) is the main quantity that scales profile behavior allowing for intercomparison between profile shapes at different sites. Eq. 11 may be regarded as a first-order approximation to compute the shape parameter controlling the EP in the offshore for profiles with one more or less well-developed bar. It should be pointed out that the analysis presented here of the field profiles contains some amount of uncertainty, not only concerning objectively determining the fitting parameters, but also regarding how close the measured profiles were to equilibrium conditions at the time of survey.

CONCLUDING REMARKS

One theoretical model to calculate the EP under breaking waves and three models to calculate the EP under non-breaking waves were briefly discussed in this paper. The theoretical models were derived based on descriptions of wave and sediment transport processes, providing physical justification for the equilibrium conditions. The approach for breaking waves resulted in a power function with a value on the power of 2/3, which is in accordance with existing field data and Dean's formulation of equilibrium based on constant energy dissipation per unit water volume across the profile. The first formulation of equilibrium for non-breaking waves was based on an assumption about the overall behavior of the offshore profile shape regarding the dissipation of wave
energy, whereas the other two formulations relied on assumptions about the predominant sediment transport mechanisms controlling the EP shape. For the two latter models, one approach started from a micro-scale sediment transport formula, whereas the other approach encompassed a conceptual description of the processes governing sediment transport in the offshore. A power function was obtained for all three approaches with the value of the power being around 0.25. Thus, these models confirm the common observations that the EP shape in the offshore has a lower curvature than in the surf zone.

Comparisons with field data showed that the theoretically derived composite EP could well describe the measured profiles over a wide range of water depths. However, in some cases, when a marked bar was present along the profile, the composite EP failed to accurately describe the shape in the bar region. The simple theoretical EP models derived here were not designed to resolve the complex flow and sediment transport conditions in the bar region, but mainly to describe the profile behavior under a steady bore propagating shoreward or a purely oscillatory wave in the offshore. It might be possible to heuristically include the bar region by some additional assumptions regarding the equilibrium conditions in this region.

Figure 6. Relationship between the shape parameter for the EP in the offshore and the depth at breaking.

Two of the approaches to calculate the EP shape under non-breaking waves were based on balances between the onshore and offshore transport. If this balance is not fulfilled there will be a net sediment transport and the magnitude of this transport is determined
as the difference between the onshore or offshore rate. Although the calculation of the net transport is straight-forward, it might be advantageous to formulate the local transport rate in terms of a deviation from the equilibrium shape. In the case such a formulation is employed, EP shapes obtained from laboratory and field data can be used to determine some of the unknown coefficients in the transport formulas (or eliminate the coefficients completely from the formulas).

EQUILIBRIUM TERRACED AND BARRED BEACHES

Mark D. Orzech\(^1\) and Nobuhisa Kobayashi\(^2\)

ABSTRACT

The results of two sediment transport models based on the sheet flow approach and the energetics approach are compared with experimental data of random waves over fine sand beaches in equilibrium in a wave flume. Two tests were conducted with a terraced profile (test 1) and a barred profile (test 2). The energetics-based model predicts the equilibrium profile better than the sheet flow model for both tests. However, the energetics model predicts offshore sediment transport and bar migration, whereas the sheet flow model predicts onshore sediment transport and bar migration. These models cannot predict zero net sediment transport rate on these equilibrium profiles with negligible profile changes, whereas the standard equilibrium profile cannot explain the existence of the terrace and bar.

INTRODUCTION

At the present time, there are no models capable of accurately predicting the development and final shape of terraced and barred equilibrium beach profiles. A profile of the form \(d = Ay^{2/3}\), with \(d\) = still water depth, \(y\) = seaward distance from the shoreline, and \(A\) = sediment scale parameter, has been shown to represent typical profiles of natural beaches [e.g., Dean (1991)]. Perturbations on the simple equilibrium profile in the form of barred and terraced beaches have also been observed. However, the processes involved in the creation of these perturbed beach profiles are not presently well understood. Trowbridge and Young (1989) developed a sheet flow sand transport model based on the time-averaged bottom shear stress and showed that this model could explain the measured onshore movement of a nearshore bar in Duck, North Carolina during the mild wave conditions between February and August, 1982. Thornton et al. (1996) and Gallagher et al. (1998) used an energetics-based sediment transport model to explain the offshore movement of a bar on the same beach during storms in 1990 and 1994, respectively. Yet no existing model can predict both onshore and offshore bar migrations satisfactorily.

This study conducted two detailed tests with a concave fine-sand beach in a laboratory wave tank, on one barred and one terraced profile in quasi-equilibrium. This ensured that the net cross-shore sediment transport rate on these profiles would be zero. The velocity and surface elevation measurements made during these tests were used to calculate bottom elevation changes predicted by the sheet flow and energetics-based models. These tests will help to identify the cross-shore sediment transport processes that take place on these quasi-equilibrium profiles and to suggest effects that have been neglected by existing transport models.

EXPERIMENT

The two tests were conducted in a wave tank that was 30 m long, 2.44 m wide, and 1.5 m high with a constant water depth of 61.0 cm. Repeatable irregular waves, based on the TMA spectrum (Bouws et al. 1985) using linear wave theory and random phases, were generated with a piston-type wave paddle. The beach was composed of fairly uniform fine sand with an initial slope of 1:12. For the random waves chosen for tests 1 and 2, the incident wave spectral peak periods were $T_p = 2.8$ s and $1.6$ s, respectively, and the spectral significant wave heights were $H_{mo} = 0.203$ m and $0.182$ m, respectively. The experimental setup is shown in Figure 1. Quasi-equilibrium profiles were obtained after repeatedly running the selected waves in bursts of 400 s for several days.

Ten capacitance wave gauges were used to measure the temporal variations of free surface elevations. Velocity statistics were measured in multiple cross-shore positions using a single Acoustic-Doppler Velocimeter (ADV) (Kraus et al. 1994). After equilibrium had been established for each test, the corresponding random wave burst was run 21 times over the stable profile, repositioning the velocimeter and several wave gauges between runs. The wave paddle motion, controlled by a computer, was approximately identical for all the runs in each test. The sampling rate for the free surface and fluid velocity measurements was 20 Hz. The measurement positions for the wave gauges and the ADV are shown in Figure 2. At two of its positions ($x = 7.35$ m and $x = 9.85$ m) the 2D probe was adjusted vertically to obtain three-point profiles of the cross-shore velocity over depth. At the remaining positions the velocity was measured as close as possible to mid-depth. Longshore velocities associated with three-dimensional turbulence were small compared with cross-shore velocities, and thus only cross-shore velocities were analyzed in these tests. The duration of each run was 400 s, from which the initial transient duration of 75 s was removed before the following analysis.

Preceding the experiment, a grain size analysis showed the beach sand to be relatively uniform, with mean diameter $d_{50} = 0.18$ mm. The average fall velocity for a spherical particle of diameter $d_{50}$ was calculated to be $w = 1.89$ cm/s and the measured fall velocity was 1.9 cm/s. During each of the two tests detailed measurements were made of the beach profile using a manual vernier pointer in the swash zone and a Panametrics 22DLHP ultrasonic depth gauge in deeper water. In both tests fairly uniform ripples (approximately 1–3 cm in height and 10–15 cm in length) were established in the regions offshore of the bar and along the terrace between the bar and the
Figure 1: Wave Tank Experimental Setup

Figure 2: Cross-Shore Positions of Wave Gauge and ADV Measurements Over Final Profiles (- - Test 1, -.- Test 2)

Figure 3: Final Equilibrium Profiles (- - Test 1; -.- Test 2) and $d = Ay^{2/3}$
swash zone. The waves in test 1 plunged intensely in a small region slightly shoreward of the terrace edge, creating a large amount of suspended sediment. Spilling breakers were more common in test 2, and breaking occurred more continuously over the bar and in shallower water up to the swash zone. Figure 3 shows the measured equilibrium profiles for tests 1 and 2 in comparison with the equilibrium profile $d = Ay^{2/3}$ with $A = 0.09m^{1/3}$ estimated for this sand using the empirical formula given by Dean (1991). The standard equilibrium profile represents the profile inside the surf zone fairly well, but there are significant deviations from the profile in the region of the terrace edge (test 1) or the bar crest (test 2) where the incident random waves broke intensively. The terraced and barred beaches for tests 1 and 2 are similar to beach profiles measured in Duck, except that the offshore slope in these laboratory tests was much steeper (e.g., Thornton et al. 1996).

**Free Surface and Velocity Statistics**

Measured wave statistics were presented in detail by Kobayashi et al. (1997), and in comparison with the corresponding results for a 1:16 slope by Kobayashi et al. (1998). The wave setup, $\bar{\eta}$, gradually increased as waves moved shoreward in shallower water, becoming tangential to the beach slope in the swash zone in both tests. The measured values of $H_{rms}$ were approximately constant in the region seaward of the bar/terrace. They reached a slight peak after passing onto the terrace, then decreased steadily in the surf zone and more rapidly in the swash zone. The measured values of $H_{rms}/\bar{H}$ reflected the beach profile fairly strongly in deeper water, then began to rise rapidly as they approached the still water shoreline. Undertow
was strong over most of the terrace region in both tests, indicating the existence of other mechanisms required to maintain the equilibrium profile against undertow. The measured undertow velocity fields are shown over the corresponding profiles in Figure 4.

Figure 5 shows profiles of velocity statistics measured at two locations \( x = 7.35 \text{ m} \) and \( 9.85 \text{ m} \) for the two tests. In general, the mean velocity, \( \bar{u} \), and standard deviation, \( \sigma_u \), remain relatively constant over the depth ranges measured. The measured undertow was within 20% of its mid-depth value for all profiles. The vertical variation of \( \bar{u} \) for irregular waves appears to be less than that for regular waves (Cox and Kobayashi 1998a). The standard deviation remains within 5% of the value calculated at mid-depth for both tests. The figures also show relative uniformity of values for the skewness, \( s_u \), and the kurtosis, \( K_u \), over the depth. The greater variability in these results at \( x = 9.85 \text{ m} \) for test 1 may be explained as a consequence of the intense wave breaking. This uniformity of the cross-shore velocity and its moments over depth provides support for our decision to calculate cross-shore sediment transport using a mid-depth velocity at each cross-shore location.

**SHEET FLOW MODEL FOR ONSHORE BAR MOVEMENT**

The sheet flow model proposed by Trowbridge and Young (1989) is presently the only existing model that attempts to explain onshore bar movement outside the surf zone in the absence of undertow. While application of this model has been limited to plane beds without ripples, the profiles obtained in these experiments did include ripples in the offshore and surf zones for both tests. However, both profiles were free of ripples in the region over the bar with the most intense wave breaking and in the swash zone. The following comparison should be interpreted in light of these limitations.

**Theory**

The measured cross-shore velocity is represented here by \( u(t) \), with \( t = \text{time} \). The overbar is used to indicate time averaging. The time-averaged rate of onshore sediment transport, \( \bar{q} \), is assumed to be expressible as

\[
\bar{q} = K \frac{w \bar{\tau}_b}{\rho g (s - 1)}
\]  

(1)

where \( w \) = sand fall velocity, \( \rho = \text{density of fluid} \), \( s = \rho_s/\rho = \text{specific gravity of sand} \) with \( \rho_s = \text{sand density} \), \( \bar{\tau}_b = \text{time-averaged bottom shear stress} \), \( g = \text{gravitational acceleration} \), and \( K = \text{an empirical coefficient} \). Trowbridge and Young (1989) analyzed the wave boundary layer and derived the following expression for the mean bottom shear stress, \( \bar{\tau}_b \):

\[
\bar{\tau}_b = + \frac{f_w \bar{u}^3}{2 \sqrt{gh}}
\]  

(2)

where \( f_w = \text{friction coefficient} \) and \( \bar{u} = (u - \bar{u}) = \text{oscillatory part of first-order wave velocity} \). Their wave boundary layer analysis did not account for undertow, which was
Figure 5: Depth variations of $\bar{u}$, $\sigma_u$, $s_u$, and $K_u$ at $x=7.35$ and $9.85$ m
significant in the present experiment. Note that while Trowbridge and Young defined the x-axis as positive offshore, the present analysis defines x as positive onshore. Substituting (2) into (1):

\[
\bar{q}_u = \left( \frac{Kf_w}{2} \right) \frac{w|\bar{u}|^3}{g(s-1)\sqrt{gh}}
\]

(3)

Trowbridge and Young calibrated the value of \(Kf_w\) for \(d \approx 0.2\) mm and recommended \(Kf_w = 0.5\). In the present tests, \(d_{50} = 0.18\) mm and \(Kf_w = 0.5\) is adopted as well. For sheet flow conditions, (3) may be used to predict the time-averaged cross-shore transport rate, \(\bar{q}_u\), based on the velocity data as indicated by the subscript \(u\).

Trowbridge and Young used linear long wave theory to relate \(\bar{u}\) to \(\bar{\eta} = (\eta - \bar{\eta})\), with the assumption that \(\bar{\eta}\) is Gaussian. Since the velocity data is available here, it is assumed instead that \(\bar{u}\) is Gaussian. This assumption yields

\[
\bar{|u|}^3 \approx \sqrt{\frac{8}{\pi}} |\bar{u}|^{1.5}
\]

(4)

which is better than the result of Trowbridge and Young because the skewness, \(s_u\), of the velocity is generally smaller than the skewness, \(s\), of the free surface (Kobayashi et al. 1997, 1998). Linear long wave theory is then assumed to obtain

\[
\bar{|u|}^3 = |(u - \bar{u})|^2 \approx \sqrt{\frac{g}{h}} |(\eta - \bar{\eta})|^2 = \frac{g}{h} |\bar{\eta}|^2
\]

(5)

Combining (4) and (5), one obtains

\[
\bar{|u|}^3 \approx \sqrt{\frac{8}{\pi}} \left( \frac{g}{h} |\bar{\eta}|^2 \right)^{1.5} = \sqrt{\frac{8}{\pi}} \frac{g}{h} \sqrt{\frac{g}{h}} \sigma ^3
\]

(6)

where \(\sigma\) is the standard deviation of the free surface elevation. Substitution of (6) into (3) yields

\[
\bar{q}_u = \frac{Kf_w w H_{rms}}{16\sqrt{\pi}} \left( \frac{H_{rms}}{h} \right)^2
\]

(7)

where the root-mean-square wave height \(H_{rms}\) is defined as \(H_{rms} = \sqrt{8}\sigma\). Eq. (7) may be used to predict the time-averaged cross-shore transport rate, \(\bar{q}_\eta\), using free surface data as indicated by the subscript \(\eta\).

An expression for the predicted rate of change of the sand bottom elevation is derived by applying the conservation equation of sediment. This yields an expression for the erosion (negative) or accretion (positive) rate \(\partial z_b / \partial t\) in terms of the gradient of the cross-shore transport rate \(\bar{q}\):

\[
\frac{\partial z_b}{\partial t} = -\frac{1}{(1 - n_p)} \frac{\partial \bar{q}}{\partial x}
\]

(8)

in which the porosity \(n_p\) was 0.4 in this experiment. Eq. (8) is combined with (3) or (7) to determine the erosion/accretion rate based on the velocity data or free surface data, respectively, where \((\partial z_b / \partial t)_u\) and \((\partial z_b / \partial t)_\eta\) are used for the computed values of \((\partial z_b / \partial t)\) corresponding to \(\bar{q}_u\) and \(\bar{q}_\eta\), respectively. In addition, \(\bar{q}_u \sim 0\) and \(\bar{q}_\eta \sim 0\) for the quasi-equilibrium profiles if the sheet flow model is applicable to these tests.
Analysis of Experimental Results

The velocity and free surface data from tests 1 and 2 were analyzed to obtain the quantities necessary for the evaluation of (3) and (7) at the 17 cross-shore measurement locations. At the locations of the three point velocity profiles the time series from only the middle position were used. A cubic spline interpolation was performed on each set of $q$ values to obtain the corresponding derivatives, $\partial q / \partial x$. Eq. (8) was then used to calculate $\partial z_b / \partial t$ at each location. The results of these calculations are displayed graphically in Figure 6 and detailed in Orzech and Kobayashi (1997).

The sheet flow model predicts large onshore transport rates and rapid profile change in the surf zone, especially for test 1. For perfectly equilibrium profiles, $\bar{q} = 0$ and $\partial z_b / \partial t = 0$, but the measured equilibrium profiles for test 1 and 2 had uncertainties on the order of 1 cm/hr. For test 2, $\partial z_b / \partial t$ based on $u$ is somewhat smaller than $\partial z_b / \partial t$ based on $\eta$, though still greater than 1.0 cm/hr over the bar. For both tests the bar is predicted to move further shoreward. Change of this magnitude was of course not observed in any part of either profile.

ENERGETICS-BASED MODEL FOR OFFSHORE BAR MOVEMENT

Unlike the sheet flow model, the energetics-based model developed by Bowen (1980) and Bailard (1981) attempts to account for both onshore/offshore transport due to wave asymmetry and offshore transport due to undertow, as well as slope effects due to gravity. This model separates sediment transport into bed load and suspended load components, including separate terms for each of the above transport mechanisms. Because these experiments were conducted in a wave flume there was no longshore current to contribute to sediment transport. This model does not account for the initiation of sediment movement, although the fine sand particles were observed to move constantly during this experiment.

Theory

In the energetics model, the time-averaged cross-shore sediment transport rate per unit width can generally be expressed by equation (2) in Thornton et al. (1996). For the present analysis with zero longshore velocity, however, the net onshore sediment transport rate $\bar{q}$ is simplified as:

$$
\bar{q} = K_b \left( |u(t)|^2 \bar{u}(t) \right) + K_b \left( |u(t)|^2 \bar{u} \right) - K_{bg} \left( |u(t)|^5 \right)
+ K_s \left( |u(t)|^5 \bar{u}(t) \right) + K_s \left( |u(t)|^5 \bar{u} \right) - K_{sg} \left( |u(t)|^5 \right)
= \bar{q}_{bw} + \bar{q}_{uw} + \bar{q}_{bg} + \bar{q}_{sw} + \bar{q}_{wu} + \bar{q}_{sg}
$$

where $u(t) =$ cross-shore horizontal velocity, which is positive shoreward in this analysis. In (9), the first three terms represent bed load (subscript $b$) produced by wave asymmetry (subscript $w$), undertow (subscript $u$), and the effects of gravity (subscript $g$) on the bottom slope, respectively. The final three terms represent suspended load (subscript $s$) produced by the same three respective effects. The coefficients in (9)
Figure 6: Net Transport Rates $\bar{q}_u$, $\bar{q}_n$ and Bottom Elevation Change Rates $(\partial z_b/\partial t)_u$, $(\partial z_b/\partial t)_n$, Over Test 1 and 2 Profiles (Sheet Flow Model)
are expressed as

\[ K_b = \frac{1}{(s-1)g} C_f \frac{\varepsilon_b}{\tan(\phi)}; \quad K_{bg} = K_1 \frac{\tan(\beta)}{\tan(\phi)} \]

\[ K_s = \frac{1}{(s-1)g} C_f \frac{\varepsilon_s}{w}; \quad K_{sg} = K_s \frac{\varepsilon_s \tan(\beta)}{w} \]

where \( s = \rho_s/\rho \) = specific gravity of sand, \( C_f \) = drag coefficient, \( \phi \) = internal friction angle of sand, \( \varepsilon_b \) = bed load efficiency factor, \( \varepsilon_s \) = suspended load efficiency factor, \( \tan(\beta) \) = local bed slope, and \( w \) = fall velocity. In this experiment, \( s = 2.66 \) and \( w = 1.9 \text{ cm/s} \), while the other parameters are given the same values as those used in Thornton et al. (1996): \( C_f = 0.003 \), \( \tan(\phi) = 0.63 \), \( \varepsilon_b = 0.135 \), and \( \varepsilon_s = 0.015 \).

The local slope, \( \tan(\beta) = dz_b/dx \), is computed using the equilibrium bottom profile, \( z_b(x) \), for each test.

After \( q \) is obtained using (9), the predicted erosion or accretion rate, \( \partial z_b/\partial t \), for the profile at given locations is found by use of (8). This corresponds to equation (1) in Thornton et al., except that here the value of \( \mu = (1 - n_p) \) is taken as 0.6 rather than 0.7 because the measured porosity \( n_p \) = 0.4 in this experiment.

**Analysis of Experimental Results**

Each of the time-averaged velocity expressions in (9) was evaluated for the 17 velocity locations, with the middle position again selected from the two three-point velocity profiles. The values of the six sediment load components are plotted over the test 1 and test 2 equilibrium profiles in Figure 7 (tabulated in Orzech and Kobayashi (1997)). In both tests the largest values predicted for all the terms in (9) occur around the location of the bar or terrace edge, in the vicinity of \( x \approx 7-8 \text{ m} \). The more intense breaking of test 1 is clearly visible from the comparison of sediment loads in this region. At \( x = 7.85 \text{ m} \) in this test, a large volume of sediment is transported seaward by both wave asymmetry and undertow effects; however, just 0.5 m shoreward at \( x = 8.35 \text{ m} \), the wave asymmetry suspended load \( q_{sw} \) suddenly reverses and becomes strongly positive onshore. In general, the predicted suspended load values are larger than the corresponding bed load terms, as would be expected from the relatively large waves and fine sand used in the experiment.

For the two velocity profile locations, the cross-shore sediment transport rate \( \bar{q} \) in (9) was found to be largely insensitive to the elevation of the cross-shore velocity, \( u(t) \), used for its prediction. Predicted sediment loads due to undertow and bottom slope remained nearly constant over the depth, while predictions of wave-asymmetry-induced loads \( \tilde{q}_{sw} \) and \( \tilde{q}_{bw} \) varied somewhat more, especially for test 1. It may thus be reasonable to predict the sediment load due to undertow and bottom effects by measuring velocities at mid-depth (as done in this study) instead of immediately outside the bottom boundary layer as specified by the theory of Bailard (1981).

The total sediment loads and rates of profile change predicted by the energetics model at each cross-shore location are plotted over the equilibrium profiles in Figure 8 (tabulated in Orzech and Kobayashi (1997)). Unlike Thornton et al. (1996), the
Figure 7: Cross-Shore Variation of Suspended Load and Bed Load Quantities Over Test 1 and 2 Profiles (Energetics Model)
Figure 8: Predicted Bed Load $\bar{q}_b$, Suspended Load $\bar{q}_s$, and Total Load $\bar{q}$ with $\partial z_b/\partial t$ Over Test 1 and 2 Profiles (Energetics Model)
suspended load, \( q_s \), is rarely an entire order of magnitude larger than the bed load, \( q_b \), in this laboratory experiment. In test 2, the total bed load \( q_b \) is actually comparable to the total suspended load, \( q_s \), at most locations. This may be reasonable under the milder wave conditions of this test. If the energetics model could predict the existence of these equilibrium profiles, one would expect that the net sediment transport \( \bar{q} = 0 \). In test 1, \( \bar{q} \) is predicted to be very weakly onshore at locations seaward of the breaker zone but strongly offshore at almost all locations on the terrace. The magnitude of the parameter \( \frac{\partial z_b}{\partial t} \) is not greater than 1 cm/hr except in the region of intense breaking. In test 2, all locations are predicted to have a weak offshore transport, with \( \frac{\partial z_b}{\partial t} \) consistently small and within measurement errors of 1 cm/hr. These values are smaller than those in test 1 because waves broke less intensely, leading to slower profile changes. For both tests the energetics model predicts the growth and offshore movement of a bar near \( x = 7 \) m and the deepening of a trough near \( x = 8 \) m. The energetics model is unable to predict quasi-equilibrium profiles with no net sediment transport, although it predicts the bottom profile change within 1 cm/hr for test 2.

CONCLUSIONS

The general failure of state-of-the-art sediment transport models to predict the equilibrium profiles illustrates the limitations on such models at the present time. While the sheet flow model predicted onshore sediment transport and bar migration, the energetics model predicted offshore sediment transport and bar migration. The energetics model, which attempts to account for effects of wave asymmetry, undertow, and bottom slope, predicted smaller profile change than the sheet flow model, which did not include the effects of wave breaking and undertow. The standard \( Ay^{2/3} \) equilibrium profile represents the profile inside the surf zone fairly well, although it does not predict the existence of a bar and terrace.

An improved sediment transport model will need to account for the combined onshore and offshore transport effects of the above two models. In this study, the energetics model was more accurate than the sheet flow model in both tests 1 and 2, very likely because of the inclusion of a greater number of sediment transport mechanisms. The assumptions involved in simulating each transport mechanism must also be carefully reviewed and questioned. In this experiment, both models assume the instantaneous response of bed load and suspended load particles to the horizontal velocity immediately outside the bottom boundary layer. However, the water was observed to be consistently very cloudy during both tests; thus the assumption of the instantaneous response of suspended load appears to be questionable. A better model of sediment suspension might need to consider the instantaneous vertical velocity associated with the coherent intermittent fluid motion, as suggested in Cox and Kobayashi (1998b).

BREAKER BAR FORMATION AND MIGRATION

Bart T. Grasmeijer\textsuperscript{1} and Leo C. van Rijn\textsuperscript{1,2}

Abstract

The formulation of Isobe and Horikawa (1982) is modified and adapted for use in a probabilistic cross-shore transport model (CROSMOR). Computed changes of wave height, peak near-bed orbital velocity and depth-averaged return flow are compared to laboratory measurements. A comparison is made between computed and measured bed profile changes for a large scale laboratory experiment.

Introduction

The generation and maintenance of longshore bars is commonly associated with the shoaling and breaking of high-frequency waves and the generation of low-frequency wave effects in the surf zone. Breaker bars may be generated and maintained by a combination of spilling and shoaling waves; the latter producing landward sediment transport due to wave asymmetry and increasing toward the break point, thereafter reducing and grading into seaward transport by undertow currents associated with spilling breakers leading to build up of the bar. Although formation and maintenance of bars may also be related to low-frequency waves, in this paper attention will be focused on the convergent pattern of sediment fluxes due to wave asymmetry and undertow. Model calculations are compared to a small and a large scale laboratory tests.

Model description

The cross-shore transport model is based on a wave by wave approach (Wijnberg and Van Rijn, 1996). The probability density function of the deep water wave height is schematised into a discrete series of wave height classes and corresponding periods. Each wave height class is assumed to propagate independently of the other classes by solving the wave energy balance separately. The waves shoal until an empirical criterion for breaking is satisfied. Wave height decay after breaking is modelled by dissipation of energy in a breaking wave and a bore. Tide, wave, and storm induced water level variations and tide, wind and wave driven longshore currents are also included in the model.

The high-frequency near-bed orbital velocities (low-frequency effects are neglected) are computed using a modification of the method of Isobe and Horikawa (1982). The method of Isobe and Horikawa method is a parameterisation of fifth-order Stokes wave theory and third-order cnoidal wave theory which can be used over a wide range

\textsuperscript{1} Dep. of Phys. Geography, Univ. of Utrecht, P.O. Box 80.115, 3508 TC, Utrecht, The Netherlands, e-mail: B.Grasmeijer@geog.uu.nl

of wave conditions. In the original formulation the near-bed value of \( \dot{u} \) (defined as: \( u_{on} + u_{om} \)) is derived from deep water wave conditions as follows:

\[
\dot{u} = 2.0 r \ u_{\text{linear}}
\]

with:

\[
r_3 = -27.3 \log_{10} \left( \frac{H_o}{L_o} \right) - 16.3
\]

(2)

\[
r_2 = 1.28
\]

(3)

\[
r_1 = 1
\]

(4)

\[
r = r_1 - r_2 \exp\left( -r_3 \frac{h}{L_o} \right)
\]

(5)

\( u_{\text{linear}} \) = peak near-bed velocity computed using linear wave theory (m/s), \( H_o \) = deep water wave height (m), \( L_o \) = deep water wave length (m), \( h \) = local water depth (m).

Hamm (1996) tested the formulation from Isobe and Horikawa and the formulation from Swart and Crowley (1988) against laboratory measurements. He found that the Isobe and Horikawa formulation can be used over a large range of wave conditions except in the surf zone when monochromatic waves are considered. Although the covocoidal theory from Swart and Crowley provides a more comprehensive description of wave properties, abnormal results were observed in a few cases. The use of one representative wave height and period in random waves may lead to an underestimation of velocity moments with low steepness waves.

Stripling and Damgaard (1997) adapted the method from Isobe and Horikawa for use in a model for morphodynamic predictions. They compared the results with vocoidal theory (Swart, 1978). Although vocoidal theory consistently over-predicted the values of the odd bottom velocity moments and the method of Isobe and Horikawa consistently under-predicted them by a similar order, the most important aspect of their comparison was not so much in the values of the moments but rather the direction in which the methods predict the moments to be in. Vocoidal theory occasionally predicted the odd moments in the opposite direction to the measurements, which was not so with the method of Isobe and Horikawa (1982). Compared to vocoidal theory the method of Isobe and Horikawa led to greater accuracy in the morphodynamic prediction capability of the profile model.

In the present modified formulation the near-bed value of \( \dot{u} \) is derived from the local wave conditions as follows:

\[
r = 1 - 3.2 \left( \frac{H}{L} \right)^{0.65} \left( \frac{H}{L} \right)^{3.4} \frac{h}{L}
\]

(6)

with: \( H \) = local wave height (m), \( L \) = local wave length (m), \( u_{\text{linear}} \) = near-bed velocity computed using linear waves theory.

The \( r \) factor was found by calibration using laboratory and field data with random waves. Basic data are given in Table 1.

Table 1. Basic data of measurements used in calibration of r factor.

Measured signals of surface elevation and horizontal orbital velocity near the bed were analysed using spectral analysis. High- and low-frequency oscillations were separated (by filtering) at a period of 2 times the wave spectrum peak period, $T_p$. The high-frequency signals were separated into shorter time series each containing 10-15 individual waves. Each of the short time series was defined as one single wave class with one representative wave height, wave period, crest velocity near the bed, and trough velocity near the bed. The mean values were chosen to represent the wave class. A comparison between measured and computed values of $\bar{u}$ is presented in Figure 2. The broken lines indicate a 20% error band.
Figure 1. Comparison between measured and computed values of near-bed orbital velocity \( \hat{u} \) defined as \( u_{\text{me}} + u_{\text{off}} \).

The following formulae, Eq.(7)-Eq.(14), were derived to account for the asymmetry of the velocity profile (Isobe and Horikawa, 1982). Eq.(7)-Eq.(12) is a parameterisation of fifth-order Stokes wave theory and third-order cnoidal wave theory. Eq.(13) and Eq.(14) were introduced to take into account the deformation of the velocity profile due to bottom slope.

\[
\left( \frac{u_{\text{me}}}{\hat{u}} \right)_a = \lambda_1 + \lambda_2 \left( \frac{\hat{u}}{\sqrt{gh}} \right) + \lambda_3 \exp \left( -\lambda_4 \left( \frac{\hat{u}}{\sqrt{gh}} \right) \right) \tag{7}
\]

with:

\[
\lambda_1 = 0.5 - \lambda_3 \tag{8}
\]

\[
\lambda_2 = \lambda_3 \lambda_4 + \lambda_5 \tag{9}
\]

\[
\lambda_3 = \frac{0.5 - \lambda_5}{\lambda_4 - 1 + \exp(-\lambda_4)} \tag{10}
\]

\[
\lambda_4 = \begin{cases} 
-15 + 1.35 \left( T \frac{g}{Vh} \right), & T \frac{g}{Vh} \leq 15 \\
-2.7 + 0.53 \left( T \frac{g}{Vh} \right), & T \frac{g}{Vh} > 15 
\end{cases} \tag{11}
\]
\begin{align*}
\lambda_s = \begin{cases} 
0.0032 \left( \frac{T}{\sqrt{h}} \right)^2 + 0.000080 \left( \frac{T}{\sqrt{h}} \right)^3, & T \frac{g}{h} \leq 30 \\
0.0056 \left( \frac{T}{\sqrt{h}} \right)^2 - 0.000040 \left( \frac{T}{\sqrt{h}} \right)^3, & T \frac{g}{h} > 30 
\end{cases} 
\tag{12}
\end{align*}

\left( \frac{u_{on}}{\dot{\bar{u}}} \right)_{\text{modified}} = 0.5 + \left( \frac{u_{on}}{\dot{\bar{u}}} \right)_{\text{max}} - 0.5 \tanh \left( \frac{\left( \frac{u_{on}}{\dot{\bar{u}}} \right)_{\text{max}} - 0.5}{0.5} \right) 
\tag{13}

\text{with:}

\left( \frac{u_{on}}{\dot{\bar{u}}} \right)_{\text{max}} = 0.62 + \frac{0.003}{\text{bed slope}} 
\tag{14}

\text{A comparison between preliminary computations using the present probabilistic model and laboratory tests showed that the influence of the bed slope might be less pronounced. The following relation gave more realistic results:}

\left( \frac{u_{on}}{\dot{\bar{u}}} \right)_{\text{max}} = 0.62 + \frac{0.001}{\text{bed slope}} 
\tag{15}

\text{The present model includes a sinusoidal distribution of the instantaneous velocities during the forward and backward phase of the wave cycle. The duration period of each phase is corrected to obtain zero net flow over the full cycle. This is in contrast to the original approach of Isobe and Horikawa.}

\text{The depth-averaged return current under the wave trough of each individual wave (summation over wave classes) is approximated with the following expression:}

\begin{align*}
U_{\text{mean, return}} = 0.125 \sqrt{\frac{g H_{\text{rms}}^2}{h_t}} 
\tag{16}
\end{align*}

\text{in which } H_{\text{rms}} = \text{root-mean-square wave height, } h = \text{mean water depth, averaged over half a wave length seawards, } h_t = \text{water depth below wave trough level defined as } h - \frac{1}{2} H_{\text{rms}}. \text{ Equation (16) is based on linear mass flux } (q = U_{\text{mean}} h_t = 0.125 \ g \ H_{\text{rms}}^2/c), \text{ an effective depth equal to } h_t = \text{depth below wave trough and } c = (gh)^{0.5} = \text{wave propagation speed in shallow water.}

\text{The sand transport rate of the model is determined for each wave (or wave class), based on the computed wave height, depth-averaged cross-shore and longshore velocities, orbital velocities, friction factors and sediment parameters. Net transport rates are obtained after time-averaging of instantaneous values over the wave period. The sediment transport model is local and horizontal advection of sediment clouds due to mean currents and long period oscillations is not considered. The net (averaged over the wave period) total sediment transport is obtained as the sum of the net bed load } (q_b) \text{ and net suspended load } (q_s) \text{ transport rates.}

\text{Small Scale Laboratory Test}

\text{The cross-shore transport model was used to compute the hydrodynamics measured during a small scale laboratory test. The tests were conducted in the Large Research}
Figure 2. Measured and computed wave heights, peak orbital velocities and depth-averaged return flows for small scale laboratory test.
The flume has a length of 45 m, a width of 0.8 m and a depth of 1.0 m. Irregular waves (following a JONSWAP spectrum) were generated with a peak spectral period of, $T_p = 2.3$ s ($\pm 0.2$ s). A nearshore bar of the form shown in Figure 2 was generated in the flume. The bed profile varies in depth from 0.60 m seawards of the bar to 0.30 m at the bar crest (Figure 2). The water depth in the trough landward of the bar crest is 0.50 m. The nearshore bar has a steep seaward slope of 1 to 20 and a steep landward slope of 1 to 25. The bed slope landward of the bar trough is 1 to 63. Measurements were performed at 10 different locations across the nearshore bar. Herein the test with an initial wave height of 0.19 m (B2) is considered. Figure 2 shows the measured and computed wave heights, peak orbital velocities and depth-averaged return flows. It can be observed that in the region near the bar crest the computed $H_{1/3}$ and $H_{1/10}$ values are about 10% too small, which may be caused by the use of linear wave theory. Better agreement between measured and computed wave heights may be obtained by using non-linear shoaling. The computed and measured return flow values show reasonably good agreement. From Figure 2 it can be observed that the significant values of the near-bed peak orbital velocities can be predicted with reasonable accuracy using the modified Isobe and Horikawa formulation. The depth-averaged return flow is rather accurately predicted by the model.

**Large Scale Laboratory Tests**

The model has been applied to compute the hydrodynamics and morphodynamics measured during large scale laboratory tests (Roelvink and Reniers, 1995). The tests were conducted in the Delta Flume of Delft Hydraulics. The Delta Flume is a large flume with the following dimensions: length = 200 m, width = 5 m and depth = 7 m. Three different test conditions were simulated: slightly erosive wave conditions, highly erosive wave conditions and strongly accretive wave conditions. The bed consisted of fine to medium coarse sand ($D_{50} = 200$ $\mu$m and $D_{90} = 400$ $\mu$m). Before and after each test the bed levels were measured in three longitudinal sections. Irregular waves (following a JONSWAP spectrum) were generated. The wave board driving system was compensated for the reflection of long waves in the flume. Water level variations were measured by pressure sensors and by resistance type wave gauge at various locations in the flume. Herein, the test with highly erosive wave conditions (test 1b) is considered. The incident wave conditions are: $H_{m0} = 1.40$ m, $T_p = 5.0$ s, duration = 6 hours. Figure 3 shows the computed and measured wave heights, peak orbital velocities and depth-averaged return flows. The computed wave heights show fairly good agreement with the measurements with exception of an overestimation of $H_{m0}$ in the region near the bar crest. It can be observed from Figure 3 that in the region seaward of the bar the significant values of the near-bed peak orbital velocities ($U_{1/3, on}$ and $U_{1/3, off}$) are reasonably well represented by the modified formulation of Isobe and Horikawa. Near the bar crest the onshore directed velocity is overestimated by the model while landward of the bar the offshore directed near-bed orbital velocity is slightly underestimated. The computed depth-averaged return flow shows good agreement with the measured values, except in the shallow surf zone ($x > 160$ m) where the depth-averaged return flow is significantly overestimated.

The initial bed profile and the measured and computed bed profiles after 6 hours of wave action are given in Figure 4. The measured profile shows an offshore migration of the bar, with erosion between 140 m and 160 m and accretion between 125 m and 140 m. The predicted profile also shows an offshore migration of the bar, however, this is too far seaward, with erosion between 138 m and 150 m and accretion between 110 m and 138 m.
Figure 3. Measured and computed wave heights, peak orbital velocities and depth-averaged return flows for large-scale laboratory test.
The formulation of Isobe and Horikawa (1982) was modified and adapted for use in a probabilistic cross-shore transport model. Comparison of model calculations and laboratory measurement showed that the near-bed orbital velocities could be predicted with reasonable accuracy using the method of Isobe and Horikawa (1982). However, the asymmetry of the orbital velocity was overestimated landward of the breakpoint. The depth-averaged mean return flow could reasonably well be represented using a simple formulation based on linear mass transport, except in the shallow surf zone where the depth-averaged mean return flow was significantly overestimated by the model. Further work is required to improve the morphodynamic predictions of the probabilistic cross-shore transport model.

Abstract

A monitoring programme has been established for the 351km of the UK Southern North Sea Coast (between the Humber and Thames estuaries). This has produced over 3300 beach profiles captured to a clear specification at 1km intervals in summer and winter since 1991. The analysis of this data has been previously linked to specific flood defence and coastal protection engineering schemes. The first analysis on a region wide basis has now been undertaken to provide some strategic insight into how the coast is evolving on an integrated scale. The analysis provides quantification of the change at the coast, and demonstrates that simple analytical tools combined with geomorphological interpretation can provide meaningful information for coastal management.

1. Introduction

The increased awareness of natural processes in the management of the coast has led to renewed efforts in the monitoring of the UK coastline. Such monitoring has been carried out in an ad-hoc fashion over the last 50-100 years with local grids and datums being employed. The purpose of such monitoring is to provide information on long term (decade - century) changes in the coast and intelligence on what is happening with the highly complex and dynamic coastal processes in the short term (month - year). Monitoring considers both the forces affecting the coastline and the response of the coast to these forces, in many cases a symbiotic relationship.

One of the core data sets in monitoring is beach profiles (for the purpose of this paper beaches may be of any sediment type, including fine-grained silt and mud). Beach profiles provide indicators of coastal change in the most important area to coastal managers, the inter-tidal zone (Davis, 1971; Pethick, 1984). However the offshore bathymetry should also not be overlooked in their importance to the inter-tidal profile (Leggett, 1995). Beach profiles provide qualitative and quantitative information on how a coastline is reacting to the forces upon it. Over time the pattern of reaction enables trends, cycles, or the impact of distinct events to be identified.
The Southern North Sea Coast of the United Kingdom (figure 1) has had a structured monitoring programme since 1991 (Child and Leggett, 1991). This paper reports on the first five years of this programme with particular reference to beach profiles.

2. Coastal Scale

The Southern North Sea Coast has 5,400km$^2$ of low lying land which alternates with soft rock cliffs (Leggett, 1993). This means it is vulnerable to flooding and coastal erosion. The management of this coast involves a number of approaches but almost all of the open coast has some form of man-made defence along it. Defence includes hard sea walls, clay embankments, groynes, nearshore reefs, and beach recharge. To be able to take effective management decisions a fundamental question is: What is the change of the beaches over medium to long time scales and how best can this be evaluated? To be able to answer such a question for over 351km of coastline there is a need to consider the philosophical approach to take.

The approach has been derived from the Coastal Evolution work in the Netherlands (Stive et al., 1990). This approach considers the relationships that exist
between the spatial scale of the coastal feature and the temporal scale over which its behaviour is manifested. Changes on the temporal scale of a tidal cycle that link to profile shape and landforms over (say) a hundred meters are Small Scale Coastal Evolutions (SSCE). Changes over about a kilometre, that take a year to form, can be considered as Medium Scale Coastal Evolution (MSCE). Large Scale Coastal Evolution (LSCE) happens over tens of kilometres and form over decades. This approach has been further developed to create the Integrated Scale Coastal Evolution or ISCE (Pethick and Leggett, 1993).

The ISCE integrates the MSCE and LSCE as critical parts of coastal evolution. It also extends the temporal frame to include high magnitude - low frequency events such as 1:250 year return period storms. The approach also extends the longshore scale to hundreds of kilometres and, importantly, integrates offshore processes to changes at the beach. The ISCE is an important philosophical approach to coastal management problems and has influenced the approach to monitoring the coast on a Regional scale.

3. Coastal Forcing Parameters

Beach surveys in themselves yield valuable information on changes at a particular site; this can be greatly enhanced if they form a carefully co-ordinated component of a broader monitoring programme. Wave, water level, wind and (estuary) tidal prism measurements all provide invaluable information to aid the interpretation of beach profile changes. The Southern North Sea Coast monitoring programme measures all these coastal forcing parameters (Townend and Leggett, 1992), however, this paper focuses on the use of beach profiles.

As analytical methods continue to become easier to apply, are better understood by managers, and become more sophisticated, it will be the paucity of data that will be a limiting factor. These long-term records are an invaluable benchmark for any future monitoring and analytical activities.

4. Strategic Beach Monitoring

The apparent ease of collecting beach profiles is very attractive in a subject area where field measurements may be highly specialised and costly. The ease of collection provides a source of valuable information that, with geomorphic interpretation, provides extremely good value for money. The ease of collection has, however, spawned a proliferation of approaches, which often means that modelling analysis cannot directly compare data sets together, limiting the value of time series information. Data capture in the past has varied from location to location meaning that spatial analysis of information is equally problematic.

To answer the main management questions it is suggested that a beach monitoring programme has, as its goal, the collection of beach survey and coastal forcing parameters in order to facilitate:

- The development of a holistic understanding of coastal processes along the coastline to guide the development of coastal defence and coastal zone management strategies.
- The provision of coastal engineering design data for the design of coastal defence.
- The monitoring of beaches to guide beach recharge and recycling programmes.

The focus of the Regional survey is not on the extreme event but on the envelopes of beach change from year to year.
5. Beach Profile Measurement Methods

There are a variety of techniques for monitoring beach profiles. These range from traditional survey techniques, to laser and active aircraft remote sensing (Cracknell and Hayes, 1991), to video imaging. These techniques all provide the same basic information, beach level. Some provide highly detailed (but less accurate) images of the beach surface whilst others provide an accurate cross section.

Collecting data and analysing it regularly requires rigorous and repeatable techniques. New techniques are always under investigation and when suitably developed may replace existing methods or provide a useful additional data set; they may in time also be able to provide suitably accurate profiles that would negate the need for direct land survey. Most remote methods provide accuracy in +/- hundreds to thousands of millimetres. This accuracy would provide considerable error over the length of Southern North Sea Coast. Until methods are proven (such as kinematic global positioning) the risk of missing a time step in the data set is too critical to contemplate embracing new techniques.

There are merits and drawbacks in all approaches but certain issues are important for any long-term monitoring activity:

- Repeatability.
- Accuracy.
- Comparability.

These principles should affect the decision of monitoring approach, rather than just following the latest technology. Repeatability is vital if any meaningful analysis is to be achieved. This requires both spatial and measurement accuracy to be well defined. If this is the case then the best approach at present is considered to be measurement of beach profiles using land based survey techniques.

5.1 Cross Section Specification

The beach profile survey lines of the UK Southern North Sea Coast monitoring programme run from the landward toe of the defence line or 200m inland of a cliff edge to MLWS as a minimum. Spot heights are taken on section lines at all breaks of slope, at a maximum of 20m intervals, and at all changes in beach material. Changes in beach material (sediment and vegetation) are recorded qualitatively against each profile.

All levels are taken to Ordnance Datum Newlyn at +/- 3mm accuracy for spot height. The corresponding plan position accuracy specification is +/- 20mm. These values correspond fairly closely to the recommendations made from analysis of annual data captured over 30 years on the Lincolnshire coast (HR Wallingford, 1990).

5.2 Ground Control

Lack of ground control in beach survey has led to errors in the repeatability of some surveys and invalidated time-series data. At worst it may yield erroneous answers and false information on which to base decisions. A sound ground control and permanent marking is considered essential for any repetitive survey work.

Survey section lines, each with their own co-ordinated reference monuments have been established along the Southern North Sea Coast at 1km intervals to determine regional beach changes. All surveys are tied to OSGB 1936 as a common co-ordinate system; being the most commonly used in the UK (Pos, 1994). This enables re-location of profiles in the event of loss during defence works or through
erosion and also instant utilisation of data transferred between coastal authorities and passed to consultants. The monuments are established from the national grid network at 1:20,000 accuracy and their existence aids the identification of profile location by surveyors.

Each profile data point has a chainage calculated for it. Zero chainage represents the original profile marker position which is normally at the first line of sea defence, or inland from a cliffline (the current position could be landward, and in a few cases seaward, of this original position). This chainage system does not change if the marker is re-established, instead the marker has a positive or negative value. Chainage is positive to seaward and negative to landward of this original position.

5.3 Frequency and Timing of Surveys

Twice-yearly surveys are a recommended minimum requirement for beach surveys. However, additional site specific surveys should be carried out at particularly volatile locations to monitor the maximum negative (or positive) beach conditions. It may also be necessary to monitor more frequently for beach recharge purposes.

Whilst profiles after storms may show the most extreme condition of the beach it is difficult to capture the most extreme profile each year along the 351km of coastline. The volatility of beaches under storms leads to daily change in beach profile and high spatial variability. For specific defence schemes such detail may be feasible to collect, and indeed critical for structural design and stability. In order to represent more 'typical' beach conditions and to determine long term change in beaches it is more suitable to survey the coast at times of reduced beach volatility. The timing must, however, still capture the key beach change between the winter (storm) and summer (swell) beach profiles (Komar, 1998). For this reason survey is undertaken in January and July where perturbation in the beach is reduced but the gross pattern of change is still represented. This reduction in perturbation also provides a wider time window to measure profiles, for the Regional beach survey, and helps to provide consistency in information from one year to the next.

5.4 Integrating Land, Aerial, and Bathymetric Surveys

The Southern North Sea Coast monitoring programme has many sources of data including:

- Historic shoreline positions (high water mark, low water mark and coastline) have been taken from Ordnance Survey maps dating back to 1880.
- Over 9000 aerial photographs, using stereo-photography methods at a scale of 1:5000 with forward motion compensation have been taken between 1991 and 1996. They are suitable for photogrammetry, timed to coincide with beach profile measurement, and cover the whole coastline.
- 3399 beach profiles and 509 bathymetric profiles were measured between 1991 and 1996.

The costs of different survey approaches are comparable but aerial techniques allow the plan form of the coast to be mapped and the movement of important geomorphic indicators (such as spits, nesses, or bars) to be quantified. The aerial technique requires suitable ground control, which can be provided by the land based survey operations. It is suggested that for consistency (and maximum necessary accuracy) profiling is best delivered through the land based survey technique with plan form being delivered from aerial or video methods (rectified using the land based
survey data). Such an approach provides high quality data on a consistent basis across all coastal types and gives a three dimensional view of coastal changes. In inaccessible or dangerous locations (such as on wide mudflats) photogrammetry can be used to extend beach profiles across the inter-tidal area. However, the different errors generated in this need to be considered and accounted for in any analysis and interpretation.

Beach surveys are undertaken in conjunction with bathymetric survey (extending the profiles offshore). These surveys extend to at least 10km offshore, or to at least 20m depth of water, which is a nominal closure depth (Hallermeier, 1981; Birkemeier, 1985). The inclusion of bathymetric profiling is on a five year rolling programme due to expense and the initial consideration that change offshore was not as volatile, or as critical, as beach change. This view has been challenged by some of the results of this work.

5.5. Data Quality

The accuracy of the survey technique, accuracy of data capture, and accuracy of data recording all effect quality. To be confident of subsequent analysis, and to generate a credible data archive, it is essential to check the data. For the Southern North Sea Coast specification checks need to be undertaken by the surveyor to identify erroneous or spurious data and consider:

- Data outside the limits of the sensor(s).
- Rates of change between data points.
- Gaps in data.
- Timing of data points within a data set.

The editing of data is restricted to deletion of clearly spurious data points. The validity of the data is checked upon receipt from the field. In 1991 this was undertaken manually using hard copy output, but this is now done automatically by checking the digital data through computer programmes. These routines check the data files for errors or changes in key data elements, for example, beach profile marker positions and level, beach profile orientation, maximum and minimum beach levels. The routines compare the new data to the previous data, and to predefined tolerances (such as 4m change in beach elevation). In some instances large change may be real, but where there is an error this approach helps to ensure it is identified quickly (within 24 hours) and if necessary re-survey of a profile can be undertaken.

Spot checks are also employed to give an independent assesment of the quality and accuracy of data capture. Where possible any errors found are corrected. Where it is not possible to correct an error the data is not used for analysis.

5.6. Data Storage and Databases

For the Southern North Sea Coast storage of data is undertaken using a Geographic Information System (GIS). The GIS (Intergraph MGE) is used to update, manipulate and supply information and data to coastal managers. This provides a consistent dataset and rapid access to information (Leggett and Jones, 1996). The development of the GIS to handle the data more efficiently, and provide analysis of data, has been recognised as an ongoing need (Leggett and Dowie, 1993). This is essential where such large volumes of information are being handled.

The quality control, visualisation and analysis software has been developed separately by the Centre for Coastal Management, University of Newcastle to allow
easy access to this data for non-specialist users. Such management tools are essential if the monitoring process is not to become just a data capture exercise.

6. Analytical Methods

A considerable number and range of analytical techniques exist for the manipulation and interpretation of beach profile data. However, the type of analysis undertaken depends upon two important factors, namely: the questions that the monitoring programme is intending to answer, and the type, quality and format of the data that are available.

Temporal analysis techniques can be employed at a specific location to identify both short-term variations in beach profile (often storm related), and the longer-term trends at that site. This can be of use when identifying the standard of defence provided by a particular beach profile. Spatial analysis techniques can be employed to determine changes in beach profiles along the coastline and to identify areas of material gain and loss on the ISCE scale.

6.1 Beach Volume Comparison

The data from the 1991 to 1996 monitoring has been analysed to determine the volume of the beach and the position of a fixed contour level. This is an initial analysis and the limits of integration and choice of fixed contour level have been chosen to be as wide as possible. There are a large number of different limits that could be used, dependent upon the use of the results; further analysis with different limits and levels is part of the on-going work to be undertaken.

Each survey yields a different total profile length because of natural changes, the tidal state at the time of survey (although all are undertaken on spring low tides), and the safe working area for the surveyor. The method of analysis must allow for this variability whilst providing a consistent spatial area for consideration. The elevation of the defined shoreline position will vary from profile line to profile line. The method allows maximum use of the available data and takes account of the varying nature of the coastal morphology (Lowe, 1997).

The analysis provides a comparative measure of beach volume, not the total beach volume surveyed for each survey campaign. This comparison is vital for coastal managers to be able to objectively consider the state of beaches. The area of beach represents the width over which energy may be dissipated, the change in volume of material within fixed bounds, and a means of comparing different geomorphological features that may have different coastal dynamics. This means that mudflat areas can be compared to sand beaches or gravel ridges in terms of their relative percentage change, rather than absolute change. This approach helps to determine whether change is independent of the type of coastline or not.

6.2 Expert interpretation

A major part of the analysis of the profiles is qualitative rather than quantitative. The ability to easily view the profiles and to determine their relation with other profiles in both time and space (through the GIS and bespoke software) allows a much greater depth of understanding of beach behaviour. Using this data in combination with information on the coastal processes and sediments helps the interpretation of the changes and to develop management advice.
7. Results and Analysis

This study is a first overview of the beach profile behaviour for the Southern North Sea Coast. Characteristic closure depths, eigenvalues, and other more recent methods of analysis have not been applied to this data yet. The analytical techniques are relatively simple but yield interesting results for comparison of change on an Integrated Scale (ISCE).

7.1 Beach Volume Results

Representative beach volumes and shoreline positions for each profile are dependent upon the nature of the morphology. It is, therefore, unwise to compare the absolute figures of change (mean and standard deviation) for the whole coast. The focus for management information is therefore the relative changes in volume and position of beaches between 1991 and 1996.

The cumulative percentage change in profile volume and the calculated shoreline position between 1991 and 1996 demonstrate the trend of beach evolution over the five-year period (figure 2).

Figure 2. Cumulative Change in Profile Volume and Shoreline Position, 1991 to 1996

These have been plotted against the distance along the shore from Grimsby; the northern limit of the study area (this was calculated from the straight-line distance between the zero chainage of neighbouring profile lines; this is therefore slightly longer than the actual length of the coastline).
The results indicate that the Southern North Sea Coast can be split into a number of distinctive coastal evolution areas. The boundaries of these represent statistical divisions where profile evolution has a fundamental change along-shore. Change may be from gross erosion to accretion, a step in the magnitude of change, or the degree of intra-variability along the coast. The divisions have been indicated on figure 2 and can be considered as LSCE Beach Units. This analysis provides some indication of the broad behaviour of the whole coast, it also serves as an important starting point for any future analysis.

The average change within each LSCE Beach Unit is presented in figure 1. A total of nine units have been identified. The recent beach profile evolution in each of these areas can be explained by both natural and anthropogenic influences; each is briefly discussed below:

Beach Unit 1 - Unit 1 is at the northern end of the region from the Humber Estuary to Mablethorpe and appears to show overall stability. Here 2.4% accretion has been recorded over the study period. This area has a variety of profiles ranging from sand beaches in front of sea walls to wide sand flats and mud flats which are relatively stable. This gain in sediment links to protective offshore banks and a seaward extension of the profile. There is also a significant sediment supply from the Holderness coast via the Humber Estuary (NRA and SWHP, 1991).

Beach Unit 2 - This runs between Mablethorpe and Gibraltar Point. There is a consistent gain in beach volume within this Unit. The effect of large beach renourishment can be clearly seen along this 23km stretch of coast. The average beach volume has been increased by nearly 40% since 1991. The impact of the individual renourishments can be clearly seen in the temporal record. The on-going monitoring will be able to evaluate loss of sediment from this scheme but historic data shows a 15% loss over the five years prior to replenishment.

Beach Units 3 and 4 - These Units demonstrate that not all beach variation is due to anthropogenic impacts. The variation in the orientation of the shoreline along the Norfolk coast and the degree of protection afforded by the offshore banks can clearly be seen in the profile results. There is an increase in erosion of the beaches from Heacham eastwards to Cromer. The average loss of volume is about 10% over the past five years, although this can reach up to 50% in the southern half of this area. The gross pattern appears to be related to the continuing long-term reorientation of this coast since the last ice age.

Beach Units 5 and 6 - The reverse of the trend of Units 3 and 4 is found here, with erosion decreasing to the south from the critical ISCE divide at Cromer (Pethick and Leggett, 1993). Sea defence schemes designed to stabilise parts of this coast are starting to have an impact on this larger, longer-term pattern, with clear steps in the data from one scheme to another. This section also sees the linkage of the beach profile change to change offshore in the sandbanks. It is believed there is a large-scale sediment circulation spanning Units 3, 4, 5, and 6, this is subject to further investigation under the Southern North Sea Sediment Transport Study (ABP, 1996).

Beach Unit 7 - Unit 7 has a 3% increase in average volume since 1991. This masks a consistent spatial pattern of stability, accretion, then erosion as one moves southwards. The maintenance of high beach levels along the Clacton frontage, by the use of beach control structures, quite clearly starves the downdrift beaches. This starvation has led
to reduced beach levels (and standards of protection) and the requirement for beach nourishment, and re-design of the structures.

**Beach Unit 8** – This Unit is on Mersea Island and is treated separately due to its geographical position. The profiles show an average loss of 9.1% since 1991. This is related to a lowering of the foreshore during this period which appears to be associated with a widening of the mouth of the adjacent estuary.

**Beach Unit 9** – This shows stable areas that are accreting. Along the Essex coast, between Dengie and Shoeburyness, the average profile has gained about 3% in volume since 1991. This is an area of wide mud and sand flats that appears to be responding well to the high relative sea level rise. These are complicated profiles that show profiles evolving around an upper 'hinge'. Seaward variations of the profiles tend to be greater than the landward end of the profiles where vegetation helps stabilise the profile.

The nine Beach Units above support the two ISCE Units (figure 1) by demonstrating the critical evolutionary divide at Cromer and the general trends of change away from that point (Pethick and Leggett, 1993). The analysis has provided a more detailed view that allows the impact of defence schemes along the coast to be identified. The fact that the Beach Units are nested into the ISCE Units demonstrates that coastal management can have considerable affect upon the wider coastline.

### 7.2 Expert Interpretation

The analysis of the data has led to some fundamental understanding of the coast. The qualitative interpretation of the data sets has provided insight into a number of issues that merit more detailed and in-depth consideration. The following sections briefly describe some of the observations made when undertaking the analysis of individual profiles.

**Orientation and Exposure** - The role of beach orientation appears to have fundamental importance, particularly in Beach Units 3 to 6, which have a systematic change in profile bearing. This is illustrated where the profile bearing is plotted against the cumulative change in volume (figure 3).

**Figure 3.** Profile Orientation vs. Cumulative Change in Beach Volume, 1991 to 1996
There are some indications that the volatility of the profiles is greatest between 60° and 100°N with another band around 120° and 150°N. These two groups, again, support the ISCE divisions. The degree of exposure to storm waves varies with orientation and the banding represent the northern ISCE beaches which are exposed to north-easterly and easterly storms, and the southerly ISCE beaches which are more exposed to the south-easterly storms (Pethick and Leggett, 1993).

**Offshore Profile** - Beach evolution is intimately related to the offshore bathymetry both in terms of the exchange of material and the dissipation of wave energy. The evolution of the offshore can be quite clearly seen in many of the longer profiles. Figure 4 is an example of the exchange of material between the offshore and the beach at Sea Palling (Beach Unit 4). Material appears to have been removed from the seaward side of the offshore bar and placed on the beach. Changes up to 1.2m in elevation are shown in 15m depth of water.

![Figure 4. Evolution of Offshore Bathymetry, 1991 to 1996](image)

The role of offshore bars (banks) in protecting the shoreline is illustrated at Orford Ness (Beach Unit 6) where profiles have distinctive bathymetric changes over a longshore distance of 4km. The northernmost profile has a large offshore bar that helps stabilise the beach profile (2% accretion 1991-1996). Further to the south the same orientation of the beach exists but no offshore bar, here 18% loss of volume occurred over the same period.

**Trends of Profile Change** - A number of different trends can be identified in the profile data (figure 5). Simple trends are shown in cliff profiles at Covehithe (figure 5a) where the cliff line can only retreat. The retreat of the cliff at Covehithe (Beach Unit 5) is a relatively simple process of parallel retreat - a constant form translates landwards.

Figure 5b shows nearshore bar movement at Cleethorpes (Beach Unit 1). The full time series shows the progressive movement onshore of this bar over the last five years. Clearly there are trends in the nearshore behaviour that will have an impact on shoreline management in the long term. These need to be identified before action is taken to stabilise the coastline.

A more complex response is shown at the Ray Sand at Dengie (Beach Unit 9). Here the saltmarsh has been accreting vertically since 1991 (figure 5c). The saltmarsh
cliff has, however, not moved. Seaward of the cliff the mudflat is also accreting but the rate increases offshore. The net result is a reduction of the slope of the mudflat, with the surface hinging around the toe of the cliff. This profile behaviour is characteristic along this stretch of the coast.

Figure 5. Examples of Profile Responses on the Southern North Sea Coast

Profile History - Knowledge of the history of each profile line (constructions, renourishments, etc) is increasingly important. This is illustrated at Chapel St Leonards in Beach Unit 1 (figure 5d). The low beach in 1991 caused sufficient problems to require the construction of a rock revetment which appears as 'accretion' of the upper profile. Beach levels at the toe of the rock revetment remained low so by the end of 1995 the beach was recharged, to completely cover the revetment. About $280m^3$ of sand was placed per metre run of the beach of which 26% was lost in the following six months ($73m^3$ per metre). This history is based on the evidence in the profiles and the detailed local knowledge of relevant coastal engineers. Without that knowledge mis-interpretation of coastal change would be common place.

8. Conclusions and Recommendations

The analysis of 3399 beach profiles and 509 bathymetric profiles has provided a broad picture of beach evolution along the whole length of the Southern North Sea Coast. These results indicate some general trends and highlight specific challenges for some methods of sea defence. A re-analysis of the profiles following further survey work should be a relatively simple matter and provide more insight to coastal changes. The results presented, and those generated in the future will always be of an interim nature.

There is a definite need to integrate the profile data more closely with the forcing data (wind, wave and tides) which are also available. This integration will increase the value of the data that has already been collected and will help explain
some of the patterns and trends that have been observed. The ISCE approach has helped to define the data and information needs for the coast and helped in the conceptual approach to interpreting the analytical outputs. The critical divide for evolution of the Southern North Sea Coast at Cromer has been confirmed, this helps coastal managers to understand the evolution of the coast and to place individual schemes into context with the surrounding coastline, nearshore and offshore area.

The effect of large beach renourishment schemes undertaken for flood defence purposes can be clearly seen in Unit 2 (Lincolnshire) along a 23km stretch of coast. The average beach volume has been increased by nearly 40% since 1991. The impact of the individual renourishments can be clearly seen in the temporal record. It is too early to determine the long term stability of these schemes; however envelopes of expected change can be constructed.

Not all the variation in beach volume is due to anthropogenic impacts. The variation in the orientation of the shoreline from Units 3 to 6 (the Norfolk and Suffolk coast) and in the degree of protection afforded by the offshore banks can clearly be seen in the profile results. The gross pattern appears to be related to the long-term reorientation of this coast (certainly since 1880 and probably throughout the Holocene). Sea defence schemes designed to stabilise the coast are starting to have an impact on this larger, longer-term pattern.

Further to the south in Unit 7, (the Essex coast) at Clacton, the negative impacts of sea defence can be seen in the spatial distribution of erosion and accretion. Here the overall picture of relative change is fairly stable (a 3% increase in average volume since 1991) but this masks a spatial pattern of downdrift erosion. The maintenance of high beach levels along the Clacton frontage, by the use of beach control structures, quite clearly starves the downdrift beaches. This starvation has led to both reduced beach levels and reduced standards of coastal protection.

There are also stable areas that are showing accretion. Along the Unit 9 coast, between Dengie and Shoeburyness, the average profile has gained about 3% in volume since 1991. This is an area of wide mud and sand flats that appears to be responding well to the high relative sea level rise. A similar picture can also be found at the northern end of the region in Unit 1, from Humber to Mablethorpe. Here an average of 2% accretion has been recorded over a similar period.

These gross figures provide an overview and, combined with the analysis of individual profiles, better understanding of the evolutionary behaviour of the Southern North Sea Coast. The relationship of the beach behaviour to the offshore bathymetry, to the orientation of the coastline and to sediment pathways and their local interruption is very evident. For the first time coastal managers of the Southern North Sea Coast have an overview of the contemporary evolution of their coastline and the impact that their interventions have along a 351km shoreline. Monitoring continues on a twice-yearly basis and it is anticipated that the analysis will be repeated and refined at regular intervals. In the long term this will improve not only our understanding of how this coast behaves but also improve management decisions.

Extracting Morphologic Information From Field Data

Nathaniel G. Plant¹ and Rob A. Holman²

Abstract

We quantified the strengths and weaknesses of two sources of morphologic data available from Duck, NC, utilizing an objective definition of nearshore morphology (Gaussian curves added to a plane slope). Directly surveyed bathymetry provided the most complete estimate of the morphologic state of the nearshore bathymetry. That is, all of the parameters of the morphologic model could be estimated from these data. Oblique video images were used to estimate the position of inner bars. This information represented only a subset of the morphologic parameters defined in the morphologic model. However, the image data were collected frequently (daily) and, thus, resolved a wide range of temporal scales. Bar crest positions estimated from the video images were well correlated with estimates extracted from the bathymetric surveys ($R^2 = 0.8$). Differences between the two estimates of bar position depended on both wave height and on the bar amplitude.

1. Introduction

Field observations of nearshore sand bar systems (Figure 1) have provided a great deal of information about the morphologic evolution (often called morphodynamics) resulting from the complicated interaction between morphology, hydrodynamics, and sediment transport (Sonu, 1973; Short, 1975, Wright and Short, 1984, and many others). Two types of measurements are commonly available to study sand bar systems. One type is visual observations, which can be made with the human eye and are a bit subjective.

¹ University of Twente, PO Box 217, WB-building, 7500 AE Enschede, The Netherlands
² College of Oceanic and Atmospheric Sciences, Oregon State University, Corvallis OR 97330, USA
Figure 1. Time exposure images of beaches from around the world, including the US East Coast (A,B), Dutch Coast (C), US West Coast (D), South Australian Coast (E), Hawaii (F). Sand bars and the shoreline may be identified by light, often shore parallel bands that correspond to shallow regions where waves tend to break.
Visual observations made with video cameras are also available (Figure 1) and these can be used more quantitatively (Lippmann and Holman, 1990). The main advantages of the video observations are that they can be made frequently (several times per day), over long time periods (decades), and they span large distances alongshore ($O(km)$). The primary disadvantage of visual observation methods is that, in most cases, they do not give a direct estimate of actual beach elevations.

The other technique for sampling nearshore morphology is direct bathymetric surveying. This technique gives high precision estimates of beach elevations. The primary constraint here is time, which, under the best circumstances, allows sampling of a region spanning 1 km in the cross-shore and 1 km alongshore in about 1 day (Birkemeier and Mason, 1984).

Figure 2. Analysis of beach profiles (A) using EOFs (B). The EOFs are spatial patterns describing correlated or anti-correlated beach variations. The EOFs clearly suggest the presence of sand bars. The EOF amplitudes (C) indicate the correlation of the actual profile at a particular time to each the EOF. The movement of the bars is not readily apparent from inspection of the amplitude time series.
Because of the complexity of some morphologic patterns (Figure 1d), it has been difficult to objectively define what we mean by morphology and treat the morphologic observations quantitatively. Several attempts to quantify morphology have used empirical orthogonal functions (EOFs) to represent, for example, surveyed profile data (Winant et al., 1975, and many others) and alongshore arrays of profile data (Wijnberg and Terwindt, 1995). The EOFs typically aide the analysis of morphologic variability by reducing the dimensionality of the bathymetric data (which contain observations at many spatial locations). Dimensionality is reduced by projecting observed beach elevations onto a small number of basis functions (i.e. morphologic patterns).

However, morphologic evolution described in terms of EOFs is often hard to interpret (Figure 2), since the EOFs may not have any clear physical interpretation. One example where they have been successfully interpreted is on the Dutch coast, where temporally periodic behavior was identified (Wijnberg and Terwindt, 1995). The ability to interpret the morphologic parameterization may be important when trying to constrain the morphology using two different data types. For example, video image data have been used to locate the position of surf zone sand bars (Lippmann and Holman, 1989; Lippmann and Holman, 1990; Lippmann et al., 1993). It is not clear how this information could be used to constrain any part of the morphologic patterns identified by an EOF model.

Both directly surveyed bathymetry and remotely sensed video images have different sampling strengths and weaknesses. We wish to combine the strengths of these data via an objective morphologic model. The goal of this paper is to evaluate whether the two data sources constrain a particular morphologic model in an identical manner. In section 2.1, a morphologic model for a nearshore sand bar system is defined. In section 2.2, the methods used to project the observations on the model are described. In section 3, sand bar crest position estimates (the only parameter estimated from the video data) are extracted from both surveyed bathymetry and video images. These estimates are compared and the differences analyzed. Section 4 contains both the discussion and conclusions.

2. Methods

2.1 morphologic model

We use a morphologic model that describes an alongshore-uniform, barred beach. The model consists of several Gaussian shaped sand bars superimposed upon a plane sloping beach (Figure 3). The bathymetry as a function of time (t) and cross-shore location (x) is expressed as
\[ Z(x,t) = \beta_1(t) + \beta_2(t)x + A_1(t)\exp\left[-\left(\frac{x-X_1(t)}{L_1}\right)^2\right] + A_2(t)\exp\left[-\left(\frac{x-X_2(t)}{L_2}\right)^2\right] + A_s(t)\exp\left[-\left(\frac{x-X_s(t)}{L_s(t)}\right)^2\right], \]

where \( \beta_1(t) + \beta_2(t)x \) describes a plane slope component, \( A_1(t)\exp\left[-\left(\frac{x-X_1(t)}{L_1}\right)^2\right] \) describes a Gaussian shaped sand bar located at \( X_1(t) \), having a characteristic length of \( L_1 \) and amplitude \( A_1(t) \). The subscript 1 refers to an inner bar and 2 to an outer bar. The subscript “s” refers to a half-Gaussian located at the shoreline, which accommodates the shape of the subaerial beach. This model allows the true sand bars (bars 1 and 2) to change amplitude and migrate, but undergo no changes in length. The “shoreline bar” is fixed in space, but may vary its amplitude and wavelength.

Figure 3. Example of the morphologic model (solid line), applied to FRF bathymetry (dashed line). The morphologic components of the model are shown as well.
2.2 Estimation of morphologic parameters

The model (1) described well the temporal and spatial variability of the bathymetric surveys obtained from the Army Corps of Engineers Field Research Facility (FRF, Figure 4). Surveys were conducted at bi-weekly and monthly intervals. The model was fit to a region north of the research pier in order to avoid inclusion of pier effects on the morphology (Figure 4). The data within a 300 m wide (alongshore) region (from \( y = 776 \) m to 1096 m) were alongshore-averaged and then fit to the morphologic model in order to extract the following 8 parameters: \( \beta_1(t), \beta_2(t), A_1(t), X_1(t), A_2(t), X_2(t) \).
As(t), Ls(t). L₁ and L₂ were fixed at 50 m and 150 m, while Xₜ was fixed at 50 m. The model was fit to the alongshore averaged bathymetry using a nonlinear least squares algorithm. A typical rms error was less than 0.1 m. The rms elevation explained by the Gaussian parts of the model typically exceeded 1 m.

Since it was designed to represent bathymetric data, the model (1) could not be employed directly on video images. Instead, we assumed that the bar crest term in the model corresponded to the bar crest determined from an analysis of time exposure, video images (Lippmann and Holman, 1989 – hereafter LH89). Bar crest positions are revealed in the images by bright bands (Figure 1) that are associated foam generated in regions of wave breaking. The bar crest position data that we used are described in detail in Lippmann et al. (1993). We discuss only the estimated position of the inner bar of the commonly double-barred FRF site. We will test the correlation of the bar crest positions identified in the video images with estimates made from the bathymetric survey data.

Figure 5. Time series of slope component of morphology (A), inner bar position (B), and inner bar amplitude (C). Morphologic components were extracted from the bathymetric surveys.
3. Results

Figure 5 shows a time series of several morphologic parameters extracted from the FRF bathymetry. In Figure 5a, a time series of the slope parameter, $\beta_2$, is shown. Variation of beach slope occurred on a variety of time scales. Interestingly, there is no evidence for a long term trend. Temporal aliasing is apparent in a comparison of the time series prior to 1992 with the time series following 1992, when the sample interval changed from 0.5 months to 1 month.

Figure 5b shows a time series of the inner bar position. Rapid offshore migration occurred in Dec. 1982 and Feb. 1989. These periods correspond to offshore migration of the inner bar, followed by the generation of a new inner bar near the shoreline (apparent rapid onshore migration). These periods are marked by minimum sand bar amplitudes (Figure 5c).

Figure 6. Time series of bar crest positions (A) from both the surveyed data sets (labeled “CRAB”) and video estimates. Sand bars are labeled in order of their appearance at the FRF site. Panel B shows the correlation between survey- and video-based bar position estimates.
Figure 6 shows a time series of bar positions that were extracted from the video image time series, plotted together with time series extracted from the bathymetric data. The two time series generally correspond well with each other and clearly capture the same interannual variations of the inner bar at Duck. The image data resolve high frequency fluctuations, which may record actual variations in the bar crest position. Alternatively, the high frequency fluctuations may be related to high frequency fluctuations in the wave height, since patterns of wave breaking are used to visually identify bars in the video images.

The correlation between the time series generated from the two data sources is described in Figure 6b. The data are divided into two categories, one for bar 2 (the inner bar that formed prior to 1989, Figure 6a) and one for bar 3 (which formed after bar 2 migrated offshore to become an outer bar). The correlation, mean difference and standard deviation of the difference are shown in Table 1. The bar position identified in the video images tended to be onshore of the bar position extracted from the bathymetric surveys. This is consistent with the observations made by LH89, who attributed the shoreward bias to the persistence of foam shoreward of the bar crest. The difference in bar positions tended to increase as the bars moved farther offshore, which was not predicted by LH89.

Figure 7a shows a comparison of the bar position differences plotted against wave height. There was a slight tendency for the difference in bar positions to decrease as the wave height increased. The relationship is more clearly seen if the discrepancy between bar positions is plotted as a function of both wave height and bar amplitude (Figure 7b). The contours are of the mean discrepancy within 0.25 m by 0.25m ranges of wave height and bar amplitude. Only means having 95% confidence regions less than 5 m wide are shown. The mean discrepancy is smallest when both wave height and bar amplitude are high. The discrepancy increases as bar amplitude decreases and increases as wave height decreases if the bar amplitude is large. If the bar amplitude is small, the discrepancy remains large and is relatively insensitive to changes in wave height.
The difference between the two bar position estimates may simply result from the definition of a bar in terms of a deviation from the background slope, as opposed to depth minimum. In all cases, the depth minimum (if it exists) occurs where the slope of the Gaussian shaped bar is equal to, but opposite of the plane beach slope. This point is onshore of the Gaussian bar position. The fractional (relative to a bar length, L) difference between the two choices of bar position is approximately $-(\beta_2 L)/(2 A)$. For the Duck case, this difference was typically less than 10%, which is within the error of the estimated differences.

4. Discussion and Conclusions

Typically, changes in the form of nearshore bathymetry involve the evolution of a number of characteristic shapes. Ideally, it is possible to describe the bathymetry in terms of a morphologic model having only a few parameters. In addition to providing an

![Figure 7. Analysis of discrepancy between survey and video estimates of bar crest positions. In panel A, the differences are plotted against the expected wave height at breaking (wave heights were transformed from observed wave heights using linear wave theory). Contours of the discrepancy are plotted in panel B as a function of bar amplitude and wave height.](image)
objective definition of morphology, this step greatly reduces the dimensionality of the problem, aiding in the statistical analysis and physical interpretation of nearshore beach response.

We utilized an objective definition of nearshore morphology (Gaussian functions and a plane slope) to quantify and compare the morphologic information contained in two sources of morphologic data available from Duck, NC. Directly surveyed bathymetry provided the most complete definition of the morphologic state of the nearshore bathymetry. That is, all of the parameters of the morphologic model could be estimated from these data. Oblique video images were used to estimate the position of inner bars. This information represented only a subset of the morphologic parameters defined in the morphologic model. However, the image data were collected frequently (daily) and, thus, resolved morphologic variability over a wide range of time scales.

In a comparison, the bar positions extracted from the video images were well correlated ($R^2 = 0.8$) with positions extracted from the direct surveys. Deviations between the two different estimates of bar position depended on both wave height (consistent with observations reported by LH89) and, most strongly, on the bar amplitude. An explanation for the bar amplitude dependence could be an increasing dominance of the slope morphology on the wave breaking process as bar amplitudes approached zero. LH89 point out that, even on a plane beach, a “bar” would be identified due to the presence of a maximum in wave energy dissipation. The foam generated provides the visual signal used to identify bars. The differences in the bar position estimates made from the different data sets may need to be reconciled either empirically or, perhaps, using process-based models (LH89 or Aarninkhof et al., 1998).

5. Acknowledgements

The video image data were graciously provided by Tom Lippmann and were published previously in Lippmann et al., 1993. The bathymetric data were provided by the Army Corps of Engineers Field Research Facility. Many different analyses of these data have been published by many other people.

Nonlinear Time-Averaged Model in Surf and Swash Zones
Bradley D. Johnson\textsuperscript{1} and Nobuhisa Kobayashi, Member, ASCE\textsuperscript{2}

Abstract

A time-averaged model is developed to predict the cross-shore variations of the mean and standard deviation of the free surface elevation from outside the surf zone to the lower swash zone on beaches. This new model includes nonlinear correction terms in the cross-shore radiation stress and energy flux that become important in very shallow water. Empirical formulas are proposed for the skewness and kurtosis as well as the ratio of the root-mean-square wave height to the mean water depth which increases rapidly near the still water shoreline. The developed model is shown to be in agreement with three irregular wave tests on a 1:16 smooth impermeable slope and two tests of quasi-equilibrium terraced and barred beaches. The model can predict the observed large increase of wave setup near the still water shoreline. The developed model and empirical formulas will need to be verified using additional experiments.

Introduction

The need for a simple model for the wave motion in the swash zone on a beach has been pointed out in relation to the prediction of beach erosion and recovery near the shoreline [e.g., Hedegaard et al. (1992)]. The time-dependent numerical model based on the finite-amplitude shallow-water equations (Kobayashi and Wurjanto 1992) has been shown to be capable of predicting the swash characteristics on natural beaches (Raubenheimer et al. (1995; Raubenheimer and Guza 1996). However, the time-dependent numerical model requires significant computation time and is hard to incorporate in beach profile models. The time-averaged models for random waves represented by the root-mean-square wave height [e.g., Battjes and Janssen (1978)] or expressed as the superposition of regular waves [e.g., Dally (1992)] are much more efficient computationally but do not predict the wave conditions in the swash zone (Cox et al. 1994).

A nonlinear time-averaged model is developed here to predict the cross-shore variations of the wave setup, $\bar{\eta}$, and the root-mean-square wave height, $H_{rms}$, from outside the surf zone to the lower swash zone where $H_{rms}$ is defined as $H_{rms} = \sqrt{8} \sigma$ with $\sigma$

= standard deviation of the free surface elevation. This model is based on the time-averaged continuity, momentum, and energy equations derived by time-averaging the nonlinear equations used in the time-dependent model of Kobayashi and Wurjanto (1992). The time-averaged equations can be solved numerically with much less computation time but require empirical relationships to close the problem. The time-averaged rate of energy dissipation due to random wave breaking is estimated by modifying the empirical formula of Battjes and Stive (1985) to account for the landward increase of $H_{rms}/\bar{h}$ near the shoreline where $\bar{h}$ = mean water depth. The skewness $s$ and the kurtosis $K$ of the free surface elevation included in the time-averaged momentum and energy equations are expressed empirically as a function of $H_{rms}/\bar{h}$.

The developed model is compared with three tests conducted on a 1:16 smooth impermeable slope and two tests on quasi-equilibrium terraced and barred beaches consisting of fine sand. This new time-averaged model is shown to be capable of predicting the cross-shore variations of $\overline{\eta}$ and $H_{rms}$ of the free surface elevation from outside the surf zone to the lower swash zone of frequent wave uprush and downrush. The model of Battjes and Stive (1985) considerably underpredicts $\overline{\eta}$ and $H_{rms}$ near the still water shoreline. The new model will need to be verified using additional experiments because the empirical formulas adopted in the model are developed using the same five tests.

New Time-Averaged Model

The assumptions of alongshore uniformity and normally incident irregular waves are made in the following. To account for nonlinear effects in very shallow water, use is made of the time-averaged equations derived from the finite-amplitude shallow-water equations. Assuming that the beach is impermeable, the time-averaged continuity equation with the overbar denoting time-averaging is expressed as

$$\bar{h}\bar{U} = 0 \quad (1)$$

where $h$ = instantaneous water depth; and $U$ = instantaneous depth-averaged horizontal velocity. The time-averaged cross-shore momentum equation is written as (Kobayashi et al. 1989)

$$\frac{dS_{xx}}{dx} = -\rho g \bar{h} \frac{d\overline{\eta}}{dx} \quad (2)$$

with

$$S_{xx} = \rho \left[ \bar{h} \bar{U}^2 + \frac{1}{2} g (\eta - \bar{\eta})^2 \right] \quad (3)$$

in which $x$ = cross-shore coordinate taken to be positive landward; $S_{xx}$ = cross-shore radiation stress; $\rho$ = fluid density; $g$ = gravitational acceleration; and $\eta$ = instantaneous free surface elevation above the still water level (SWL). The time-averaged bottom shear stress may be neglected in (2) as explained by Kobayashi and Johnson (1998). The bottom elevation $z_b$ given by $z_b = (\eta - h)$ is assumed to depend on $x$ only. The time-averaged energy equation corresponding to (1) and (2) may be expressed as (Kobayashi and Wurjanto 1992)

$$\frac{d}{dx} \left( \overline{E_F} \right) = -\overline{D_B} \quad (4)$$
with
\[ E_F = \frac{1}{2} \rho h \overline{U}^3 + \rho g \overline{\eta} h \overline{U} \]  
(5)
in which \( E_F \) = energy flux per unit width; and \( \overline{D_B} \) = energy dissipation rate due to wave breaking which needs to be estimated empirically in this time-averaged model.

To simplify (1), (2), and (4), the instantaneous free surface elevation \( \eta \) is expressed as
\[ \eta = \overline{\eta} + \sigma \eta_* \]  
(6)
where \( \overline{\eta} \) and \( \sigma = \text{mean and standard deviation of } \eta; \) and \( \eta_* = \text{normalized free surface elevation with } \overline{\eta}_* = 0 \) and \( \eta_*^2 = 1 \). If wave reflection is negligible, linear long wave theory may be used locally to relate the oscillatory components \((\eta - \overline{\eta})\) and \((U - \overline{U})\) inside and outside the surf zone (Guza and Thornton 1980; Kobayashi et al. 1998). This relationship together with (6) yields
\[ U = \overline{U} + \sqrt{\frac{g}{h}} \sigma \eta_* \]  
(7)
Eq. (7) is necessary to reduce the number of unknown variables in the time-averaged model although the local reflection coefficient may not be small near the still water shoreline on beaches (Baquerizo et al. 1997). Substitution of (6) and (7) into (1) with \( h = (\eta - z_b) \) and \( \overline{h} = (\overline{\eta} - z_b) \) yields
\[ \overline{U} = -\sigma_*^2 \sqrt{gh} ; \quad \sigma_* = \frac{\sigma}{\overline{h}} \]  
(8)
which indicates that \( \overline{U} \) is negative and represents return current (Kobayashi et al. 1989). Although (8) does not account for the landward mass flux due to a surface roller, it predicted the undertow measured at the mid-depth below SWL fairly accurately (Kobayashi et al. 1997, 1998).

Substitution of (6) and (7) with (8) into (3) yields
\[ S_{xx} = \frac{1}{8} \rho g H_{rms}^2 \left[ \left( 2n - \frac{1}{2} \right) + C_s \right] ; \quad H_{rms} = \sqrt{8} \sigma \]  
(9)
with
\[ C_s = \sigma_* s - \sigma_*^2 \]  
(10)
where \( s = \text{skewness of } \eta \) and \( \eta_* \) with \( \overline{\eta}_*^3 = s \); \( n = \text{finite-depth adjustment parameter with } n = 1 \) in shallow water; and \( C_s = \text{nonlinear correction term for } S_{xx} \). For linear progressive waves in finite depth, \( n \) is normally expressed as [e.g., Battjes and Stive (1985)]
\[ n = \frac{1}{2} \left[ 1 + \frac{2k_p h}{\sinh \left( 2k_p h \right)} \right] \]  
(11)
where \( k_p = \text{linear wave number corresponding to the spectral peak period } T_p \) outside the surf zone. The cross-shore variation of \( T_p \) may be neglected in (11) because \( n = 1 \) in shallow water for any reasonable representative wave period used to calculate \( k_p \). The cross-shore radiation stress \( S_{xx} \) based on linear wave theory is given by (9) with
$C_s = 0$. $C_s$ is on the order of unity near the still water shoreline and can not be neglected in the swash zone (Kobayashi and Johnson 1998).

Substitution of (6) and (7) with (8) into (5) yields

$$E_F = \frac{1}{8} \rho g H_{rms}^2 n C_p (1 + C_F)$$

(12)

with

$$C_F = \frac{3}{2} s \sigma_\eta (1 - \sigma_\eta^2) + \frac{1}{2} \sigma_\eta^2 (K - 5) + \sigma_\eta^4$$

(13)

where $C_p = \text{phase velocity based on } T_p$ with $C_p = \sqrt{\frac{g}{h}}$ in shallow water; $C_F = \text{nonlinear correction term for } E_F$; and $K = \text{kurtosis of } \eta$ and $\eta_*$ with $\eta_0^2 = K$. The finite-depth adjustment is included in (12) in the same way as (9) where $n C_p$ in (12) is the group velocity based on $T_p$. The cross-shore energy flux $E_F$ based on linear wave theory is given by (12) with $C_F = 0$ where $C_F$ is on the order of unity near the still water shoreline (Kobayashi and Johnson 1998).

The momentum equation (2) with (9) and the energy equation (4) with (12) need to be solved numerically to predict the cross-shore variations of the wave setup $\bar{\eta} = (h + z_h)$ and the root-mean-square wave height $H_{rms} = \sqrt{\bar{s} \sigma}$. These equations reduce to those used in the existing time-averaged models [e.g., Battjes and Stive (1985)] if $C_s = 0$ and $C_F = 0$. To estimate the nonlinear correction terms $C_s$ and $C_F$ using (10) and (13) with $\sigma_\eta = \sigma / h$, the skewness $s$ and the kurtosis $K$ are assumed to be expressed in the following empirical forms

$$s = f_s \left( \frac{H_{rms}}{h} \right) \quad ; \quad K = f_K(s)$$

(14)

where $f_s$ and $f_K = \text{empirical functions which will be obtained using the five tests discussed later.}$

Finally, the energy dissipation rate $D_B$ due to wave breaking in the energy equation (4) needs to be estimated. The empirical formula proposed by Battjes and Janssen (1978) and calibrated by Battjes and Stive (1985) is adopted here for its simplicity. The formula proposed by Thornton and Guza (1983) may predict the distributions of breaking and nonbreaking wave heights more accurately but requires additional empirical parameters. In the present formulation, the exponential gamma function may be used to describe the probability density function of $\eta$ instead of wave heights after the cross-shore variations of $\bar{\eta}$, $s$, and $K$ are predicted (Kobayashi et al. 1997, 1998).

The calibrated formula by Battjes and Stive (1985) is given by

$$D_B = \frac{\alpha}{4} \rho g f_p Q H_m^2$$

(15)

with

$$\frac{Q - 1}{\ln Q} = \left( \frac{H_{rms}}{H_m} \right)^2$$

(16)
\[ H_m = \frac{0.88}{k_p} \tanh \left( \frac{\gamma k_p \bar{h}}{0.88} \right) \] (17)

\[ \gamma = 0.5 + 0.4 \tanh \left( 33 \frac{H_{rms0}}{L_o} \right) \quad ; \quad L_o = \frac{g T_p^2}{2\pi} \] (18)

where \( \alpha \) = empirical coefficient recommended as \( \alpha = 1 \); \( f_p = T_p^{-1} \); \( Q = \) local fraction of breaking waves in the range \( 0 \leq Q \leq 1 \); \( H_m \) = local depth-limited wave height; \( k_p = \) linear wave number calculated using \( f_p \) and \( \bar{h} \); \( \gamma = \) empirical parameter determining \( H_m = \gamma \bar{h} \) in shallow water; \( L_o = \) deep-water wavelength based on \( T_p \); and \( H_{rms0} = \) deep-water value of \( H_{rms} \) calculated using linear wave shoaling theory with \( T_p \), \( \bar{h} \) and \( H_{rms} \) specified at the seaward boundary of the numerical model.

The empirical parameter \( \gamma \) is uncertain in light of the field data by Raubenheimer et al. (1996) but is estimated using (18) without any additional calibration. Relatedly, Battjes and Janssen (1978) indicated that \( D_B \) given by (15) would underestimate the actual energy dissipation rate and produce \( H_{rms} > H_m \) near the shoreline, although (16) with \( Q \leq 1 \) requires \( H_{rms} \leq H_m \). They recommended use of a cutoff of \( H_{rms} = H_m \) when \( H_{rms} > H_m \). This adjustment leads to \( H_{rms} = \gamma \bar{h} \) near the shoreline. However, \( H_{rms}/\bar{h} \) is not constant and increases landward where \( H_{rms}/\bar{h} \simeq 2 \) at the still water shoreline for the SUPERTANK data of Kriebel (1994). As a result, (15) with (16)–(18) is assumed to be valid only in the outer zone \( x < x_i \) with \( x_i = \) cross-shore location where \( Q \) computed by (16) becomes unity and the still water depth decreases landward in the region \( x > x_i \). The latter condition is required for a barred beach to allow \( Q < 1 \) landward of the bar crest where \( Q = 1 \) may occur. For the inner zone \( x > x_i \), the ratio \( H_s = H_{rms}/\bar{h} \) is assumed to be expressed as

\[ H_s = \gamma + (\gamma_s - \gamma) x_i^{\beta} \quad ; \quad x_i = \frac{x - x_i}{x_i - x_i} > 0 \] (19)

where \( \gamma_s \) = value of \( H_s \) on the order of two at the still water shoreline located at \( x = x_s \); and \( \beta \) = empirical parameter. The values of \( \gamma_s \) and \( \beta \) will be calibrated using the five tests discussed later. Eq. (19) describes the landward increase of \( H_s \) from \( H_s = \gamma \) at \( x = x_i \) to \( H_s = \gamma_s \) at \( x = x_s > x_i \). For the inner zone \( x > x_i \), the momentum equation (2) and (19) are used to predict the cross-shore variations of \( \bar{h} \) and \( H_{rms} \), whereas the energy equation (4) is used to estimate \( D_B \) which must be positive or zero.

The numerical model called CSHORE (Kobayashi and Johnson 1998) is developed to solve (2) and (4) with (9)–(19) where CSHORE includes the option to include the bottom friction effects neglected in (2) and (4). The seaward boundary of CSHORE is located at \( x = 0 \) where the values of \( T_p \), \( H_{rms} \) and \( \bar{h} \) at \( x = 0 \) are specified as input. The bottom elevation \( z_b(x) \) in the region \( x \geq 0 \) is also specified as input and the location \( x_s \) of the still water shoreline is found using \( z_b(x = x_s) = 0 \). First-order finite-difference approximations of (2) and (4) are expressed as

\[ \bar{\eta}_{j+1} = \bar{\eta}_j - \frac{g}{\rho} \left( \bar{h}_j \right) \left[ \frac{1}{2} \left( (S_{xx})_{j+1} - (S_{xx})_j \right) \right] \] (20)

\[ \left( \bar{E}_F \right)_{j+1} = \left( \bar{E}_F \right)_j - \frac{\Delta x}{2} \left[ (\bar{D}_B)_{j+1} + (\bar{D}_B)_j \right] \] (21)
where the subscripts \((j + 1)\) and \(j\) indicate the quantities at nodes located at \(x_{j+1}\) and \(x_j\), respectively, with \(\Delta x = (x_{j+1} - x_j)\) being the nodal spacing. In the subsequent computations for the laboratory data, use is made of \(\Delta x \approx 10\) cm. For the known quantities at node \(j\), the unknown quantities at node \((j + 1)\) are computed by solving (20) and (21) using an iteration method starting from \(\sigma_{j+1}^2\) computed using (21) with \((\overline{D_B})_{j+1} = (\overline{D_B})_j\). The adopted iteration method is found to converge within several iterations. The convergency is based on the differences between the iterated values of \(\sigma_{j+1}\) and \(\overline{h}_{j+1}\) being less than the specified small value \(\epsilon\), where \(\epsilon = 0.01\) mm is used in the subsequent computations. If \(Q_{j+1} = 1\) and \((dz_b/dx) > 0\) for \(x > x_{j+1}\), the inner zone is reached and \(x = x_{j+1}\) is set.

For the nodes located in the inner zone \(x > x_i\), (19) is used to obtain \(H_* = H_{rms}/\overline{h}\) and \(\sigma_* = H_*/\sqrt{8}\). Since the mean water depth \(\overline{h}\) can become very small in the inner zone, (2) with (9) is rewritten as

\[
(2P + 1) \frac{d\overline{h}}{dx} = -\overline{h} \frac{dP}{dx} - \frac{dz_b}{dx} \quad \text{for} \quad x > x_i \tag{22}
\]

with

\[
P = \sigma_*^2 \left[ \left(2n - \frac{1}{2}\right) + \sigma_* s - \sigma_*^2 \right] \tag{23}
\]

A first-order finite difference approximation of (22) between nodes \(j\) and \((j + 1)\) yields

\[
\overline{h}_{j+1} = (3P_{j+1} + P_j + 2)^{-1} \left\{ (P_{j+1} + 3P_j + 2) \overline{h}_j - 2 \left[ (z_b)_{j+1} - (z_b)_j \right] \right\} \tag{24}
\]

Eq. (24) is solved using an iteration method starting from the value of \(n_{j+1}\) involved in \(P_{j+1}\) calculated using \(\overline{h}_j\) where \((\sigma_*)_{j+1}\) and \(s_{j+1}\) are known using (19) and (14), respectively. Since \(n\) given by (11) is essentially unity in shallow water, this interaction method converges rapidly. After \(\overline{h}_{j+1}\) is computed, the energy equation (4) is used to obtain \((\overline{D_B})_{j+1}\). The computation is marched landward until \(\overline{h}_{j+1} < \epsilon\).

**EXPERIMENTS AND EMPIRICAL FORMULAS**

Two different experiments were conducted in a wave tank that was 30 m long, 2.4 m wide, and 1.5 m high. These experiments were explained in detail by Kobayashi et al. (1997, 1998). Irregular waves based on the TMA spectrum were generated with a piston-type wave paddle. Three tests were conducted with a plywood beach of a 1:16 slope. The water depth in the tank was 76.2 cm. For each test, 17 runs were performed to measure free surface elevations using eight capacitance wave gages. Wave gages partially immersed in gage wells were used for the free surface measurements near the still water shoreline. In addition, two tests were conducted with a fine sand beach whose initial slope was 1:12. The sand was well-sorted and its median diameter was 0.18 mm. These two tests with specified random waves were conducted after the sand beach was exposed to the specified wave action for several days and became quasi-equilibrium with the bottom elevation changes less than about 1 cm/hr. For each of the two tests, 21 runs were performed to measure free surface elevations using ten wave gages. Wave gages near the still water shoreline were partially buried in the sand. The duration of each run in these five tests was 400 s and the initial transient duration of 75 s was removed. The sampling rate was 20 Hz.

Table 1 lists the wave conditions at the seaward boundary located at $x = 0$ for each of the five tests where $d =$ still water depth; $\bar{\eta} =$ wave setup or set-down; $T_p =$ spectral peak period; and $H_{rms} =$ root-mean-square wave height defined as $H_{rms} = \sqrt{8} \sigma$ with $\sigma =$ standard deviation of the measured free surface oscillation. Tests 1, 2 and 3 are the 1:16 slope tests described by Kobayashi et al. (1998), whereas tests 4 and 5 correspond to the sand beach tests explained by Kobayashi et al. (1997). The wave setup or set-down is very small at $x = 0$ outside the surf zone. The measured wave conditions at $x = 0$ include the slight effects of reflected waves. The incident and reflected waves at $x = 0$ were estimated using a three-gage method by Kobayashi et al. (1997, 1998). Table 1 lists the estimated values of the spectral root-mean-square wave height, $H_{inc} = \sqrt{8} m_{oi}$, with $m_{oi} =$ zero-moment of the incident wave spectrum at $x = 0$, and the average reflection coefficient, $R = \sqrt{m_{or}/m_{oi}}$, with $m_{or} =$ zero-moment of the reflected wave spectrum at $x = 0$. The difference between $H_{rms}$ and $H_{inc}$ is negligible except for test 2 with $(H_{rms} - H_{inc})/H_{rms} = 0.065$. The reflection coefficient was in the narrow range $0.14 \leq R \leq 0.25$ and slightly larger for tests 4 and 5 with the foreshore slope of about 1:5 at the still water shoreline.

The measured values of $\bar{\eta}$, $T_p$, and $H_{rms}$ at $x = 0$ listed in Table 1 are specified as input to CSHORE. The measured bottom elevation $z_b(x)$ in the region $x \geq 0$ is also specified as input where Table 1 lists the cross-shore location $x_s$ of the still water shoreline for each test. The bottom profile $z_b(x)$ will be presented in conjunction with the measured and predicted cross-shore variations of $\bar{\eta}$ and $H_{rms}$. The breaker parameter $\gamma$ calculated using (18) and the cross-shore location $x_i$ at the seaward limit of the inner zone computed by CSHORE are listed in Table 1.

The measured values of $H_s = H_{rms}/\bar{\eta}$ in the inner zone $x > x_i$ are used to calibrate the new empirical parameters $\gamma_s$ and $\beta$ in (19) for the five tests. Fig. 1 shows the
measured values of \((H_* - \gamma)/(\gamma_s - \gamma)\) with \(\gamma_s = 2\) as a function of \(x_* = (x - x_i)/(x_a - x_i)\) where the values of \(\gamma, x_i,\) and \(x_a\) for each test are listed in Table 1. The trend of the scattered data points for the five tests may be represented by (19) with \(\gamma_s = 2\) and \(\beta = 2.2\). Fig. 1 shows that \(H_*\) increases gradually from \(H_* = \gamma\) at \(x_* = 0\) and more rapidly above the still water shoreline located at \(x_* = 1\). It is noted that the large scatter in the region \(x_* > 1\) is caused partly by the scatter of data points obtained in repeated runs due to the difficulty in measuring \(\bar{h}\) and \(H_{rms}\) accurately in the swash zone.

The measured values of \(H_*\), \(s\), and \(K\) in the entire region \(x \geq 0\) for the five tests are analyzed to obtain the empirical relationships expressed by (14). Fig. 2 shows the skewness \(s\) as a function of \(H_* = H_{rms}/\bar{h}\). The trend of the scattered data points in Fig. 2 are simply represented by three straight lines

\[
\begin{align*}
    s &= 2H_* & \text{for } 0.1 < H_* \leq 0.5 \\
    s &= 1.5 - H_* & \text{for } 0.5 \leq H_* \leq 1.0 \\
    s &= 0.7H_* - 0.2 & \text{for } 1.0 \leq H_* \leq 5
\end{align*}
\]

The skewness \(s\) increases initially with the increase of \(H_*\) due to wave shoaling but decreases after wave breaking. Both \(s\) and \(H_*\) increase rapidly near and beyond the still water shoreline. Fig. 3 shows the relationship between the kurtosis \(K\) and the skewness \(s\) which may be expressed as

\[
K = 3 + s^{2.2} \quad \text{for } 0.2 < s \leq 3
\]
Figure 2: Empirical Formula for Skewness $s$ as a Function of $H_{rms}/\bar{h}$.

Figure 3: Empirical Formula for Kurtosis $K$ as a Function of Skewness $s$.
The empirical relationship between $K$ and $s$ proposed by Ochi and Wang (1984) yields similar agreement as shown in Fig. 3. However, their expression is more complicated and (26) is adopted here for its simplicity.

COMPARISONS WITH FIVE TESTS

The numerical model CSHORE is compared with the five tests listed in Table 1 and used to develop the empirical formulas (25) and (26) as well as (19) with $\gamma_s = 2$ and $\beta = 2.2$. Figs. 4–8 compare the measured and computed cross-shore variations of $\bar{\eta}$ and $H_{rms}$ for tests 1–5, respectively. The variations of $\bar{\eta}$ and $H_{rms}$ computed by the model of Battjes and Stive (BJS hereafter) are also plotted in these figures. The bottom elevation $z_b(x)$ above and below SWL is shown in the first and second panels, respectively, in Figs. 4–8 to show the effects of the beach profile on the wave setup $\bar{\eta}$ and the root-mean-square wave height $H_{rms}$. The data points from repeated runs in each test are presented without averaging to indicate the degree of the data scatter which was apparent in the swash zone because of the difficulty in measuring small water depth accurately (Kobayashi et al. 1997, 1998).

For tests 1–3 shown in Figs. 4–6, breaker types on the 1:16 smooth slope varied from mostly spilling breakers for test 1 to predominantly plunging breakers for test 3. Correspondingly, the inner zone became wider from test 1 to test 3 where $(x_s - x_i) = 0.9, 3.0$ and $4.7$ m for tests 1, 2, and 3, respectively, in Table 1. Comparing CSHORE and the BJS model, the computed variations of $\bar{\eta}$ and $H_{rms}$ in the outer zone $x < x_i$ are practically the same in view of the larger uncertainty associated with the empirical formula (15) with (16)–(18). No attempt is made to calibrate $\gamma$ to improve the agreement for $H_{rms}$ in the outer zone for test 2. In the inner zone $x > x_i$, CSHORE is capable of predicting the larger increase of the wave setup $\bar{\eta}$ and the more gradual decrease of the wave height $H_{rms}$ in the inner zone.

For tests 4 and 5 shown in Figs. 7 and 8, incident waves shoaled and broke on the small bar at the edge of the terrace. Plunging breakers at the terrace edge were intense in test 5. Wave breaking was reduced on the terrace before incident waves broke again in the swash zone. The BJS model is capable of predicting this wave transformation across the terrace except for the detailed variations of $H_{rms}$ at the terrace edge. The differences between CSHORE and BJS model are limited essentially in the narrow inner zone where $(x_s - x_i) = 0.5$ and $1.3$ m for tests 4 and 5, respectively, in Table 1. CSHORE allows the extension of BJS model into the lower swash zone.

CONCLUSIONS

A time-averaged model is developed to predict the cross-shore variations of the mean and standard deviation of the free surface elevation from outside the surf zone to the lower swash zone. This time-averaged model derived from the time-dependent continuity, momentum, and energy equations which were used successfully to predict irregular wave runup on beaches includes nonlinear corrections terms in the cross-shore radiation stress and energy flux. The correction terms involving the skewness and kurtosis are important in very shallow water. The time-averaging of the time-dependent equations reduces computation time considerably but creates a closure problem. The energy dissipation rate due to wave breaking is estimated using an

Figure 6: Measured and Computed Setup $\bar{\eta}$, and Height $H_{rms}$ for Test 3.

Figure 7: Measured and Computed Setup $\bar{\eta}$, and Height $H_{rms}$ for Test 4.
existing empirical formula in the outer zone. In the inner zone near the still water shoreline, a new empirical formula for \( H_s = H_{rms}/h \) is proposed to describe the landward increase of \( H_s \). In addition, simple empirical formulas are proposed to express the skewness and kurtosis as a function of \( H_s \).

The developed model is compared with three irregular wave tests on a 1:16 smooth impermeable slope and two tests on quasi-equilibrium terraced and barred beaches. The major improvements of the new model in comparison to existing models are that it is capable of predicting the wave setup and root-mean-square wave height near the still water shoreline. Since the new empirical formulas are developed using the same five tests, the new model will need to be verified using additional tests. Coupling of the new wave model with a cross-shore sediment transport model may make it feasible to predict the erosion and recovery near the still water shoreline.

Swash Zone Morphodynamics and Sediment Transport Processes

K. Todd Holland¹, Asbury H. Sallenger, Jr.², Britt Raubenheimer³, and Steve Elgar³

Abstract

Observations of foreshore morphologic change and swash flow velocities were made at Duck, NC in an effort to estimate cross-shore sediment flux magnitudes. The three-dimensional foreshore surface over an approximately 10 x 20m study area was determined repeatedly to roughly centimeter accuracy using a stereometric video method. Sediment flux magnitudes derived from the temporal gradient of these data showed erosion rates of over 25 cm/hr. Near-bed, cross-shore swash velocities were measured at multiple cross-shore locations using a separate video technique. Swash velocities estimated using this method were found to be consistent with current measurements obtained using acoustic Doppler and ducted impeller current meters. The swash zone profile observations and velocity estimates were used to test an energetics-based total load sediment transport model. Although the trends of both the model and the observations were qualitatively consistent, the magnitudes and positioning of observed sediment fluxes did not match the transport model predictions. This discrepancy implies that other factors, such as water depth variations, infiltration, or sediment advection, may be important.

Introduction

It is generally recognized that gradients of sediment flux across the swash zone contribute significantly to beach morphological change. However, the present understanding of sediment transport mechanisms in this region is poor, partially owing to the complexity of foreshore processes. Nonlinearity and feedback between forcing and response are common. Yet even more problematic is the fact that measurements of fluid motions and sediment concentrations are difficult to obtain in this dynamic region. Swash flows move in a Lagrangian sense requiring either very dense arrays of in-situ sensors, dual-resistance runup wires (Guza and Thornton 1982; Raubenheimer et al. 1995), or

2799
remote sensing methods (Holland et al. 1995). In addition, the foreshore surface itself may change rapidly making estimation of the measurement elevation complicated.

In previous studies of swash zone morphology and associated sediment transport, coarsely sampled changes in bed elevation have been used to infer total load sediment transport rates (Duncan 1964; Howd and Holman 1987; Sallenger and Richmond 1984; Waddell 1976); and either optical sensors or traps have been used to monitor suspended and bedload concentrations (Beach and Sternberg 1992; Horn and Mason 1994; Osborne and Rooker 1997; and others). Although much is known about fluid motions in the swash zone and the above studies give glimpses of relative sediment concentration magnitudes, there is a great need for simultaneous measurement of hydrodynamic forcing and morphodynamic response to advance foreshore sediment transport modeling. This deficiency is even more pronounced with respect to relatively large temporal and spatial scales (hours to days and 10s to 100s of meters, respectively).

This paper presents new swash observations collected at Duck NC with a recently developed stereometric video system and a video-based current meter method that show great promise in overcoming the difficulties mentioned above. The observations of profile change and cross-shore swash velocity are used to develop and validate a simple model of swash zone sediment transport. The correlation between model estimates and observations is then discussed.

Study Site and Field Methods

Data were obtained at the US Army Corps of Engineers’ Field Research Facility (FRF) at Duck, NC. Duck is multi-barred, intermediate to reflective beach with a tidal range of approximately 2 m. The foreshore slope is roughly 1:12. A large number of experiments have taken place at the FRF field site with many swash observations indicating infragravity dominated motions at the shoreline, especially during storms.

To quantify net sediment transport and morphologic change in the swash zone, foreshore surface measurements were made over a study region of dimensions 10 m in the cross-shore and 20 m in the alongshore during the DUCK94 experiment. Three-dimensional (3-D) foreshore topography was determined to roughly centimeter accuracy by using a stereometric video method (described fully in Holland and Holman 1997). By monitoring the progression of the swash line using edge detection algorithms, multiple views of the foreshore study area allow determination of point object positions \((x,y,z)\) for each pixel along the swash edge. Repeating the process for each subsequent edge over the swash cycle results in several thousand estimates of the foreshore surface per wave. Although observations were made over a much larger time interval, the data presented in this paper were obtained during a particularly dynamic period of erosion on October 10, 1994. A burst sampling mode was employed to measure swash excursions and elevations over the foreshore region approximately once every 15 minutes at a rate of 6 Hz [Figure 1].
Figure 1: Left panel shows stereo-estimated swash edge positions intensity coded by time (temporal separation interval of 0.33 s). Right panel shows elevation versus cross-shore distance as determined by the stereo method (dots) and GPS surveying methods (dashed). Optimal interpolation of the nearly 7000 stereo estimates (solid) yields a cross-shore profile with a root-mean-square deviation from the surveyed profile of 1.4 cm.

Corresponding cross-shore swash velocities were estimated using a new application of an existing video method known as a timestack (Holland et al. 1995). Since timestacks [Figure 2] represent the temporal variation in pixel intensity along a given cross-shore profile, Lagrangian estimates of the swash edge speed can be calculated as the time derivative of the measured cross-shore swash position. In contrast, Eulerian estimates of cross-shore currents, \( u(x) \), were calculated at specific cross-shore distances using the edge speeds during uprush and backwash derived from timestacks (sampled at 10 Hz). In doing so we assumed that fluid particles immediately behind the bore front move at the speed of the bore and that a constant velocity gradient exists from the moment the swash bore reaches the video sensor till the time of maximum backwash. Velocities were set to zero for times during which the virtual sensor was dry. Using this method, saw-toothed, swash velocity time series were computed at eleven locations spaced by one meter along the cross-shore transect in the center of the study area. Figure 3 exemplifies the differences in velocities at two cross-shore positions.
Figure 2: Video timestack showing swash edge position (dashed) as a function of time and cross-shore position (from Holland and Holman 1993).

Figure 3: Schematic of video method for extracting cross-shore swash currents at two cross-shore ($x=123$ and $x=120$, middle and bottom respectively) locations from position time series (top). Position decreases landward and negative velocities correspond to onshore flow.
To determine the validity of this video method for deriving cross-shore currents in the swash zone, measurements made using this technique were compared to velocity measurements obtained using Acoustic Doppler Velocimeter (ADV) and ducted impeller current meters. During the SANDYDUCK experiment, horizontal and vertical swash velocities approximately 5 cm above the bed were measured at a 2 Hz sampling rate at one location using a Sontek ADV [Figure 4]. Additionally, 4-Hz cross-shore current measurements at 4 and 8 cm above the beach surface were available from “Smith” ducted impeller sensors deployed during an experiment at Glenden OR in 1994 (Puleo et al. submitted). Figure 5 shows an example of the comparison. In general, the results are similar. The timing of the uprushes measured by the in-situ gauges closely corresponds to that of the leading edge of the swash as it reaches the sensor location. Current meter velocities were also very small during time intervals where the video indicated the sensor was dry \((u = 0 \text{ m/s})\). Peak uprush and backwash velocity magnitudes were often similar and the slopes of the temporal velocity gradients from each method were roughly equivalent. Since there was only a small amount of structure in the interval between the beginning of uprush and the end of backwash, the constant gradient assumption in the video method appears justified.

Figure 4: ADV instrumentation designed to monitor swash velocities as part of the SANDYDUCK experiment.
Table 1 shows the quantitative results of the comparison of 333 swash events. The means of the various parameters are comparable, although video-based uprush and backwash speeds and swash durations were on average of greater magnitude than the observations from the in-situ instrumentation. Estimates of higher moments of cross-shore currents (e.g. $u'^3$) were quite variable, even between sensors of the same type. However, these discrepancies are somewhat expected since the ADV and Smith meters sampled flows at higher elevations than that sensed by the video. For example, the minimum depth required for the in-situ gauges is on the order of 4 to 5 cm; and for optimal operation, the ADV sensor (positioned 5 cm above the sampling volume) must be fully immersed, thereby requiring depths of over 10 cm. The response times of the in-situ instrumentation appear to be somewhat slow, especially during uprush. Given that the in-situ instrumentation was out of the flow more often, coarsely sampled, and essentially excluded portions of the swash signal very near the bed, the video results, although simplified, appear sensible. One possible source of additional error is that obliquely incident swash motions will positively bias the cross-shore current estimates from the video. Measurements of the longshore trend of the swash edge suggest this error with respect to mean velocities was on the order of 10%. Longshore swash currents sampled with the ADV were less than 0.08 m/s.

Table 1. Comparison of video-based and in-situ estimates of cross-shore swash velocity parameters. Symbols denote various swash moments, mean swash durations, and slope of the temporal velocity gradient.

Swash Velocity Characteristics

Unfortunately, no in-situ instrumentation was deployed during the Duck94 experiment, therefore, only video-based cross-shore current measurements were made. Over the approximately six-hour period of measurements, velocity magnitudes of up to 1.78 m/s were observed. The mean duration of a swash cycle at the approximate setup level was 3.9 s. Average initial uprush and final backwash speeds were essentially equivalent with magnitudes of 1.16 and 1.19 m/s respectively. However, shorter-term averages of the swash time series showed a tendency toward offshore-dominated flow prior to high tide and onshore-dominated flow during the falling tide. Also observed was an inequality between peak uprush and backwash velocities for individual swash events. Spatial gradients in the velocity structure tended to follow the trends in the mean velocities with positive gradients during the rising tide and negative gradients after high tide.

Foreshore Profile Change

Stereo-estimated foreshore surfaces on Oct 10 are shown in Figure 6. An optimal interpolation technique was used to fit the estimates to a constant grid surface, $h(x,y)$, with an even spacing of 40 cm between grid points. Temporal derivatives of the surfaces showed erosion rates of over 0.25 m³/hr with a maximum of 60 cm of erosion occurring in the center of the study area. Figure 7 shows the alongshore-averaged profile change rate as a function of cross-shore distance and time. A fairly constant loss of sediment is apparent proceeding in the landward direction with the rising tide. Of particular interest was the fact that the offshore wave conditions throughout the run were approximately equivalent, yet morphologic response was dramatically different before and after high tide.
Figure 6: Stereo surfaces gridded and contoured following optimal interpolation analysis. The foreshore morphology changed from cuspate at 0845 hours to plane by 1045 with more than 60 cm of erosion measured over the entire four-hour period.
Sediment Transport Model

A simple numerical model was developed and validated using the time histories of foreshore surface change in conjunction with video-based swash velocity measurements. Bagnold’s (1963; 1966) energetics-based, depth-integrated volume transport equation was adopted as the description of sediment dynamics for these data since it directly relates transport rates to instantaneous shear stresses derived from the local velocity field, \( u(x) \). The form of the equation is given by:

\[
q_i = \frac{\rho_w c_f}{(\rho_i - \rho_w)} \left[ \frac{\varepsilon_i (1 - \varepsilon_p)}{\langle w/\langle u \rangle \rangle - \tan \beta} + \frac{\varepsilon_p}{\tan \phi - \tan \beta} \right] \langle u^3 \rangle
\]

where \( q_i \) represents the time-averaged, cross-shore volumetric total sediment load transport per unit width per unit time, \( \rho = 1.025 \text{ g/m}^3 \) is the seawater density, \( \rho_i = 2.65 \text{ g/m}^3 \) is the sediment density, \( \beta \) is the beach gradient, \( \phi \) is the friction angle of the sediment (\( \tan(\phi) = 0.63 \)), \( w \) is the sediment fall velocity (~ 6 cm/s assuming a mean grain diameter of 0.5 mm), and \( g \) is the gravitational acceleration. Angle brackets represent
time averaging and values for the friction, bedload, and suspended load efficiency factors, \((c, \varepsilon_b, \text{ and } \varepsilon_s, \text{ respectively})\) were defined following Bagnold (1966). This type of formulation has been previously applied to the swash zone (Hardisty et al. 1984; Hughes et al. 1997a; Masselink and Hughes in review) and serves as a good candidate model for these data using inputs of cross-shore current at a given cross-shore location and time varying beach slope.

Model results were compared to observations obtained using the stereo method by estimating profile change given spatial gradients in sediment transport predictions via the sediment continuity equation:

\[
\frac{\partial h}{\partial t} = \frac{1}{1 - v} \frac{\partial q}{\partial x} \tag{2}
\]

This relation assumes that no alongshore gradients in sediment transport contribute to profile change and ignores advection of sediment from the surf zone into the swash zone. The results, shown in Figure 8, indicate that the model was successful at describing the qualitative trends in profile evolution, however the magnitudes and positioning of observed sediment fluxes did not match the transport model predictions. For example, the erosion of the foreshore surface was observed to occur earlier than predicted. Also, a period of accretion was predicted after high tide (approximately 1230), while the measured profile remained stable.

Figure 8: Measured (left panel) and predicted (right-panel) profile change as a function of cross-shore distance and time.
Discussion and Conclusions

Video-based methods were utilized to allow rapid and simultaneous measurement of swash zone hydrodynamic forcing and morphodynamic response. Although a small number of prior investigators have presented observations of swash zone sediment transport and cross-shore flow velocities, namely Hardisty et al. (1984), Hughes et al. (1997b), and Masselink and Hughes (in review), this study is distinguished by the large temporal and spatial coverage allowed by the video techniques. Another advantage of these methods is that velocity patterns associated with infragravity band wave motions are sampled. However, at present, alongshore currents cannot be directly estimated and extension of these methods to deeper surf zone flows is difficult.

An energetics-based sediment transport model (Bagnold 1963; Bagnold 1966) was validated using these data and was shown to be insufficient in predicting the magnitudes, and in some cases sign, of transport observed. Qualitative correlation between the model and observations during the first half of the measurement period suggests that swash flow velocity is an important parameter affecting foreshore sediment transport, however, the magnitude discrepancies indicate that other factors should be considered in future efforts. For example, the effects of water depth variations, infiltration, groundwater, and the influx of sediment from offshore, may well be responsible for a significant portion of the mismatch. One possibility for future adaptation of the model is through the use of variable efficiency coefficients during uprush and backwash as suggested by Masselink and Hughes (in review).

FIELD MEASUREMENTS OF SWASH INDUCED PRESSURES WITHIN A SANDY BEACH

D. P. Horn\textsuperscript{1}, T. E. Baldock\textsuperscript{2}, A. J. Baird\textsuperscript{3} and T. E. Mason\textsuperscript{2}

Abstract

This paper describes field measurements of near-surface hydraulic gradients within a sandy beach during individual swash cycles. We show several different types of behaviour which may have implications for swash zone sediment transport: (1) measurements of swash depth; (2) 'unloading' events with large upward-acting hydraulic gradients; (3) infiltration events with smaller downward-acting hydraulic gradients; (4) situations where the probes lower in the bed measure significantly lower heads than the probe at the surface, leading to strongly downward-acting hydraulic gradients; and (5) measurements in the capillary fringe. Large hydraulic gradients, which are more than sufficient to induce fluidisation, occur in the top 15 mm of the bed under swash and backwash. These large hydraulic gradients, which occur only in the very top section of the bed, may coincide with a significant depth of water (up to 40 mm), which suggests the potential for entrainment of the fluidised bed under backwash.

Introduction

Accretion and deposition on the foreshore is a function of the interaction of surface and subsurface flow regimes in the swash zone, and an understanding of the interaction between surface and groundwater flows is necessary to model swash zone sediment transport. Previous research has suggested that infiltration and exfiltration in the swash zone may be important mechanisms in beach profile changes, governing sediment deposition and erosion rates above mean sea level. Much of this work has focused on examining the link between tidally-induced groundwater flows and swash infiltration/exfiltration, with the assumption that changes in swash volume would alter swash/backwash flow asymmetry. However, Turner and Nielsen (1997) identified several other mechanisms by which vertical flow through a porous bed could affect swash zone sediment transport, including an alteration in the effective weight of the surface sediment due to vertical fluid drag and modified shear stresses exerted on the bed due to boundary layer thinning due to infiltration or thickening due to exfiltration.

It has been suggested by a number of authors going back to Grant (1946, 1948) that groundwater outflow from a beach during the ebb tide may enhance the potential for fluidisation of sand, and thus the ease with which sand can be transported by swash flows. However, groundwater outflow from a beach in response to a falling tide is unlikely to be sufficient to induce fluidisation since hydraulic gradients under the sand surface will tend to be relatively small, generally of the order of the beach slope (1:100 to 1:10). Baird et al. (1996, 1997, 1998) suggested a different mechanism for the local fluidisation of the sediment bed due to the propagation and release of a pressure pulse into the seepage face during swash. They showed theoretically how hydraulic gradients in the saturated sediment beneath swash can exceed the threshold for fluidisation.

Despite recent measurements of pore water pressures under swash such as those of Turner and Nielsen (1997), there is still considerable uncertainty about the effects of hydraulic gradients on sediment transport mechanisms and rates (Oh and Dean, 1994; Baldock and Holmes, 1998, this volume), and it is important to determine the magnitude of the hydraulic gradients near the surface of the sediment bed in order to identify the nature of the seepage flow within the bed. This paper addresses this point and describes field measurements of the near-surface hydraulic gradients within a sandy beach during individual swash cycles.

**Field site and methodology**

Field measurements were made on a sandy beach at Canford Cliffs, Poole, England, a groyned beach with a mean slope of 3.2° (\(\tan \beta = 0.055\)) on the upper foreshore and a mean slope of 1.5° (\(\tan \beta = 0.027\)) on the lower foreshore. The sand is well-sorted and negatively skewed, with a mean sediment size of 0.24 mm. The mean hydraulic conductivity of the sediment was 0.00225 ms\(^{-1}\), with a range from 0.00036 to 0.01179 ms\(^{-1}\), and a coefficient of variation of 143%, which is typical for this parameter. The beach is backed by a concrete sea wall set in underlying poorly-permeable silts giving no-flow conditions on the inland and lower boundary. The tidal range at Canford Cliffs varies between 0.2 and 2.2 metres on neap and spring tides respectively. The field site is described in more detail in Baird et al. (1998).

Two deployments were undertaken, one in March 1997 and one in October 1997. The March 1997 deployment was conducted on a spring tide, with a tidal range of 1.3 metres. The wave conditions during the March deployment were atypical for this coastline, with long period swell (\(T=16\) s, \(H_b=0.8\) m) resulting in a swash zone in excess of 30 m width and with little interaction between sequential swash cycles. The October 1997 deployment was also conducted on a spring tide, with a tidal range of 2 metres. Wave parameters seaward of the swash zone were measured with a seabed-mounted pressure transducer located approximately 17.5 m seaward of the swash instruments. All instruments were logged at 4 Hz. The wave conditions in the October deployment were much more typical of this limited-fetch coastline. The significant wave height varied over the measurement period between 0.23 and 0.43 m, while \(H_{ms}\) varied between 0.16 and 0.3 m. The peak wave period varied between 3 and 4.7 seconds, and the width of the swash zone varied between 3 and 7 m. The value of the surf scaling parameter \(2\pi^2H_{ms}gT^2\tan^2\beta\) varied between 9 and 16.9, indicating intermediate conditions. Low values of the surf scaling parameter (<2.5) indicate reflective conditions, whereas high values of the surf scaling parameter (>20) are associated with dissipative conditions.

Near-surface hydraulic gradients in the swash zone were measured by a technique developed by Baldock and Holmes (1996). This uses a series of 2 mm internal diameter probes, inserted into the sediment and connected to pressure transducers above the water surface (Figure 1). Pressure variation is transmitted into each probe through twelve 0.4 mm holes drilled into the tip. The probes cause negligible disturbance to the
swash flow or the sediment, and may be moved vertically within the bed to compensate for bed level changes over several swash cycles. The whole system may be easily moved to any location on the foreshore and therefore swash zone measurements can be made at different tidal stages. Four probes were deployed with a horizontal spacing of 1 cm (shore parallel) and with a range of vertical spacings (minimum 1 cm). Vertical hydraulic gradients could therefore be obtained within the upper 3 cm of the beach sediment at a single position in the beach.

Figure 1. The pressure measurement system.

In the October deployment, the spacing between the top probe and the second probe was 11 mm, the spacing between the second probe and the third probe was 11 mm, and the spacing between the third probe and the fourth probe was 10 mm. Measurements were taken with the array at a number of positions, the lowest of which was with the top probe at -65 mm and the bottom probe at -97 mm. However, the most common configuration was with the top probe 5 mm below the surface, and probe 2 at -16 mm, probe 3 at -27 mm and probe 4 at -37 mm. The position of the array was adjusted.

Figure 2. The beach profile and instrument locations on 19 October 1997.
constantly to ensure that the top probe remained at the surface as the bed level changed. Measurements were made at two positions on the flood tide and one position on the ebb tide (Figure 2); however, only data obtained on the rising tide are shown in this paper. Measurement was begun when the instruments were at the landward edge of the swash zone, and the swash zone moved past the measurement point as the tide rose. Twenty-six data sets were collected in March 1997 and thirty-two data sets in October 1997. A selection of the results will be shown here, mainly from the October data. Some results of the March deployment were presented by Baird et al. (1997).

Results

All data are shown as either head \((h)\) in mm or hydraulic gradient \((dh/dz)\), which is expressed in head units and therefore dimensionless. All pressure readings from the probes were zeroed to hydrostatic pressure with the watertable at the sand surface. In effect, therefore, all probe readings can be converted to length units to give total head values with the surface acting as a datum. Thus, positive values mean that the water level is above the sand surface: in other words, swash or backwash. Negative head values mean the water level is below the sand surface. However, negative heads do not necessarily mean a real negative pressure (i.e. suction). Only if the head value is less than the probe elevation below the surface is there a suction. In the convention used here, a positive hydraulic gradient represents a downward-acting seepage force (infiltration) and a negative hydraulic gradient represents an upward-acting seepage force. The fluidisation criterion adopted here is based on Packwood and Peregrine (1980), who noted that for many sands and fine gravels, fluidisation occurs when the upward-acting dynamic hydraulic gradient is greater than (i.e. more negative than) about -0.6 to -0.7 (in the convention used here).

Figures 3 and 4 show time series of heads 5 mm below the bed surface (in effect the swash depth) for the March and October deployments, respectively. Small changes in the saturated bed level can be seen, indicated by deviations from zero head at the end of the backwash. Wave groups are evident in both diagrams, with little interaction between sequential swash cycles. Despite the difference in the wave conditions on the two deployments, grouping is evident in all of the swash records. Low-frequency swash motions will be directly induced by these wave groups and are probably dominant over standing long waves in this case (Baldock et al., 1997). However, here we are mainly concerned with short wave swash motion.

![Figure 3. Swash-induced head 5 mm below the bed surface (run 1, 25 March 1997).](image-url)
Figures 4, 5, 6, 7, and 8 show heads immediately below the surface from the March and October deployments, respectively, while Figures 6 and 8 show the associated hydraulic gradients in the 15-16 mm immediately below the bed surface. Despite the difference in incident wave conditions, a similar phenomenon is observed in both cases (and in many others not shown here). All data were obtained on a rising tide. Similar effects were not observed on a falling tide, where positive hydraulic gradients appeared to dominate. Only very small positive hydraulic gradients (infiltration) were observed during the uprush, while large negative hydraulic gradients (upward flow) were observed at the end of the swash cycle. In both Figures 5 and 7, the head at the top probe (-5 mm) drops more rapidly than the head at the second probe (-15 or -16 mm). This is associated with large negative (upward-acting) hydraulic gradients, as illustrated in Figures 6 and 8. The maximum (i.e. most negative) hydraulic gradient associated with the first case (Figures 5 and 6) is -2.7 and the maximum (most negative) hydraulic gradient in the second case (Figures 7 and 8) is -2.3. In both cases, this is more than sufficient to fluidise the bed, as the fluidisation criterion is a hydraulic gradient of -0.7.

---

Figure 4. Swash-induced head 5 mm below the bed surface (run 2, 19 October 1997).

Figure 5. Swash-induced heads at -5 mm and -15 mm (run 12, 25 March 1997).
These large upward-acting hydraulic gradients appear to be the result of a rapid drop in the head in the upper 15-16 mm of the sediment, which occurs prior to the release of head/pressure deeper in the bed. Although this could indicate suction and hence partial drainage of the sediment, this effect may also be due to the rapid unloading experienced by the sediment as the swash retreats, as suggested by Baird et al. (1996). Suction without drainage could be produced if air trapped in the sediment comes under positive pressures during loading, whereas during unloading the air is no longer under pressure and suction forces develop around the sand grains. However, the unloading occurs on every swash event in the data set from 25 March, whereas it occurs only occasionally in the data from 19 October. The sediment in this region was loosely consolidated and probably had a small but significant air content. Observations on 25 March, when significant cliffing occurred on the beach face and ebullition from the bed was observed, suggested that the air content in the sediment was higher on that day than in October. Also, during the March deployment the longer swash cycles, with very little swash interaction, allowed more time for drainage of the beach between swashes.
Figure 8. Hydraulic gradients under swash (run 11, 19 October 1997). The solid line is the hydraulic gradient between the probes at -5 and -16 mm. The dotted line is the hydraulic gradient between the probes at -16 and -27 mm.

Figure 9. Hydraulic gradients in the top 37 mm of the bed for the 'unloading' event illustrated in Figures 5 and 6 (run 11, 19 October 1997).

Figure 9 illustrates the hydraulic gradients from the same data on 19 October, showing that the extremely large hydraulic gradient associated with the release of pressure as swash retreats occurs only in the top 16 mm of the bed. The hydraulic gradients lower in the bed are much smaller, and are generally not sufficient to fluidise the bed. At deeper depths (-27 to -37 mm) hydraulic gradients were in the range -0.3 to 0.5, which although less than the hydraulic gradients in the top 16 mm, are still considerably in excess of tidal groundwater hydraulic gradients (of order $\beta$). As reported by Baird et al. (1997), in some of the data, gradients in the sand bed were observed to be acting both downwards and upwards at the same time. For example, in the section of the record shown in Figure 9, the hydraulic gradient between -16 mm and -27 mm is positive (downward), whereas all of the others are negative. (The hydraulic gradient over the whole measurement area, between -5 mm and -37 mm, which is also
negative, is only included on Figure 9 to show that if the sensors had been further apart, a much smaller hydraulic gradient would have been measured and much useful information would have been lost.) There are a number of possible explanations for these apparently anomalous results. The beach sediment was probably not uniform with depth, in which case the hydraulic properties of the sediment, such as hydraulic conductivity, packing, or air content would also have varied. There may have been divergent flow because of lags in the system due to changes in specific storage. One of the probes may have had an air bubble, which would have distorted the results. This last reason is unlikely, however, as the phenomenon was observed on many occasions.

![Graph](image)

Figure 10. Head at top probe (-5 mm) and hydraulic gradient for the 'unloading' event illustrated in Figures 5, 6 and 7 (run 11, 19 October 1997).

Figure 10 shows the swash depth (head at -5 mm) and the hydraulic gradient in the top 16 mm of the bed for the 'unloading' event which occurs between 145 and 155 seconds, which is also illustrated in Figures 7, 8 and 9. The fluidisation criterion is exceeded while a significant depth of swash exists (maximum 40 mm), and exceeds the fluidisation criteria for several seconds while still under swash/backwash. These data also appear to support the hypothesis of Baird et al. (1996, 1997, 1998), where the large upward hydraulic gradients, sufficient to induce fluidisation of the sediment at the surface, may occur during the latter stages of backwash, thus providing readily entrainable material that can be carried seaward by the backwash flow. Note that this does not necessarily conflict with the findings of Turner and Nielsen (1997). The hydraulic gradients reported here were measured in the top 16 mm of the bed, whereas Turner and Nielsen's top pressure measurement was at a depth of 40 mm. Our data showed strongly negative hydraulic gradients only in the top 1-2 cm of the bed.

Figure 11 shows another example of an 'unloading' event from earlier in the tide on 19 March. The first swash event begins at t=7s, as the head and water depth rise rapidly. The hydraulic gradient before the swash arrives fluctuates around zero and is mainly just barely positive (and therefore downward-acting), indicating drainage after the previous swash. As the swash depth increases, the hydraulic gradient increases. The hydraulic gradient then begins to decrease as swash depth decreases. However, the hydraulic gradient remains positive throughout this swash event, suggesting infiltration is occurring under both swash and backwash. Between t=12s and t=32s, both the swash depth and the hydraulic gradient fluctuate around zero, suggesting conditions similar to those observed by Turner and Nielsen (1997), with the top of the capillary fringe at the sand surface and the phreatic surface fluctuating within this zone of tension.
saturation. The hydraulic gradient begins to rise at about t=32s, before the water level begins to drop. At t=38s, the hydraulic gradient reaches its maximum and the water level begins to drop rapidly. Between t=39s and t=49s, the hydraulic gradient is very slightly positive, while the water level decreases at a slower rate, suggesting less rapid drainage. In this section of the record, the water surface is below the probe, suggesting that it is measuring pressures/heads in the capillary fringe. The next swash arrives at t=49s and the water level rises almost instantaneously. The hydraulic gradient becomes negative for the first second of this swash event, and then rises until t=53s, when it begins to fall. Just before t=54s, the swash reaches its maximum depth and the hydraulic gradient becomes negative (upward-acting). Between t=54s and t=56s, the hydraulic gradient is less than (i.e. more negative than) -0.7 (sufficient to induce fluidisation of the bed), reaching the most negative value of -1.2 while there is still a significant depth of water in the backwash (30 mm). Throughout the time that the swash depth is decreasing, the hydraulic gradient remains negative, suggesting upward flow at the end of the swash/backwash cycle. However, as in the previous examples, the very large upward-acting hydraulic gradient is only measured in the top 16 mm of the bed. The upward-acting hydraulic gradients lower in the bed are much smaller, between -0.1 and -0.5. The swash depth reaches zero at t=56s; at this time the hydraulic gradient is increasing, but still negative. The hydraulic gradient does not become positive again until t=59s. Both the depth and the hydraulic gradient then fluctuate slightly around zero until the next swash arrives at t=77s.

Another phenomenon can be seen in the portion of this data set where infiltration is occurring, between t=32s and t=49s, which is associated with a hydraulic gradient of 0.7. This is illustrated in Figure 12, which shows the head at the top probe (-5 mm) and the bottom probe (-37 mm). Although the head measured by the surface probe does not begin to drop until t=38s, the head measured by the bottom probe begins to decrease several seconds earlier, at t=32s. At t=40s the two probes are again measuring the same head, which they continue to do for the rest of the infiltration event. The reason why the bottom probe drops off before the top one is not clear. There may be several explanations for this time lag between the pressure drop at the top and bottom probes. These data were collected when the saturated sand surface was moving back and forth past the measurement point. One possibility, based partly on our ideas and a suggestion from Nielsen (pers. comm.), who suggested that the formation and destruction of meniscuses between sediment particles could cause the pressure at the bottom probes to drop before the pressure at the top probe, is that there is a thin 'tongue' of fully saturated sediment (i.e. no meniscuses) propagating within the sediment. This thin

Figure 11. Head at top probe (-5 mm) and hydraulic gradient (run 8, 19 October 1997).

Figure 12. Head at bottom probe (-37 mm) and hydraulic gradient (run 8, 19 October 1997).
totally saturated zone, just below the bed surface, may influence the pore pressure within sediment that is not quite fully saturated (i.e. a capillary fringe where meniscuses are present). This tongue of full saturation may propagate in advance of swash or may be formed due to small amounts of swash infiltration. Below this saturated zone, the sediment is likely to be less than fully saturated due to drainage between sequential swashes. A second fully saturated zone is then reached at the tidally-induced watertable elevation. The observed head difference occurs between the top probe and the bottom three probes, over only a few centimetres of the beach material, which suggests that the subsurface layer of full saturation is quite thin.

Figure 12. Head at top and bottom probes (run 8, 19 October 1997).

Figure 13 illustrates a possible configuration of this subsurface water under backwash on a flood tide. At time 1 (equivalent to the period before t=32s on Figures 11 and 12), the position of the saturated surface is shoreward of the measurement point, and both probes are within the saturated tongue and measuring virtually the same head. At time 2 (t=32s), the tongue has moved downslope. The bottom probe is no longer in the tongue, whereas the top probe is. Therefore the bottom probe measures a lower head than the top probe. At time 3 (before t=40s) the tongue has moved further.
downslope and neither probe is in it. After this, the head measured at both probes decreases at the same rate due to natural drainage of the beach. This continues until the next swash arrives (before t=49s).

Figure 14 illustrates a situation similar to that described by Turner and Nielsen (1997), showing rapid groundwater response to swash, with a near instantaneous rise followed by a slower rate of decline. Large watertable fluctuations (>80mm) can be seen under relatively shallow swash flows (<20mm). In this data set, the top probe is at -15 mm and the bottom probe is at -47 mm. At the beginning of the record, the apparent water level is below the elevation of both probes and they are measuring 'real' negative pressures, suggesting both are in the capillary fringe. The uprush arrives at the measurement point at t=286s and the head at both probes rises instantaneously, although the head measured by the bottom probe does not rise as much. Both probes are measuring positive pressures, but they are not measuring the same head of water. Between t=287s and t=298s, the head decreases at both probes, suggesting a falling local watertable. However, throughout this period the top probe continues to register a higher head than the bottom probe. The two probes measure the same head and decrease at the same rate for a brief time after t=298s, until at t=300s the next swash arrives and the same pattern recurs. The head rises instantaneously at both probes as the swash arrives, but the bottom probe again registers a lower head than the top probe. On this second uprush, however, the discrepancy between the heads measured at the top and bottom probes only lasts for about 2 seconds. From t=301s both probes measure the same head again. The reason for the differences in head measured by the top and bottom probes is not totally clear, but could be due to downward vertical drainage, which would give lower heads at depth. After backwash, infiltrated water will tend to drain downwards and seawards, and even though such drainage may be minimal and short-lived, it should be sufficient to give rise to the differences in heads observed.

Figure 14 shows the head measured at the top probe and the hydraulic gradient between the top probe (-15mm) and the bottom probe (-47 mm) for the same event as Figure 14. The times when the top and bottom probes are measuring different heads are associated with large positive (downward-acting) hydraulic gradients, suggesting infiltration into the beach. However, it is also possible that the observations illustrated in Figure 14 could be explained by the thin sloping tongue of fully saturated sediment hypothesised earlier. Figure 16 illustrates a possible configuration of this tongue under uprush on a flood tide, which could correspond to the conditions shown in Figure 14.
At time 1 (corresponding to the period before $t=286s$ in Figure 14), the uprush has not reached the measurement point, and both probes are in the partially saturated zone or capillary fringe and measuring the same heads. At time 2 ($t=286s$), the uprush has just reached the measurement point. The bottom probe is not yet in the fully saturated layer and therefore measures a lower head of water than the upper probe. At time 3 ($t=298s$ and $t=301s$), the uprush and the fully saturated layer have moved past the measurement point and both probes measure the same head of water. After this, the head measured at both probes decreases during the backwash and then due to natural drainage of the beach. This continues until the next swash arrives.

**Figure 15.** Head at top probe (-15 mm) and hydraulic gradient (run 20, 19 October 1997).

![Figure 16](image)

**Figure 16.** Possible configuration of subsurface water under uprush on a flood tide.

Figure 17 shows a longer time series of the same record (run 20, 19 October 1997). Even larger fluctuations can be seen than in Figure 14 (>90mm) under shallow swash (<20mm). On several occasions (starting at $t=110s$ and $t=236s$), the uprush does not reach the measurement point; however, the head at the top and bottom probes rises, although suctions still persist at both probes. Although in these cases the probes are not measuring pressures under swash, they still appear to be measuring pressure changes related to swash motions. We interpret this as pressures in the not fully saturated zone.
or capillary fringe being influenced by pressure changes around its boundaries as groundwater moves up the beach in response to swash. Again, Figure 16 illustrates the possible saturation levels but, in this instance, neither the swash or the total saturation line reach the measurement position. The pressure in a medium which is not fully saturated appears to respond in the same way as the watertable. In the event beginning at \( t=110s \), both probes are in the capillary fringe and are measuring real negative pressures (suction), as the water level is below the elevation of the probes. In the event beginning at \( t=236 \), the top probe is measuring a real negative pressure and is thus in the capillary fringe. The water level is slightly above the elevation of the bottom probe, so the bottom probe is not in the capillary fringe. At other times \( (t=75s, t=187s, t=202s, t=286s \) and \( t=299s) \), the uprush reaches or very nearly reaches the measurement point. In these cases, a situation similar to that shown in Figure 14 is observed, where the head rises instantaneously at both probes as the swash arrives. However, the bottom probe measures a lower head than the top probe, again suggesting that the sediment is not fully saturated. This situation occurs on each of these events and is associated with positive (downward-acting) hydraulic gradients of between 1.1 and 2.8. Note that the long time scale between individual swashes reaching the measurement point is due to wave grouping effects. This leads to large amplitude low-frequency fluctuations in the pressure just below the sand surface (which may also occur deeper in the bed). However, these pressure fluctuations are not due to long wave pressure pulses propagating through the beach material, but are simply due to the intermittent nature of the pressure forcing toward the landward limit of the swash zone.

![Figure 17. Head at top and bottom probes (run 20, 19 October 1997).](image)

**Conclusion**

Field measurements of near-surface heads and hydraulic gradients within a sandy beach during individual swash cycles have been presented. The hydraulic gradients measured under swash are considerably larger than the hydraulic gradients produced by tidal groundwater motion. The data shown here demonstrate several different types of behaviour which may have implications for swash zone sediment transport: (1) measurements of swash depth; (2) 'unloading' events with large upward-acting hydraulic gradients; (3) infiltration events with smaller downward-acting hydraulic gradients; (4) situations where the probes lower in the bed measure significantly lower heads than the probe at the surface, leading to strongly downward-acting hydraulic gradients; and (5) measurements in the capillary fringe. Of particular note is the situation when large hydraulic gradients, which are more than sufficient to induce fluidisation, occur in the top 15 mm of the bed under swash and backwash. These large
hydraulic gradients may coincide with a significant depth of water (up to 40 mm), which suggests the potential for entrainment of the fluidised bed under backwash. The fact that these large upward-acting hydraulic gradients occur only in the very top section of the bed highlights the importance of measuring pressures very close to the sand surface. The results also indicate that regions which are fully and less fully saturated appear to develop below the sand surface, particularly a thin layer of totally saturated sediment which moves up and down the beach with the swash. This suggests that very small changes in the amount of water in the sediment can lead to large differences in heads, which highlights the importance of knowing more about the saturation characteristics of the bed.

Acknowledgements

We would like to thank Poole Borough Council, who kindly allowed us to use the Surf Lifesaving Club building at Canford Cliffs. We would also like to thank Emily Altham, Mike Bloys, Gerry Delbourgo, Matt Foote, Mark Lee and Pat Stephenson for assistance with the measurements in the two deployments. Funding for the design of the swash measurement technique was provided by an EPSRC grant (GRK20514) to Professor Patrick Holmes and Tom Baldock in the Department of Civil Engineering, Imperial College. Other instruments were provided from a Natural Environment Research Council grant (GR9/01726) awarded to Andrew Baird and Diane Horn. Funding for the field deployments was from a Royal Geographical Society HSBC Holdings research grant to Diane Horn. Finally, we would like to thank Peter Nielsen for useful discussions about the data.

Abstract

In order to understand the external and internal flow structures of broken waves on a sloping bottom, a special design of run-up gauge combined with LDV measuring system is used to detect the velocity fields of run-up and run-down in our experiments. According to the experimental results, it is found that the heights of run-up and run-down are mainly determined by incident wave steepness. The dimensionless heights of run-up, run-down and the related swash length for different wave breakers are also discussed respectively. In addition, the elaborate measurements of flow structures, turbulent intensity and Reynolds stress in swash zone are also analyzed in this paper.

Introduction

The internal and external flow fields of swash zones were investigated on plunging breakers and spilling breakers. To understand the transformation processes of broken waves is of great importance for predicting wave-induced currents and sediment transport in the swash zones. Many researches, such as Hunt (1959), Battjes (1974), Kemp and Plinston (1968) and Fuhrboter (1986), have reported on the external flow fields in the swash zones, of which the relations between the uprush lengths, backwash lengths and wave conditions were proposed. On the other hand, only few researches have paid attention on the internal flow fields. Miche (1944) assumed that the uprush and backwash is a symmetrical cycle and obtained a formula to evaluate the run-up velocity. Kemp and Plinston (1974) proposed a model to calculate the velocities of surging breakers. Kato and

Matsuno (1986) used a high-speed camera to obtain the velocity profiles of the first broken wave from the taken images of released hydrogen bubbles.

The objective of this paper is to investigate the flow structures of swash zones. The uprush lengths, the backwash lengths and the velocities of broken waves along a sloping bottom are detected by a special design of run-up gauge combined with LDV measuring system, and the comparison between our experiments and previous studies are made in this paper. Furthermore, the turbulent intensity and Reynolds stress induced by the different wave breakers are also discussed.

**Experiments**

The experiments were carried out in a wave flume of 950 cm in length, 70 cm in depth and 30 cm in width as shown in Fig. 1. Only one slope condition, 1/15, was conducted throughout the experiments. The wave body being very thin in swash zones, therefore, the velocities have to be measured by a 2-D laser Doppler velocimetry. Besides, a capacitance gauge leaning parallel with the sloping bottom was used to measure the uprush and backwash lengths. In order to avoid capillary effects, the gauge was carefully designed and installed on the sloping bottom until the recording signals were good performance.

![Fig. 1 The Sketch of Wave Flume](image)

The processes of run-up and run-down are recorded by capacitance gauge, and the relating velocity measurements are detected simultaneously by LDV system in this experiment. The typical spilling and plunging breakers are generated in wave flume.
All the test conditions and the arrangements of measured points are shown in Fig. 2. The shoreline, where the still water surface and the slopping bottom intersected, is defined as the origin of X axis, and the origin of Z axis is defined at the local bottom boundary upward.

Based on the dimensional analysis, we obtained that the dimensionless run-up (Ru/H) and dimensionless run-down (Rd/H) are function of $H/gT^2$, $H/L$, $h/L$, $v\sqrt{gH}$ and $\tan\theta$ respectively. Where, $H$ is the incident wave height, $T$ is wave period, $L$ is wave length, $h$ is water depth, $v$ is water particle velocity and $\theta$ is the angle of sloping bottom. Therefore, three kinds of water depths and the appropriate wave conditions are made in the experiments.

**Results**

The flow fields of swash zone being so furious and chaotic that traditional analysis methods, such as the phase averaged method and the inverse fast Fourier transform method, are subject to overestimate or underestimate the turbulent components. It is consequent that a weight moving average method combined with modified phase average method is used to analyze the experimental data.

The results show that the uprush lengths are mainly associated with the incident wave steepness. For the both types of breakers, the dimensionless uprush height, $R_u/H_0$, decreases as the wave steepness increases, as plotted in Fig. 3. In addition, the dimensionless downrush height, $R_d/H_0$, decreases as wave steepness increases for $H_0/L_0>0.03$, however, for $H_0/L_0<0.03$, the dimensionless downrush height decreases
as wave steepness decreases. The comparison between the experiments and the previous studies are displayed in Fig. 4. From the above two figures, the relationship between dimensionless height difference of \((R_u - R_d)/H_0\) and wave steepness is plotted in Fig. 5. It shows that the experimental results are coincided with the empirical formula proposed by Battjes (1974) and Shuto (1984).

Fig. 3 The relationship between dimensionless uprush height and wave steepness

Fig. 4 The relationship between dimensionless downrush height and wave steepness

Fig. 5 The relationship between dimensionless height difference and wave steepness
Regarding the internal flow fields, Kemp and Plinston (1974) indicated that the whole water body moves, either shoreward or seaward, in the same direction in swash zone for surging breakers. While in our experiments of plunging breakers and spilling breakers, they show that both shoreward and seaward directions of flows are existent in swash zone simultaneously. The velocity profiles of different phases along the sloping bottom for plunging breakers are shown from Fig. 6(a) to 6(e). The different phases shown are referred to the locations of the wave tip where 6(a) is the phase of run-up beginning at $t/T = 0.0$, 6(b) is the phase of run-up moving at $t/T = 0.18$, 6(c) is the phase of approaching the highest run-up at $t/T = 0.42$, 6(d) is the phase of beginning backwash at $t/T = 0.6$, and 6(e) is the phase of backwash at $t/T = 0.9$. Furthermore, it is obvious that at $X/L_i = -0.05$ where is located in the initial run-up region, most of the velocity profiles are moving on-shore except around the phase of $t/T = 0.42$. This is resulted from the set-up of wave breaking. At the location of $X/L_i = 0.00$, it has similar phenomena, while the velocity profile is moving offshore only between the phase of $t/T = 0.42$ and $t/T = 0.6$. However, at $X/L_i = +0.05$ where is located in the end of run-up region, most of the velocity profiles are moving offshore except from $t/T = 0.18$ to $t/T = 0.42$ are onshore.

![Fig.6 Velocity profiles at different phases (case B7)](image-url)
In order to obtain the relevant flow structures in swash zone, the on-shore extreme velocity profiles, $(u)^{+}$, offshore extreme velocity profiles $(u)^{-}$, horizontal mean velocity profiles, $\bar{U}$, and vertical mean velocity profiles, $\bar{W}$, of spilling and plunging breakers are plotted in Fig. 7 and Fig. 8 respectively. Herein, it is found that both of spilling and plunging breakers, the on-shore extreme velocities are larger than the offshore extreme velocities and the horizontal mean velocity profile is moving shoreward in the initial run-up region. However, the offshore extreme velocities are larger than on-shore extreme velocities and the horizontal mean velocity profile is moving seaward in the end of run-up region. Generally speaking, the uprush of the water body is mainly related to the onshore velocity and the phase celerity, while on the other hand, the offshore velocity and the gravity determine its backwash. The exchanges between kinetic energy and potential energy during the uprush and the backwash stages are of reason. Thus a retardation of velocities along the uprush process is expected, and vices versa. Fig. 9 shows that the mean velocities and the onshore extreme velocities decrease as $x/L_i$ increases. An interesting result is that the offshore extreme velocities also decrease as $x/L_i$ increases, which do not follow our intuition to exhibit an opposite tendency with the onshore ones. Yet the backwashing water body is evidently not only controlled by the gravity but the propelling of the subsequent uprush water body which must be also taken into account.

Fig. 7 Extreme velocity profiles and mean velocity profiles at different locations on sloping bottom (case B7, $H_0/L_0 = 0.042648$)
Fig. 8 Extreme velocity profiles and mean velocity profiles at different locations on sloping bottom (case B8, $H_b/L_0 = 0.018340$)

The turbulent flow in swash zone is created by wave breaking, bottom boundary and the mixing during the processes of uprush and backwash. According to LDV measurements, the Reynolds stress of plunging and spilling during the wave period are displayed in Fig. 10 and Fig. 11 respectively. It is evident that the maximum Reynolds stress almost occurs at the phase of backwash stage, and the Reynolds stress of plunging breaker is bigger than that of spilling breaker.

Fig. 9 The onshore, offshore extreme velocities and the mean velocities along the slopping bottom (case B2)
Fig. 10 The Reynolds stress during a wave period (plunging $H_o / L_o \approx 0.01834$)
Fig. 11 The Reynolds stress during a wave period (spilling $H_0/L_0 \approx 0.05958$)
Conclusions

The swash height and the velocities of broken waves along a slopping bottom are recorded and analyzed. The remarkable conclusions are as follows:

1. The run-up heights decrease as the wave steepness increase for the both types of breakers.

2. The moving direction of the water body of a spilling-plunging breaker shows that both shoreward and seaward movements are existent simultaneously either in the uprush or backwash stages, which is not consistent with that of a surging breaker described by Kemp and Plinston (1974).

3. The mean velocities, the onshore extreme velocities and the offshore extreme velocities all decrease as $x/L_i$ increases.

1. The maximum Reynolds stress almost occurs at the phase of backwash stage, and the Reynold stress of plunging breaker is bigger than that of spilling breaker.

MODELLING LARGE-SCALE DYNAMICS OF HEL PENINSULA, PL

Marek SZMYTKIEWICZ, Ryszard B. ZEIDLER, Grzegorz RÓŻYŃSKI & Marek SKAJA

Abstract

Two-stage methodology of shoreline prediction for long coastal segments is presented in the study. About 30-km stretch of seaward coast of the Hel Peninsula was selected for the analysis. In 1st stage the shoreline evolution was assessed ignoring local effects of man-made structures. Those calculations allowed the identification of potentially eroding spots and the explanation of causes of erosion. In 2nd stage a 2-km eroding sub-segment of the Peninsula in the vicinity of existing harbour was thoroughly examined including local man-induced effects. The computations properly reproduced the shoreline evolution along this sub-segment over a long period between 1934 and 1997.

Introduction

The study presents the methodology of shoreline change analysis, which was developed for large scale modelling of shoreline evolution of potentially eroding coastal segments. Results of the study are intended to optimise shore protection activities. A case study of the Hel Peninsula (Fig. 1) is used to demonstrate the concepts of such an approach.

The observed shoreline changes are induced by a number of mutually correlated hydro-meteorological and lithodynamic factors. They can be roughly divided into two basic groups:

- external factors encompassing spatial and temporal distribution of wave energy, followed by similar distribution of longshore currents and sediment transport, coupled with bed topography and granular diversification of sediment;
- local factors attributed to the presence of man made constructions, such as groins, seawalls and harbour breakwaters, which intensify coastal processes in their vicinity.

Shoreline changes are modelled in two steps. The first step takes account of the whole coastal segment ignoring the existing constructions and hypothetically assuming that all variations of shoreline positions are caused solely by external factors. The
calculations identify potentially eroding coastal sub-segments and explain main causes of erosion.

In the second step calculations are executed for shorter, eroding sub-segments, which must be protected for various reasons. These calculations include the effects of all local factors; the existing shore constructions in particular and the results from 1st step are utilised to determine boundary conditions of 2nd step.

For 1st step shoreline change computations for a 22-km seaward stretch of Peninsula's coastline were carried out. It was assumed that with exception of the harbour at Władysławowo, situated at the root of the Peninsula, the shore could be treated as a free segment without any artificial structures. A numerical model SAND94 was developed to analyse the possible diversification of wave energy, longshore currents and sediment transport rates. The computations allowed for identification of potentially eroding locations and were done for the period between 1991 and 1995. For that period detailed bed topography was used. Simultaneous comparative shoreline change computations were also obtained with the UNIBEST computer package.

For 2nd step a 2-km long sub-segment lying in the vicinity of Peninsula's root, in the close proximity of the Władysławowo harbour was selected. The harbour was erected in the 30-ties and the computations were aimed at long-term shoreline evolution between 1934 and 1997. The evolution of this area has been controlled by local factors i.e. the construction of harbour breakwaters in 1936-37 followed by shore protection structures on the lee side of the harbour, which were built after 2nd world war. Shoreline change for step 2 was computed with four models: UNIBEST, GENESIS, LITPACK and SAND94. Currently, extensive artificial beach nourishment is conducted in this part of the Peninsula, so practical objective of the study was to predict the future shoreline evolution with proper reproduction of local effects, followed by optimisation of future beach fills.
Hel Peninsula and Władysławowo harbour

Being a fairly narrow, 35-km barrier separating the Gulf of Gdańsk from open waters of the Baltic Sea, the Hel Peninsula is an important segment of the Polish coast. Its area measures 32.4 km$^2$ and its width varies from 200 m to 3 km. The western part of the Peninsula is narrow and rather flat, with heights ranging from 1 to 2 m above mean sea level (MSL), higher dune crests up to 13 m above MSL. The south-eastern part is much wider (1-3 km) and higher (between 3 and 5 m above MSL). Hel Peninsula is a holiday place for thousands of people. There are two towns and three villages.

Władysławowo harbour construction was started in early 1936 and completed in late autumn of 1937. The length of the western breakwater is 763 m, while its eastern counterpart is only 320 m long. Immediately after construction they reached some 400-m offshore. In 1937, because of the anticipated shore erosion east of the harbour, the shore there was protected with a heavy seawall, which was 250 m long. The seawall is a massive, concrete wall, resting on wooden piles and a bulkhead. It was elongated by 300 m in 1952, to prevent scour east of the initial seawall.

The first group of groins at the root of the Peninsula, east of the harbour, was built after heavy storms in February and March 1946, which severely hurt the Peninsula on the first 3 kilometres of its stretch. The first groins were completed in August 1946 and until 1949 another group of 44 groins was built from km H 0.02 to km H 4.45 of Peninsula’s chainage. They were made of wood in form of a single palisade, each 100-m long. The span between them was 90 m, doubled to 180 m between the last four. The groins were intended to be perfectly impermeable to sand, but in reality they exhibit cavities on some 20%-30% of the length. The groins were being gradually destroyed, mainly by ice phenomena.

Protection work had been continued in the next years. Currently, there are 162 groins between Władysławowo and Kuźnica and 1500 m of sand dike with seaward slope jointly protected by rubble mound and concrete sleepers in the Kuźnica region.

The dredging, primarily at the harbour entrance, started in 1948, and in total 2.217 million m$^3$ was dredged until 1975. Artificial nourishment of the Peninsula was started at the end of 70-ties and was associated with the maintenance of the navigation channel of the Władysławowo harbour. Before that time, the sediment was deposited offshore. Later, it was being dumped closer to the shoreline, at depths of 3-5 m. In 1984 the sediment was dumped at about km H 3.4-3.5 in the surf zone at depths 2-3 m. Since 1989, the sediment has been dumped directly onto the beach.

Shoreline change during and after harbour construction

Before the harbour construction, the zone up to 300m offshore exhibited two longshore bars. The inner one was smaller and was usually situated some 150m offshore. The outer one was greater, the average distance to that bar was 200-250m. The average depth over crest of the outer bar was 2m. The depth of trough between that bar and the shore reached some 3-4m. Outside the outer bar the depths were increasing gently and steadily. Distinct bottom movements occurred at depths up to 7 m; the comparison of hydrographic maps implies that at greater depths the bed is either stable or its movements are insignificant.

During and after the harbour construction, bathymetric surveys were executed twice a year. They covered a stretch of some 1000-m west and east of the harbour. The construction of the harbour triggered bed movements, whose intensity was coupled
with increasing breakwater lengths. Figure 2 illustrates the early construction stage, where underwater part of breakwater body was nearly completed, and shows a developing shoal running west and far east of the future harbour. The shoals are very distinct and run along the whole surveyed area and further east. Outside western breakwater they formed a sand bank. Natural depths at the harbour entrance were 6 m.

Figure 2. Depth changes at Władysławowo harbour from May 1936 to March 1938

The completion of the harbour at Władysławowo started the accretion of sand west of the western breakwater. This effect appeared rapidly (Adamski 1938), and the rate of deposition became the basis of longshore sediment transport assessments in the harbour area. The transport rate for the period between spring 1936 and spring 1938 was calculated at 70,000 m$^3$ per year, upon the assumption that no bypassing occurred during that period. Gradual beach accretion west of the harbour led to such bed configuration that the bar, which was cut by the breakwater, surrounded it and maintained the 2-3 m depth over crest (Szopowski 1958). This fact gave a clue that the longshore sediment transport, which was initially interrupted by the breakwater, was restored at the time the bar appeared in front of it (Hueckel 1968, Mielczarski 1984, Szopowski 1958, Tubielewicz 1957). Restoration of longshore sediment transport due to beach accretion updrift of the breakwater was also reported in many other cases (Zenkowicz 1962). The appearance of the main bar in front of the breakwater led to gradual shallowing of the harbour channel. Therefore, dredging became indispensable as early as in 1948.

Upon the analysis of shoreline changes along the Hel Peninsula and along the whole Polish coast, it can be assumed that the existence of breakwaters has only a local influence on shoreline evolution, so the changes become insignificant 2 km west and east of the harbour (Basiński, Szmytkiewicz 1990).

Description of forecast model SAND94

With a realistic evaluation of the factors controlling the decadal evolution of the Polish
A single-line numerical model SLineR has been formulated with IBW's package SAND94. The computer package SAND94 was developed at IBW PAN. SAND94 is the software package intended for computations of waves, wave-induced currents, sediment transport and shore evolution. Deep-water wind wave parameters for SAND94 are computed on the basis of wind speed, direction and fetch, stemming from Krylov's quasi-spectral forecast method, which involves semi-empirical equations of the following form:

\[
\frac{gH}{W^2} = f_1\left(\frac{g}{W^2}, \frac{gt}{W}\right)
\]

\[
\frac{gT}{W} = f_2\left(\frac{gX}{W^2}, \frac{gt}{W}\right)
\]

where:

- \( g \) - gravity acceleration, \( \bar{H} \) - mean wave height, \( W \) - wind speed, \( \bar{T} \) - mean wave period,
- \( X \) - wind fetch and \( t \) - time of duration.

This approach takes account of the arbitrary shoreline layout and bathymetric variability along each directional spectral component. The directional energy distribution in terms of \( \cos^2 \alpha \) in the range \( \pm \pi \) from wind direction is assumed, each directional sector comprises \( 22.5^\circ \) while the radii in all directions are divided into the segments of constant depth maximum 40 Mm long. For each segment, the average depth is determined for the stripe 20 Mm wide. The compliance between measured and post-dicted deep-water wind wave parameters is good for the conditions of open sites, undisturbed by headlands, harbour breakwaters etc. The model yields wave parameters at the offshore deep-water boundary of a coastal zone.

Coastline evolution package is based on a standard one-line model. The single-line routine can be run either for sediment transport rates determined from wave input given in chronological order or for net sediment transport computed for the entire analysed period. In the first (full run) option the transport is computed at each time step and for each cross-shore profile, taking account of instantaneous wave-shoreline angle. In the second (simplified run) option the net transport rates for each transect, treated as the representative ones for all period, are computed and then are modified in all time steps as functions of changes of shoreline angles determined in the previous step. It should be noted that only longshore-related routines have been used in the SAND94 full run, to match the general objective of the project, dealing with coastal evolution due to longshore transport variability.

**Hel Peninsula shoreline change modelling**

As mentioned before, the 22-km seaward stretch between Władysławowo and Jastarnia was chosen for 1st step of the analysis. For simulation the period between 1991 and 1995 was selected, because detailed bed topography from 1991 and measurements of shoreline positions in 1991 and 1995 provided real data for model input and testing.
Distribution of wave energy, velocity of longshore currents and intensity of sediment transport along the Peninsula were computed with numerical model SAND94. The computations embraced spatial change of wave field including refraction-diffraction effects in a strip of 40 km from Rozewie (first mainland locality west of Władysławowo) to Hel town. The width of that strip varied between 9 km for Rozewie and 38 km for Hel town. Bed topography for those computations, recorded in 1991, is shown in Figure 3. It can be seen that the bed topography along the Peninsula is featured by two distinct troughs, surrounded by shallow waters in direct proximity of the coast. The first one is situated between Władysławowo and Chalupy (km H 4.0), the second one lies in the vicinity of Kuźnice (km H 12-13).

Assuming the computed wave climate parameters *i.e.* significant wave height $H_s$, wave period $T_p$ and angle of wave incidence $\Theta$ as boundary conditions, dissipation of wave energy was calculated together with change of wave height along profiles approximately perpendicular to average shoreline configuration in the wave transformation zone and the surf zone. The spacing between consecutive profiles was set to 100 m.

On the basis of wave height change velocities of longshore currents were computed, which were used as the input for Bijker-type routine for longshore sediment transport calculations.

For long-term assessment of Peninsula’s vulnerability to erosion, the conditions of average statistical year were chosen. In order to properly discretise the conditions of that year, the wind rose of all seaward winds from W to SE was thoroughly examined with the 22.5° resolution. Wind speed ranged between 1 and 20 m/s with 1m/s step. Exemplary fields of significant wave heights and azimuths of wave ray for 10 m/s of wind speed and the most frequent westerly winds are shown in Figs. 4a and 4b.
Wave ray azimuth represents the direction of wave approach. For sake of computations the average azimuth of shoreline was assumed to equal 121.5° (equivalently 301.5°). The isolines of wave heights and wave ray azimuths indicate spots of intensive wave energy, reaching the vicinity of coastal zone. Upon thorough scrutiny of individual stormy situations, the following conclusions can be drawn:

- for westerly winds (W) the amount of wave energy reaching the shore is fairly evenly distributed along the Peninsula and the angle of wave incidence equals some 40° with respect to a shore normal direction, waves come from the western sector (Figure 4a and 4b);
for north westerly winds (NW) high concentration of energy was identified on a short, 1 km long, sub-segment between Władysławowo and Chalupy and in the proximity of Kuźnica, the angle of wave incidence is 40° and is identical to the case of westerly winds;

for northerly winds (N) spots with higher energy concentrations are scattered all over the Peninsula, the incidence angle is between 75° and 80° with regard to a shore-normal direction, winds come from the western sector;

for north easterly winds (NE) energy concentrations were found in the vicinity of Kuźnica and locally close to the Władysławowo harbour, the incidence angle is equal to some 85° to a shore normal direction, waves arrive from the eastern sector;

for easterly winds (E) the Chalupy region absorbs most of the energy, whose distribution then gradually declines heading east along the Peninsula, waves come from the eastern sector at 50° to the shore-normal line;

for south easterly winds (SE) energy distribution is fairly uniform; it only gently grows east of Jurata, waves reach the shore from the eastern sector at 20° to the shore normal direction.

The computed, resultant sediment transport curves for average statistical year is plotted in Figure 5. It can be seen that the littoral drift is directed eastwards and is characterised by two distinct areas where it grows. The former is well pronounced and lies on first four kilometres of the Peninsula between Władysławowo and Chalupy. The latter, less conspicuous but still clearly visible, is situated between Kuźnica and Jastarnia. The sediment transport pattern thus has a positive gradient in those two areas, so it can be expected they are exposed to erosion. The computational results comply well with the observed spots of local erosion. They show that the most heavily eroded segments are 2 km stretch just east of Władysławowo harbour breakwaters, the zone at km H 4.0, the Chalupy region and the area between Kuźnica and Jastarnia.

Artificial beach nourishment between 1991 and 1995 was being executed at the following locations:

- 1991: KM H 0.0-0.8, 3.2-3.7, 10.3-13.6, 16.3-16.5, 18.2-19.2
- 1992: KM H 0.145-4.6, 10.0-10.9, 15.8-17.2, 22.1-22.5
- 1993: KM H 0.0-2.0, 4.1-4.56, 9.55-12.45, 14.45-17.15, 21.5-22.8
- 1994: KM H 0.2-2.75, 9.6-11.0, 16.3-17.2
- 1995: KM H0.1-0.5, 3.1-4.4, 10.0-10.7, 15.2-16.25, 22.1-22.7

The amounts of sediment deposited on the beaches and nourishment periods were precisely quantified in SAND94 input files. The hindcast input wave data, was assumed constant in each 24-hour interval, being the computational time step for the whole simulation. The depth of closure was also constant and set to 7 m.

The mean grain size diameter used in the computations varied from 0.18 to 0.26 mm. The lower limit stems from extensive field studies of the Peninsula, carried out since 1983, the upper one – from the data collected recently. The latter data are distorted by artificial nourishment, which has been carried out eastwards of Władysławowo since 1990.

Results obtained by SAND94 were verified with UNIBEST, which requires only one cross-shore profile assumed to represent the entire modelled coastal zone. Upon detailed analysis of all transects from 1991 year the one of km H 10.0 was chosen.
The results of shoreline change computations along the Peninsula by SAND94 and UNIBEST for 1995 are jointly presented in Figure 6. The comparison shows that both models yield very similar results, which are fairly consistent with measurements done in 1995. Certain discrepancies can be attributed to local effects, which were deliberately ignored on this stage of the analysis.

Figure 5 Net longshore sediment transport rates computed along Hel Peninsula by UNIBEST and SAND94 without beach fills

Figure 6 Computed and measured coastline changes along Hel Peninsula in 1991-1995; beach fills included
Modelling of the Władysławowo harbour effect

The 2nd step of shoreline change modelling takes into account local effects. Such modelling is aimed at detailed examination of local effects on small sub-segments of the area analysed in the 1st step. Man-made structures locally disturb natural processes, so special attention should be paid to properly reproduce the effects they cause. Hence, the vicinity of Władysławowo harbour, and the relative abundance of data acquired over decades, gives an excellent opportunity for analyses of coastal phenomena as well as extensive model testing.

Shoreline evolution in the proximity of the Władysławowo harbour was modelled by four models (GENESIS, LITPACK, SAND94 and UNIBEST) in the long-term time scale, for the shore segments stretching 2-km westwards and 2.3-km eastwards of the harbour. The initial conditions for computations were set to the year before the harbour construction (1934) and the simulation period covered more than 60 years until 1996/1997. The computations were designed to provide proper representation of the long-term shoreline migration in the close vicinity of the harbour on its both sides. The available model options were used to arrive at the most accurate reproduction of shoreline positions. The tests were carried out with wave input based on the representative meteorological annual chronology, retrieved for the period 1952-1990. The analysis of statistics of the meteorological data for each of those years revealed that the year 1970 was the most similar to the mean statistical year. The meteorological record of this year was then assumed as typical in determination of wave input for the modelled shoreline changes in 1934-1996/97. Hence, the offshore wave conditions were calculated from the actual wind measurements taken in 1970, with the time step of one day, and were assumed to be valid for the entire analysed period of 62 years. Wind parameters were assumed constant during each 24-hour interval. In all tested models the depth of closure in the single-line models was set to 7 m. Artificial beach fills on the lee side were included into consideration for the period in which detailed records of fills are available, i.e. 1991-1996.

Apart from LITPACK, the tested models assume the same sediment grain size in the entire region modelled; GENESIS uses a median grain size only. The median grain diameter used in the computations varied as in the 1st step from 0.18 to 0.26 mm. The sensitivity tests for all models except for LITPACK show a very weak response of the modelled shoreline to the variation of grain diameter.

Most groins east of Władysławowo are damaged and their influence on coastal processes was found to be negligibly small. The efficiency of these groins in the past is reported as very doubtful, so their existence in the modelling processes could be neglected. The simplified run option of SAND94 was used. The transport of 1934 was computed from the model of Bijker, yielding net value of 50000 m³/year at average for the analysed shore segment. This transport was directed eastwards. The harbour was represented in the modelling procedure by two jetties closed by an offshore breakwater. The seawall was defined in its actual location, as well as beach fills in accordance with the actual records of nourishment.

In order to include the harbour impact, the longshore transport was modified and the blocking percentage was assumed, varying gradually from 20 % in 1936 (harbour appearance) to 1% in 1965-1997. The modified transport distributions for consecutive three sub-periods is shown in Figure 7. It can be seen that both spatial and temporal trends of sediment transport were reproduced satisfactorily. The sediment transport
variability has produced the reasonable shoreline evolution, which is presented in Figures 8. It can be seen from the plot that the model result for west side of the harbour is proper, while the erosion at the close east side is underestimated. The latter results from beach fills of 1991-1996, which apparently are not in model balance with erosive processes. Further eastwards of the harbour, the model shoreline changes are correct for the entire analysed period.

![Figure 7 Net longshore sediment transport rates computed from SAND94 in 3 consecutive sub-periods](image)

![Figure 8 Shoreline positions nearby the harbour measured and computed from 1934-1996/97 from SAND94](image)
The above results have been compared with the output provided by the other three models (GENESIS, LITPACK and UNIBEST). The comparison of final measured and computed shoreline positions is given in Figure 9. It can be seen that the long-term accretion westwards of the harbour are well represented. Almost the same accuracy of hindcast in the long time scale has been achieved at the lee-side of the harbour. It can be concluded that UNIBEST produced at least satisfactory shoreline positions in all sub-periods of the analysed period. The modelled transport rates also look very realistic.

In general it can be seen that all outputs are at least satisfactory. Westwards of the harbour, the outputs produced by all models are acceptable. The most accurate shoreline representations have been obtained from UNIBEST and LITPACK. Eastwards of the harbour, however, LITPACK clearly underestimates the lee-side erosion effects, while the shoreline retreats produced by GENESIS and UNIBEST are quite satisfactory.

![Figure 9 Shoreline positions nearby the harbour computed for 1934-1996/97 by GENESIS, LITPACK and UNIBEST](image)

**Conclusions**

Two-step shoreline change modelling for the case study of the Hel Peninsula is presented in the study.

In the 1st step the large-scale calculations done for the vast portion of the Peninsula allowed for identification of potentially eroding spots and gave way to explain the causes of erosion.

In the 2nd step the vicinity of the Władysławowo harbour was thoroughly examined including local man-made effects. Long-term shoreline evolution was properly modelled and thus prediction of future evolution can easily be simulated. This in turn
modelled and thus prediction of future evolution can easily be simulated. This in turn facilitates and optimises future beach fills design and other shore protection activities in this region.

The following detailed conclusions for 1st step can be drawn:

- bed topography along the Peninsula, featured by two distinct troughs in the shallow water zone results in local concentrations of wave energy that reaches the shore in two regions adjacent to troughs;
- the 1st region of high energy concentration is situated between Władysławowo and Chałupy (km H 4.0), the 2nd one lies near Kuźnica (km H 12.0 – 13.0);
- analogously to wave energy, the calculated resultant longshore sediment transport is characterised by two zones of increasing intensity, one between Władysławowo and Chałupy and the other between Kuźnica and Jastarnia, such configuration implies that increasing transport rates are driven by high wave energy concentrations;
- energy concentrations occur mainly for north westerly winds, energy distributions for other winds is far more uniform;
- shoreline change computations comprising beach fills were done for the period between 1991 and 1995 by means of SAND94 and UNIBEST; the selection of that period guaranteed extensive background information in form of detailed bed topography and measurements of shoreline positions, a fairly good compliance with final shoreline configuration was achieved, certain discrepancies between computational results and measurements can be ascribed to local effects, which were ignored on this stage of analysis.

Results of computations in the 2nd step indicate that:

- thorough mapping of local conditions around Władysławowo harbour helped to properly model shoreline evolution history between 1934 and 1996/97;
- computations were executed with four models (GENESIS, LITPACK, UNIBEST and SAND94), the compliance with final shoreline positions is excellent for them all on the updrift (west) side of harbour breakwaters, good compliance on the lee side was achieved for GENESIS, LITPACK and SAND94, UNIBEST reached even better fit after tuning in with available user defined options;
- the results allow for accurate forecasting of future shoreline evolution and can be used for optimisation of artificial beach fills.

MORPHODYNAMICS OF
SHOREFACE-CONNECTED RIDGES

A. FALQUES\textsuperscript{1} D. CALVETE\textsuperscript{1} H. E. DE SWART\textsuperscript{2} N. DODD\textsuperscript{3}

Abstract

A morphodynamic model is developed and analyzed to gain fundamental understanding on the basic physical mechanisms responsible for the characteristics of shoreface-connected sand ridges observed in some coastal seas. These alongshore rhythmic bedforms have a horizontal length-scale of order 10 km. It is found that the positive feedback between the topographic disturbances of a sloping bottom and the subsequent deflection of the mean coastal current is the main cause of the ridges. To be effective, this mechanism needs an averaged sediment transport mainly due to wave stirring during storms and an averaged current driven by pressure gradients rather than surface stresses. Even in the presence of significant tidal currents, their origin — related to the mean current instead of tidal oscillation — is essentially different from that of tidal sand banks.

1 Introduction

Shoreface-connected ridges are elongated sand banks found in the inner part of some continental shelves in horizontal patterns with a length-scale of order \(O(10 \text{ km})\). Such ridges are present, for example, near the Dutch coast (see e.g. Van de Meene, 1994, and figure 1), near the east coast of the United States of America (Swift \textit{et al.} 1985), near the Argentinian coast (Parker, Lanfredi \& Swift, 1982). They start at the offshore end of the shoreface and they extend seaward forming an angle of \(20^\circ - 35^\circ\) with respect to the coastline. In contrast with the

\textsuperscript{3}Coastal Group, HR Wallingford. OX10 8BA Wallingford, United Kingdom
more offshore tidal sand banks (see e.g. Hulscher, De Swart & De Vriend, 1993), their orientation is not cyclonically oriented with respect to the tidal current, but it is related to the alongshore mean coastal current, the seaward end of the ridge being shifted upstream with respect to its shoreface attachment. Hereafter we will refer to this as upcurrent rotated bars. The opposite orientation will be defined as downcurrent rotated.

The alongshore spacing between successive crests of shoreface-connected ridges ranges between 5 and 10 km. The length of individual crests is between 10 and 25 km. Their height is between 1 and 6 m in water depths between 4 and 20 m. The ridges slowly migrate in the direction of the dominant current with a celerity of a few m yr$^{-1}$.

In general, sand banks are important, since they may form shallow areas which are hazardous for shipping traffic and may affect the stability of pipelines and oilrigs, due to lateral movements. They are also possible sources for sand mining. The shoreface-connected ridges, which form the seaward boundary of the nearshore zone, play a relevant role in the dynamics of the coastal system (Van de Meene, 1994).

There is geological evidence that the ridges are not relict features, that is, they are active under the present hydrodynamic conditions and their growth has taken place during the Holocene. For instance, on the Dutch inner shelf they started to form about 3400 years ago. Therefore, as it is the case for many sea bed patterns an explanation of the origin of the ridges as an inherent free instability of the coupled bottom-fluid system under the action of some current seems plausible. Given a small disturbance of a simple reference topography (e.g., a flat bottom) the response of the flow to this perturbation can result in a sediment transport pattern which reinforces the bottom undulation. Then a positive feedback is induced and both disturbances will grow in time.

According to Trowbridge (1995), storms are the main cause of the currents capable of generating shoreface-connected ridges. Indeed, storm driven currents can be of order $0.5 - 1$ m s$^{-1}$ in the areas where ridges are observed off the coast of Holland, Florida and Argentina. However, while tidal currents are rather weak on the American shelf, they are important near the Dutch coast ($0.7 - 1.1$ m s$^{-1}$, at the surface). Also, as we will see, an important contribution from alongshore gradients on the free surface elevation can occur on the mean current.
Trowbridge (1995) studied the morphologic stability properties of a storm-driven alongshore current, with a cross-shore gradient, on a shelf bounded by a straight coast and with a transverse slope. It was shown that the system is unstable and leads to the growth of bedforms very similar to the observed ridges. It was suggested that the basic physical mechanism was the offshore deflection of the flow over the shoals and the related loss of sediment carrying capacity in the offshore direction due to the transverse slope. However, a severe assumption in this model is the condition of irrotational flow. This implies that the production of vorticity due to bottom frictional torques and Coriolis terms, which has been proven to be very important for tidal sand banks dynamics (see Zimmerman 1981; Hulscher et al. 1993) is neglected. In addition, a crude sediment transport parametrization is used, where the sediment flux is assumed to be linear in the mean flow velocity and the downslope effect on the transport direction is not accounted for. As a result his model does not predict any preferred spacing between ridge crests. Furthermore, the model deals with linearized evolution equations just allowing for the initial growth of small amplitude solutions.

In this paper we investigate a generalized and physically more realistic model for both the water and sediment motion. The fluid is described by the full 2D shallow water equations, which include bottom friction and Coriolis terms. The sediment flux is assumed to be proportional to some power $m$ of the current so that the role of different choices for $m$ can be explored. Finally, a nonlinear extension of the model is briefly described and some preliminary results of finite amplitude evolution is presented.

2 Model formulation

2.1 Equations of motion. Scaling

As shown in figure 2, the inner shelf is schematized as a sloping sea bed, bounded by a straight vertical wall which represents the seaward end of the shoreface. Further offshore, a horizontal flat bottom describes the outer shelf. An orthogonal coordinate system is taken with the $x$, $y$ and $z$-axes pointing in the cross-shore, longshore direction and vertical direction, respectively. The still water level is represented by $z = 0$. Although the vertical structure of the currents can have an important role in the ridge area, in view of earlier studies on large scale bedforms it is worthwhile to investigate whether a 2D model can describe the main characteristics of the ridges. Therefore, the fluid motions are considered to be governed by the 2D shallow water equations, which consists of the depth-averaged momentum equation and mass conservation equation. The bottom evolution follows from the sediment conservation equation.

In order to make the equations of motion dimensionless we now introduce characteristic magnitudes $L_H$, $L_V$ and $U$ for the horizontal length, the depth and the current. $L_H$ is the width of the inner shelf, $L_V$ and $U$ are typical values of the water depth and the mean current. For example, representative values for the Dutch inner shelf are $L_H \sim 12 \times 10^3$ m, $L_V \sim 15$ m and $U \sim 0.25$ m/s. The variables are made dimensionless as follows:

$$
(x, y) \rightarrow L_H(x, y) \quad z_b \rightarrow L_V z_b \quad v \rightarrow U v \quad t \rightarrow T m t \quad z_s \rightarrow \frac{U^2}{g} z_s. \quad (1)
$$
The scaled momentum and mass conservation equation read:

\[
\varepsilon \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v} + \mathbf{j} \times \mathbf{v} = -\nabla z_s + \frac{\tau}{D} \tag{2}
\]

\[
\varepsilon \frac{\partial D}{\partial t} + \nabla \cdot (D\mathbf{v}) = 0 \tag{3}
\]

and the sediment conservation equation read:

\[
\frac{\partial z_b}{\partial t} + \nabla \cdot q = 0. \tag{4}
\]

Here \( \mathbf{v} \) is the current vector, \( \mathbf{j} \times \mathbf{v} \) is the Coriolis acceleration, \( \tau \) represents the free surface and bottom stress terms \((\tau = \tau_s - \tau_b)\). The free surface, the bottom and the total height of the water column are given by \( z = z_s, z = z_b \) and \( D \), so that \( D = F^2 z_s - z_b \). The nabla-operator is defined by \( \nabla = (\partial/\partial x, \partial/\partial y) \). The volumetric sediment flux per unit width is denoted by \( q \). It is important to note that, since the growth of the ridges takes place on very long time scales \((O(10^3 \text{ yr}))\), all the quantities in the governing equations have to be considered as averages over a long time \( O(1 \text{ yr}) \).

The boundary conditions imposed for this system are periodic conditions in the longshore direction. Furthermore, at \( x = 0 \) (the transition shoreface-inner shelf) and for \( x \rightarrow \infty \) we assume that the cross-shore flow component vanishes and the bottom elevation is fixed to its reference value.

In order to close the model parametrizations for the bed shear stress \( \tau_b \) and the sediment flux \( q \) are required. We will consider a linear friction law and the volumetric sediment flux parametrized as

\[
\tau_b = rv \quad q = |v|^m \left( \frac{\mathbf{v}}{|\mathbf{v}|} - \hat{\gamma} \nabla h \right). \tag{5}
\]

The coefficient \( \hat{\gamma} \) is related to the angle of repose of the sediment, so the term \(-\hat{\gamma} \nabla h\) accounts for the tendency of sand to move downslope and \( m \) is an exponent which is usually between 1 and 6. Finally, \( h \) is the elevation of the bottom with respect to a specific equilibrium profile, to be discussed in the next subsection. Further details on sediment transport can be found in Van Rijn (1993) and Fredsoe & Deigaard (1993).

Two time scales appear which are defined as

\[
T_h = \frac{L_H}{U} \quad T_m = \frac{L_H L_V}{\nu U^m} \tag{6}
\]
The hydrodynamic time scale $T_h$ follows from scaling the three equations (2)-(3) and the morphodynamic time scale $T_m$ results from scaling equation (4). Here $\nu$ is the coefficient that multiplies the right hand side in the dimensional version of the sediment flux parametrization (eq. (5)). For simplicity, it has been assumed to be constant. Other parameters in the model are $l_m, g, v, U, U_L, V, L_H$

The hydrodynamic timescale is assumed to be much smaller than the morphodynamic one. This allows for the adoption of the quasi-steady hypothesis, that is, the fluid instantaneously adjusts to the bathymetric changes. This permits to drop the time derivatives ($\epsilon \approx 0$) in the three differential equations (2)-(3). Using the scales of motion, it appears that the Froude number $F$ is very small, $F \approx 0.02$. Consequently, in the forthcoming analysis the water column is assumed to be equal to the bottom, $D = -z_b$.

### 2.2 Basic state

In this study we model the reference bottom profile as

$$H(x) = \begin{cases} 1 + \beta x & (0 \leq x < 1) \\ 1 + \beta & (x \geq 1) \end{cases}$$

(8)

Note that $H(x)$ and $x$ are dimensionless, and that the depth at the seaward end of the shoreface has been chosen as vertical length-scale, $L_V$. In case of the Dutch inner shelf, $L_V \sim 15 \text{ m}$, $L_H \sim 12 \times 10^3 \text{ m}$ and the water depth on the outer shelf is $\sim 20 \text{ m}$, so that $\beta = 0.33$.

It is easily seen that a steady basic state of the form

$$v = (0, V(x)) \quad z_s = \delta y + \xi(x) \quad z_b = -H(x)$$

(9)

where $\delta = g s L_H/U^2$ is the dimensionless parameter for the longshore gradient, $s$, is a solution of the governing equations (2), (3), (4). The alongshore momentum balance between forces related to the longshore pressure gradient, windstress and bottom friction is achieved by

$$V = \frac{\tau_{sy} - \delta H}{r}$$

(10)

It has been demonstrated by Scott & Csanady (1976) and Van der Giessen, De Ruijter & Borst (1990) that the momentum balance using the linear friction law (5) yields a good description of mean currents in the coastal zone.

Analysis of current data obtained on the East American inner shelf (Scott & Csanady 1976; see also Chase 1979) indicate that the sea surface slope $s \sim 1 - 2 \times 10^{-7}$ and the friction coefficient $r_s \sim 5 \times 10^{-4} \text{ m s}^{-1}$. Similar values appear to apply to the Dutch inner shelf. The physical mechanism causing the longshore pressure gradient is discussed by Chase (1979). Based on the field data discussed above we choose $\tau_{sy} \approx -0.1 \text{ Nm}^{-2}$ and $s \approx 2 \times 10^{-7}$. This yields an estimate of the longshore velocity scale: $U \equiv V(x = 0) \approx 0.25 \text{ m s}^{-1}$. Both the longshore windstress and pressure gradient are comparable and force a flow in the same, negative, $y$-direction.
Combining equations (8) and (10) and including the new parameter \( a = \frac{\delta}{r} \), the velocity profile for the basic state reads:

\[
V(x) = \begin{cases} 
\pm(1 + a \beta x) & \text{if } 0 \leq x \leq 1 \\
\pm(1 + a \beta) & \text{if } x > 1 
\end{cases}
\]  

(11)

and the sign of the flow is determined by the direction of the applied wind and longshore pressure gradient forces. The parameter \( a \) measures the relative effect of the longshore pressure gradient in maintaining the basic state velocity. By using the definition of velocity scale \( U \) it follows that \( a \) can vary between 0 (no pressure gradient) and 1 (wind stress negligible).

2.3 Linear stability analysis

The formation of rhythmic bedforms can then be investigated by studying the dynamics of small perturbations evolving on this steady state:

\[
z_s = \zeta + \eta(x, y, t) \quad z_b = -H + h(x, y, t) \quad v = (0, V) + (u(x, y, t), v(x, y, t))
\]  

(12)

where \( \zeta = \delta y + \xi(x) \). The scaled linearized momentum (2) and mass conservation equation (3) read:

\[
V \frac{\partial u}{\partial y} - \ddot{f}_u = -\frac{\partial \eta}{\partial x} - \frac{r}{H} u, \quad V \frac{\partial v}{\partial y} + \frac{\partial V}{\partial x} u + \ddot{f}_u = -\frac{\partial \eta}{\partial y} - \frac{r}{H} v + \frac{\delta}{H} V
\]  

(13)

\[
\frac{dH}{dx} + H \frac{\partial u}{\partial x} + H \frac{\partial v}{\partial y} - V \frac{\partial h}{\partial y} = 0
\]  

(14)

and the sediment conservation equation (4) reads:

\[
\frac{\partial h}{\partial t} = -|V|^{m-1} \left\{ \frac{(m-1)}{V} \frac{dV}{dx} u + \frac{\partial u}{\partial x} + m \frac{\partial v}{\partial y} - \dot{\gamma} |V| \left( \frac{m}{V} \frac{dV}{dx} \frac{\partial h}{\partial x} + \frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} \right) \right\}
\]  

(15)

The equations (13)-(15) allow for alongshore travelling and growing wave solutions of the form

\[
(u, v, \eta, h) = \text{Re} \{ (\hat{u}(x), \hat{v}(x), \hat{\eta}(x), \hat{h}(x))e^{iky+\omega t} \}
\]  

(16)

Here \( k \) is the wavenumber and \( \omega \) a complex frequency. The real part, \( \text{Re}(\omega) \), denotes the growth rate of the perturbation and \( -\text{Im}(\omega) \) the frequency. Instability occurs if \( \text{Re}(\omega) \) is positive: then the mode grows exponentially in time. The part which describes the bottom is called a topographic wave. As a result of (16), equations (13)-(15) can be written as an eigenvalue problem where \( \omega \) is the eigenvalue and \( h(x) \) the eigenfunction. The mathematical details and the solution procedure can be seen in Falqués et al. (1997), Falqués et al. (1998b).
3 Model Results

In this section the results obtained with the linear numerical model will be presented. In order to fit our model to the situation on the Dutch inner shelf, we choose values for the parameters $L_v$, $L_H$, $U$, $r_\tau$, and $s$ as discussed in section 2.3. A value $\gamma = 0.08$ will be adopted for the Coulomb coefficient in the sediment flux. The Dutch coast is at a latitude of 51°N, thus the Coriolis parameter is $f_c = 1.12 \times 10^{-4}$ s$^{-1}$. Consequently, the default values of the non-dimensional parameters in our study are

$$\hat{f} = 5.35 \quad r = 1.5 \quad \hat{\gamma} = 1 \times 10^{-4} \quad \beta = 0.33 \quad a = 0.23$$

In this study we will focus on the dynamics of bedforms in the case where the current has the coast to the right in the Northern Hemisphere ($\hat{f} > 0, V < 0$), which is the case of the Dutch and the North American coasts. On the Argentinian shelf the current is directed to the north ($V > 0$ in the present model) but then, $\hat{f} < 0$. However, the latter situation is equivalent to the former one because the system has a mirror symmetry with respect to the $y = 0$ plane, so that there are only two independent situations, $fV < 0$ and $fV > 0$. Some results for the latter case will also be presented when discussing the effect of Coriolis force.

A sediment transport proportional to the current will be considered, i.e., $m = 1$. This choice is representative for situations where the wave-induced orbital velocity near the bed is much larger than the steady current. The sediment is then stirred by the waves and subsequently transported by the current. The effects of a sediment transport faster than linear, $m > 1$, have also been explored. In this case, the model gives bedforms different from the observed shoreface-connected ridges. These can be of two types: patches of alternate shoals and pools or cyclonically oriented ridges, see figure 3 up and down, respectively. The results in the case $m > 1$ can be seen in Falqués, Calvete & De Swart (1998a) and will be not further described here.

In figure 4 curves are presented of the growth rates of the first three eigenmodes for $a = 1$. In this case the basic state current is fully determined by the longshore pressure gradient. Note that the ratio $V/H$ is constant, as was also studied by Trowbridge (1995). An important difference is that in the present model the preferred downslope movement of the sediment is accounted for. This causes the growth rate to have a maximum for $k \approx 10$, which corresponds to a spacing...
Figure 4: Nondimensional growth rate, $\sigma = \text{Re}(\omega)$ as a function of the wavenumber, $k$, for the first three modes (upper part). Parameter values are $m = 1, \alpha = 1, r = 1.5, \hat{f} = 5.35, \hat{\gamma} = 10^{-4}, \beta = 0.33$ and $V < 0$. The contour plots of the three bottom modes with the largest growth rate, are shown below. Crests and troughs are indicated by continuous and dashed lines, respectively. In each plot the $y$ axis (vertical on the left) represents the shoreface and the $x > 0$ axis (horizontal on the bottom) the inner shelf. The direction of the basic current is shown by a big arrow. Note the upcurrent rotation of the ridges.

of about 7 km. This agrees with the observed spacings of shoreface-connected sand ridges on the Dutch inner shelf (Van de Meene, 1994). The corresponding phase speeds are $\simeq -1$ and this variable shows almost no dependence on $k$. This means that ridges behaves like topographic waves which migrate downcurrent with a celerity $V_{mi} \sim L_H / T_m$. In view of the fact that the maximum growth rate is $\simeq 0.1$, the amplitude of the dominant bottom mode grows approximately 6% during the period that the perturbation travels one wave-length. An estimate of the characteristic growth time (e-folding time) can be obtained from the horizontal lengthscale, $L_H \sim 12$ km and a typical migration speed, $V_{mi} \sim 4$ m yr$^{-1}$, by means of $\tau = cL_H / V_{mi}\text{Re}(\omega)$. This yields $\tau \sim 3 \times 10^4$ yr. The shape of the modelled ridges are shown in figure 4b. Clearly, the orientation of the dominant bedforms is such that they are upcurrent rotated: the seaward ends of the crests are shifted upstream with respect to their shoreface attachments. This agrees well with the observed orientation of the three ridge patches discussed in the introduction. Figure 5 shows the contour plot of mode 1 in figure 4 along with the corresponding perturbation on the current. The offshore deflection of the current over the crests and the onshore deflection over the troughs can be seen.

For $\alpha < 1$, the longshore windstress contributes to the maintenance of the basic current profile and hence the ratio $V/H$ is no longer constant. This leads to substantial differences compared with the case that $\alpha = 1$. For $\alpha$ close to 1 the
dominant wavenumber is close to 7, but with decreasing $a$ this role is taken over by a much lower wavenumber, $k_m \approx 7$ for $a = 0.8$ and $k_m \approx 1$ for $a = 0.6$. Obviously, the predicted ridge spacings become much larger than those observed in the field. Besides, the growth rates decrease with decreasing $a$ and hence the $\epsilon$-folding time scale of the bedforms becomes unrealistically large. Another interesting aspect is the competition between different modes with different spatial structures. The main differences are that some of them are attached to the shoreface while some are not. Sometimes they appear to be very elongated. Anyway, a striking overall characteristic of all modes is the upcurrent orientation of their crests.

The effect of earth rotation on the instability mechanism has been investigated by carrying out experiments with all parameters having their default values but for $a = 1$ and different values of the Coriolis parameter: $f = 0, 7, -7$. The results, shown in figure 6, indicate that earth rotation hardly affects the topographic waves in the observed wavenumber range, $k \sim 10$. In this range, Coriolis force produces just an inshore shift of the ridges (C) in the Southern Hemisphere and an offshore shift in the Northern Hemisphere (A) along with a slight inhibition of the instability in the latter case. In contrast, earth rotation has a strong influence on long topographic waves, making the instability mechanism to be much more effective on the Southern Hemisphere. In this case, a sharp peak in the growth rate curve occurs for very long wave-lengths. The corresponding bedforms show a little obliquity with respect to the coast and differ substantially from the observed elongated ridges (D).

The sensitivity of the model results to the friction parameter has also been investigated. The general trend appears to be that growth rates increase with increasing $r$, in particular for relatively small wavenumbers ($k < 8$). However, for $k$ around 10 or larger, the growth rates hardly depend on $r$. Furthermore, the wavenumber for which the instability mechanism is most effective become smaller if the friction parameter is increased. The shape of the preferred bottom modes do not change significantly.
Figure 6: Growth rate curves of the first mode for different values of the Coriolis parameter $\dot{f}$. All other parameter values are $m = 1$, $a = 1$, $r = 1.5$, $\gamma = 10^{-4}$, $\beta = 0.33$ and $V < 0$. The bottom contours are also shown, for $k = 12$ (A,B,C) and for the peak at $k = 1.5$ (D).

The bed slope $\beta$ and the Coulomb coefficient $\dot{\gamma}$ have counteracting effects, the former de-stabilizing, the latter stabilizing. If $\dot{\gamma}$ becomes larger than about $8 \times 10^{-4}$ instabilities do not longer exist.

4 Physical mechanisms

In this section the physical mechanisms which originate the formation of the ridges according to our model will be discussed. For this purpose it is useful to combine the continuity equation (14) and the bottom evolution equation (15) to obtain (in the quasi-steady limit $\epsilon \to 0$ and for small Froude number $F \to 0$)

$$
\frac{\partial h}{\partial t} + \frac{mq_0}{V} \frac{V}{H} \frac{\partial h}{\partial y} - \frac{\partial}{\partial x} \left( \dot{\gamma} q_0 \frac{\partial h}{\partial x} \right) - \frac{\partial}{\partial y} \left( \dot{\gamma} q_0 \frac{\partial h}{\partial y} \right) = \frac{q_0}{V} \left( \frac{m}{H} \frac{dH}{dx} - \frac{(m-1)}{V} \frac{dV}{dx} \right) u + (m-1) \frac{q_0}{|V|} \frac{\partial u}{\partial x} 
$$

where $q_0 = |V|^m$. On the left-hand side an advective contribution and two diffusive terms appear. Thus, in absence of the right-hand side, this equation would describe just migrating and decaying bedforms. The principle sources for instability appear on the right-hand side. The first term only acts in case there is a transverse sloping reference bottom. The last two terms are only active in case $m > 1$ (i.e., a 'faster than linear' sediment transport parametrization).

Consider the first term on the right-hand side of equation (17). It shows that an offshore deflection over a bar ($u > 0$) on a transverse sloping reference bottom causes a growth of the bar ($\partial h/\partial t > 0$). This can be intuitively understood by considering a control volume at a crest (where $\partial/\partial y = 0$) with vertical sides
parallel and perpendicular to the coast (see figure 7). In case of an offshore flow component \((u > 0)\) the mass deficit caused by the movement of the column into deeper water must be compensated by a convergence of the flow. As the sediment flux, \(q\), is proportional to a power of the velocity of the current, there will be convergence of sediment above the crests and thus the ridges will grow (see figure 7). Therefore, what we need now to explain the formation of the ridges is just a confirmation of the offshore deflection of the current over the crests. As a consequence of mass conservation in case of irrotational flow (Falqués et al., 1998a) it can be seen that an upcurrent oriented ridge causes an offshore deflection and that an downcurrent oriented ridge causes an inshore deflection. This is also confirmed by numerical simulation of the flow (see figure 5). Therefore, this behaviour achieves a positive feedback between bedforms and flow disturbance which is responsible for the growth of upcurrent oriented ridges.

The numerical simulation described in section 3 shows that the mechanism just explained is quite robust and that coriolis and frictional forces have only a moderate effect on it. What has a strong influence on the effectiveness of the transverse slope mechanism are the exponent \(m\) of the sediment transport and parameter \(a = \delta/r\). The mechanism is most efficient for \(m = 1\) and \(a = 1\). This seems related to the fact that in this case the local migration celerity of the topographic waves, \(mq_0/H\) (according to eq. (17)), is cross-shore uniform. Apparently, the cross-shore gradients on the migrational celerity inhibit the growth mechanism. The reason has not yet been fully understood.

In case of \(m > 1\), and in connection with the last term in equation (17), two different instability mechanisms appear which are related to the production of vertical vorticity. The first one is caused by bottom frictional torques over an uneven sea bed and tends to produce patches of alternate shoals and pools (see figure 3). The second one comes from the stretching of planetary vorticity by an uneven sea bed and tends to originate elongated ridges which are cyclonically oriented (see figure 3). A detailed analysis of them can be seen in Falqués et al. (1998a).
5 Nonlinear model. Preliminary results

Nonlinear theory provides the tool for examining the long-term evolution of the shoreface-connected ridges into some form that is observable in the field. Following Schuttelaars (1997), the nonlinear solution is expanded in terms of the linear eigenfunctions. Time evolution equations are derived by inserting the expansion into the full nonlinear equations and then projecting the resulting equations onto the adjoint linear eigenfunctions. This Galerkin-type method has the considerable appeal of using actual linear solutions as a basis—rather than, say, some arbitrary polynomial—so that comparatively few terms are necessary to describe the nonlinear evolution accurately. Work regarding the nonlinear equations is in progress. Figure 8 is shown as an example of some preliminary results. The time evolution of bathymetric contours from \( t = 0 \) to \( t = 2 \) (morphological time units) can be seen for \( m = 1, a = 1, r = 1.5, \hat{f} = 5.35 \). A number of 30 long-shore modes have been used, ranging from \( k = 1 \) to \( k = 30 \).

6 Conclusions

It has been shown that shoreface-connected sand ridges are formed due to a positive feedback between the water motion and the erodible bottom. However, the results of the model depend essentially on the sediment transport parametrization through the exponent \( m \). In case \( m = 1 \) (sediment transport proportional to the current) the dominant bedforms are trapped to the inner shelf and they are elongated and upcurrent rotated. The growth rate and longshore spacing are largely determined by the relative contribution of wind and the longshore pressure gradient in the maintenance of the background current. In case the latter effect dominates the model results show good agreement with field data, e.g. in case of the Dutch inner shelf a spacing of about 7 km is obtained (see figure 1). With increasing wind effects the growth rates become smaller and the wave-lengths increase. Coriolis and bottom friction also affect the instability mechanism, but they do not induce significant qualitative changes. Physically, the bedforms are due to the transverse sloping bottom mechanism and their formation is associated with an offshore
current deflection over the bars. The mechanism is effective only for $1 \leq m < 1.05$.

If a larger exponent $m$ in the sediment flux is considered other types of bottom modes are obtained which do not resemble the observed shoreface-connected ridges. They are generated by the coupling between topography and flow through the vorticity production due to an uneven sea bed either by frictional torques or by planetary vortex stretching.

It appears that the best comparison between model results and observed shoreface-connected ridges is obtained in case $m = 1$. A further condition is that the ratio $V/H$ is almost constant, where $V$ is the background current and $H$ the equilibrium bottom profile, which is realistic if the background flow is mainly controlled by a longshore pressure gradient and not by the windstress. Thus, the present modeling provides a valuable information on the regions where shoreface-connected ridges occur: apparently, the long term averaged sediment transport is mainly due to wave stirring plus advection by the mean current which is in turn controlled by pressure gradients.

It is important to realize that observed shoreface-connected ridges on the inner shelf are finite amplitude features while the linear analysis only yields information on their initial formation. This limitation can be overcome by the nonlinear model which has been set up. Preliminary results reported here have proven to be promising.

An examination of the large-scale bedforms in the map of the Southern Bight of the North Sea presented in figure 1.1 of (Van de Meene, 1994), suggests that the Dutch shoreface-connected ridges could very well be tidal sand banks just distorted by the proximity of the coast. However, the present study shows that shoreface-connected ridges have an entirely different origin. Indeed, tidal sand banks are associated to a $m > 1$ power in the sediment transport and to bottom friction, and their orientation depends on earth rotation (Hulscher et al., 1993). On the other hand, the observed orientation of the ridges is obtained only if $m \approx 1$ and is not affected by Coriolis. Therefore, it is clear that the transverse slope mechanism is the main cause of the observed ridges and this has nothing to do with tidal oscillations. Nevertheless, it is conceivable that tidal currents affect the ridges in some way. To explore this possibility, an important extension of the present model consists in the assumption of a basic undisturbed current with a steady component plus an oscillatory one (tidal). This type of modelling is currently in progress and preliminary results are reported in Falqués et al. (1997).

THE SPATIAL VARIABILITY OF LARGE SCALE SAND BARS

C. R. Worley¹, T. C. Lippmann¹, J. W. Haines², A. H. Sallenger²

Abstract

In this work we describe preliminary results from a newly developed aerial video system which can be used to rapidly (2-4 hours) and accurately (5 m resolution) sample the horizontal scales of sand bar morphology over several hundred km's of coastline. Observations from, for example, the North Carolina coastline on the central eastern seaboard of the U. S., indicate marked changes in the alongshore morphological patterns, which can be cyclic with lengths scales of 5-10 km's along one stretch of coast but adjacently the bars can be absent altogether. Other observations from the lower sloping west coast beaches of the U. S. Pacific Northwest show highly complex sand bar morphology which also exhibit marked alongshore variability. Along this coast the beach systems are not continuous and are separated by large headlands, and the morphology at any particular beach behaves independently from the bar morphology in adjacent compartments.

Introduction

Nearshore morphology exhibits spatial variability spanning over 5 decades of scale. Morphologies ranging from wave- and mega-ripples (10-100's of centimeters) to large scale sand bars and shoreline features spanning 10-100's of kilometers reflect a variety of fluid-sediment interactions spanning comparable scales. The temporal response of these features is similarly broad (from 10's of seconds to years). This wide range of scales presents difficult sampling problems. Commonly used nearshore

¹Center for Coastal Studies, Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA, 92093-0209, USA
²Center for Coastal Geology, U. S. Geological Survey, St. Petersburg, FL, 33701, USA
surveying techniques are limited in spatial and especially temporal resolution, require a large resource of manpower, and are generally only feasible in moderate wave conditions. Yet, for many applications it is of interest to sample the sometimes rapid, large changes in beach morphology that occur during single storm events, or over a series of several to many storm cycles.

One remote sensing technique which has successfully resolved rapid changes in large scale sand bar morphology is based on sub-aerial video of surf zone wave breaking (Lippmann and Holman, 1989; 1990). Time-averaged video images detect the horizontal scales of the average wave breaking patterns, and because waves preferentially break over shallow regions, the large scale morphologic features associated with bars are revealed. The video techniques are not limited by adverse wave conditions, and have thus proven useful in sampling long time series (up to 5 years and continuing today) of nearshore morphologic variability (Lippmann and Holman, 1990; Lippmann, et al., 1993).

The most severe limitation of the video techniques is that the resolution of the images degrades rapidly as the distance from the camera increases, particularly for the highly oblique views typically used to study nearshore processes (i.e., Holman, et al., 1993). The useful spatial coverage of the land-based video techniques is determined by the pixel resolution of the image, which depends strongly on camera elevation above mean sea level and the distance to the target (Holland, et al., 1997). For the Duck, NC, camera location, the useful ground coverage imaged in Lippmann and Holman (1990) and Lippmann, et al. (1993) spanned alongshore distances of about 400 m alongshore. Since the bar position was averaged over the entire view for the time-exposure data used in Lippmann, et al. (1993), any alongshore variability that may have been present at wavelengths greater than 400 m could not be addressed, nor the potential for alongshore migrating large-scale bar features which could also produce the transition sequence observed by either Lippmann, et al. (1993) or Birkemeier (1984).

Sand bars with large alongshore length scales of $O(10 \text{ km})$ have been observed to migrate along the Dutch coast using 40 years of annual profile measurements spanning 350 km alongshore (Wijnberg, 1995). These large scale features dominate the variability over the 40 year time series, and show variability in time and length scales that is presently not understood. The Dutch JARKUS profile data is unique in
its breadth of temporal and spatial sampling. It is, however, a very difficult task to produce a single survey of 350 km of coast, often taking 6 months to complete one survey.

**Aerial Video System**

Recent advances in aerial videography have shown that rapid acquisition of the spatial patterns of large scale sand bar morphology is possible (Worley, et al., 1997). The development of an aerial system was motivated by the need to measure larger length scale sand bars accurately and in a timely manner. The modular, low-cost system was configured so that it could be quickly deployed in easily accessible, inexpensive Cessna 172 or 182 aircraft at locations where forecasted weather predictions indicated the development of large storm systems, and thus the potentially large scale changes of the beach system to could also be quantified. The system utilizes a gyro-stabilized compass and inclinometer to maintain the camera in a vertically down-ward orientation within a walk-circle of 1 degree diameter. The azimuthal angle of the camera view and altitude (measured with a pressure sensor) is recorded on a lap-top PC and is synchronized with the video using timing obtained from a hand-held GPS receiver. The horizontal real-word UTM coordinates and vertical elevation of the aircraft are also measured using differential GPS systems with reliable positioning and high accuracy of order 0.05-0.5 m, depending on distance to the base station.

The precision and accuracy of the components of the aerial video system and image resolution and averaging times are summarized in Worley, et al. (1997). Assuming precise positioning, and for a typical deployment using a 2/3 inch format video camera with wide angle lens, the expected image resolution ranges between 1.1-5.9 (1.6-8.8) meters in the cross-shore (longshore) directions, depending on flight altitude ranging 457-2438 m (1500-8000 ft). With a typical aircraft ground speed of 80-100 knots (~50 m/sec) we expect sampling periods and averaging times in one flyby to be about 17-89 seconds for flight altitudes. The averaging time can be increased linearly by making several flyby's of the same ground area.

**Field Data**

We have conducted over-flights periodically for the past 13 months at several regions of the U. S. (Figure 1). Approximately bi-monthly flights have been
conducted from the Mexican border to Santa Barbara, spanning the entire Southern California Bight. Flights have been conducted also along the Central California coast from Monterey to Tomales Bay at the north end of Pt. Reyes, and along the northern Oregon-southwest Washington coast from Waldport, OR, to Pt. Grenville, WA. Finally, several flights have been conducted along the North Carolina coast from Cape Hatteras to the Virginia border, and span the period of the 1997 SandyDuck experiment.

Sand bar morphology is inferred from the location of average breaking patterns in time-exposure images created over the approximately 30-40 second duration (for aircraft altitude of 3000 ft) that ground features remain within the camera field of view, similar to the land-based methods (Lippmann and Holman, 1989; 1990). In the aerial techniques, the image transformation must be done on a frame-by-frame basis, and is accomplished by synchronous integration of the measured azimuthal orientation of the camera view and position of the aircraft with the VITC time-stamp on each video frame. Individual frames are rectified into the UTM ground coordinate system and digitally added in sequence using image processing, video, and computer hardware in our laboratory. Time-exposure images span the length of the flight-track which ranges about 75 km for some of the shorter southern California flights to about 300 km in the Pacific Northwest.

The data have shown remarkable alongshore variability in sand bar morphology, and have revealed, for example, alongshore regular patterns in sand bars along the North Carolina coastline with length scales of the order of 5-10 km that dominates the alongshore variability in bar position. An example 35 second aerial time-exposure spanning about 10 km alongshore, obtained about 20 km north of Duck, NC, on 27 September 1997, is shown in Figure 2. The resolution for this image is 5 m horizontally, and shows well defined sand bars emanating obliquely away from the shoreline, eventually fading away seaward behind adjacent, more shoreward bars further down the coast. Interestingly, several similar obliquely oriented bars were observed at approximately regular spacing along 36 km of the same stretch of coast (Figure 3), yet just to the south, the aerial time-exposure indicates the presence of only a single bar very close to shore (Figure 4).

The possible migration of the large scale bar features can be addressed from time series of aerial time-exposures. The behavior of the coast to changing wave
conditions in relation to the alongshore configuration of the bar system, and is the subject of ongoing research.

The morphologic variability can also be quite high at other beaches with different characteristics than North Carolina, where low-relief barrier islands span the length of coastline and the beaches are relatively steep. Along the U.S. Pacific Northwest coast, most beaches are backed by cliffs or high dunes and bounded laterally by many headlands, are generally more gently sloping, and are subjected to the more energetic Pacific swell for much of the year. Figure 5 shows an 11 km section of coast near Siletz Spit (shown in the center of the image) in the central Oregon coast obtained on 2 June 1998. The wave heights were over 2 m for this day and the surf zone spans about 400 m across-shore. The alongshore variability is quite complicated, without any particular regularity apparent. In contrast, about 90 km or so to the north the bar forms appear more regular in morphology, with sinuous bars extending alongshore continuously for several kilometers and sometimes attach to the shoreline (Figure 6).

Summary

Results from deployment of a recently developed aerial video system for measuring large scale sand bar morphology are briefly discussed. The system, based on inferring sand bar shapes and location from time-averaged breaking patterns, was deployed on both the west and east coasts of the U.S. Observations of sand bars, for example, offshore of North Carolina coast along the central eastern seaboard and along the Pacific Northwest coast, reveal substantial alongshore variability in sand bar patterns. Series of large scale oblique bars, emanating from the shoreline and diminishing down the coast behind other similar bars, were observed over 30-40 km of part of the North Carolina coast, yet observations of the 30-40 km just to the south revealed only a single bar located close to shore. In the Pacific Northwest, highly complex bar patterns were observed with no apparent connection between adjacent beach systems separated by headlands. The evolution of these large scale bar forms, from both the steeper east coast beaches and the more gently sloping, energetic west coast beach systems, are the subject of ongoing investigations utilizing data obtained from the aerial video system.
Acknowledgments

Expert piloting for the over-flights was done by Kimball Millikan, John Stanley, Chuck Rosenfeld, and Dean Morris, and we greatly appreciate their conscientious efforts. Several people generously helped with differential base station deployment and post-processing, particularly Jeff List, Amy Farris, Tom Reiss, Mark Hanson, Peter Ruggiero, Mike Leffler, and Jerry Sain. Funding was provided by the U. S. Geological Survey and the California Department of Boating and Waterways.

The large scale nearshore morphology shows long, sinuous bar features which sometimes attach to the shoreline.
MODELING THE DYNAMICS OF A BAR SYSTEM AT DUCK, NC, USA

B. Boczar-Karakiewicz¹, W. Romanczyk¹, J.L. Bona² and E.B. Thornton³

ABSTRACT

The temporal evolution of nearshore bar topography forced by incident, wind-generated waves is predicted by a two-dimensional (2D) model. Predictions are compared with observed bathymetry from Duck, North Carolina, USA, acquired by the Field Research Facility (FRF) of the US Corps of Engineers over a period of 17 years (1980 - 1997). The model simulations presented are seen to approximate well the formation of the most frequently-observed shore-parallel bars at Duck as well as dynamic changes in their pattern caused by storm waves and varying mean water level.

1. INTRODUCTION

The two-dimensional model applied in the present work describes the temporal evolution of nearshore bar systems forced by incident, wind-generated waves (Boczar-Karakiewicz et al. 1987 and 1995). In this model, surface waves are described by simplified Boussinesq equations. Nonlinear wave forcing is transmitted through a wave-induced boundary layer to the bed, which is characterized by small-scale bed roughness. The model allows a finite-amplitude beach response which, in turn, feeds back to modify the wave field. At present, we consider the temporal evolution of the bed when it is forced by incident monochromatic and regular wave trains at the observed wind-wave peak-frequency. The energy is exchanged among the evolving wave modes as the wave propagates into shallower water. In the simulations presented, wave breaking and related undertow are not considered, though their incorporation is currently under development. Such simplifications allow the application of

a model without free parameters. According to the model, distances between bar crests, the number of bars, their position and amplitude, at a given site, are scaled by naturally-occurring and site-specific units: the bar geometry is scaled by the incident wavelength, while the time of bar formation and their dynamics are scaled by the wave energy. These model predictions also explain changes in bar position in response to waves at high water levels induced by tides and storm surges.

Incident wave parameters and typically observed bed topographies are selected from field data in Section 2 and compared with model predictions in Section 3. General conclusions drawn from our work are set forth in Section 4.

2. FIELD DATA AND INITIAL MODEL PARAMETERS

In the present section, wave and bathymetry data from Duck, NC, spanning a period of 17 years (1980 - 1997) are analyzed. These data were acquired by the Field Research Facility (FRF) of the US Corps of Engineers in the following way: directional wave data were measured every 3 hours at a 10 m water depth, and bathymetry was carried out at least monthly.

In this report, a single line of cross-shore bathymetry is analyzed (\#62 according to the FRF coordinates). This profile was chosen to represent the entire experimental area. It is located close to the northern extreme of the site to avoid the local topography effects of the piers. Measured data are scattered as shown in Figure 1 and no prevailing bar pattern is visible in the cloud of points. From this data, a featureless mean bed profile was determined (heavy line in Figure 1), by use of Dean's beach

![Figure 1: Foreshore morphology data at profile 62, Duck, NC, (1980-1997) and the featureless equilibrium profile](image-url)
equilibrium formula with an additional function fitting observations lying in the very nearshore and on the upper beach. This profile was selected as the topographical input to the model calculations simulating bar formation in Section 3.

A subsequent, more detailed analysis of the topography observations was conducted to understand better the dynamics of the bed. First, the temporal sequence of profiles measured in the period 1980-1997 was animated. This interesting exercise revealed considerable temporal variability, and, occasionally, rapidly-changing bed configurations. These data suggested that metastable states exist which result from a longer sequence of wave events and not just from a single storm preceding the measured bathymetry. We proceeded by selecting from the temporal sequence of profiles (1980-97) several groups of typical bed types. The segregation criteria were based on morphological similarity, including the position of bar crests and number of bars. One among the selected groups of bed profiles is shown in Figure 2. This result confirmed conclusions from earlier work (see, e.g., Birkemeier 1984, Lippmann et al. 1993): the most frequently-observed bed profile at Duck is a two-bar system with bar crests at about 200 and 400 m relative to the FRF coordinates and the mean shoreline position at 100 m.

![Figure 2](image_url)  
Figure 2: Typical two-bar system at Duck, NC, with indicated dates of data acquisition (based on measurements at cross-section 62)

However, during the period 1988-1995, a distinct one-bar topography (as shown later in Section 3) was predominant and the outer bar corresponding to the two-bar morphology seemed to be completely flattened out. Generally, in 17 years of measurements, the position of the nearshore bar crest varied over an interval of some 150 m, and the second offshore bar crest, when it existed, migrated about its mean 400 m position by ± 100 m.
Observations at Duck also show that every 8-9 years the previously mentioned "slow" changes in bar patterns are disturbed by episodic "anomalies" that occur at inter-seasonal cycles. During these anomalies, the bar crest positions change rapidly: for example, the inner bar may migrate 100 to 150 m in only a day or two (Birkemeier 1984, Holman and Sallenger 1993, Lippmann et al. 1993). These anomalous episodes are puzzling, especially in light of the metastability exhibited in Figure 2. In Section 3, we show a simulation of an anomalous event at Duck using our previously described model (see Section 1 and the references mentioned there). The observed wave environment pertaining to anomalies is now described.

In the predictions of the bar dynamics made in Section 3, the observed prevailing bar patterns, as seen in Figure 2, and the episodic change in the bar system are correlated with events in the local wave climate, in particular with single storms, or sequences of storms with and without a simultaneous water level change.

Input wave parameters, which are required by the model, are specified at the deep-water end of the nearshore zone by peak periods $T_p$, incident wave energy $a^2$ (where $a$ denotes wave amplitude), and the mean water level. These data were obtained by analyzing the measured parameters of waves and water levels from 1980-1997 as presented in the format shown for the year 1990 in Figure 3.

![Figure 3: Observed wave and water level parameters at Duck, NC, in 1990](image)

The analysis of data showed the wave climate at Duck to be, quite "noisy". Peak periods and related wave energy in incident waves vary irregularly during the year
with large differences between consecutive years. However, certain “seasonal” patterns could be discerned: extreme storm events and hurricanes occur predominantly in the autumn-winter season (with \( T_p \) from 12 s to 20 s); these stormy periods are followed by a summer season of moderate wave activity (\( T_p \) below 10 s). During the episodic anomalies mentioned above, there occur major storm events with water levels on the order of +1 m above the mean (see again Figure 3).

In the model predictions, the value \( T_p = 15 \) s was chosen to initiate simulations of major storm events both at mean and high water levels. Extreme storm events are represented by incident waves of period \( T_p = 17.5 \) s. On the other hand, summer waves are represented in the model by wave trains with \( T_p = 10 \) s.

3. PREDICTIONS AND COMPARISONS WITH OBSERVATIONS

Formation of the most frequently-observed two-bar system (Figure 2) by major storm events was simulated by the model with topographical input in the form of the mean featureless bed profile (heavy line in Figure 1) and deep-water incident wave parameters with peak period \( T = 15 \) s and wave amplitude \( a = 1.5 \) m. The temporal evolution of the seabed in the surveyed part of the nearshore is shown in Figure 4a.
Figure 5: Comparison of predictions (heavy dashed line) and measurements of the most frequently-observed two-bar system at Duck, NC.

Figure 6: Prediction of changes from the typical two-bar system by extreme autumn-winter storms (with $T_p = 17.5s$): (a) temporal evolution of the new two-bar system from the original two-bar profile, (b) initial and final profiles from (a).
Figure 7: Prediction of changes from the typical two-bar system by moderate summer storms (with $T_p = 10s$): (a) temporal evolution to a one-bar system from the typical two-bar profile, (b) initial and final profiles from (a).

Figure 8: Comparison of predictions (heavy dashed line) and measurements of an observed two-bar system at Duck, NC (with bar crest positions at 250 m and 500 m).
and the initial and final profiles are depicted in Figure 4b.

In Figure 5, the heavy dashed line showing the predicted final bed configuration from Figure 4 is superimposed on observations from Figure 2. Comparisons of position, the number of predicted bars and their amplitudes are in quite good agreement with the 17 years of observations.

In the following simulations, the dynamics are initiated with the two-bar bed topography provided by the model, as depicted in Figures 4a and 4b. In the simulation shown in Figure 6a, the incident waves represent hurricane waves ($T_p = 17.5$ s). In a second calculation shown in Figure 7a, initiated with the same two-bar initial profile, the incident waves are moderate summer waves ($T_p = 10$ s).

![Figure 9](image.png)

Figure 9: Comparison of predictions (heavy dashed line) and measurements of an observed one-bar system at Duck, NC (with the bar crest position at 220 m).

In both the cases shown in Figures 6 and 7, the model predicts the response of the frequently observed two-bar bathymetry to ambient hydrodynamic regimes representing simplified versions of winter ($T_p = 15$ s and 17.5 s) and summer ($T_p = 15$ s and 10 s) wave activity. In the winter season (Figure 6a), the model predicts a transformation of the primary two-bar system via the migration of bar crests to new locations: the inner bar shifts from its 200-m position to a 250-m location; the outer bar migrates offshore by some 100 m from its mean 400-m position. In the first stages of the summer calculation (see bed profile at time $t = (2 \times 10^4)T_p$ in Figure 7), the post-storm two-bar system is only slightly changed by moderate waves ($T_p = 10$ s). However, the model also shows that at later stages of the calculation (a long-lasting period of moderate waves in a non-stormy year), the two-bar system goes over into a single bar system (see the final profile in Figures 7a and 7b).

In Figures 8 and 9, the final bed configurations from Figures 7b and 8b are
superimposed on observations. Again, the comparison of predicted positions, number of bars and their amplitudes shows quite acceptable agreement.

Figure 10: Prediction of an episodic change in the two-bar system at Duck, NC (a) migration of the post-storm profile under extreme waves ($T_p = 15$ s), accompanied by a 1.2-m surge above the mean water level, (b) initial and final bed profiles from (a).

The final simulation reported here was concerned with an "anomalous" situation wherein a storm with $T_p = 15$ s came on with a simultaneous 1.2-m surge in the water level. As shown in Figure 10, the bottom response to extreme waves at this high water level was for the primary two-bar system to shift to a new position. In a period of two days, the outer and inner bar crests migrate some 100 m in the shoreward direction (compare the initial and final bed profiles in Figures 10a and 10b).

Comparisons of the predictions depicted in Figure 10 with observations are shown in Figure 11. During this episode, the calculation predicts a significant increase in the volume of the outer bar as measured at the site.

5. CONCLUSIONS

1. The model simulations presented here are aimed at approximating the temporal
Figure 11: Prediction (heavy dashed line) and observations of episodic, nonstationary behavior of the two-bar system at Duck, NC.

evolution of the most frequently-observed shore-parallel bars at Duck and the dynamic changes in their pattern.

The following results were obtained.

- The predominant two-bar bed configuration is associated with forcing by large storms \( T_p = 15 \text{ s} \) and the model approximates the observations, as shown in Figure 8.

- Predicted modifications of bar crest positions in the most frequently-observed two-bar system occur in the winter season during extreme storm events, as shown in Figure 7. The predicted bed configuration correlates well with observations (Figure 9).

- Predicted modifications from the most frequently-observed two-bar system to a single bar occur over several months of moderate storm activity, as seen at the site and illustrated in Figure 10.

2. The rapid and episodic response of the most frequently-observed two-bar system are predicted during extreme storm events accompanied by elevated mean water levels (Figure 10). Figure 11 illustrates the relation between model predictions and observed changes in bar morphology. These anomalous events occur on an abnormal cycle of several years duration. The one featured in our comparison was taken from 1989 data.

DEPTH OF CLOSURE:
IMPROVING UNDERSTANDING AND PREDICTION

Robert J. Nicholls¹, Magnus Larson², Michele Capobianco³
and William A. Birkemeier⁴

ABSTRACT

The closure concept is a fundamental cross-shore boundary condition for morphodynamics and other applications such as beach nourishment and sediment budgets. This paper examines closure at a range of scales, particularly from events up to years. At these scales, closure is primarily a function of direct external forcing (cross-shore redistribution of sediment by waves), indirect external forcing (sediment loss/gain by littoral transport and the resulting profile translation) and internal system dynamics (bar dynamics). Therefore, simple wave-based models such as Hallermeier (1981) cannot be expected to predict the actual closure, although they can predict distributional properties such as the limit. A general approach to develop more user-orientated estimates of closure over a range of timescales is outlined based on equilibrium theory. This will include a user-defined depth change criterion as a function of timescale.

INTRODUCTION

Depth of closure is widely used within coastal engineering as an empirical measure of the seaward limit of significant cross-shore sediment transport on sandy beaches. More fundamentally, it is an important parameter which distinguishes two cross-shore zones with different levels of morphodynamic activity. The closure

2888
concept initially arose from the comparison of repetitive beach-nearshore profiles (henceforth beach profiles). Such profiles define an envelope of variation which declines with depth. The seaward limit of this envelope is generally interpreted as the "depth of closure". However, the precise location of closure is a matter of the depth change criterion used to define closure from a set of measurements: the larger the criterion the more deeper changes are ignored and the shallower the estimate of closure. In practical terms closure is often defined using the measurement accuracy.

Models to predict closure are limited. Using an argument based on the critical value of a sediment entrainment parameter, Hallermeier (1981) developed the only analytical approach to estimate an annual depth of closure on sandy beaches \( d_\infty \). It is a function of extreme wave conditions and in a generalised time-dependent form is:

\[
d_{\infty,t} = 2.28 H_{e,t} - 68.5\left(\frac{H_{e,t}}{gT_{e,t}^2}\right)
\]

where \( d_{\infty,t} \) is the predicted depth of closure over \( t \) years, referenced to Mean Low Water; \( H_{e,t} \) is the non-breaking significant wave height that is exceeded 12 hours per \( t \) years; \( T_{e,t} \) is the associated wave period; and \( g \) is the acceleration due to gravity. This method explicitly recognises that some sediment movement will occur seaward of \( d_{\infty} \).

Given that depth of closure is an important morphodynamic parameter common to all scales, it has been explored as part of the EU-funded MAST III PACE (Predicting Aggregated-Scale Coastal Evolution) project. This has included investigating its field characteristics, testing existing models and developing new models, which cover the range of engineering timescales (\( \leq 50 \) years) (e.g., Nicholls et al., 1996; Capobianco et al., 1997). The datasets which have been examined are summarised in Table 1. It is important to distinguish the wide range of time (and space) scales considered in Table 1 and the following terminology is used: (1) small scale for events to seasons, (2) medium scale for one year to one decade, (3) large scale for decades to one century, and (4) very large scale for centuries to millennia (cf. Stive et al., 1990; Hinton and Nicholls, 1998). Collectively, these data covers the morphological response to individual storm events (small scale) up to the integrated effects of several decades of morphological evolution (large scale). All sites are wave-dominated, microtidal beaches, with the exception of Terschelling which is mesotidal.

The following generic results are apparent.

- Depth of closure is time and space-scale dependent, and generally increases with timescale (Capobianco et al., 1997).
- Depth of closure is a morphodynamic boundary, not a sediment transport boundary. Sediment transport should be expected to occur seaward of closure, especially during storms (Wright et al., 1991; Garcia et al., 1998). However, at the timescale defined by a closure measurement, the start of measurable morphological change is a good empirical indicator of an increasing capacity.
for cross-shore sediment transport. At longer timescales, this may not be the case.

- At small scales, depth of closure is usually the product of bar migration due to surf zone processes (Nicholls and Birkemeier, 1997; Nicholls et al., 1998). As the scale increases, so beach-nearshore profile translation and ultimately shoreface processes come to control the location of closure (Hinton and Nicholls, 1998). At large scales on the Holland coast, it is possible to distinguish a "shoreward" closure due to breaking waves, reopening of the profile lower on the shoreface, and then a deeper middle/lower shoreface closure due to shoreface processes. Thus, the closure concept can define four distinct cross-shore zones at this scale.

- Equation 1 provides robust estimates of the limit to closure for individual erosional events up to the annual timescale (Nicholls et al., 1996; 1998; Garcia et al., 1998; Rozynski et al., 1998). At medium scales, it continues to act as a limit, but with an increasing tendency for overprediction. Equation 1 only considers cross-shore redistribution of sediment and excludes the effects of beach-nearshore profile translation (Nicholls and Birkemeier, 1997). In particular, it is invalid in areas which are accreting rapidly due to longshore supply of sand.

- Analysis of closure at a nourished site (Terschelling) finds that Equation 1 and pre-nourishment profiles provide a good estimate of the limit of post-fill closure (Marsh et al., 1998).

Therefore, the processes which control closure vary with scale. At small scales, closure is a product of episodic, short intense erosional events (and offshore transport), and/or more continuous accretional processes (and onshore transport) (Nicholls et al., 1998). Over days and weeks, we might associate closure with a specific process and cross-shore transport direction, but over seasons and longer, closure is the integrated result of onshore and offshore sediment transport. As the scale increases, so the number of processes which influence closure increases. At large scales, slow progressive morphological changes on the shoreface may become significant, moving closure to significantly greater depths than typically considered by engineers (Hinton and Nicholls, 1998). At very large scales, both models and geological evidence suggest that closure will lie at the base of the shoreface (cf. Stive and deVriend, 1995; Niedoroda et al., 1995; Cowell et al., 1995).

Based on these results, this paper reviews and refines our understanding of the methods available to predict closure for engineering application. Small and medium scales are considered using the Duck dataset (e.g., Lee and Birkemeier, 1993) for validation. Given that closure is user-defined, the concept can be generalised as a family of depth change contours, which define a number of cross-shore zones (Capobianco et al., 1997). This approach allows a user to select the most appropriate depth change criteria for their application.

When considering the prediction of closure, it is important to understand what forcings and internal dynamics influence this morphological response. Based on our present understanding, a conceptual model linking forcing to closure is shown in Figure 1. The primary forcing which produces closure under microtidal, wave-dominated situations appears to be wave action (Capobianco et al., 1997; Nicholls et al., 1998). The skill of Equation 1 in predicting the limit of closure for erosional events and annual timescales is one indicator of the importance of this forcing. Wave action may produce closure in two distinct ways: (1) directly by cross-shore redistribution of sediment; and (2) indirectly by net gains or losses of sediment due to longshore transport and the resulting profile translation (see Nicholls and Birkemeier, 1997). While the indirect effect of waves might be observed at small scales, it is more important at medium scales due to the cumulative effects of littoral transport.

The response to this forcing is constrained by the internal dynamics of the morphological system. At small scales, the pre-event bar configuration influences closure during erosional events (Nicholls and Birkemeier, 1997; Nicholls et al., 1998). At medium/large scales, the shoreward closure along the Holland coast shows two distinct closure provinces in response to (broadly) the same wave climate (Hinton and Nicholls, 1998). However, these two provinces can be directly related to zones of distinct bar behaviour, showing that bar morphodynamics influence closure at these scales.

Therefore, closure is a response to the direct and indirect wave forcing, conditioned by the starting morphology and/or bar dynamics. In terms of prediction this has important implications. To predict closure both the forcings and the internal dynamics need to be described and this is not presently possible (see Capobianco et al., 1997). Models which only consider the forcing can only predict properties of the distribution of closure for that forcing (i.e., a minimum, or a maximum, or a mean). This limits our prediction capability, although just knowing the limit to closure is often useful to engineers (Nicholls et al., 1996; 1998).
CLOSURE AT SMALL SCALES

Nicholls et al. (1998) examined closure (defined with a 6-cm depth change criterion) at weekly to monthly intervals using data from Duck. Each closure event was defined as erosional if associated with consistent offshore bar movement, and accretional if associated with consistent onshore bar movement. The limit to closure is well-predicted by Equation 1 during erosional events (the closure response can normally be related to a specific storm). However, the scatter below Equation 1 is large and partly due to pre-event profile configuration: for the same wave forcing deeper closures occur when an outer bar is well-developed (Nicholls and Birkemeier, 1997). An empirical best fit shows that observations are 67% of predictions. Under accretional conditions, Equation 1 often underpredicted the observed closure. This is not a surprising result as Equation 1 is based on extreme waves, while accretion is a slow steady process which may have occurred near continuously between surveys.

To generalise closure at small scales for a range of depth changes, Capobianco et al. (1997) examined empirical relationships with the wave forcing, again using data from Duck. Closure was defined using an automatic algorithm for 5-cm, 10-cm and 20-cm depth change criteria. Empirical distribution functions were derived from the waves and the calculated depths. Assuming that there is a general relationship between waves and depth variation, the exceedance probabilities can be matched (i.e., the x% highest waves produce the x% largest depth changes). Note that accretional and erosional closures are not distinguished. The result is given in Figure 2.

An empirical fit which allows extrapolation to larger wave heights is also shown:

\[ D_p = kH^{0.67} \]  

where \( D_p \) is the predicted depth of closure, \( H \) is the mean wave height over the 12 hour exceedance (see Equation 1), and \( k \) is a constant of 2.1, 2.8 and 3.4 for 20-cm, 10-cm and 5-cm change, respectively. For the deeper closures, Equation 2 provides a good fit for 20-cm change. However, for the 5-cm and 10-cm change, there is significant underprediction for the deepest closures that one would most like to predict. However, this could represent spurious data generated by the automatic algorithm used to estimate closure and an independent check of these results is required.
The dataset of accretional and erosional cases from Duck developed by Nicholls et al. (1998) is suitable for such a check as it has been manually quality controlled to remove spurious values. It is compared with Equations 1 and 2 in Figure 3. The general form of Equation 2 is shown to provide a reasonable limit to the all the closure observations. For 5-cm change, the accretional and erosional cases occupy distinct areas, as discussed above. Equation 2 provides a limit to both the accretional and erosional cases, but Equation 1 provides a better limit for the deeper erosional cases. For 20-cm change, there is less distinction between the erosional and accretional cases, and Equation 2 still defines a reasonable upper limit to the entire dataset, although this can be improved with adjustment to $k$ (Table 2). For the deep erosional cases, Equation 1 still provides a better limit than Equation 2 if an empirical adjustment is made (Table 2).

The general applicability of Equation 2 to sites other than Duck is less certain, given its empirical basis. However, it provides useful guidance and shows the potential for the prediction of a limit to closure for a range of depth change criteria. Finally, these results reinforce the value of distinguishing erosional from accretional closures at small scales.
Figure 3. Depth of closure versus the mean extreme 12-hour deep-water wave height. Equation 1 (straight line) and Equation 2 (curved line) are shown together with data from Duck using a 5/6-cm, 10-cm and 20-cm depth change criteria. (A), (B) and (C) show erosional cases, and (D), (E) and (F) show accretional cases.
Closure at medium scales is an integrated response to both erosional and accretional processes, including cross-shore redistribution of sediment and profile translation. At the annual timescale, Nicholls and Birkemeier (1997) showed that while Equation 1 acted as a limit to the closure data, volume change was an additional controlling factor. Profile retreat and volume loss reduces closure compared to a case with no translation, while it was inferred that volume gain and profile advance enhanced closure compared with no translation. The residual \((d_{\epsilon t} - \text{observed closure})\) versus volume change is shown for annual, two-yearly and four-yearly time intervals in Figure 4. Linear regression explains 21% of the variance. However, net volumetric changes at Duck have been relatively minor over the period of observations. An analysis of more data on closure from other sites with large net volume changes is needed to better understand this factor.

However, these results show that a better test of Equation 1 is under conditions of no volume change. In the subsequent analysis, only closures defined using a 6-cm criterion using profiles where the volume change is <50 m\(^3\)/m are considered. Table 3 summarises the data in terms of residuals, including erosional events for comparative purposes. While the sample size is small, the mean residual is smallest for the annual timescale, and then increases with timescale. Regression coefficients (forced through the origin) are also given in Table 3:

\[
D_c = a d_{\epsilon t} \quad (3)
\]

where \(D_c\) is the observed closure and \(a\) is the regression coefficient. The regression coefficient shows a similar pattern to the mean residuals and is closest to unity at the annual timescale. These results are all consistent with the results of Nicholls et al. (1996) that Equation 1 provides best agreement with observations at annual timescales.
The slower growth of observed closure than predictions using Equation 1 at timescales above annual may be related to bar migration. Annual closure is strongly related to cross-shore bar movement. However, cross-shore bar migration is constrained to the shore and the crest of the outer bar at Duck rarely moves more than 300 m offshore (Lee et al., 1998). Therefore, as timescale increases the influence of bar movement at depth changes little and deeper closures are related other processes such as larger-scale cross-shore sediment redistribution or profile translation.

**MODELLING DEPTH OF CLOSURE USING EQUILIBRIUM PROFILE THEORY**

The analysis above gives insight into the factors which control closure. However, it also shows that the prediction of closure as a function of both depth change criteria and timescale is quite difficult with the existing range of tools. This section outlines how a general predictive approach might be developed based on recent improvements to equilibrium profile (EP) theory (see also Capobianco et al., 1997).

In many cases it is possible to describe a beach profile through simple analytical expressions derived from EP theory (e.g., Dean 1977, Inman et al. 1993, Larson and Wise 1998). These expressions contain empirical parameters that depend on the beach and wave characteristics. Therefore, profile dynamics can be predicted as a function of wave climate. Although such an approach involves considerable simplifications, it may provide a basis for a generalised statistical definition of the depth of closure that is more easily adapted to engineering use than existing methods. Figure 5 outlines a proposed modelling approach based on EP theory which takes account of all the key variables, including wave statistics, slope and grain size and could provide useful estimates of closure at all engineering scales (small, medium and large scales).

A preliminary investigation on the possible timescale dependency of the equilibrium profile was undertaken using wave data from Duck. A 13-year long time series of waves measured every 6 hr was used. The approach of Larson and Wise (1998) for non-breaking conditions was adopted to evaluate the EP using the wave climate resulting from a period ranging from one month to 12 years using steps of one month. Clearly the significance of the statistics for one month is lower than that for

</table>
the statistics of twelve years; nevertheless we expect such an approach to give an
indication of possible trends or of the possible changes of the EP. We expect such
computations to be significant as the one month time-step is considered to be
sufficient for the profile to respond to the most significant storms.

Figure 5. Proposed method to model depth of closure using EP theory

The resulting EP data were analysed using Principal Component Analysis; in
Figure 6 the behaviour of the First Principal Component is shown as a function of time. It
is interesting to note that it stabilises after 4 years. While we must interpret such results
with caution, from this simple analysis it appears reasonable to conclude that when the
whole profile is considered an (engineering significant) EP requires several years to
become established.

Larson and Wise
(1998) have derived a composite EP where the equilibrium shapes differ in the surf zone and offshore zone (compare Inman et al. 1993). The typical break point location separates the two zones; in the surf zone the Dean (1977) EP is employed, while in the offshore zone a lower exponent (0.3) is used. Two empirical shape parameters (A and B) define the composite EP: in the surf zone the shape parameter (A) depends primarily on grain size; and in the offshore zone shape parameter (B) depends mainly on the typical depth at breaking. Thus, if the characteristic wave conditions are known in the offshore, the break point may be calculated and the composite EP could be constructed from knowledge of the grain size. The composite EP includes one mobile bar related to the break point, and so captures some of the bar dynamics raised by Figure 1. For a series of offshore waves a corresponding series of EP may be computed from which statistical properties describing profile variability at different cross-shore locations can be derived.

In order to evaluate this method to compute profile variability, data from Duck was again employed. The time series of waves was used to compute the corresponding EPs for various values on the shape parameter B (A was set to 0.1, which approximately agrees with the grain size at the site -- 0.2 mm (see Larson, 1991)). The conditions at breaking were computed from the significant wave height and peak spectral period in the offshore using the formula given by Larson and Kraus (1989) and a ratio between wave height and water depth at breaking of 0.78. From the generated time series of EP the standard deviation was computed. Figure 7 displays this quantity for two different values of B and compares it with the standard deviation for profile lines 62 and 188 at Duck. While the qualitative form of the results is encouraging, they clearly illustrate that some aspects of the method need to be improved before reliable quantitative results can be obtained. For example, no attempt was made to translate the shoreline in response to changing wave conditions in the model leading to zero standard deviation at the shoreline in marked contrast to the data. Also, since the composite EP responds instantaneously to the wave conditions much more depth variation is predicted in deeper water than is observed. However, these two deficiencies in the model could be remedied by introducing a mobile shoreline (depending on the wave conditions) and a response function that takes into account the increasingly lagged response of the profile with depth. After the introduction of these features a simple EP based model may be used to theoretically determine the profile variability from which statistically defined depth of closures could be derived.
CONCLUSIONS

Closure is a time- and space-scale dependent concept and hence, the controlling processes also vary with scale. Therefore, while closure is an empirically simple concept, its prediction remains difficult. For specific scales and circumstances, robust tools are already available. Equation 1 defines a limit to observations using a 6-cm depth change criterion for erosional events and at annual timescales, assuming limited net profile translation. As timescale increases above one year, so Equation 1 tends to increasingly overpredict the actual closure. This reflects a change in the processes that control closure from cross-shore bar migration to net gains and losses of sediment (and the resulting profile translation) and ultimately, shoreface processes. At sites with sufficient data, empirical methods to predict closure can also be developed as a function of different depth change criteria. These relationships may be applied at other sites with caution. They also illustrate the utility of treating depth change as a variable which can be of benefit to endusers.

Further analysis is required and this includes continued data analysis and preparation of calibration datasets (cf. Table 1). In addition, new robust modelling approaches are required which can generalise the different factors which influence closure over the range of engineering timescales. The equilibrium profile theory approach presented here is one promising method for quantifying profile variability over these scales.

Short-term relatively deep sedimentation on the Ebro delta coast.
Opening the closure depth

Vicente Gracia¹, José A. Jiménez¹, Agustín Sánchez-Arcilla¹,
Jorge Guillén² and Albert Palanques²

Abstract

Morphological changes at the shoreface of the Ebro delta have been analysed
with emphasis on the Trabucador barrier, using two types of approximations: (i) an
aggregated-scale approach, i.e. by evaluating the depth of closure from comparison
of beach profiles from a data set of 4 years and, (ii) a process-oriented one, where
changes are analysed in terms of driving factors and resulting sediment transport
from a small scale experiment. Results from the depth of closure analysis show that
acting processes are restricted down to an average depth of 6.5 m, with an important
spatial variability. A year with high energy contents gives same results than using the
whole data set. A sedimentation of about 7 cm was detected during the small scale
experiment at 8.5 m and 12.5 m depth under the passage of several storms. The
analysed velocity field and sediment flux showed that onshore transport close to the
bottom and offshore transport in the upper part prevailed under storms. These forcing
conditions were similar to the registered in previous analysis although no
morphological changes were previously detected. Results show that the depth of
closure analysis is a good starter point to define morphological activity in the
nearshore profile, but it has to be complemented with other type of approaches such
as the process-oriented one to accurately define the limits for morphological activity.

Introduction

The closure depth is a common concept, which is usually applied in coastal
morphology studies. Basically it consists in the determination of a depth beyond that
no significant changes can be detected in the bathymetry. Recently, some authors
have introduced the effect of the temporal scale to permit its variation as the time
scale increases and, as a consequence, the probability of occurrence of more energetic
wave states (Nicholls et al. 1996).

2902
One of the intrinsic problems is that profiles used to estimate closure depth usually do not have a good temporal resolution or, its spatial coverage does not permit to measure the deepest part of the profile, which implies to make an initial assumption of negligible variation.

Recently, Gracia et al. (1998a) have estimated the averaged medium-term (at the scale of several years) closure depth along the Ebro delta coast to be about 7.5-8 m. Their estimations were based in the analysis of beach profiles down to 15 m depth taken every 3-4 months during a period of 4 years. During that time span, several very energetic storms impacted the Ebro delta coast although no significant deep changes were observed in the surveyed profiles.

However, in a very recent experiment, in which two instrumented tripods were deployed on the Ebro delta shoreface at 8.5 m and 12 m depths (figure 1), an "unexpected" behaviour was observed (Jiménez et al. 1997a; Guillén et al. 1997), resulting in a sedimentation of about 7 cm at both places.

It is the aim of this paper to characterise the depth of closure at a medium term scale and to link it with the observed "deep" bottom changes. To do this, a process-oriented analysis of this sedimentation event is presented. The results are compared to estimates of the medium term depth of closure for the area.

Study Area

The Ebro delta is located on the Spanish Mediterranean coast, with a 50 km sandy shoreline with two spits at the north and southern part (see figure 1).

Figure 1. The Ebro delta. Arrows indicate Tripod deployment.
At present the delta is a micro-tidal wave dominated environment with an astronomical tidal range of about 0.25 m, being the average significant offshore wave height of about 0.7 m with an associated mean period of 4 s (Jiménez et al. 1997b).

Cross-shore distribution of sediment grain size (Guillén and Jiménez 1995) shows a finning trend offshore with medium sands (250 μm) at the shoreline to very fine sands (125 μm) at 12 m depth. At about 15 m depth there is a mud belt surrounding the delta and in consequence the system can be considered as close at the present evolutive state.

A typical cross-shore profile of the area shows up to 3 bar systems which have experienced in some sites an important longshore growth (Guillén and Palanques, 1993; Gracia et al. 1995).

The study is focussed in a barrier beach, the Trabucador bar, located at the southern part of the delta which has a length of about 5 km, a width between 150 m to 200 m and a height above the mean sea level of 1.5 m.

Medium term closure depth

The Medium term closure depth has been analysed by Gracia et al. (1998a) using a set of bathymetric profiles surveyed every 3 to 4 months from 1988 to 1992, which basically consists of 36 nearshore profiles spaced every 1-2 km reaching depths up to 15 m. Two techniques were used: a topographic survey for the inner part and a vessel with echo-sounder with a positioning system for the deeper one, giving a nominal accuracy of ± 5 cm, which defines a non significant change threshold value of 10 cm (the best case).

![Figure 2. Wave energy events during the surveyed period and associated direction, from visual observations at Casablanca oil ridge.](image)

The analysis has been done in three different time frames according to the wave energy conditions observed during the surveys (see figure 2). The first window corresponds to fair-weather year with a moderate wave energy content. The second is defined as a year of high energy conditions, with several eastern storms, where one of them impacted the coast producing the breach of the barrier (Sanchez-Arcilla and Jiménez, 1994). This high-energy event had a significant wave height of 4.5 m and peak period of 10 s, being the associated return period of 10 years. Finally, the depth of closure has been analysed using the overall data set, i.e. 4 years. Moreover within
these 3 time frames the Hallermeier formula was also tested. The equation was fed with the corresponding local significant wave height propagated from offshore to 10 m depth for each profile, in order to have a more realistic characterisation (in terms of nearshore waves) and to account spatial variability in wave conditions due to changes in bathymetry.

Among the different methods analysed by the authors by comparing cross-shore profiles the standard deviation of bottom depths is presented here for the entirety coast (see figure 3). This technique is usually applied when a relative large number of campaigns are available, although they must be well distributed on time to avoid “false” values. Moreover, the standard deviation is the most proper technique to retain short-term changes, i.e., the highest variability (Gracia et al., 1998a).

![Figure 3. Depth of closure for the Ebro delta coast using the standard deviation method applied at three different time frames (Trabucador bar indicated in a window).](image)

As expected, the fair-weather year presents the lowest values being the average closure of about 4 m depth for the central part of the barrier with a maximum value of about 5.5 m. The resulting closure using the Hallermeier equation at this time windows was almost constant along all the barrier and about 6 m depth. For the stormy year an average depth of closure ($d_c$) of about 6 m was found whereas the predict $d_c$ was about 6.5 m. Using the overall data set similar values of $d_c$ were
obtained. In any case, the Hallermeier equation over predicts the values obtained by comparing profiles, and these differences are greater in the Trabucador bar.

Another aspect that must be pointed out is the high spatial variability in the estimated $d_c$. This is, the spits, and, in the area of interest at the Trabucador bar, which maintains a more or less constant value in the central part while at the ends of the barrier there is an important increase, with independence of the time span analysed.

As a summary, looking at the aggregated scale, i.e. morphological changes, most of the acting processes in the area of study are important (in terms of the observed changes) down to 6.5 m depth (as an average value), i.e., the estimated medium-term depth of closure. However, since this $d_c$ has been obtained from a discrete set of data, this result can not be generalised without including some "confidence band", since changes between surveys are not recorded unless they are reflected in a longer time scale. Moreover, it has to be stressed that $d_c$ does not represent a limit for sediment movement and, in this sense, it can not be used as an indicator of sediment mobility.

![Figure 4. Forcing conditions during the inner shelf campaign at the shallowest position (8.5 m depth).](image)

**Inner shelf experiment**

From December'96 till January'97 an inner shelf experiment was carried out in the surveyed area (Trabucador bar), which basically consisted in the deployment of two instrumented tripods at depths of 8.5 m and 12.5 m (see fig 1 for location). The basic configuration was, three bi-axial electromagnetic current meters (Delft...
Hydraulics, 1993) and three optical backscatterance sensors (D & A Instruments, 1991), placed at 0.1 m, 0.5 m and 1 m above the bottom, an absolute pressure transducer (Druck PDCR-1830) and a compass (KV Industries C-100). The sampling interval selected during the experiment was 1 Hz obtaining data during 20 minutes every 3 hours (see Jiménez et al., 1998, for further details). Additionally, the outer tripod had a Doppler current meter with a nephelometer. Before deployment and after recovery, bottom surface sediment and core samples were taken.

The wave and atmospheric conditions are summarised in figure 4, up to six consecutive moderate storms can be identified with significant wave heights up to 3 m and associated peak periods from 4 s to 10 s. These storms mobilised large amounts of sediment, reaching near-bottom suspended sediment concentration up to 8 gr./l. The resulting morphological response was a sedimentation of about 7 cm at both locations.

The surface granulometric distribution obtained before and after deployment in the inner site shows a very small change in fine percentages of 1%, a slight increase in mean grain size (from 150 μm to 160 μm) and better classified sediments. On the other hand, in the deepest site (12 m depth) the fines percentage drastically increased (from 15% to 40%), the mean grain size decreased from 90 μm to 30 μm and the sediment was better sorted (decrease in deviation).

Figure 5. Vertical distribution of core samples before and after recovery. From left to right 8.5 m and 12.5 m depth deployment
Figure 5 shows the vertical distribution of fine percentages and median diameter at both locations before and after tripod recovery for the first 20 cm below the bottom. In the inner site, the median diameter is almost the same whereas the fine percentage increases in the upper part reflecting the changes observed in the surface samples. The highest variations are detected in the outer location, where, in the upper layer there is a significant decrease of the grain size diameter with an associated increment of fines of about the 40%.

Therefore, the resulting morphological response of the energetic conditions during the surveyed period was visible and, in principle, if it was “permanent” has to be detected in the previous analysis. However, wave conditions are not more energetic to those covered in the analysis of $d_c$ for the stormy year.

![Graph](image)

Figure 6. Near-bottom cross-shore velocity at 8.5 m depth and initiation of sediment movement according to Shields criteria.

To study the capacity of mobility of the monitored conditions, a detailed process-oriented analysis is done. The objective is to see if hydrodynamic conditions and resulting sediment transport were important enough to explain such sedimentation. Figure 6 shows the near bottom velocity (10 cm) at 8.5 m depth where the pass of the different storms are reflected. According to the sediment characteristics for the area it can be seen that during most of the time the threshold value for initiation of movement (according to the Shields criteria) was exceeded in a significant manner, i.e. there was a high capacity of transport. Considering the third order velocity moment as an indicator of the transport capacity (figure 7) it can be seen that during the storms it was significantly different from zero and directed onshore (negative values in the figure).

Computing the mean and total cross-shore sediment flux directly from the measurements at 8.5 m depth (see figure 8), the impact of the different storms at all elevations can be identified, more evident at the lowest level. However a differential behaviour is detected in the water column: close to the bottom, most of the transport is directed onshore whereas in the upper part some reversals can be observed. These reversals were found to be related to the presence of seaward directed currents due to the presence of strong wind blowing offshore (Jiménez et al. 1998). Preliminary analysis of the vertical structure of the current showed that under certain conditions (just after storms), the mean current close to the bottom (0.1 m) was onshore whereas in the upper part of the water column was offshore (Gracia et al. 1998b).
Figure 7. Third order velocity moment at 10 cm above the bottom for the 8.5 m depth deployment.

Figure 8. Cross-shore transport rates (gr./l-m/s) at 8.5 m depth. From top to bottom, 1 m, 0.5 m and 0.1 m above the bottom.

Mean current (assuming waves energetic enough to mobilise the sediment) mainly controls sediment flux but during storms the asymmetry of the wave-induced
velocity field increases and largely contribute to it. This can be clearly seen in figure 8, where the contribution of the mean current to the total transport increases towards the surface due to an increase in current speed whereas oscillatory velocity is almost the same.

The longshore component (see figure 9) shows a more or less similar pattern. It is mainly directed towards the north changing the direction during the pass of storm events.

![Figure 9. longshore transport rates (gr./l-m/s) at 8.5 m depth. From top to bottom. 1 m, 0.5 m and 0.1 m above the bottom.](image)

**Summary and discussion**

Results of the depth of closure analysis show that at the aggregated-scale, morphological changes in the study area (Trabucador bar) are restricted down to an average depth of 6.5 m. However, in a yearly scale analysis, the deepest closure is obtained for high energetic periods, which fully control this depth when a longer time span is considered, i.e. the time window is not relevant per se but the energetic conditions during the considered time frame. Moreover, a high spatial variability in \(d_c\) was found, mainly at the spits and the area of interest (Trabucador Bar), the former presenting deepest values and the latter showing an important decrease. Thus, the Trabucador bar is usually overwashed during E storms (two to three times per year) which can "subtract" energy from the outer coast resulting in a decrease in the magnitude of the return flow in the upper shoreface. This could explain the shallower depth of closure values obtained in the central part of the barrier, in comparison with those observed at the barrier ends.
When a deterministic approach such as the Hallermeier's method is applied, an overprediction of the depth of closure is obtained. In this sense, it is a conservative choice for engineering purposes. However, it is not able to reproduce the actual spatial variability unless other factors such as the evolutive behaviour of each coastal stretch or alongshore variability in wave conditions are considered.

Thus, results following this approach seems to suggest that the maximum depth for morphological changes is restricted to 6.5 m. However, during an experiment at the inner shelf, a sedimentation event of about 7 cm was detected at 8.5 m and 12.5 m depth. This occurred under the action of several storms in one month, but the energetic content of the storms did not exceed the recorded in previous data (those included in the previous analysis). A detailed analysis of the velocity field and the sediment fluxes close to the bottom showed a strong sediment mobility, specially under the storms. In a general manner, onshore sediment transport close to the bottom and offshore transport in the upper part of the water column prevailed during storms. The high mobility as well as the magnitude of the sediment concentration measured during the experiment are able to explain the observed changes, including the variability of the sediment grain size distribution in the first cm of the bottom layer.

Since the forcing conditions during this small scale experiment are relatively frequent in the area (at least one per year), this type of "deep" changes should be relatively frequent, although they had not been detected at the aggregated scale analysis. The only way to do it, is by increasing the frequency of profile data acquisition (covering periods before and after storms) and reaching the deeper parts of the profile.

As a summary, although depth of closure is a good starter point to define morphological activity in a nearshore profile, the analysis has to complemented with other type of approaches, not only to define the limit of sediment transport (which in fact cannot be considered as included in the depth of closure analysis) but also to characterise the induced changes.

Abstract

Depth of closure has been identified and its characteristics investigated over larger temporal (≥ 25 years) and spatial (< 100 kilometres) scales than previous research. In addition to the 'normal' shoreward closure produced by breaking waves and cross-shore bar migration, at longer timescales (≥10 years) shoreface morphodynamics also produce significant profile changes. The shoreward closure is primarily controlled by wave breaking with a secondary control of bar morphodynamics. Shoreface changes are slow and steady and as timescale increases, so more profiles exhibit re-opening in depths typically greater than 10 metres. This is then usually followed by the re-closure of the profile on the middle/lower shoreface. Such phenomena have not been observed in past studies of this type and result from the large temporal and spatial extent of the data set used here. Over long time scales (≥ 10 years) such changes have a coastal engineering significance.

Introduction

The application and scope of coastal engineering schemes i.e. shore protection and land reclamation, is increasing. For example, the present Dutch coastal policy is to maintain its coastline at its 1991 position for the foreseeable future. In order to ensure the long-term reliability of such projects it is vital that coastal evolution over the same temporal scale is understood. So, with the advent of focused research within this field, many relevant concepts are being developed through both observation and predictive techniques.

*Flood Hazard Research Centre, Middlesex University, Queensway, Enfield, Middlesex, EN3 4SF. United Kingdom
A key concept in beach morphodynamics is depth of closure (Dc). Dc represents the "seaward limit of 'significant' depth change" (Nicholls et al., 1996); it does not, however, refer to an absolute depth beyond which there is no cross-shore sediment transport. Therefore, it is seen to act as a morphodynamic boundary separating a landward, morphodynamically active region from a more seaward inactive region, where vertical changes are less than the criterion chosen to define closure. (Figure 1.)

![Diagram](image)

Figure 1. Zonation of a cross-shore profile over time \( t \) where Dc represents the seaward limit of significant depth change using the depth change criterion shown (adopted from Hallermeier, 1981).

Dc is of fundamental importance in coastal sediment budgets and associated applications such as beach and shoreface nourishment. Specific examples of its use are; i) as a boundary between active and inactive zones it allows for the correct placement of offshore mounds; location in the active region could provide material for onshore feed (Hands and Allison, 1991); and ii) as the limit of morphological change enabling the volume of beach fill material to be calculated (Davison et al., 1992).

In this paper the Large Scale Coastal Evolution concept of Stive et al. (1990) is used to distinguish different scales of closure behaviour. The three scales are i) Large-Scale which has a morphodynamic length scale of 10 km and time scale of decades; ii) Medium-Scale with a morphodynamic length scale of 1 km and time scale of years; and iii) Small-Scale which has a morphodynamic length scale of 100 m and time scale of storms to seasons.

Closure has previously been investigated on the Medium-/Short-Scale (Garcia et al., 1997; Nicholls et al., 1996, 1998; Nicholls and Birkemeier, 1997). For example the Duck, North Carolina data has a 12 year time span and extends 1.2 km alongshore and 0.8 km cross-shore (Nicholls et al., 1996). These investigations have shown that Dc is time- and space-scale dependant (cf. Capiobianco et al., 1997). In particular, as the time interval increases then closure increases in depth.
The control of the extreme wave conditions upon closure is used in the analytical Hallermeier (1978) model to predict $D_c$. It has been adapted to a time-dependant form:

$$d_{s,t} = 2.28H_{s,t} - 68.5 \left( \frac{H_{s,t}^2}{g T_{s,t}^2} \right)$$

(1)

where: $d_{s,t} =$ closure ($D_c$) (referenced to MLW); $H_{s,t} =$ significant wave height exceeded 12 hours per $t$ years; $T_{s,t} =$ associated wave period; and $g =$ acceleration due to gravity.

Field validation of Equation 1 has shown that it provides a limit to the observed closure on micro-tidal, wave-dominated, sandy coasts during i) storms; and ii) annual periods (Nicholls et al, 1996, 1998). This suggests that spatially similar regions of closure will exist; a less energetic hydrodynamic environment will result in shallower closure values than those in a more energetic environment (cf. Marsh et al, 1998).

Most closure studies are limited to the surf zone and upper shoreface due to survey constraints (a maximum depth of 8m is reached at Duck, North Carolina; Lee et al, 1998). The JARKUS data set used here offers the opportunity to extend analysis to the Large-Scale; 100 km alongshore, 25 years (1965 to 1990) and 16 m depth. In addition this will allow the existence of 'significant depth changes' on the shoreface at depths exceeding previous observations of closure to be investigated (as previously recognised by Stive et al, 1990).

**Study Area**

The study area is the Holland coast bound from Den Helder in the north to Hoek van Holland in the south. (Figure 2.) It is a closed coast uninterrupted by tidal inlets or barrier islands, allowing the determination of $D_c$ characteristics in a wave-dominated, alongshore uniform environment. Anthropogenic interventions are mainly smaller-scale beach nourishment schemes, although the Petten sea dike (km 20 - 26) and Ijmuiden harbour moles (km 55/56) are present in the north and centre of the coast, respectively.

The study area is a micro-tidal, wave-dominated sandy coast with multiple bars. The bars extend to a maximum depth of approximately 8 m. The mean tidal range is 1.4 m in the north increasing to 1.7 m in the south. Peak tidal velocities generally do not exceed 1 ms$^{-1}$. The annual mean wave height is 1.2 m (associated wave period 5 sec); whilst the extreme annual wave height is 5.3m (associated wave period 7.7 sec) (Roskam, 1988). The wave climate is relatively similar along the length of the coast, deviations in wave height from north to south are in the order of 0.2 m.

Cross-shore bathymetric measurements have been measured by the Rijkswaterstaat since 1963 at regular, fixed locations alongshore. The measurements are held within the JARKUS data set. They have a vertical accuracy of 0.25 m which is the standard
deviation of the measurements, as determined within this study. An independent study, using both stochastic and systematic error sources, has also determined the accuracy of the data to be 0.25 m (Nanninga, 1985). Annual (short) profiles extend 0.8 km seaward, equivalent to a depth of approximately 6 m, with alongshore spacing of 0.25 km. In addition there are five-yearly long profiles ('doorlodingen') which extend to a minimum 2.5 km seaward, equivalent to approximately 15 to 16 m depth, and have an alongshore spacing of 1 km. (Figure 3.) It is due to the greater cross-shore extent of the doorlodingen that it is analysed in this study; primary analysis indicates that Dc is not observed in the annual data even over a 1 year period. In addition, the most northern and southern profiles are rejected due to the tidal influence of the Marsdiep and the Europort inlets, respectively. The total study area therefore covers an alongshore distance of 81 km (km 16 to 97; Figure 2).

![Location map showing the closed Holland coast.](image)
Figure 3. Example of the bathymetry along the closed coast using the doorlodingen from 1965 and 1990, located at km 31 (Noord-Holland).

Data Analysis

Values of $D_c$ have been derived using two methods: i) the standard deviation of depth change (Kraus and Harikai, 1983) and ii) the fixed depth change (Nicholls et al, 1996). This analysis has been performed for all profiles over a range of temporal periods, 5, 10, 15, 20 and 25 years.

**Standard deviation of depth change (sddc)**

This is a simple method, effective in both dealing with large data sets and removing bias from outlying values. Variation in the standard deviation of elevation is shown as a function of the cross-shore distance for $x$ number of profiles from the same alongshore location. $D_c$ is then equated to that point at which the standard deviation reaches a constant, non-zero tail, which often has a value of about 0.25 m (the measurement accuracy). (Figure 4.)

Figure 4. Sddc for km 31 which exhibits closure at a seaward distance of approximately 0.8 km for all time periods. ($D_{c5yr}$ ≈ 8 m depth; $D_{c20yr}$ ≈ 9 m depth)
Fixed depth change (fdc)

Dc can also be equated to that point at which, for 2 profiles from the same location, the depth variation is equal to, or less than, a pre-selected criteria. Here two criteria are selected: 0.25 m and 0.5 m. This means that there is 66% and 95% confidence that a real change in the bathymetry has occurred, respectively, assuming that the data measurement errors are normally distributed with a standard deviation of 0.25 m.

Results

General

Both methods produce similar results for all profiles along the Holland coast; the fdc criteria of 0.5 m generally gives the more landward value of closure as it allows the greatest depth variation.

Upon the examination of all results it became apparent that, in some instances, not only does the profile close at some distance x from the shore, but the profile re-opens and then usually re-closes towards its seaward limit. Such behaviour can be most clearly seen using the sddc plots. (Figure 5.) These phenomena are hereafter termed i) the shoreward closure (Dc_s), ii) the re-opening point (Ro) and associated re-opening zone; and iii) the middle/lower shoreface closure (Dc_ml), respectively. Re-opening is only observed over the longer time scales (>10 years) and at distances offshore greater than 1.5 km (typically 12 m water depth). In addition, as the temporal period is increased the number of cases in which this behaviour occurs increases (18% of profiles re-open after 10 years increasing to 37% over 20 years).

Large-Scale Behaviour

All three ‘modes’ of behaviour only exist in temporal periods greater than one decade; therefore the observed behaviour during the 20 year period will be concentrated on here. The results from both methods show similar spatial behaviour. (Figure 6.) However, the sddc method does give a greater proportion of profiles which do not close; as sddc depends on a self-selecting non-zero tail, it was hard to extract exact values of the re-opening zone and middle/lower shoreface closure using this method. A fixed non-zero tail could overcome this problem and may be used in subsequent analysis.

Shoreward closure

It is apparent in Figure 6 (a) and (b), that two distinct alongshore regions exist. The first is in the north (Noord-Holland), and can be sub-divided into two; km 16 to 24 and 25 to 54 where Dc_s is quite deep (x = 8.5 m) and erratic. In the south (Zuid-Holland), km 55 to 97, a different regime is observed; Dc_s is shallow (x = 5.0 m) and relatively

constant in depth. (Table 1.) Interestingly, the regions observed here are bound by the two major anthropogenic influences on this coast; the Petten sea dike (km 20 - 26) and Ijmuiden harbour moles (km 55/56).

Table 1. Characteristics of the shoreward closure over 20 years in the 3 regions, as given by the fdc criteria of 0.5 m.

Application of Hallermeier (1978)

The shoreward closure can be compared with a value calculated using Equation 1. The input data is a time series of wave heights and associated periods measured over a five year period at a station offshore from Ijmuiden, in 18 m water depth. Given the alongshore similarity of the wave climate this is a reasonable comparison for all observed Dc. The calculated value for this study is 9.2 m (relative to MLW) over a 5 year period (1980 to 1985). (Hydrodynamic data is insufficient at present to allow calculation over a 20 year period.) This predicted value is a limit to the observed value over the same period, and over 20 years (Table 1), and is consistent with the behaviour observed in earlier studies and Marsh et al (1998).
Re-opening and middle/lower shoreface closure

The re-opening zone represents a ‘significant’ depth change on the shoreface, as defined by the criteria selected. This behaviour is typically followed in the cross-shore by middle/lower shoreface closure. Those instances in which it does not re-close may result from data limitations. It is hypothesised that if the measurements were extended in the seaward direction then re-closure would be observed.

Re-opening does not occur along the whole of the Holland coast. (Figure 6.) It occurs in four alongshore zones defined in Table 2.

Discussion

General

This data has shown a shoreward closure in 5 m to 8 m depth similar to that observed at other sites such as Duck, North Carolina (Nicholls et al, 1996, 1998). As the time scale increases it has also shown significant profile changes seaward of this shoreward closure.

Shoreward closure

$Dc_s$ appears to be primarily a function of sediment movement under extreme breaking waves (cf. Nicholls et al, 1996). Comparison of closure predicted with Equation 1 and that observed on the Holland coast suggests that this is also true here. These preliminary calculations show that Hallermeier (1978) can be used as a predictive tool for the seaward limit of $Dc_s$ along the Holland coast. Similar results have also been observed in past studies; at Terschelling, The Netherlands (Marsh et al, 1998) and Duck, North Carolina (Nicholls et al, 1996, 1998). Interestingly, $Dc_s$ does not appear to increase with time scale as rapidly as Equation 1 would suggest.

Alongshore variation of closure defines two main regions; i) Noord-Holland, which can be further sub-divided into two, and has a mean closure of 8 m; and ii) Zuid-Holland which has a mean closure of 5 m. This indicates that processes, in addition to extreme waves, exist which play a role in the morphological behaviour of the active zone over time scales greater than 5 years. Other factors which have been shown to be of some importance in past studies are i) pre-event outer bar volume (at the Small-Scale); and ii) sediment budget (at the Middle-Scale) (Nicholls and Birkermeier, 1997).
Scale); and ii) sediment budget (at the Middle-Scale) (Nicholls and Birkermeier, 1997). Wijnberg (1995) classified the Holland coast using bar behaviour, defined using eigenfunction analysis which shows both i) the different time scales of active bar behaviour; and ii) the along- and cross-shore migratory behaviour. For the area studied here, three regions of similar behaviour were observed; 1) km 16 - 23; 2) km 24 - 55; and 3) km 57 - 97. These directly correlate with the three regions identified using Dc. (Figure 7).

The multiple bars in Holland migrate offshore at different rates and ultimately disappear; the morphological cycle repeats every 15 years in regions 1) and 2) (Noord-Holland) and every 4 years in Zuid-Holland. The degeneration of the outer bar in the Noord-Holland system occurs at a greater depth than in Zuid-Holland. This agrees with the greater closure depths observed in Noord-Holland as compared to Zuid-Holland. It is therefore concluded that shoreward closure is primarily controlled by extreme breaking wave conditions with the bar morphodynamics acting as an additional control, similar observations have been made on the meso-tidal barrier island of Terschelling, The Netherlands (Marsh et al, 1998).

Re-opening and middle/lower shoreface closure

This behaviour has not been systematically observed in previous studies. Activity on the shoreface has, however, been recognised in past studies (Stive et al, 1990), although the processes which control this behaviour are poorly understood. The occurrence and size of the re-opening zone is seen to be time-dependant; as the time period increases, the extent (both in the cross-shore distance and degree of depth variation) steadily increases. This suggests that this behaviour is due to slow, cumulative change, rather than fast, infrequent events. Indeed, the middle/lower shoreface behaviour has been indicated to be morphodynamically weakly varying (Stive et al, 1990). In most cases the re-opening is associated with a local shoreface steepening. Roelvink and Stive (1990) and Stive et al (1990) have shown that the significant depth change observed on the shoreface represents the effect of the onshore transport of material to the active zone. The specific location of this phenomena within four zones along the Holland coast may help towards the identification of the controlling processes; at present only tentative correlations between process and response have been made. It is expected that this behaviour will be related to hydrodynamic parameters, as with the shoreward closure. It is hypothesised that it is the asymmetry of shoaling waves which are the primary influence, with an additional forcing introduced by tidal and wind-induced currents, which become more significant in the offshore (Komar, 1976; Stive et al, 1990).

In addition the two major anthropogenic structures along the closed coast, the Petten sea dike (km 20 - 26) and Ijmuiden harbour moles (km 55/56), are located in the two largest re-opening zones, km 16 -29 and km 47 - 72 respectively. These can influence offshore behaviour. The Ijmuiden harbour moles, which are 2.5 km in length, have influenced tidal excursion and so accretionary/erosive behaviour for substantial distances, tens of kilometres, from the structure (Roelvink et al, 1998). Other morphodynamic controls should be considered. For example, shoreface-connected ridges are present from km 45 - 65 (Van de Meene, 1994); coinciding with the
occurrence of re-opening. These ridges are mapped to minimum depths of 14 m although they may occur further onshore.

Figure 7. Alongshore correlation between the shoreward depth of closure (a) and bar behaviour (b) (as defined by eigenfunction analysis; Wijnberg, 1995).
Conclusion

The large temporal and spatial extent of the JARKUS data set has enabled Large-Scale closure behaviour to be determined. The profile closes at depths of 5 m to 8 m (shoreward closure). In addition, as the time scale increases significant profile changes are observed in four alongshore zones seaward of the shoreward closure; re-opening of the profile occurs and is typically followed in the cross-shore by middle/lower shoreface closure. All of the observed characteristics are temporally dependant.

Shoreward closure shows alongshore variation with deeper values observed in the north. It is hypothesised that $D_c$ is primarily under the control of wave breaking, as seen by the generalised value given by the Hallermeier (1977, 1981) formulation. An additional control is imposed by bar behaviour (Wijnberg, 1995). Profile re-opening and the subsequent middle/lower shoreface closure is identified in four distinct zones along the closed coast. The possible hydrodynamic, morphodynamic and anthropogenic controls are being investigated.

In addition to the obvious engineering applications of closure, e.g. for the calculation of beach fill volumes, the occurrence of the re-opening zone reminds users that significant depth changes can occur seaward of the shoreward closure. It is vital that this is taken into consideration by engineers, especially over decadal and longer time scales.

Depth of Closure and Seabed Variability Patterns

Grzegorz Różyński, Zbigniew Pruszak, Tomasz Okrój and Ryszard Zeidler

Abstract

A method of analysis of depth of closure and bed variability is presented in the study. Statistical analysis of measurements showed standardized depths are gaussian random variables. Repetitive measurements revealed peaked patterns of standard deviation of depth change and range between extreme measurements. They were approximated by a smooth functional type in form of a sum of exponential curves. The peaks were then associated with both the corresponding time scales and locations of bed features. The patterns can thus be used to identify segments of beach profiles controlled by events typical of given time scales. The tail of the outermost peak was extrapolated to evaluate decadal depth of closure.

Introduction

Depth of closure (Dc) describes the seaward limit of significant depth change (Hallermeier, 1978, 1981), basing on repetitive records of beach profiles showing that their vertical variability declines with increasing depth. It is therefore a morphological boundary between an active and non-active part of the nearshore zone over the period determined by observations of the profile. For high-quality data Dc is assigned to a point where depth changes beyond that point become small. The position of Dc is a function of several factors. The closure criterion, and the associated time scale are usually regarded as the most important ones, because the former frequently depends on data accuracy, whilst the latter deeply affects Dc per se; a fixed closure criterion moves offshore for increasing time scales. Dc can be defined for (i) single events e.g. storms, where surveys before and after the event are examined (ii) time interval change, where bed evolution between two routinely done surveys is investigated, or (iii) time integrated (cumulative) change, where the history of bed evolution can be traced, providing very ample datasets are available. The processes controlling Dc in the current study are associated with quasi-seasonal, annual and decadal time scales, given 10 years of available observations. The site was usually sampled twice a year, which matched the concept of time interval Dc.

Nicholls et al. (1997) investigated Dc upon a high-quality dataset, consisting of 12 years of systematic surveys, taken twice a month and after extreme events, which were collected at Field Res. Facility at Duck, NC, USA. The variability of beach...
profiles of that tidal shore \((m = 1.5\%, D_{50} = 0.2\pm0.4 \text{ mm})\) revealed the existence of peaked bed variability patterns. The analysis of a steeper \((m = 2\%, D_{50} = 1 \text{ mm})\), non-tidal shore of Thyrrenian Sea at Cecina Mare I, cf. Różyński et al. (1998) also detected the existence of at least one peak. Too short records failed to undoubtedly establish the position of 2\textsuperscript{nd} peak and \(D_c\) at that site. Since similar patterns were discovered for multibar, mildly sloping shore \((m = 1\text{ to }1.5\%, D_{50} = 0.22 \text{ mm})\) at Coastal Res. Facility (CRF) at Lubiatowo PL as well, the idea of generalized bed variability patterns is proposed in order to establish a universal concept of cross-shore variability.

The Lubiatowo Dataset

CRF Lubiatowo is a wave dominated, non-tidal sandy beach located on Polish coast of the Baltic Sea, some 80 km north-west of Gdansk. It is a natural, mildly sloping, dune type unit, which usually exhibits 3-4 longshore bars (Fig.1).

![Fig.1 Typical beach profiles at CRF Lubiatowo](image1)

![Fig.2 3-D picture of bar system at Lubiatowo in 1997](image2)
An ephemeral 5th innermost bar is sometimes observed, bars 1-3 are very stable, clear-cut features. They show little alongshore variability and perform some oscillations about their average positions (Pruszak et al. 1997, Pruszak & Różynski 1998). The outermost bar is a transitional entity between a typical bar and deep water sediment deposit. It exhibits high alongshore irregularities on its offshore slope (Fig.2), so the determination of Dc needs long surveys, because the irregularities show unexpectedly large variations. For average storms the significant wave height outside the surf zone (h = 7 m) reaches $H_s = 2+2.5$ m (3.5 m at the most) with the period $T = 5+7$ s. During shoreward transformations the wave height is only $0.5+1$ m and $T = 4+5$ s at depths $2+3$ m.

The bathymetric data applied in the analysis consists of surveys done along four neighbouring beach profiles between 1987 and 1996, spaced every 100 m and referred to as profile 4 (westernmost), 5, 6 and 7 (easternmost). All surveys are attached to a geodetic base in order to eliminate errors caused by a moving shoreline. The profiles were sampled with an echosounder, usually twice a year, more or less in the same time of spring and autumn, so quasi-seasonal and annual Dcs could be found. They all extend beyond the crest of the outermost bar, but few are long enough to capture the full, initially unexpected variability of its offshore slope. Only one survey was executed in 1991, 1994 and 1995, the 1991 records were too short for the Dc study and they were skipped. On the other hand, four surveys were done in 1987 and six in 1996, but only two of them for each of those years were selected for the Dc study (cf. Tab.1).

(+) - quasi-seasonal time scale, (++) - annual time scale

**Quasi-Seasonal and Annual DC**

Various criteria yield various estimates of Dc. A standard deviation of depth change ($\text{sddc}$) is a widely used criterion, provided the number of surveys $n$ sufficiently reduces the scatter of $\text{sddc}$ value. Its value at closure is usually chosen between 0.06 and 0.15 m. However, equations (1) and (2) indicate the scatter of $\text{sddc}$ declines very slowly, as the mean value is a random variable itself, and the $\text{sddc}$ precision is proportional to squared number of observations:

$$\bar{h} = \frac{1}{n} \sum_{i=1}^{n} h_i$$

(1)
Hence, it is better to apply a criterion which is less dependent on number of observations, such as the range of depth change ($rdc$), which quantifies the scatter between extreme measurements of given sample space. For Dc purposes this criterion was adapted in 'tight' and 'loose' variant i.e. 0.2 m and 0.3 m respectively. These values match well findings based on much more ample datasets (cf. Nicholls et al.,1997), where such $rdc$ corresponded to $sddc$ of 0.06 to 0.15 m.

Tab.2 presents quasi-seasonal Dcs between spring and autumn surveys (Fig.3). It shows that quasi-seasonal closures do not always occur, so even during summer period of a year the wave climate may be severe enough to produce quite substantial depth changes.

![Fig.3 Exemplary quasi-seasonal closure](image_url)

In most cases Dcs for loose criterion could be found on offshore slope of the outermost bar. However, their estimates for even neighbouring profiles vary to unexpected extent, e.g. profiles 4 and 5 in 1989 with Dc being equal to 6.6 m vs. 8.0 m respectively, or the same lines a year later, where Dc values are nearly ideally reversed (8.0 m vs. 6.3 m).
This indicates that local effects at offshore part of the outermost bar may play very important role in evolution of that part of the littoral zone even during apparently calm periods between late spring and early fall. This can be supported by routinely observed intermittent breaker patterns in the vicinity of 4th bar during stormy events, which profoundly influences local bed changes. For example the bed was so active in 1992 that no Dc could be found whatsoever. Consequently, high bed activity allowed for only few estimates of Dc for tight criterion. Tab.2 gives an overview of quasi-seasonal Dc as a random variable. It varies widely from 4.7 m to 10.7 m for tight, and from 4.6 m. to 8.7 m for loose criterion.

The only closing cases of annual Dc were obtained for autumn surveys of pairs 1989-90 (Fig.4) and 1995-96. These closures are rather shallow and valid for both tight and loose criteria, indicating rapid profile convergence. All this suggests a mild wave climate in winter seasons of those years.

![Fig.4 Exemplary annual closure](image)

![Fig.5 Exemplary annual non-closing case](image)
By contrast, huge divergence of 1992-93, 1993-94 and 1994-95 (Fig.5) profiles over deeper portions of littoral zone proves high wave action intensity. The closing cases show much lower variability of Dc at various profiles i.e. for 1989-90 it is equal to 5.5 m for profile 4 and 7 to 7.5 m for the other three. The 1995-96 is even more stable and equals 6 m for profiles 5, 6, 7 and 5.5 m for profile 4. Such a result suggests that local effects, clearly visible in quasi-seasonal closures, were averaged to some extent over annual periods. The estimated values provide information on lower limit of annual Dc, which is greater than most annual Dcs Nicholls detected in Duck between 1982 and 1993. Therefore, greater average annual Dcs should be expected, which can be explained by extending further offshore, more complex multibar system at Lubiatowo, than basically 2 bar shore at Duck.

General Statistical Properties of Beach Profiles

The surveys employed in the study extend 1000 m offshore with some exceptions, where the depths were recorded up to 1400m. This prevents direct, empirical assessment of decadal Dc. However, it still can be evaluated, if the existing records of offshore slope of the outermost bar share the same general statistical properties. To verify this, depths corresponding to offshore distances of 800, 850, 900, 950, 1000, 1050 and 1100 m from geodetic base were lumped together ignoring individual profiles. This could be done, because the geodetic base forms a straight line and is parallel to the shoreline, so offshore distances are generally retained. A family of standardized probability distribution functions was then constructed and plotted together with a normal pdf, (Fig.6).

Fig. 6 Standardized empirical pdfs of depths 800-1100 m offshore vs gaussian

It can clearly be seen that the distributions do not depart much from normal pdf. What is more important those departures seem to be normal themselves, i.e. some of them are positive and other negative at a given point with respect to gaussian curve. Thus, no systematic behaviour of pdfs can be detected, so it may be assumed they are all gaussian and share the same general statistical properties, although mean depths and their standard deviations vary with distance offshore. This finding implies that depth changes are caused by independently acting factors, (wave height and direction, duration of a
given wave climate, storms, breaker locations, longshore and cross-shore currents, bed configuration at a given time, etc.) It may thus be inferred that similar general statistical characteristics are retained further offshore, so the seabed variability pattern(s) can be analytically extrapolated.

The same pdf analysis was carried out for less remote depths 300 - 600 m offshore. It shows that also this part of beach profiles is generally gaussian (Fig.7). This finding is very interesting, because statistical normality of beach profiles allows for 2nd moment analysis with loss of no information. In other words mean depths and their covariance structure contain all probabilistic information on beach profile evolution.

\[
\sigma(x) \text{ or } r(x) = \sum_i a_i \exp[-b_i ((x - p_i)/p_r)^2]
\]  

To illustrate the concept, the two peak $sdde$ pattern for Lubiatowo was obtained for truncated surveys taken from 1964 until 1994. Even though these records are attached to a movable shoreline and lumped together, the pattern is still clearly visible (Fig.8).

In Eq.3 $p_i$ denotes the position of $i$-th peak on the profile, read from the line of standard deviations or ranges, the coefficients $a_i$ and $b_i$ need to be least square fitted. The peak positions can be associated with phenomena that occur in different time scales, the greater $p_i$ the longer the corresponding time scale. They may also be linked to characteristic profile features, such as bar crest, location of trough, etc. The bed
variability pattern can thus be used in order to identify segments of beach profiles controlled by events typical of given time scales, which can be done for each pair of \( a_i \) and \( b_i \). At locations sufficiently remote from the peak, the influence of that peak becomes negligible and it can be assumed the events associated with it no longer affect a beach profile at that location. Hence, such an analysis of the outermost available peak may determine the \( Dc \) associated with its time scale. In case when surveys do not reach the spot, where the tail of the outermost peak is sufficiently small, bearing in mind common general statistical properties of depths, the tail is extrapolated beyond the longest surveys and the bed equilibrium curve is employed:

\[
h = A \cdot x^{3/2}
\]  
(4)

The average value of \( A \) for the 1987-1996 period is equal to 0.084. The peak line of \( sddc \) or \( rdc \) Eq.3 converges towards the bed equilibrium curve Eq.4 and \( Dc \) associated with the outermost peak can be evaluated. Fig.9 shows raw \( rdc \) lines of 4th, 5th, 6th and 7th profile together with the line of average \( rdc \). Two clear-cut peaks, the greater one some 300 m and the smaller one at 580 m from geodetic base can be distinguished immediately. Interestingly, the inner one ideally corresponds to the position of 2nd bar crest, while the outer one perfectly matches the position of trough between 3rd and 4th bar (Figs.10a-d). They are both concentrated over small portions of beach profiles, which is a direct consequence of their link to very stable cross-shore locations of two morphological bed features. The 3rd peak is also visible, although it is very long and flat. It should not be surprising, because it matches the location of offshore slope of the outermost bar, which is very long and sometimes merges with sediment deposits further offshore. Since bed evolution of that part of the littoral zone is controlled by extreme storms, it should be expected that bed variability generating the outermost peak is spatially distributed. Its character is thus different from inner peaks, which are associated with firmly stable cross-shore bed features (crest of 2nd bar and trough between 3rd and 4th bar). Upon thorough scrutiny and the goodness of fit criterion, its
position was established at 1200 m from geodetic base, knowing that more long surveys will yield a better estimate.

![Graph showing distance from geodetic base vs. range](image)

Fig. 9 Rdc for profiles 4-7 with average rdc

![Graph showing collective chart of surveys for profile 4](image)

Fig. 10a Collective chart of surveys for profile 4 between 1987-1996

The fit for mean ranges produced quite a peculiar result; a three peak model was assumed but the combination of 2nd and 3rd one resulted in a plateau between them (Fig. 11). It slowly declines with distance offshore, so the decadal Dc can be evaluated by extrapolating the fitted line out of the existing surveys, cf. fitted functional type, Eq. 5.

\[
rdc(x) = 1.4 \cdot \exp\left[-1.8 \cdot \left(\frac{x}{300}\right)^2\right] + 0.5 \cdot \exp\left[-1.4 \left(\frac{x}{580}\right)^2\right] + 1.3 \cdot \exp\left[-\left(\frac{x}{1200}\right)^2\right]
\]  

(5)
The fit of Eq. 5 is very accurate, given $R = 0.85$ correlation between the model and data. Other attempts, aiming to retain the vivid 2nd peak produced results with worse goodness of fit, so they were skipped. Employing the bed equilibrium curve, a $D_c$ could be found for both 'tight' and 'loose' $r_d c$ criteria. For a 'tight' variant it lies some 2800 m offshore and equals 17 m vs. 2600 m offshore and 16 m obtained for its 'loose' counterpart. This estimate appears to be realistic, given extreme ranges recorded 1300 m offshore for profile 7 and 1400 m for profile 5, where the greatest depth of 12.5 m was recorded. By contrast, the longest survey, reaching 1500 m in 1988 for profile 7, revealed the depth of only 11 m. Knowing such high irregularities of offshore slope of 4th bar and the tendency to merge with sediment deposits further offshore, it can be believed that the decadal $D_c$ should lie much further offshore, and be quite great itself, as the extrapolation of bed patterns indicates.

![Fig. 10b Collective chart of surveys for profile 5 between 1987-1996](image)

![Fig. 10c Collective chart of surveys for profile 6 between 1987-1996](image)
evaluated, even though general statistical properties of depth between 300 and 600 m offshore are also gaussian. This however is not enough to assign a particular time scale to the innermost peak. The application of a tight \( rdc \) criterion shows that its tail practically disappears 600 m from geodetic base, corresponding to shallow \( Dc \) of 5.7 m. This value is equal to the most shallow quasi-seasonal \( Dc \), which clearly indicates that the innermost peak is in general governed by a shorter time scale. It could only be detected if the bed was sampled more than twice a year.

**Annual \( Dc \) and Hallermeier Formula**

\( Dc \) can also be calculated from extreme (deep water) wave conditions. Such computations can be done for different types of shores (tidal, non-tidal, one bar, multi-bar, etc.). In cases the \( Dc \) was established upon the analysis of bathymetric profiles, the approach basing on wave climate can be directly verified for a given shore type. Hallermeier, 1978, 1981 postulated that annual \( Dc \) can be assessed from the formula:

\[
Dc = 2.28 - H_s - 68.5H_s^2/g \cdot T^2
\]  
(6)

where \( H_s \) stands for significant, non-breaking wave height that is exceeded 12 hours in a year, \( T \) is the corresponding period and \( g \) is gravitational acceleration. The application of Hallermeier’s formula needs long-term deep water wave measurements. In case they are not available, wave parameters can be hindcast from existing wind records. Wind measurements were carried out between 1960 and 1986 at Hel Harbour, situated some 50 km east of Lubiatowo and they are deemed representative for Lubiatowo. Only wave heights were hindcast, but knowing that the 2\(^{nd} \) term in Eq.6 is usually close to unity, one may crudely assess annual \( Dc \) as \( 2.28 \cdot H_s - 1 \). Wave height hindcasts were calculated upon wind samples, which were obtained every three hours as averages of 10 minutes time window, from 1\(^{st} \) Jan. 1960 until 31\(^{st} \) Dec. 1986. Bathymetric data and reconstructed wave heights do not overlap in time, so it is not possible to directly compare the results from the same years. Moreover, eight daily records appear to be too crude to extract wave heights lasting 12 hours a year. Therefore, annual Hallermeier \( Dc \) estimates could only be found for a small subset of years, cf. Tab.3.

**Table 3 Hallermeier estimates of annual \( Dc \)**

The value of 7 m for 1984 and equally shallow empirical annual \( Dcs \) for 1989-90 and 1995-96 show that shallow annual \( Dcs \) are not uncommon and may occur quite frequently. On the other hand, two cases where 12 hour wave could be identified (1963, 1968) indicate that more severe wave climate produces realistic, deeper \( Dc \). Hence, Hallermeier’s criterion seems to provide a reliable assessment of annual \( Dc \) for multibar shore at Lubiatowo, which a bit contradicts Nicholls’es view, based on Duck study, that it is biased towards conservative bound of annual closures. It may be justified by high
Fig. 10d Collective chart of surveys for profile 7 between 1987-1996

Fig. 11 Generalized 3-peak seabed variability pattern for Lubiatowo

As mentioned before, each peak corresponds to a certain time scale and spatial distribution of the 3\textsuperscript{rd} peak implies it accounts for longer periods, such as decades. The time scale of the 2\textsuperscript{nd} peak can be found upon the following reasoning: if we skip the 3\textsuperscript{rd} peak and apply either tight or loose rdc criterion, we arrive at $h = 8.4$ or $7.7$ m respectively, calculated from Eq.4 for 1000 and 880 m offshore. General statistical properties of depths are the same, so it may be assumed that Dc associated with 2\textsuperscript{nd} peak is equal to some $8$ m. This value defines a boundary for time scale, which in light of tab.2 corresponds to quasi-seasonal variability. Hence, the 2\textsuperscript{nd} peak is generated by quasi-seasonal events. The time scale of the most conspicuous 1\textsuperscript{st} peak cannot be
complexity of bar system at Lubiatowo with highly irregular offshore slope of the outermost bar vs. fairly regular, basically two bar shore at Duck.

Conclusions

1. The analysed beach profiles are gaussian all over their cross-shore range, so their covariance structure contains the whole statistical information. The profiles at other sites are likely to exhibit similar behaviour.

2. Repetitive measurements reveal the existence of peaked profiles of \( rdc \) and \( sddc \). The peaks can be associated with relevant time scales generating them and can be analytically expressed by least square fitted sum of exponential functions. \( Sddc \) lines yield better description of profile variability, provided sufficient number of samples (50+) is available. \( Rdc \) lines need less samples to map profile variation, so they are handy in remote parts of beach profiles, where samples are usually scarce.

3. Statistical normality of beach profiles and their peak features permit to split beach profiles into segments associated with time scales of peaks.

4. Inner peaks correspond to locations of spatially concentrated bed features i.e. position of bar crest for the innermost peak and trough between two bars for the middle peak. The outermost peak corresponds to spatially distributed offshore slope of the outermost bar.

5. Temporal resolution of measurements prevents the evaluation of the time scale of the most conspicuous, innermost peak, so more frequent sampling would be needed to remedy this. The middle peak was identified as being driven by quasi-seasonal phenomena. The outermost peak is generated by much longer time scales of a decade or so, which is supported by its spatial distribution. Such distribution is characteristic for extreme events, where the whole profile, including its deeper parts, undergoes substantial evolution.

6. All detected Dcs that are situated outside the crest of the outermost bar, either on its offshore slope or on sediment deposits situated further offshore. Quasi-seasonal Dcs are equal to 5±10 m and exhibit significant alongshore variation, which shows the importance of local effects in short time scales. Only few annual Dcs were found between 5.5 and 7 m, and they seem to represent upper bound of annual Dcs. Alongshore variation, although visible, is much less pronounced than for quasi-seasonal cases. It is not surprising, because longer time scales average local effects. Longer surveys up to 1500 m offshore are recommended to establish a set of empirically determined annual Dcs, if gentle nearshore slopes with multi-bar profiles, similar to CRF Lubiatowo are examined.

7. Very high bed irregularity outside the crest of the outermost bar results in high estimate of decadal Dc (16±17 m), obtained from extrapolation of the outermost peak. The verification of this value would require very long surveys (3 km offshore) taken at least once a year over decades. Before this is done, an extrapolation based on the same general statistical profile properties, provides an unverified, yet based on realistic assumptions, assessment of decadal Dcs.

8. Hallermeier’s formula for annual Dc seems to work well for the case of multibar shore with very irregular offshore slope of the most seaward bar.

Abstract

A 2D-horizontal sediment transport energetics model is developed in this work for the evaluation of the wave-induced sediment transport. The time dependent energy equation is incorporated into a nonlinear dispersive wave model in order to simulate breaking wave propagation in the surf zone. Total immersed weight transport is related, through an energetics approach, to the total dissipated fluid power. Both the dissipation due to bed friction and, inside the surf zone, due to the wave breaking are considered. The methodology is applied to predict the longshore transport rate and to simulate the coastline evolution in beach nourishment scenario assuming a trapezoidal beachfill.

Introduction

Long-shore and cross-shore sediment transport due to wave action play an important role in various engineering problems. One of the most important problems is the wave and the wave-induced sediment transport effects on coastal environment in terms of the bed morphology changes.

There exist two main approaches for the estimation of the sediment transport rate inside and outside surf zone: the deterministic and the energetics. The deterministic models are based on the description of both the wave induced mean flow and the concentration of suspended sediment, usually using quasi 3D models and linear wave theory (deVried and Stive 1987, Katopodi and Ribberink 1992, Briad and Kamphuis 1993). The energetics approach is based on the idea that the sediment transport is related to the rate of energy dissipation of the flow (Bailard 1981, Roelvink and Stive 1989). In the present work the second approach is adopted.

E-mail: karambas@civil.auth.gr
A 2DH non-linear breaking wave model is developed based on the numerical solution of the time dependent wave energy equation which is incorporated into a Boussinesq model. The main advantages of the use of the Boussinesq type of equations are outlined below:

- A unified model, without the assumption of progressive waves, is used for non-linear wave refraction, shoaling, diffraction, reflection (presence of structures), breaking, dissipation after breaking, run-up.
- The equations are easily extended in deeper waters.
- The propagation of irregular waves is modelled including LFW and non-linear wave-wave interactions.
- Breaking wave induced current are automatically incorporated. Thus there is no need for additional current and sediment transport model (i.e. coupling of 3 models).
- 3D effects (inclusion of a 'mean' undertow) are present.
- The models can be extended for the simulation of sediment transport in swash zone.

For the evaluation of the sediment transport rate (i.e. bed load and suspended load) the Bailard (1981) theory is used as in the 1D version of the model (Karambas et al. 1995). Following the sediment transport calculations, the morphological changes of the sea bed are updated in the model according to the conservation equation of sediment mass.

2DH non-linear wave breaking wave model

Karambas (1996) incorporated the time dependent energy equation into a nonlinear wave model based on the Boussinesq equations in order to simulate breaking wave propagation in the surf zone. Extending the analysis in two dimensions the continuity and the momentum equations are written (Peregrine 1972, Madsen and Svendsen 1979):

\[
\frac{\partial \zeta}{\partial t} + \frac{\partial (Uh)}{\partial x} + \frac{\partial (Vh)}{\partial y} = 0
\]

\[
\frac{\partial (Uh)}{\partial t} + \frac{\partial}{\partial x} \left( \int u^2 dz \right) + \frac{\partial}{\partial y} \left( \int uvdz \right) + gh \frac{\partial h}{\partial x} = \frac{d^2 \partial^2 (Ud)}{2 \partial x^2} + \frac{d^3 \partial^3 U}{6 \partial x^2 \partial y} + \frac{d^2 \partial^2 (Vd)}{2 \partial x \partial y} - \frac{d^3 \partial^3 V}{6 \partial x \partial y} + \frac{\partial}{\partial x} \left( v_t h \frac{\partial U}{\partial x} \right) + \frac{\partial}{\partial y} \left( v_t h \frac{\partial U}{\partial y} \right) - \frac{\tau_{bx}}{\rho}
\]
\[
\frac{\partial (Vh)}{\partial t} + \frac{\partial}{\partial x} \left( \int_d u v dz \right) + \frac{\partial}{\partial y} \left( \int_d v^2 dz \right) + gh \frac{\partial \zeta}{\partial y} = \frac{d^2}{\partial x^2} \left( \frac{\partial^3 (Vd)}{\partial y^3} \right) - \frac{d^3}{\partial y^3} \frac{\partial^3 V}{\partial x^3} + \frac{d^2}{\partial x^2} \frac{\partial^2 (Ud)}{\partial y^2} - \frac{d^3}{\partial y^3} \frac{\partial^2 U}{\partial x^2} + \frac{\partial}{\partial x} \left( v_r \frac{h}{\partial x} \right) - \frac{\partial}{\partial y} \left( v_r \frac{h}{\partial y} \right) - \frac{\tau_{by}}{\rho}
\]

(1)

in which \( \zeta \) is the surface elevation, \( d \) is the still water depth, \( h \) is the total depth, \( u \) and \( v \) are the horizontal velocity components in the \( x \) and \( y \) directions respectively, \( U \) and \( V \) are the depth integrated velocities, \( v_r \) is the eddy viscosity coefficient and \( \tau_{bx} \), \( \tau_{by} \) are the bottom shear stresses.

The shear stresses are estimated from:

\[
\frac{\tau_{bx}}{\rho} = \frac{f_w}{2} u_o \sqrt{u_o^2 + v_o^2}
\]

\[
\frac{\tau_{by}}{\rho} = \frac{f_w}{2} v_o \sqrt{u_o^2 + v_o^2}
\]

(2)

where \( u_o, v_o \) are the components of the bottom velocity (adopting the velocity distribution given by Peregrine, 1972) and \( f_w \) a friction factor (Nairn and Southgate 1993):

\[
f_w = \exp(5.2 (r/\alpha)^{0.2} - 6.0)
\]

(3)

in which \( \alpha \) is the orbital amplitude at the bed and \( r \) is the bottom roughness:

\[
r = 170 \sqrt{\beta_{2.5} - 0.05} D_{50}
\]

(4)

where \( \beta_{2.5} \) is the Shields parameter for \( f_{2.5} = \exp(5.2 (2.5D_{50}/\alpha)^{0.2} - 6.0) \).

The equation of the conservation of the energy density \( E \) of the mean flow per unit horizontal area is written:

\[
\frac{\partial E}{\partial t} + \frac{\partial E_x}{\partial x} + \frac{\partial E_y}{\partial y} = -D - u_o \tau_{bx} - v_o \tau_{by} + U BT + V BT
\]

(5)

\[
E_x = \int_d \frac{1}{2} u^3 dz + \int_d \frac{1}{2} u^2 v dz + g \zeta U h,
\]

\[
E_y = \int_d \frac{1}{2} v^3 dz + \int_d \frac{1}{2} u v^2 dz + g \zeta V h
\]
The dissipation of the wave energy $D$ is given by (Karambas, 1996):

$$D = \Omega \ (c - u_{ot})^3$$  \hspace{1cm} (7)

in which $c$ is the wave celerity, $u_{ot} = \sqrt{v_o^2 + v_0^2}$ is the bottom velocity in the direction of the wave propagation and $\Omega$ a constant, $\Omega = 0.03$.

The eddy viscosity coefficient $\nu_t$ is calculated from the solution of the turbulent kinetic energy equation (Nwogu, 1996):

$$\frac{\partial k}{\partial t} + U V k = \nu_t \nabla^2 k + B D - C_d k^{3/2}/l_t$$  \hspace{1cm} (8)

in which $U = (U, V)$, $k$ is the turbulent kinetic energy, $C_d = 0.08$, and $l_t$ is the turbulent length scale, $l_t = 0.15 \ d$.

In the 1D case (Karambas, 1996) the constant $\Omega$ is equal to 0.015. In the present work a greater value ($\Omega = 0.03$) is adopted. This value (according to Morfett, 1995) is claimed to give a good fit to measured longshore transport rate. To compensate the increase of the value of $\Omega$, the turbulent length scale $l_t$ is taken equal to $l_t = 0.15 \ d$, instead of $l_t = 0.3 \ d$ which has been adopted in the 1D case.

The rate of production of turbulent kinetic energy is taken equal to the dissipation $D$ of the wave energy (equation 7). The parameter $B$ (Nwogu, 1996) is introduced to ensure that turbulence is produced only when horizontal velocity at the wave crest $u_{st}$ exceeds the celerity $c$.

$$B = \begin{cases} 0 & \text{in the region where } u_{st} < c \\ 1 & \text{in the region where } u_{st} > c \end{cases}$$

where $u_{st}$ is the velocity at the wave crest, $u_{st} = \sqrt{u_s^2 + v_s^2}$, and $u_s$ and $v_s$ are its components from Boussinesq theory (Peregrine, 1972).

The eddy viscosity is given by:

$$\nu_t = k^{1/2} \ l_t$$  \hspace{1cm} (9)

The two integrals in the equations (1) are estimated form (Karambas 1996):

$$\int_{-d}^{0} \frac{1}{2} u^2 \ dz = E - \int_{-d}^{0} \frac{1}{2} v^2 \ dz - \frac{1}{2} g r^2$$
\[ \int_{-d}^{1} \frac{1}{2} v^2 dz = E - \int_{-d}^{1} \frac{1}{2} u^2 dz - \frac{1}{2} g \zeta^2 \] (10)

The integrals in equations (1) and (6), containing the terms \( u^3 \), \( v^3 \), \( uv \), \( u^2v \), \( uv^2 \), are estimated numerically adopting the following horizontal velocity distribution in the turbulent region of a breaking wave (Karambas 1996):

\[ u(z) = u_o + u_d f(\sigma) \]
\[ v(z) = v_o + v_d f(\sigma) \quad \text{for} \quad \zeta - \delta < z < \zeta \] (11)

where \( \delta \) is the depth of the turbulent region and

\[ u_d = u_s - u_o, \quad v_d = v_s - v_o, \quad f(\sigma) = -A\sigma^3 + (1 + A)\sigma^2, \quad \sigma = (d+z)/h, \quad A = 1.4 \]

Using the definition of the mean velocity \( U \) and equation (11) the turbulent region depth \( \delta \) can be estimated from (Karambas, 1996):

\[ \delta = \frac{U - u_o}{u_d} \cdot \frac{h}{0.45} \] (12)

In the non-turbulent region, \( D = 0 \), \( E = 0.5hU^2 + 0.5g\zeta^2 \) and the system reduces to the classical Boussinesq equations.

An important result of the above model is the prediction of the nonlinear instantaneous bottom velocity which also includes the mean motion (mainly responsible for the sediment transport).

Figure 1. Perspective view of the wave field for oblique wave incidence. Wave height \( H = 1 \text{m} \), period \( T = 6 \text{ secs} \) and slope 1:30.
Numerical solution

The system of equations (1) and (5) is simultaneously solved as in the 1-D model (Karambas, 1996) in the following way:

1. Calculation of $U^{n+1}$, $V^{n+1}$, $\zeta^{n+1}$ (at time level $(n+1)\Delta t$) from the solution of the Boussinesq equations (1).
2. Calculation of $E^{n+1}$ explicitly from the energy equation (5) using exactly the same Finite Differences approximations (both new time step $(n+1)\Delta t$ and previous time step $n\Delta t$ values of the variables are employed). The integrals containing the terms $u^3$, $v^3$, $u^2v$, $uv^2$, are estimated numerically (equation 6).
3. Calculation of the integral in the momentum Boussinesq equations (1) using equation (10). The integrals containing the terms $uv$ are estimated numerically.
4. Next time step: replacement in the non linear terms of the momentum Boussinesq equations (1) the values of the integrals of step 3.

In this manner energy equation is numerically solved simultaneously with the Boussinesq equations and its effects are introduced explicitly in the momentum equation. The main advantage of the above procedure is that it can be easily introduced in the existing models without the need for changing their numerical scheme.

Waves propagating out of the domain are artificially absorbed using sponge layer technique. The Orlanski open boundary condition is also applied, since it is more efficient for the absorption of the generated currents and long waves.

The ‘dry bed’ boundary condition is used to simulate runup (Figure 1). Consider the one-dimensional case the condition is written:

$$\text{if} \ (d+Q)<0.00001 \ \ \text{then} \ \ z=-d$$

(13)

The above conditions has been successfully used in long wave runup modelling (Karambas et al., 1991).

The Finite Differences numerical scheme is described in Karambas et al. (1990).

An energetics sediment transport formula

The energetics approach is based on the Bagnold’s original idea that the sediment transport load is proportional to the time averaging energy dissipation of the stream (Bailard 1981).

In an energetics approach the submerged weight transport rates, $i_x$ in the $x$ direction and $i_y$ in the $y$ direction, are given by Bailard:

$$<i_x> = \left[ \frac{\epsilon_b}{\tan \phi} \left( \frac{u_o}{u_{ot}} + \frac{d_x}{\tan \phi} \right) \omega_b + \epsilon_s \frac{u_{ot}}{w} \left( \frac{u_o}{u_{ot}} + \epsilon_s \frac{d_x}{w} \right) \omega_t \right]$$
where the angled brackets represent (numerical) time-averaging, \( w \) is the sediment fall velocity, \( \phi \) is the angle of internal friction, \( \varepsilon_b \) and \( \varepsilon_s \) are the bed and suspended load efficiency factors respectively, \( \omega_t \) is the local rate of energy dissipation given by:

\[
\omega_t = \omega_b + C_d k_b^{3/2} / h
\]

where \( k_b \) is the turbulent kinetic energy at the bottom and \( \omega_b \) is the dissipation at the bottom:

\[
\omega_b = \frac{f_c}{2} u_{ol}^3
\]

The above sediment transport formula has been derived directly from the primitive equations (equation 7 of Bailard 1981 paper) without the assumption that the only dissipation mechanism is the bed friction. This is the most important limitation of the Bailard theory and precludes the use of the original formula within the surf zone, where the dissipation of energy associated with the process of wave breaking is largely dominant.

Since a Boussinesq model automatically includes the existence of the mean wave-induced current there is no need to separate the bottom velocities \( u_{ot}(t) \) and \( v_{ot}(t) \) into a mean and an oscillatory part as in most of the previous works which adopt only period-mean approaches. This is another significant advantage of the present model since the approach is based on the original energetics formula without the above simplification. In addition there is no need for the decomposition of the moments by assuming that the bottom wave velocity is larger than the mean current velocity. This assumption (Roelvink and Stive, 1989) is not always valid, especially in complicated wave fields near coastal structures (behind a detached breakwater there is a strong mean current without significant wave motions). Finally the present model includes a quasi 3D structure of the motion (mean and oscillatory) predicting in this way the undertow effects on the cross-shore sediment transport rate.

According to the original Bagnold estimations (from river data) the bed and suspended load efficiency factors \( \varepsilon_b \) and \( \varepsilon_s \) take the values \( \varepsilon_b = 0.13 \) and \( \varepsilon_s = 0.01 \).

Bailard (1981) first calibrated the energetics approach based on laboratory and field measurements. Least square estimates of \( \varepsilon_b \) and \( \varepsilon_s \) resulted in values 0.21 and 0.025 respectively. However, the Bailard's value of \( \varepsilon_s \) has to compensate for increased turbulence due to breaking in the surf zone. Since the breaking wave-induced dissipation has already been incorporated, the Bailard's value is not valid. Here the value \( \varepsilon_b = 0.01 \) is used, considering the following exponential, over the depth, decay of the turbulence kinetic energy \( k \) (according to Roelvink and Stive 1989):

\[
k_b = k[(\exp(d/H)-1)^{-1}
\]
in which \( H \) is the wave height.

For typical values of the ratio \( d/H \) inside surf zone the dissipation of \( k \) (i.e. the term \( C_d k_b d^2 / l_t h \)) is finally multiplied by a factor 0.002, which is similar to the value proposed by Morfett (1995).

**Morphology module**

The morphological changes are calculated by solving the conservation of sediment transport equation:

\[
\frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} = \frac{\partial z_b}{\partial t}
\]  

(18)

where \( z_b \) is the bed elevation above arbitrary datum and \( q_x, q_y \) are the volumetric sediment transport rate related to the immersed weight sediment transport through:

\[
q_{x,y} = \frac{i_{x,y}}{(\rho_s - \rho)gN}
\]  

(19)

in which \( N \) is the volume concentration of solids of the sediment (\( N = 0.6 \)) and \( \rho_s \) and \( \rho \) are the sediment and fluid densities.

**Applications**

In two previous work of the author (Karambas et al, 1995, and Karambas et al., 1997) the 1D version of the model has been successfully used to predict cross-shore sediment transport and bed evolution. In the present model the simulation of the runup leads also to the prediction of the sediment transport in swash zone. In this work two applications are presented: the prediction of the longshore transport rate and the simulation of the coastline evolution in a beach nourishment scenario.

In the computations of the longshore transport rate it is assumed that the shoreline and depth-contour lines are straight and parallel to each other, the incident waves are regular and uniform in the alongshore direction and that the sediment grain size is spatially uniform. The following four parameters are varied in the numerical experiments: breaking wave height \( H_b \), incident angle \( \theta_b \), beach slope \( \tan \alpha \) and grain size \( D_{50} \). Wave period \( T \) is assumed constant, \( T = 9 \) secs. For certain values of the three of the above parameters and different values of the fourth, the longshore transport rate \( Q \), from the swash zone across the surf zone to deep water, is calculated by the cross-shore integration of \( q_y(y) \):

\[
Q = \int_{R_u}^{\infty} q_y(y) \, dy
\]  

(20)
where $R_u$ is the location of the run-up point.

![Graph](image)

Figure 2. Comparison of longshore transport rate between Kamphuis formula and present model in different breaking wave heights $H_b$ ($T=9$ secs, $D_{50}=0.0003$ m, $\theta_b=0.3$ rad, slope=0.015).

The Kamphuis longshore transport formula is used for comparison with the present model. The improved Kamphuis formula (Schoones and Theron, 1996) is written as follows:

$$Q_{\text{Kamphuis}} = \frac{63433}{(1-p)\rho_s} \left( \frac{\rho}{T} \right)^{1.25} L_o^{1.25} H_b^2 (\tan a)^{0.75} (1/D_{50})^{0.25} (\sin 2\theta_b)^{0.6}$$

(m$^3$/year)

(21)

where $p$ is the porosity, $L_o$ is the deep-water wavelength, $H_b$ is the wave height, $\theta_b$ is the incident angle, $\tan a$ is the beach slope and $D_{50}$ the grain size.

Model predictions are plotted against $H_b^2$, $(\sin 2\theta_b)^{0.6}$, $\tan a^{0.75}$ and $(1/D_{50})^{0.25}$ in Figures 2 to 5. The longshore transport rate $Q$ which is predicted by the model is generally close to the values obtained by Kamphuis formula. In general a more strong dependence on breaking wave height, incident angle and grain size is predicted by the model. However, for the verification of the model, comparisons with experimental data and field measurements are required.
Figure 3. Comparison of longshore transport rate between Kamphuis formula (solid line) and present model (dashed line) in different wave directions $\theta_b$ ($H_b=1.0$ m, $T=9$ secs, $D_{50}=0.0003$ m, slope=0.015).

The model is also applied to simulate the coastline evolution in a beach nourishment scenario assuming normal wave incidence on a trapezoidal beachfill (Figure 6). In Figure 7 the predicted shoreline change after nondimensional time $T=0.5$ is compared with an analytical solution of the Pelnard-Considere equation (one-line model, Work and Rogers, 1997). The nondimensional time $T$ is defined as: $T=4(Gt)^{0.5}/l_1$, where $G$ is ‘longshore diffusivity’ parameter (Work and Rogers, 1997) and $l_1$ is the longshore length ($l_1=20$m in the present case). The depth at the toe of the beachfill is $h_t=1.5$m, the slope 1:15, the incident wave height $H=1$m, the period $T=6$ secs and the fall velocity $w=0.03$ m/s.

In an one-line model changes in shoreline position are assumed to be produced by spatial differences in the longshore sand transport rate. However present model is also able to simulate cross-shore transport (Karambas et al., 1995, Karambas et al., 1997). Thus the predicted shoreline change is expected to include the effects of the cross-shore (offshore or onshore) transport, i.e. erosion or accretion. In Figure 7 the difference between the present model and the analytical solution is the shoreline displacement due to offshore transport. Under the applied conditions ($H=1$m, $T=6$ secs and $w=0.03$ m/s) the nondimensional fall speed $N=H/(wT)=5.55$, also known as the Dean number, is greater than the critical value $N_c=3.2$ and consequently the direction for the cross-shore sediment transport is expected to be offshore (erosion).
Figure 4. Comparison of longshore transport rate between Kamphuis formula (solid line) and present model (dashed line) in different slopes $\tan\alpha$ ($H_b=1.0$ m, $T=9$ secs, $D_{50}=0.0003$ m, $\theta_b=0.3$ rad).

Conclusions

The 2DH energy and the Boussinesq equations are simultaneously solved for the simulation of breaking wave propagation in the surf zone. Model results are used in an energetics sediment transport model based on the Bailard formula.

The unified model is capable of predicting:
- 2DH breaking wave propagation
- Longshore transport rate from the swash zone to shoaling region
- Coastline evolution in a beach including cross-shore sediment transport

The comparison of longshore transport rates between present model and Kamphuis formula shows close agreement.

Coastline evolution is also predicted well in comparison with an analytical solution of the one-line equation.
Figure 5. Comparison of longshore transport rate between Kamphuis formula (solid line) and present model (dashed line) in different median grain size $D_{50}$ ($H_b=1.0 \text{ m}, T=9 \text{ secs}, \theta_b=0.3 \text{ rad}, \text{slope}=0.015$).

Figure 6. Perspective view of the wave field for normal wave incidence on a trapezoidal beachfill. Wave height $H=1\text{ m}$, period $T=6 \text{ secs}$, depth at toe $h_t=1.5\text{ m}$ and slope 1:15.

Comparison of Storm Longshore Transport Rates to Predictions

Herman C. Miller¹, M ASCE

Abstract

Longshore sediment transport (LST) is of primary importance to long-term shoreline changes and must be accounted for in most coastal designs. Predicting LST has been hampered by the lack of direct measurements during storm conditions against which the models can be calibrated. The Sensor Insertion System (SIS) developed at the US Army Corps of Engineers (USACE) Field Research Facility provides a way to directly measure LST during storms. The SIS was operated during the growth, peak, and waning stages of three storms between April, 1997 and February, 1998 in which the waves reached a maximum individual height of 5.6m. In up to 14 cross-shore locations, concentration and velocity measurements were made throughout the water column. These measurements were compared to total transport models of USACE 1984, Kamphius 1991, Kraus, et al. 1988, Walton 1980, and the cross-shore distribution model of Bodge and Dean 1987. The results show the storm measurements had a consistent pattern; rapidly increasing to a peak rate, then gradually decreasing during the waning stages of each storm. Cross-shore distributions of longshore flux tended to peak over the offshore bar and at the beach where wave dissipation caused high suspended sediment concentrations. These peaks were not co-located with maximum longshore currents, which tended to peak at mid-surf. The comparisons show that the models would benefit from comparison to the storm measurements.

Introduction

Anticipating long-term shoreline changes; designing coastal structures and beach renourishment projects; determining funding allocations for the maintenance of our navigable waterways, inlets, and harbors are some of the reasons it is important to predict longshore sediment transport (LST). Accurate predictions of LST has been a goal of coastal

¹US Army Engineer Waterways Experiment Station Coastal & Hydraulics Laboratory Field Research Facility, 1261 Duck Road, Kitty Hawk, NC 27949, USA
engineers for decades. While many models have been introduced, some very sophisticated, others simple and robust, few have attained wide use (see reviews, Bodge 1989, Sternberg et al. 1989, Komar 1990, Kraus and Horikawa 1990). Consequently, the need for improvement continues. Until new models, based on a better understanding of the transport mechanisms are developed, improving the modeling capability might best be achieved by comparing existing models to field measurements during storms. It is well known that storms, with waves generally higher than 2 m, are responsible for the largest changes in our coasts. Thus, the models need to work well under these conditions. The problem is there is a paucity of these data. A thorough review of the LST data by Schoonees and Theron (1993) concluded that almost all field data were for wave heights below 1.8 m. The consequence is that existing transport models are calibrated against rates measured during low to moderate wave conditions.

This study has produced a number of high quality storm data sets. LST rates and highly-resolved cross-shore distributions of longshore sediment flux during three storms are compared to five easy to use LST formulations. The results demonstrate how LST models could benefit from field measurements under storm conditions. The paper includes brief descriptions of the site characteristics, a new system for making direct measurements during storms, instrumentation, and data collection/analysis procedures. Then, examples of the measurements are given and comparisons are made to LST models.

Site Characteristics

This investigation was conducted in the United States (US) at the US Army Engineer Waterways Experiment Station, Coastal and Hydraulics Laboratory's Field Research Facility (FRF) located in Duck, North Carolina (NC), on the Atlantic Ocean (Figure 1). With an average of 20 storms per year, including the close passage of tropical storms and hurricanes, this site is ideal for studying sediment transport during storms.

The characteristics of the FRF have been well studied and the processes are summarized in the series of annual reports, (Leffler et al. 1998). Average annual significant wave height is near 1 m with a 9-sec period. Significant wave heights in excess of 4 m (in 8 m depth) are not uncommon. The tide is semi-diurnal tide with a spring range of 1.2 m and storm surges in excess of 1 m have been recorded. Wave information used in this study were collected from the FRF directional array located in 8 m depth (Long and Oltman-Shay 1991).

The beach, locally oriented NNW-SSE, is typical of the barrier island system along the mid-Atlantic coast of the US. The typical nearshore profile has two bars, but varies with season and longer time scales (Birkemeier 1984). The nearshore consists of 0.15 to
0.18 mm sand that grades toward 0.12 mm further offshore, with coarse sand and gravel from submerged river beds abundant at the beach (Stauble 1992, Schwartz et al. 1997).

Sensor Insertion System

There are many reasons for the lack of direct measurements of LST during storms, including the expense and logistics required to operate a monitoring program that can operate in severe wave conditions through many storms. To overcome this, the FRF has developed the Sensor Insertion System (SIS). The pier based SIS, Figure 2, is capable of measuring hydrodynamic processes and the resulting sediment transport anywhere across 500 m of the nearshore.

The SIS is a 70,000 kg crane with an array of instrumentation that is moved along the length of the research pier to measure sediment transport at different positions across the surf zone during storms. The SIS is designed to operate in up to 5.6-m individual wave heights. To minimize the influence of the pier, the SIS, with 20-m-long booms, can place instruments on the ocean bottom in 9 m depth as far as 22 m updrift of the pier centerline. This system provides an economical way to make these measurements. It does not require divers and can reposition the sensors as the profile evolves during a storm. A disadvantage of the SIS measurement system is that measurements across the shore are not simultaneous, but occur over a 3-hour period.

Instrumentation

Optical backscattering concentration sensors (OBS) in combination with electromagnetic current meters (EMCMs) have proven most reliable during storms for measuring sediment flux throughout the water column. Each concentration sensor is considered representative of a portion of the water column as shown in Figure 3. Many of
the sensors are positioned near the bottom since the measurements show that much of the sediment is transported within 1 m of the bed. The lowest concentration sensor is typically 3 to 5 cm above the bottom. Distance to the bottom is measured with a down-looking sonic altimeter.

The instruments are held updrift of the SIS on a frame as shown in Figure 4. This minimizes contamination of the measurements by any wake effect off the SIS. Since the instrumentation is parked on the pier deck between use, the instruments can be frequently inspected, rinsed with fresh water, are virtually unaffected by biological fouling, and thus tend to hold their calibrations well.

**Data Collection And Analysis**

This single instrument array was used to directly measure sediment concentration and fluid velocity at a large number of cross-shore locations. From these measurements the cross-shore flux distribution can be determined and integrated to compute the LST rate. Starting about 1½ hrs before high or low tide, and operating for 3 hours, up to 14 cross-shore locations can be measured while the water level changes very little. This provides a quasi-synoptic "snap-shot" of the cross-shore distribution of the longshore sediment flux. At each location along the pier, 512-sec-long records were sampled at 16 Hz. The high sample frequency is required because sand resuspension events last for only a fraction of the wave cycle. All of the cross-shore measurement locations along the pier during one tide will be referred to as a "transect."

Instantaneous concentration and velocity values are used to compute the flux at each gauge location in the water column by multiplying the instantaneous concentration, \(c(x,z,t)\), after accounting for the "turbidity" offset (Ludwig and Hanes 1990, Schoelhamer 1993), by the instantaneous longshore velocity, \(v(x,z,t)\), and time-averaging the products.

\[
F(x,z) = \frac{1}{N} \sum_{i=1}^{N} c(x,z,t_i) v(x,z,t_i)
\]

where \(N\) is the number of samples and \(F(x,z)\) is the longshore sediment flux, which is the rate per unit area in the \(x\) (cross-shore) and \(z\) (vertical) directions.

Cross-shore distribution of the longshore flux was obtained by summing the vertical contributions at each location along the transect.
\[ G(x) = \sum_{j=1}^{M} F(x, z_j) \delta z_j \]  

(2)

where \( G(x) \) is the vertically integrated flux per unit cross-shore length and \( M \) is the number of concentration sensors.

Longshore transport rates were computed in a similar way by summing the across-shore contributions

\[ I = \sum_{k=1}^{L} G(x_k) \delta x_k \]  

(3)

where \( L \) is the number of measurement locations and \( I \) is the longshore sediment transport rate. These rates were converted to volume transport rates, \( Q \) (m\(^3\)/hr), assuming the density of quartz sand is 2,650 kg/m\(^3\), the density of sea water is 1,025 kg/m\(^3\), and the solid fraction is 0.6.

Results

Measured Transport Rates

Three storms were selected for analysis because the measurements included the growth, peak, and waning storm stages. The peak rates are compared in Table 1. With approximately the same peak wave directions and periods, the measured LST was observed to vary approximately linearly with wave energy up to a rate of 3,400 m\(^3\)/hr, the highest measured to date.

The LST rates for each transect during the growth, peak, and waning stages of the October, 1997 storm are shown in Figure 5. The rapid growth to a peak, followed by a
gradual waning of the LST is typical of the storm measurements at the FRF. On 19 October, a total volume of 33,200 m$^3$ of sediment was measured moving south.

Cross-Shore Distribution

The unique capabilities of the SIS to rapidly reposition the sensors during a storm resulted in highly-resolved cross-shore distributions of longshore flux measurements. Cross-shore locations were selected to document both the peak and minimum values, so an accurate representation of the LST rate could be determined. From experience obtained during many prior storm tests, a minimum of 8 cross-shore positions are required across the barred profile. An example of a cross-shore distribution of the longshore sediment flux with 14 measurement positions is shown in Figure 6. The graph is for one transect on 20 October, 1997 during low tide when the waves were 2.4 m. This example was chosen because it is a typical storm distribution. The two curves represent the vertically integrated sediment flux per unit cross-shore length and water depth at the measurement locations. As can be seen, peak flux values are associated with the inner and outer bars along the profile.

It is interesting to compare the resulting flux values to the cross-shore distribution of the processes. In Figure 7, wave height, longshore current from the near surface EMCM, and near-bed sediment concentrations are displayed. Beginning offshore, the waves shoal and dissipate energy over the outer bar; remain consistent across the trough between the bars, before dissipating energy again at the inner bar and beach. The break point defining the surf...
The zone would be considered located near position 425 m where predominant breaking occurred; however, breaking of the highest waves was observed seaward of that location. The longshore current builds to a peak over the trough between the bars. This distribution is somewhat like the classic longshore current distribution of Longuet-Higgins (1970) and has been observed previously at the FRF (Smith et al. 1993). Sediment concentration peaks are associated with wave shoaling and wave energy dissipation.

Comparing Figure 6 to 7 shows that the longshore sediment flux and sediment concentration peak at the same locations, which do not coincide with the longshore current peaks. The importance of wave dissipation suspending sediment in the cross-shore distribution of longshore flux is well documented in all of the storms measured to date. That is not to say this is the only cross-shore distribution of longshore flux. In fact, many different distributions have been measured that reflect differences in profile features and wave energy levels. For example, during low wave conditions, a single peak near the inshore bar or beach occurs.

Comparison to LST Rate Models

Arguably, the most widely used LST model is that given in the Shore Protection Manual (SPM) (USACE 1984). This formulation equates, \( I \), the immersed weight transport rate to a constant, \( K \), times the longshore wave energy flux factor, \( P_{lb} \)

\[
I = K \cdot P_{lb}
\]  

(4)

where \( K \) equals 0.39 when using significant wave height. This constant was determined primarily from long-term averaging of waves and sediment accumulation at coastal structures.

The longshore wave energy flux factor is given in terms of the wave conditions at breaking

\[
P_{lb} = (EC_g)_b \sin \alpha_b \cos \alpha_b
\]  

(5)

where \( E \) is the wave energy, \( C_g \) is the wave group velocity, \( \alpha \) is the wave crest angle relative to the beach, and "b" denotes breaking conditions.

For these predictions, the peak wave parameters measured at the FRF's directional array were shoaled conserving wave energy flux according to

\[
E_{d.a.} \cdot C_{gd.a.} \cdot \cos \alpha_{d.a.} = E_b \cdot C_{gb} \cdot \cos \alpha_b
\]  

(6)
and the waves were refracted using Snell's Law:

\[
\frac{\sin \alpha_{d.a.}}{L_{d.a.}} = \frac{\sin \alpha_b}{L_b}
\]  

(7)

where \( L \) is the wave length and "d.a." is at the directional array. A breaking criteria of \( H/d = 0.78 \) was used.

The SPM predictions were made every 3 hrs when the wave data were available. The LST measurements are only at times of high or low tide. Figure 8 compares the measured and predicted LST rates. In this case, the SPM somewhat overpredicted the lower rates and underpredicted the peak rate. However, in general, it compared reasonably well with the measurements. Note, after more storm measurements are obtained and an error analysis is performed, many of these differences may prove insignificant.

The SPM predictions show a high degree of variability. This is in part because the SPM assumes all the wave energy is in a single wave train. Because the storms tend to move along the coast past the FRF, multiple peaked spectra frequently are measured. Small shifts in the energy level of similar spectral peaks can cause considerable variation from one prediction to the next.

Figure 9 shows a similar comparison between SPM predictions and measurements for the storm in April, 1997. Again there is reasonable agreement, particularly, during the growth and peak of the storm; although, in this case the peak was over predicted. The measured LST gradually decreased as is common during the waning stages of the storm.
Negative predictions indicate a direction reversal caused by the arrival of the southerly swell after the storm passed.

For the February, 1998 storm (Figure 10) the waves were from the south side of the pier and the transport was directed to the north as designated by the negative values. The SPM formulation over predicted the peak.

The Kamphius 1991 model was attractive because it included bottom slope, sediment size, and wave period, in addition to the wave height and angle of approach.

\[ Q = 7.3 \ H_{sb}^2 \ T_p^{1.5} \ m_b^{0.75} \ D_{50}^{-0.25} \ \sin^{0.6}(2\alpha_b) \]  

where \( H_{sb} \) is the significant wave height at breaking, \( T_p \) is the peak spectral wave period, \( m_b \) is the bottom slope, \( D_{50} \) is the sediment size, and \( \alpha_b \) is the wave angle at breaking.

Using the transects near the peak of the April, 1997 storm, Figure 11, shows the model underpredicts the magnitude of the rates. The Kamphius coefficient was evaluated primarily with laboratory data. It appears the predictions are off by an order of magnitude. When the Kamphius coefficient is multiplied by a factor of 10, Figure 12, the predictions are improved.
Kraus et al. (1988) proposed a LST rate model which included a water discharge parameter, \( R \), which must exceed a critical discharge value they call \( R_c \),

\[
I = 2.7 (R - R_c)
\]

(9)

where the discharge parameter, \( R \), is

\[
R = V X_b H_{sb}
\]

(10)

with \( V \) the longshore velocity, \( X_b \) the surf zone width, \( H_{sb} \) the significant wave height, and \( R_c = 3.9 \text{ m}^3/\text{sec} \).

This model, which was developed from field measurements under low to moderate wave conditions, is compared to three transects during the April, 1997 storm (Table 2). These transects were chosen because of the range of wave heights. The model underpredicts the measured values from 30 to 60 percent.

Kraus et al. (1988) provide a velocity term correction based on the standard deviation of the velocity and another correction based on the wave height gradient, but these did not improve the results. This model, which is easily applied, may only lack the storm measurements to recalibrate the model coefficient.

The Walton (1980) model was intriguing because it included Longuet-Higgins cross-shore current distribution and a water discharge parameter that resembled that of Kraus et al. (1988).

\[
P_{ls} = \rho g \frac{H_{sh} W V C_f}{\frac{5}{2} \pi \left(\frac{v}{v_o}\right)_{LH}}
\]  

(11)

where \( W \) is the surf zone width, \( C_f \) is a friction coefficient and the Longuet-Higgins current distribution is given by

\[
\left(\frac{V}{V_o}\right)_{LH} = 0.2 \left(\frac{X}{W}\right) - 0.74 \left(\frac{X}{W}\right) \ln \left(\frac{X}{W}\right)
\]

with \( X \) being the cross-shore position that the velocity was measured.

For the same three transects, the Walton model greatly overpredicts the LST rate (Table 3). However, there is some similarity in how the Walton and Kraus et al. models differed from the measurements. The prediction to measurement factor, \( Q_{pred}/Q_{meas} \), for transects 4 and 6 are about twice that for transect 2 for both models. The similarity in how the models perform is probably because both models have a water discharge parameter. Recalibration with data from multiple storms should benefit these models.

Comparison to Cross-Shore Distribution Models

The new USACE Coastal Engineering Manual (CEM) (scheduled for publication and public release in 2000) presents the cross-shore distribution of longshore sediment flux proposed by Bodge & Dean (1987) as an example of the available models. This model is attractive because it includes wave energy dissipation and longshore velocity and therefore
can account for local wind effects and depth.

\[ q_s(y) = \frac{k_q}{d} \delta \left( E \frac{\partial C_y}{\partial x} \right) V_I \] (13)

The dimensional constant, \( k_q = 48 \) sec, was evaluated from laboratory experiments and low to moderate wave conditions in the field. As can be seen in Figure 13, the model re-creates the peaks over the bars for this transect near the peak of the storm. It is interesting to note that the strong dependence of the model on wave dissipation resulted in negative predictions, (that do not represent a direction reversal), at the seaward most locations where the waves were shoaling. Figure 13. Bodge and Dean Predictions, 1 April, 1997 Bodge & Dean (1987) indicate the model is only valid inside the surf zone where the wave energy is expected to dissipate. The magnitudes of the predictions appear to be much larger than the measured flux values. Bodge and Dean do provide a correction that is dependent on the bottom slope; however, that made the agreement worse. Since it appears from matching the first few values in Figure 13 that the predictions are approximately a factor of four larger than the measurements, \( k_q \) was reduced to 0.12 sec and replotted in Figure 14. The agreement, although not perfect, is better. The intent here is not a rigorous recalibration of the models, but simply a first attempt to demonstrate the utility of the measurements. After more measurements are obtained, model recalibrations will be performed. The goal of the SIS measurement program is to gather data during storms so models, such as this, can be calibrated under a range of storm wave conditions and improve our ability to predict LST. Two other distribution models (Briand and Kamphius 1993, Watanabe, et al. 1991) were considered, but proved difficult to apply.

Figure 13. Bodge and Dean Predictions

Figure 14. Modified Bodge and Dean Predictions
Conclusions

The SIS provides a powerful platform to measure LST during storms. Quasi-synoptic "snap shots" of highly-resolved cross-shore distributions of longshore flux have been obtained for storms with significant wave heights that reached 3.8 m. LST rates as high as 3,400 m$^3$ per hour were measured. For the three storms presented, the transport rate rapidly increased to a peak, then gradually decreased during the waning stages of the storms.

The cross-shore distribution of longshore sediment flux shows that, near the peak of a storm, maxima occur over the bars where the wave dissipation increases the suspended-sediment concentration. These, in general, are not co-located with the longshore current maxima which tends to peak over the trough between the bars.

The SPM formulation seemed to capture the trend of the measurements reasonably well. The SPM tends to over predict low wave conditions. The SPM shows considerable variability, even direction reversals, during the waning stages of a storm. This was due to the presence of sea and swell with comparable energy levels due to the rapidly moving storm systems which are common at the FRF. The Kraus et al. (1988) model underpredicted the LST rates. Walton (1980) over predicted the rates. These models would benefit from comparison to storm measurements.

The shape of the cross-shore distribution of longshore sediment flux was modeled reasonably well in the surf zone by Bodge and Dean (1987). Their wave energy dissipation model overpredicted the magnitude. Reducing their coefficient by a factor of four improved the agreement.

While this investigation is a start toward filling the need for storm measurements that can be used to calibrate existing models and develop improved formulations, additional measurements over a range of conditions are still needed and will be a future focus.

Depth of Erosion Under Storm Conditions
John F.A. Sleath

Abstract

A model is presented for the dynamics of the mobile layer of sediment on the sea bed under sheet flow conditions. The Karman-Polhausen method is used to determine the thickness of the mobile layer, the scaling for velocity phase and amplitude, and the phase lead of the velocity at the bottom of the mobile layer. The model does not make use of constitutive equations such as those suggested by Bagnold (1956). Agreement between the predictions of the model and existing laboratory measurements is good.

1. Introduction

When a pipeline is trenched into the seabed it is important to know how far below the surface of the bed the sediment may be disturbed by the action of extreme waves or currents. One element in a calculation of this disturbance depth is the thickness of the mobile layer of sediment.

In oscillatory flow, the thickness $\delta$, of the mobile layer depends on the relative importance of the bed shear stress and the force due to the pressure gradient. When the pressure gradient term is small $\delta$ is also small and is determined by the magnitude of the Shields parameter. However, when the pressure gradient is no longer negligible $\delta$ increases rapidly. It is this situation which is of most concern when considering the stability of structures on or in the seabed. Unfortunately, the experimental measurements (see, for example, Horikawa et al, 1982, Sawamoto and Yamashita, 1986, Dick and Sleath, 1991, Asano, 1992, Ribberink and Al-Salem, 1994, 1995, Li and Sawamoto, 1995a, and Zala Flores and Sleath, 1998) show considerable scatter under these conditions.

Several theoretical models have been proposed for the fluid/sediment motion in mobile layers in oscillatory flow (Bakker and Van Kesteren, 1986, Asano, 1990, Nadaoka and Yagi, 1990, Dibajnia and Watanabe, 1992, Li and Sawamoto, 1995b, Kaczmarek et al, 1995, Ono et al, 1996, Katori et al, 1996). Unfortunately, here too, there is significant disagreement between the predictions of the various models when

2968
\( \delta_s \) is large. Part of the problem is that some models assume quasi-steady relationships for sediment transport rate, etc., and are consequently most relevant to the situation where \( \delta_s \) is small and pressure gradient and inertia terms may be neglected. Others, make use of constitutive equations, such as those of Bagnold (1956), whose reliability in oscillatory flow is uncertain.

The aim of the present paper is to re-examine this question using the well-known Karman-Polhausen method (see, for example, Schlichting, 1979). This method has been shown to give good results in a variety of applications. One of its advantages in the present case is that it allows us to choose a form of velocity profile which is known to be physically realistic when pressure gradient is significant and \( \delta_s \) is large. Another advantage over the model presented by Sleath (1994) is that it is not necessary to make use of constitutive equations like those of Bagnold (1956).

Only oscillatory flow will be considered here. Also, since the main objective is to examine the mobile layer under extreme wave conditions, the discussion will be limited to flat beds, i.e. sheet flow.

2. The present model

A first step in the Karman-Polhausen method is to select a generalized velocity profile with sufficient disposable constants to ensure a good fit to the unknown real profile. For present purposes we take the horizontal component of velocity to be given by

\[
\begin{align*}
\text{for } K_1 y & \leq 1 \\
\quad u &= U_0 \ K_1 y \ R \left\{ e^{(\omega + \phi - K_2 y)} \right\}, \\
\text{for } K_1 y & > 1 \\
\quad u &= U_0 \ R \left\{ e^{i\omega} \right\}
\end{align*}
\]

where \( R \left\{ \right\} \) indicates the real part, \( U_0 \) is the amplitude of the fluid velocity in the free stream above the bed, \( \omega \) is the angular frequency, \( K_1, K_2, \phi \) are coefficients which remain to be determined and \( y \) is measured vertically up from the still bed level. This form of velocity profile was shown by Dick and Sleath (1991) to give good agreement with their measurements.

The Karman-Polhausen method involves integration of the momentum equation. In the present case we integrate between the still bed level \((y=0)\) and the initial bed height \((y=\delta_s)\) which we define as the level of the crests of the grains on the surface when the flow is stationary and all sediment has settled on the bed. Thus

\[
\delta_s = \frac{1}{C_\ast} \int_0^\infty C \ dy
\]

where \( C \) is the concentration of sediment at any height \( y \) and \( C_\ast \) is the limiting value of \( C \) for a stationary bed.

To start with we consider only the situation where \( K_1 \delta_s \leq 1 \). If we denote the amplitude of \( u \) at \( y=\delta_s \) by \( U_m \) we have
Also, if there is to be no discontinuity in phase at $K^2 = 1$ we must have

$$K_2 = \frac{\phi U_m}{\delta_x U_0}$$

We take the shear stress at $y = \delta_S$ to be

$$\tau = \tau_0 R \{e^{i(\omega t + \delta)} \},$$

where $\tau_0$ and $0$ are constants. At the lower boundary ($y = 0$)

$$\left( \tau \right)_{y=0} = \text{const} \mu \left( \frac{\partial u}{\partial y} \right)_{y=0}$$

where $\mu$ is dynamic viscosity. The constant in this equation is intended to allow for the fact that the effective viscosity is a function of $C / C_r$. We assume that it is a constant because $C / C_r$ must reach some limiting value as $y \to 0$ and so effective viscosity must tend to a limit also.

If Eq (7) holds it follows from Eq (1) that we may also write

$$\left( \tau \right)_{y=0} = \tau_0 \left( e^{i(\omega t + \delta)} \right).$$

The momentum equation is

$$\rho_m \frac{\partial u}{\partial t} = -\frac{\partial p}{\partial x} + \frac{\partial \tau}{\partial y},$$

where $\rho_m$ is the density of the fluid/sediment mixture. Outside the boundary layer at the bed it follows from Eqns (9) and (2) that

$$\frac{\partial p}{\partial x} = \rho U_0 \omega \sin \omega t$$

where $\rho$ is fluid density. Substituting in Eq (9) and integrating from $y = 0$ to $y = \delta_S$ we have

$$\tau_0 e^{i(\omega t + \delta)} - \tau_0 e^{i(\omega t + \delta)} = \int_0^{\delta_S} \left[ \rho_m \frac{\partial u}{\partial t} - i \rho U_0 \omega e^{i\omega t} \right] dy$$

$$\tau_0 e^{i(\omega t + \delta)} - \tau_0 e^{i(\omega t + \delta)} = \frac{\rho_m U_0 \omega}{K_1} \left[ B^2 \left( \frac{U_m}{BU_0} \right) e^{i(\omega t + \delta)} - B^2 e^{i(\omega t + \delta)} - \frac{i U_m \rho}{U_0 \rho_m} e^{i\omega t} \right]$$
where

\[ B = \frac{K_1}{K_2} = \frac{1}{\phi}, \]  

and we have assumed \( \rho_m \) to be constant throughout the mobile layer. Dividing through by \( \exp(i(\omega t + \phi)) \) and then equating real and imaginary parts of Eq (11) we find

\[ \tan(\phi - \theta) = \frac{\cos(\phi - \theta) - \cos \gamma + \frac{U_m \phi}{U_0} \sin \gamma + \frac{U_m \rho}{U_0 \rho_m} \phi^2 \cos \theta}{\tau_b K_2 \phi^2 - \sin(\phi - \theta) + \sin \gamma + \frac{U_m \phi}{U_0} \cos \gamma + \frac{U_m \rho}{U_0 \rho_m} \phi^2 \sin \theta} \]  

(13)

and

\[ \tau_b \sin(\phi - \theta) = \frac{\rho_m U_0 \omega}{K_2 \phi^2} \left[ \cos(\phi - \theta) - \cos \gamma + \frac{U_m \phi}{U_0} \sin \gamma + \frac{U_m \rho}{U_0 \rho_m} \phi^2 \cos \theta \right] \]  

(14)

where

\[ \gamma = \phi \left( 1 - \frac{U_m}{U_0} \right) - \theta \]  

(15)

As mentioned earlier, the flow may be treated as quasi-steady when the pressure gradient and inertia terms are negligible, i.e when the parameter

\[ S = \frac{\rho U_0 \omega}{(\rho_s - \rho) g} \]  

(16)

is small. Here \( \rho_s \) is the density of the sediment. Under these conditions the normal stress due to grain/grain interactions supports the sediment above at each instant in the wave cycle. If the ratio of shear stress to normal stress at the bottom of the mobile layer is some constant \( K \) (as shown by Bagnold, 1954, Savage and McKeown, 1983, Hanes and Inman, 1985)

\[ \tau_b = K(\rho_s - \rho) g \delta_s \]  

(17)

where \( \delta_s \) is, under these conditions, the maximum thickness of the mobile layer during the course of a half cycle.

Dick and Sleath (1991) showed that \( \delta_s \) remains nearly constant during the cycle at larger values of \( S \). Under these circumstances we assume that it is the average value of the normal stress over a half cycle which supports the sediment above. Thus
\[
\tau_b \frac{2}{\pi} = K(\rho_s - \rho) g C_1 \delta_s
\]  
(18)

Substituting from Eq (14) into Eq (18)

\[
\frac{\pi}{2} \sin(\phi - \theta) KC_s = \frac{\rho U_0 \omega}{(\rho_s - \rho) g} \rho K_i \delta_s \phi^2 \left[ \cos(\phi - \theta) - \cos \gamma + \frac{U_m \phi}{U_0} \sin \gamma \right. \\
\left. + \frac{U_m \rho - \phi^2}{U_0 \rho_m} \cos \theta \right]
\]  
(19)

(This is the expression for high \( S \). The expression for low \( S \) is the same with the leading \( \pi / 2 \) deleted).

Finally, from Eqns (1), (7) and (18),

\[
\text{const} \mu K_i U_0 = \frac{\pi}{2} K(\rho_s - \rho) g C_1 \delta_s .
\]  
(20)

Eqns (4), (13), (19) and (20) allow us to determine \( U_m / U_0, \rho U_0 \omega \delta_s / \tau_0 \) and \( \phi \) for any value of \( \rho U_0 \omega / (\rho_s - \rho) g \) provided we know the flow conditions, the sediment properties, and the value of the constant in Eqn (7).

So far, we have considered only the case where \( K_i \delta_s \leq 1 \). This is the situation which applies at small to medium values of \( S \). At large values of \( S \) we need to consider \( K_i \delta_s > 1 \). This involves extending the integration in Eq (11) into the region covered by Eq (2). The extension is straightforward and, consequently, will not be discussed further here.

3. Comparison with experiment at large \( S \)

The main aim of the present paper is to investigate trends at high values of \( S \). Consequently, we will compare the computed curves with the measurements of Dick and Sleath (1991) and Zala Flores and Sleath (1998) for acrylic sediment of density 1141 kg/m\(^3\) and median diameter 0.7 mm.

The best fit of the experimental data for mobile layer thickness to the computed curves gives a value for the constant in Eq (7):

\[
\text{const} = 14860
\]  
(21)

Assuming this value to be correct, we can calculate curves for the various quantities of interest for given values of the parameter \( V \) defined as

\[
V = \int_0^\infty \frac{U_0}{(\omega V)^{1/2}}
\]  
(22)

where
is the friction factor calculated from Jonsson's (1963) curve for flat beds.

Fig. 1 shows how the ratio of the scaling factors $K_1 / K_2$ varies with the parameter $S = \rho U_0 \omega / (\rho_s - \rho) g$. Both theory and experiment show that the ratio is close to unity over a wide range of $S$, although the theory predicts a rise in $K_1 / K_2$ as $S \rightarrow 0$. The theoretical value of $K_1 / K_2$ at large $S$ shows little dependence on the value chosen for the various constants.

The way in which the phase lead $\phi$ of the velocity at the bottom of the mobile layer varies with $S$ is shown in Fig. 2. The parameter $S$ is a measure of the importance of the pressure gradient terms in the equations of motion. As $S \rightarrow 0$, the
pressure gradient terms become negligible and the flow is dominated by the shear stress acting on the upper surface of the mobile layer. Consequently, in this limit $\phi \to \theta$. As $S$ increases from zero, pressure gradient becomes more important and the phase $\phi$ moves closer towards that of the pressure gradient. However, when $S$ exceeds $C,K$ the thickness of the mobile layer becomes much larger and consequently the inertia of the fluid/sediment mixture in the mobile layer becomes significant. This is why the value of $\phi$ falls at large $S$.

In Dick and Sleath's (1991) tests with acrylic sediment the values of $V$ ranged from 6.8 at $S=0.55$ up to 18.5 at $S=0.96$. Consequently, the agreement between these tests and the computed curves in Fig. 2 is good. Zala Flores and Sleath's (1998) tests with acrylic sediment, which cover a similar range of values of $S$ and $V$ also show good agreement with the computed curves. This is more surprising since most of these
tests showed plug formation. It would appear that plug formation does not significantly modify the value of \( \phi \).

Fig. 2 also shows Zala Flores and Sleath’s (1998) results for PVC granules. Once again there is good agreement with the trend of the computed curves even though we would expect the computations to be less reliable at small \( S \).

In both Figs 1 and 2 the value of \( C, K \) has been taken as 0.35. An increase in \( C, K \) would move the computed curves bodily to the right and a decrease to the left. The value of 0.35 was chosen so that the maximum of the computed curves fell in approximately the right place in Fig. 2. The value of \( \theta \) selected for the computations is typical of velocity measurements over rough beds. The computed curves were found to be relatively insensitive to the value chosen for \( \theta \).

It was suggested by Bagnold (1954) that under some conditions the component of shear stress due to grain/grain interactions is proportional to the square of the velocity gradient rather than directly proportional to it. He referred to this situation as the “inertial” regime. The interstitial component of shear stress at the bottom of the mobile layer would be relatively small in this situation and so Eq (7) would have to be replaced by an expression of the form

\[
(\tau)_{y=0} = \text{const} \, \rho_s D^2 \left( \frac{\partial \mu}{\partial y} \right)^2_{y=0}
\]  

where \( D \) is median grain size. Fig. 2 shows, for purposes of comparison, a curve computed with this inertial boundary condition instead of Eq (7). For this curve, the constant in Eq (24) has been taken equal to 125 and the parameter

\[
I = \int_{\omega} \left[ \frac{a}{D} \right]^{2/3}
\]

is equal to 0.8. Clearly, the use of an inertial boundary condition does not significantly change the general trend of the computed curves.

A quantity of great interest from the engineering point of view is the thickness \( \delta_s \) of the mobile layer. At low values of \( S \) pressure gradient terms are unimportant and consequently \( \delta_s \) is a function only of \( \tau_0 / (\rho_s - \rho)g \). Sleath (1994) suggested, from comparison with experiment, that

\[
\frac{\delta_s}{D} = 2.94 \frac{\tau_0}{(\rho_s - \rho)gD} \tag{26}
\]

At high values of \( S \) it is the shear stress which is unimportant and, consequently, we expect the parameter \( \beta \delta_s \) to be a function of \( S \) alone. Fig. 3 shows how the computed curves for \( \beta \delta_s \) compare with the measurements of Dick and Sleath (1991) and Zala Flores and Sleath (1998) for acrylic sediment. We see that there are distinct curves for different values of \( V \) at low values of \( S \) but that at high values of \( S \) the various curves are almost identical. Dick and Sleath’s (1991) results lie in the range 6.8 < \( V < 18.5 \) so the agreement with the computed curves is good. The agreement with the experimental results of Zala Flores and Sleath (1998) is less good. This is probably because these tests showed plug formation. Under these conditions the assumption leading to Eq (18) is not correct.
Fig. 3 Variation of $\beta \delta_s$ with $\rho U_0 \omega / (\rho_s - \rho) g$. Dick and Sleath (1991):
○ (acrylic), ● (nylon). Zala Flores and Sleath (1998): □ (acrylic). Curve 7,
$V=10$; curve 8, $V=25$, ($C, K=0.35, \theta = 12.5^\circ$ in each case).

Fig. 3 also shows Dick and Sleath's (1991) measurements with Nylon pellets
of density 1137 kg/m$^3$ and median diameter 4.0 mm. The agreement with the
computed curves is less good than for the acrylic sediment, particularly at low values
of $S$. The reason may be that curves 7 and 8 in Fig. 3 are upper bounds, as discussed in
the next Section.

4. Upper bound and lower bound

So far, we have assumed that the thickness of the mobile layer varies little
during the course of a wave cycle and, consequently, it is the average value of the
dispersive stress which supports the weight of sediment above. The measurements of
Dick and Sleath (1991) showed that this was the situation at very large values of $S$. At
low values of $S$, the sediment settles onto the bed as the flow slows down and then is
eroded again after flow reversal, so there is significant variation in mobile layer thickness during the course of the cycle. Under these circumstances we should use Eq (17) rather than Eq (18).

Most flows show variations in mobile layer thickness during the course of the wave cycle which are somewhere between the two extremes outlined above. Consequently, we should regard curves computed with the aid of Eq (18) as upper bounds and those computed with the aid of Eq (17) as lower bounds. Fig. 4 shows how these upper and lower bound curves compare with the measurements of Li and Sawamoto (1995a) and of Zala Flores and Sleath (1998) with PVC pellets. The upper bound curves are the same as those shown in Fig. 3. We see that the measurements lie between the upper and lower bound curves.

Fig. 4 Variation of $\beta \delta_s$ with $\frac{\rho U_0 \omega}{(\rho_0 - \rho) g}$. Li and Sawamoto (1995a): $\bigcirc$. Zala Flores and Sleath (1998): $\square$ (PVC). Upper bound, Eq (18): curve 7, $V=10$; curve 8, $V=25$. Lower bound, Eq (17): curve 9, $V=10$; curve 10, $V=25$. ($C, K=0.35$, $\theta = 12.5^\circ$ in each case).
5. Maximum thickness of mobile layer

The experimental measurements in Figs 1, 2, 3, 4 extend to much larger values of $S$ than those likely to be encountered on site. For example, even under extreme conditions the value of $S$ in the Leman Field in the Southern North Sea does not exceed about 0.2. Madsen's (1974) calculations suggest that a local value of $S$ under the steep forward slope of a near-breaking wave might be as high as 0.36. But, even accepting this higher figure, it would seem from Figs 3 and 4 that the value of $\beta \delta_s$ for beds of sediment on site is unlikely to exceed about 100.

For the Southern North Sea a typical value of wave period for a 50-year storm might be about 13s. With $\beta \delta_s = 100$ we obtain $\delta_s \approx 0.2$ m. This value is significantly less than that given by existing empirical formulae for depth of disturbance in the surf zone. For example, the results of King (1951) suggest a depth of disturbance of about 0.5 m for a 50-year storm in the Southern North Sea and Williams' (1971) results lead to even larger values. The most likely explanation for this difference is that the empirical formulae include effects such as the movement of the offshore bar or the migration of sand waves. Clearly, the experimental data and the computations discussed in this paper are for very restricted conditions. The existence of effects such as bed form migration needs to be borne in mind when extending the results to the real world.

6. Conclusions

(1) Use of the Karman-Polhausen technique makes it possible to calculate parameters of interest without having to assume constitutive equations such as those suggested by Bagnold (1954).

(2) The calculated curves show good agreement, at high values of $S$, with existing laboratory measurements of the mobile layer thickness, the phase lead of the velocity at the bottom of the mobile layer, and the ratio of the velocity amplitude and phase scales $K_1 / K_2$.

(3) It is suggested that curves based on the assumption that $\delta_s$ is constant during the course of a wave cycle provide an upper bound on the value of $S$ for any given value of $\beta \delta_s$. A lower bound is provided by the assumption that maximum $\delta_s$ during the course of a cycle correlates with maximum dispersive stress.

(4) Although the calculated curves show good agreement with laboratory measurements, the estimates of mobile layer thickness are smaller than the values for depth of disturbance in the surf zone provided by existing empirical formulae. This may be because the present results are for flat beds and, consequently, do not include any allowance for the effects of bed form migration.

Numerical Investigation of Sediment Transport for Combined Waves and Currents

Juan Savioli

Abstract

This paper presents a numerical investigation of sediment transport under the combined effect of waves and current motion. Comparison of predictions to experimental measurements showed good agreement. The presence of a second peak over the decelerating and flow reversal was predicted by the numerical model due to the inclusion of an extended bed reference concentration and a turbulence model that is able to predict a sudden increase of the turbulent properties of the flow over this stage. Evidence suggests that the second peak is caused by an inflection point in the velocity profile leading to high diffusivities near the wall.

Introduction

Sediment transport in a coastal environment occurs under the action of a number of hydrodynamic processes. These cover flow situations ranging from waves to currents while passing through a variety of combined wave-current situations. In order to describe these complex mechanisms it is rather common to simplify them into ideal cases as pure waves or pure currents, but in most real situations we are confronted with rather complex situations, where waves and currents interact. The purpose of this work is to perform a numerical experiment of sediment transport under the combined effects of waves and currents.

Model Description

The temporal description of the suspended sediment can be expressed as a transport equation where particles are advected by means of their own settling velocity and
diffused by the natural turbulence of the flow. This, for the one-dimensional (in vertical) case, can be mathematically expressed as:

$$\frac{\partial c}{\partial t} = \frac{\partial (cw_z)}{\partial z} + \frac{\partial}{\partial z} \left( \varepsilon \frac{\partial c}{\partial z} \right)$$  \hspace{1cm} (1)$$

where $c$ is the concentration of sediment particles, $w_z$ the settling velocity of the particles and $M_S$ the turbulent diffusion of sediment particles.

This equation can be solved numerically if the value of the settling velocity, the turbulent diffusion of the sediment particles and an appropriate reference concentration or sediment flux are known. The description of the flow is carried out by solving the momentum equation in the x-direction

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \frac{\partial}{\partial x} \left( \nu \frac{\partial u}{\partial x} - u'w' \right)$$  \hspace{1cm} (2)$$

where $u'w'$ is the effective component of the Reynolds-stresses and $\nu$ is the kinematic viscosity.

Since the case to be simulated is associated with high Reynolds numbers the viscous stresses are negligible. The turbulent stresses, on the other hand, have to be expressed as a function of the mean quantities. A turbulence model has to be applied then to express the correlation between the turbulent velocities as a function of the mean flow variables. Adopting the Boussinesq assumption, the effective shear stress, arising from the cross-correlation of fluctuating velocities, can be replaced by the product of the mean velocity gradient and a turbulent viscosity; the turbulent stresses can then be expressed for the one-dimensional case as:

$$u'w' = \nu, \frac{\partial u}{\partial z}$$  \hspace{1cm} (3)$$

where $\nu$, unlike the molecular viscosity $\nu$, is not a property of the fluid. Under this assumption, the Reynolds stresses are defined in terms of only one unknown quantity, the eddy viscosity, therefore it is necessary to express the value of the turbulent eddy viscosity in terms of the known mean-flow quantities therefore the $k-M$ model was applied (Rodi, 1984).

This model is based on two transport equations, one for the turbulent kinetic energy $k$ and a second one to compute the rate of turbulent energy dissipation $M$. These two equations are expressed for the one-dimensional case as:
\[
\frac{\partial k}{\partial t} = \frac{\partial}{\partial z} \left( \nu_t \frac{\partial k}{\partial z} \right) + \nu_t \left( \frac{\partial u}{\partial z} \right)^2 - \varepsilon \\
\frac{\partial \varepsilon}{\partial t} = \frac{\partial}{\partial z} \left( \frac{\nu_t \frac{\partial \varepsilon}{\partial z}}{\sigma_\varepsilon} \right) + c_e \frac{\varepsilon}{k} \nu_t \left( \frac{\partial u}{\partial z} \right)^2 - c_{e2} \frac{\varepsilon^2}{k}
\]

where the turbulent eddy viscosity is defined as:

\[
\nu_t = c_1 \frac{k^2}{\varepsilon}
\]

The value of the constants considered for this type of flow are expressed in Table 1

\textit{Table 1} Values of the constants applied in the \(k-M\) model

In the case of combined waves and current it can be assumed that the ambient pressure can be obtained as a combination of the oscillatory component added to the pressure gradient that drives the current, therefore the 'total' ambient pressure can be obtained as the sum of the individual components. In oscillatory boundary layers it is assumed that the ambient pressure penetrates the entire boundary layer undisturbed. The pressure gradient can be obtained by applying the momentum equation in the \(x\)-direction to an outer boundary layer where the turbulence-representing quantities are assumed to vanish and the velocity approaches the free stream velocity \(u_\infty\). In the case of a pure current the pressure gradient is then related to the slope of the energy line and the pressure gradient of both effects can be expressed as follows:

\[
\frac{1}{\rho} \frac{\partial p}{\partial x} = - \frac{\partial u_\infty}{\partial t} - g HS
\]

The resulting one-dimensional equation for the mean flow is then expressed as:

\[
\frac{\partial u}{\partial t} = \frac{\partial u_\infty}{\partial t} - g HS - \frac{\partial}{\partial z} \left( \nu_t \frac{\partial u}{\partial z} \right)
\]

Boundary conditions at the free boundary must be also introduced. Here the distribution of kinetic energy and the rate of dissipation of kinetic energy are defined as a symmetric condition.
\[ \frac{\partial k}{\partial z} = 0 \quad \frac{\partial \varepsilon}{\partial z} = 0 \] (9)

On the wall, a non-slip condition applies, so that the velocity is considered to be zero

\[ u = 0 \] (10)

The behaviour of the wall can be considered hydraulically rough, so that the friction velocity can be obtained by assuming a logarithmic velocity distribution

\[ u = \frac{u_f}{k} \ln \left( \frac{z}{z_0} \right) \] (11)

where \( u_f \) is the friction velocity, \( P \) is the von Karman constant and \( z_0 = k_n/30 \), \( k_n \) being the Nikuradse equivalent roughness.

In this area close to the wall, the Reynolds stresses are nearly constant so that the convection and diffusion of turbulence can be considered negligible and local equilibrium prevails. Accordingly, the production and dissipation of kinetic energy balance out and applying the assumption of a logarithmic velocity distribution, the values of \( k \) and \( M \) at the wall boundary can be expressed as follows:

\[ k = \frac{u_f^2}{\sqrt{\varepsilon}} \] \[ \varepsilon = \frac{u_f^4}{k \, z_0} \] (12)

The solution of the transport equation requires also the definition of the boundary conditions for the bed and the free surface. In the case of the free surface, no flux of sediments is possible; therefore:

\[ w_s c + \varepsilon_s \frac{\partial c}{\partial z} = 0 \] (13)

In the case of the bed the definition of the concentration of more complicated. In this case the ratio between the stabilizing and agitating forces, defined as \( \Pi' \), is related to the value of the concentration at the bottom, so that a relationship between a bed concentration and \( \Pi' \) can be established. Zyserman and Fredsøe (1994), proposed and empirical formulation which related the bed concentration at \( z = 2 \, d_{so} \) to the Shields parameter, \( \Pi' \). This formulation, which will be applied in the present model, is expressed as follows:

\[ c_b = \frac{A(\theta \, \theta_c - \theta_c)^m}{1 + A / c_m (\theta \, \theta_c - \theta_c)} \] (14)

where \( \Pi' > \Pi_c = 0.045 \) and \( A=0.331 \), \( c_m=0.46 \) and \( m=1.75 \).
Figure 1 shows a comparison of the bed reference concentration as obtained from this empirical equation with measured data.

In the case of a flow which is reduced from a value of $\Pi'$ which is larger than the critical value to zero, the reference concentration drops to zero as soon as the value $\Pi'$ is less or equal to the critical value, and this does not seem physical correct. For this reason Justesen et al. (1986) proposed a so-called flux boundary condition where the value of the bed concentration, $c_b$, is also a function of the settling velocity of the particles, expressed as:

$$c_b = \max\{c_b(Q'), c(w_s)\}$$

(15)

![Figure 1. Comparison of Zyserman and Fredsøe's empirical formulation with measured data](image)

This expresses that the concentration is obtained as the maximum value of the predicted concentration based on the instantaneous shear stresses or the one obtained by considering the sediment settling down by its falling velocity. This was further developed, as presented by Savioli and Justesen (1997), by including the effect of the turbulent
diffusion in the movement of the sediment particles. The boundary condition is then expressed as:

\[ c_b = \{c_0(\theta'), c(w, \varepsilon_x)\} \] (16)

In this case the bed concentration is obtained as the maximum value obtained for the concentration based on the instantaneous shear stresses, or by considering the sediment settling down and being also influenced by the turbulent diffusion generated by the flow. A detailed description of the implementation of this boundary condition is presented in Savioli and Justesen (1997). It should be remarked that this boundary condition has been applied in order to investigate the behaviour of sediment for waves and current but it is not readily applicable in practical engineering cases.

**Comparison of Results and Discussion**

In order to compare the model with measured data a test case was simulated. The test case has been obtained from the experimental work carried out by Katopodi et al. (1994). This was performed at the Large Oscillating Water Tunnel of Delft Hydraulics where waves, currents and wave-current flow can be simulated. Natural uniform sand was used for the tests where sediment concentrations were measured. The mean grain size of the sediment particles was \(d_{50} = 0.21\) mm with a settling velocity of 2.6 cm/s. Test case E1 has been chosen for the comparison which is based on a sinusoidal wave combined to a current. Table 2 presents the values of the mean current velocity \(U_m\), the wave amplitude velocity \(U_0\) and the period \(T\) for the test case.

*Table 2. Characteristics of the flow for test case*

Figure 2 shows the time evolution of the measured and calculated sediment concentrations at different heights from the bed: \(z = 1.45\) cm, 2.35 cm and 3.65 cm. At the top the undisturbed velocity is also presented.

Two major concentration peaks occur when the flow velocity is at its maximum, these are not equal in magnitude due to the combined effect of the wave and current motion. Very good agreement is obtained between the predicted and the measured data, especially close to the bed at \(z = 1.45\) cm. The model predictions show remarkable agreement in phase and value of the concentration, during the first peak. The second peak, on the other hand, is slightly underestimated. As we move up from the bed, to \(z = 2.35\) cm and \(z = 3.65\) the difference between the predicted and measured values of concentration becomes more significant.
It is also observed a peak in the sediment concentration at flow reversal in the measured data. This has been captured by the numerical model due to the inclusion of an extended formulation which makes sediment available at flow reversal when the flow velocity is nearly zero and therefore the Shield's parameter value is smaller than the critical value $\Pi_c$.

**Figure 2** Observed and predicted sediment concentrations during a whole wave period

If the bed reference concentration would have been related only to the instantaneous bed shear stresses, $c_b = f(\theta')$, the concentration increase at flow reversal would not have been obtained since the value of the shear stresses over this period of
time is smaller than the critical value. In fact the inclusion of an extended bed reference concentration allowed this increase in the concentration at flow reversal to occur.

In order to observe the behaviour of this extended boundary condition, the values of the turbulent eddy viscosity have been extracted at three different elevations above the bottom. Figure 3 shows the temporal variation of the turbulent eddy viscosity at $z=0.1$, $0.26$ and $0.52$ cm. It can be observed that the value of the turbulent eddy viscosity follows closely the flow velocity so that it is at its maximum when the velocity is also peaking. Nevertheless, at flow reversal, a sudden and large increase of the turbulent eddy viscosity occurs generating a period of high diffusivity that promotes the spreading of sediment particles if the sediment particles are available, as introduced in the extended boundary condition.

**Figure 3** Predicted value of the turbulent eddy viscosity at different distances from the bottom during a whole wave period
As it has already been introduced, the value of the turbulent eddy viscosity is dependent on the turbulent kinetic energy to the power 2 and the rate of dissipation of the turbulent kinetic energy. If we now follow the evolution of the instantaneous value of $k^2$ and $M$ over a wave period, as presented in Figure 4, it is clear that the rate of growth of both of these during the acceleration stage is rather similar. On the other hand, over the deceleration phase, the rate of decay of $M$ is much larger than and a singular point is observed at flow reversal. At this particular moment there is an inflexion point in the instantaneous velocity profile, the velocity gradient is at its maximum and there is a large production of turbulence (the production term in the $k$ and $M$ equations is dependent on the velocity gradient to the power 2).

![Figure 4](image)

**Figure 4** Evolution of $k^2$ and $M$ at different distances from the bottom during a whole wave period
By analogy from the theory of gases the turbulent diffusion can be expressed as $v_i \propto u' l$ where $u'$ is related to $k$ and $M$ to the mixing length $l$. What is visible from the results is that, at maximum velocity, $u'$ is dominant while, at flow reversal, $l$ predominates.

One of the explanations regarding this behaviour was presented by Smith in 1977 where it was expressed in the form that the non-slip condition at the bed causes the fluid close to the bed to have a smaller inertia. It will consequently respond more rapidly to the free stream pressure gradient prior to the fluid both in the upper part of the boundary layer and in the free stream. Thus, the boundary layer leads the free stream flow, resulting in an inflection point (see Figure 5) in the bottom boundary profile during flow deceleration, reversal and subsequent acceleration.

![Figure 5. Schematization of the flow velocity profiles during deceleration and flow reversal](image)

Foster, in 1984, presented a theoretical study that suggested that flow in the bottom leads that of the free stream, resulting in an inflection point (a necessary condition for an instability to occur) in the vertical profile of cross-shore velocity during flow deceleration and reversal. During this period small perturbations may grow exponentially to breaking, leading to increased levels of turbulence. The existence of shear instabilities during the period of flow reversal was modelled by a simple linear stability analysis on a time varying bottom boundary layer. Predicted growth rates were large enough to yield an order of magnitude increase in initial perturbation amplitudes.
Conclusions

A numerical investigation has been performed in order to predict sediment transport in a combined wave-current flow. The predictions showed good agreement with the experimental measurements. A second peak near flow reversal has been predicted due to the use of an extended boundary condition and a turbulence model that is able to predict a sudden increase of the turbulence over the deceleration stage and at flow reversal. The results suggest that there is an inflection point, a necessary condition for a shear instability. Nevertheless further analysis should be carried out to investigate the flow behaviour and the bed reference concentration in this type of flow. Soon the advance of computer technology will allow to carry out Direct Numerical Simulations which resolve all the flow features avoiding the use of turbulence models based on average quantities.

A Morphodynamic Model for River and Estuary Management

Volker Barthel* and Ulrich Zanke**
* Directorate North, Federal Administration of Waterways and Navigation, Kiel, Germany
** Technical University of Darmstadt, Germany

1. INTRODUCTION

The Elbe estuary as part of the German Bight of the North Sea provides the waters for the world's most frequented waterway to the City and Port of Hamburg in Northern Germany (Fig. 1). At semi-diurnal tides with a range of approx. 3.5 m, alternating tidal currents and sediments ranging from fine cohesive material such as clay or silt to fine and coarser sands signify the estuary. Maintenance of approximately 100 kilometers of navigational channel with widths ranging from 250 to 450 m and minimum depths of

13.5 m below chart datum is mostly done by dredging. Some stretches are holding natural depths of more than the required depth; in other parts the necessary flushing force of the current is achieved by concentration of flow through the arrangement of groynes and training walls.

Dredging quantities are dependent on the hydrological conditions and vary between
12 and 20 Mio. m$^3$ / year. In the early eighties, dredging strategies permitted material to be pumped directly ashore for deposition. However, decreasing space and increasing prices for dump sites required a change of strategy. Nowadays, most dredged spoils stay within the system. Consequently, it is dumped in deeper parts of the estuary and even of the navigational channel. In either case, the sediment dynamics of the system will replace the dredged material and erode the dump sites and, therefore, lead to a continuous change between accumulation and erosion. Sediment which has been dredged at point A and deposited at point B can easily be transported back to A by tidal currents in no time. Therefore, the choice of dumpsites and the right time when to dump the material is of major importance.

The immediate effect of dredging operations and river training measures can easily be monitored through surveying and bathymetric comparisons. The complex nature of the estuary system and the multitude of factors of influence, however, prevent a direct correlation between bathymetric changes and the abiotic changes. This, and an effective prognosis can only be done by applying sophisticated engineering prognosis tools.

2. MORPHODYNAMIC MODELLING

The development of numerical models as engineering tools has made an enormous leap from simple 1-D-models for the simulation of hydrodynamic processes to 3D-models including the simulation of the most complicated turbulence structures in currents and waves, the transport of matter etc. Limitations are more or less set by the available computing power. While the 'real-time' inclusion of sediment transport in hydraulic modelling had found its way fairly early into physical models where scaled bed-material such as sand, coal, bakelite, ground walnut shells etc. was used to simulate the real world, the consideration of sediment transport in numerical models went through various steps of development. From a sole estimate of sediment transport on the basis of the computed hydrodynamic conditions various methods of computing sediment transport capacities were used. The hydrodynamic computation, however, was always based on a non-modified bathymetry. The step to the morphodynamic model has finally closed another gap in the suite of prediction tools by including in real time the bathymetric changes in a model (Fig.2).

The continuous calculation of the sediment transport and the sediment balance in a single grid point leads to upgrading the bathymetry at every time step. The immediate reaction of the bottom to waves and currents and, vice versa, the reaction of the hydrodynamic conditions to the changing bathymetry guarantees a much more realistic simulation of the processes than could be done with only a hydrodynamic model.

A very detailed study of morphodynamic modelling has been undertaken under the auspices of the MAST project of the European Community (Ref. Ref. To KÜSTE-paper in prep.). While the inclusion of the very details of the physical processes
involved in the transport of sediment under currents and waves can be included in the simulation process, the necessity to introduce filtering procedures [3] and/or

3. THE MODELLING CONCEPT

This paper describes the application of the well proven code TICAD \cite{2} for the
solution of the shallow water equations on the basis of a finite element system. The
subsequently developed code TIMOR3 \cite{7} includes the sediment transport. Basis of
the morphodynamic processes is the evolution equation for the bottom:

\[
\frac{\partial z}{\partial t} = \frac{\partial q_{tx}}{\partial x} + \frac{\partial q_{ty}}{\partial y} + E - S
\]

with:

- \( z \) = bottom elevation
- \( q \) = transported quantity in x-direction
- \( q \) = " " y-direction
- \( E \) = source term for erosion due to re-suspension
- \( S \) = sink term for deposition

The equation is being solved numerically in time steps \( \Delta t_s < \Delta t \) by an upwinding
scheme. For the computation of the transported volume several sediment formulae
were included in the model:

a) Integrated transport equation by Vollmers/Pernecker \cite{8}, without
transition between immobility and mobility:

\[
G^* = 25 \cdot Fr^* - 1
\]

with

- \( G^* \) = dimensionless transport parameter
- \( Fr^* \) = Froude number of the grain

Zanke \cite{9} expands this equation by adding a likelihood function for the incipient
motion:

\[
G^* = 25 \cdot Fr^* \cdot R
\]

with

- \( R \) = risk of motion acc. to equ. 4 in Zanke \cite{8}

\[
R = (10 \cdot Fr^*/Fr^{*_{cr}})^9 + 1)^{-1}
\]
with

$$Fr_{crit}^* = \text{Froude number of the grain at beginning of motion}$$

The dimensionless transport parameter $G^*$ can be expressed in terms of the transported volume to be

$$G^* = \frac{q_{tx}^* \rho' g}{u'^3}$$

with

$$q_{tx}^* = \text{transported sediment volume per unit of time and } x\text{-direction}$$

$$q_{ty}^* = \text{transported sediment volume per unit of time and } y\text{-direction}$$

$$\rho' = \text{relative density } (\rho_s - \rho_w) / \rho_w$$

$$\rho_s = \text{sediment density}$$

$$\rho_w = \text{water density}$$

$$g = \text{acceleration of gravity}$$

$$u'^* = \text{shear stress velocity}$$

This equation is set equal to the integrated transport equation to be solved for the transported volume per unit time and length:

$$q_{tx} = \frac{u'^*}{\rho' q} (25 \cdot Fr^* \cdot R)$$

$$q_{ty} = \frac{u'^*}{\rho' q} (25 \cdot Fr^* \cdot R)$$

with:

$$G^* = \text{dimension less transport } = q_t \rho' g / u'^3$$

$$q_t = \text{transported sediment volume per unit of time and width relative density}$$

$$\rho' = \text{relative density } (\rho_s - \rho_w) / \rho_w$$

$$\rho_s = \text{sediment density}$$

$$\rho_w = \text{density of water}$$

$$g = \text{acceleration of gravity}$$

$$u'^* = \text{shear stress velocity}$$

In the case of the total load based equation $E$ and $S$ are implicitly included in the transport formula. The simulation of erosion, suspended transport and sedimentation
is solved in TIMOR3 by using entrainment-settlement-terms. The basic principle is demonstrated in Figs. 4 and 5. Dependent on the net sediment flux of bed-load and suspended load in the bottom evolution equation the nodes of the topographic mesh change their level.

Fig. 4 Movable bed

This concept permits to continuously lift sediment from the bottom, carry it in the water column under concentration control and dump it depending on the hydrodynamic conditions. By doing this, the concentration of the suspension is not handled deterministically but simulates nature in a dynamic equilibrium. The entrainment rate for non-cohesive sediment can be taken from van Rijn [7], while the terms given by Partheniades [5] are best suited for cohesive material.

A major advantage of TIMOR3 against its predecessors is the ability to handle layered material where at every node in each layer an individual grain distribution can be defined. More than 1000 layers at each node and 10 grain size classes in each layers are possible dependent on computer capacity. Investigations with more than 100 layers have been carried out. These layers were static layers of constant thickness.

The thickness of the top layer, however, is related to the processes in the bed. As a mixing layer, which is dependent on the height of bottom ripples or dunes and follows the bed evolution, it can include one or more of the static layers. In case of accumulation active layers in the mixing zone switch from active to static one after the other. The main difference of this TIMOR3 concept to other mixing layer concepts, based only on two or three active layers [6] is the memory effect of the sediment distribution of the bottom in case of alternative and repeated accumulation and erosion. Fig. 5 demonstrates the multi-layer concept.
During the calculation the grain distribution within the active surface layers can change according to the hydrodynamic activity. As an example for the validation of the implemented sediment mixing procedure, all laboratory tests on armouring carried out by Günther [1], were re-run numerically. A main result was, that the resulting size distributions of the armour layer found by TIMOR3 were independent of the used transport formula. Only the computational time differed.

Fig. 5 The Multi-Layer Concept for an Element Cluster

Fig. 6: Comparison between measured and calculated sediment transport
dashed line: initial cond. - o : measured values + x : calculated values
Considering the possibilities of the numerical code as mentioned before and the problems to be solved through the model application the steps in the various simulation runs, as indicated in Fig. 7 had to be followed.

The simulation of long term processes such as the evolution of an estuary under currents and waves considering the variability of the tide can be a time consuming operation. For short term simulations such a neap-spring cycle reproducing the actual tidal signal may be still feasible. However, if the development of the bathymetry and the long-term effect of construction measures is to be investigated the computational costs can become excessive. Therefore, methods needed to be developed which reduce or simplify the number of events driving the model and increase the bathymetrical time step, i.e. reduce the number of updates of the bathymetry during the process.

Latteux [3] has described in detail the methods which can be applied to achieve this goal. For the simulation, e.g. of the tidal climate of one year, a limited set of natural events has to be found which forms the bathymetry as an actual set of tides would do. This could, e.g., be a weighed combination of mean and storm tides. The upgrade of the bathymetry is done at every 'tidal phase' where the definition of the "tidal phase' is not quite clear. Within this study we have achieved good results by integrating the sediment transport and bathymetric changes every x minutes with x ranging from 0.5 to 2 minutes. After extended research on the effect of mean and storm tides on the bed

---

**Fig. 7 Computational Steps for the Morphodynamic Model**
of the Elbe a weighted combination of mean and storm tides was used to control the model.

4. THE STUDY

The investigation area had to be selected carefully on the basis of the availability of permanent recording stations for water levels and field investigations of currents in the area. Boundaries were also chosen such as not to cut across side branches and tributaries of the river. Moreover, the area was limited by economic considerations of available computer power. Thus, a 25 km stretch of the Elbe estuary which is prone to high sedimentation and/or sediment drift, was chosen. Included in this reach of the estuary is a shallow water region where tidal flats frame the access channel to a small craft harbour, a tidal barrage and a ferry terminal. The stability of this channel is very much threatened by continuous drift and deposition of silt and clay, the removal of which approaches the limits of economical maintenance. The drift and deposition of very fine sands and silt at the southern tip of the island 'Rhinplatte' triggers frequent dredger deployment and has caused several navigational restrictions in the past. Quantities to be dredged in this area can amount to several million cubic metres if the hydrodynamic conditions show low tides combined with a frequently low or average fresh water discharge. Fig. 8 shows a map of the Elbe estuary, the main navigation channel and the investigation area.

Boundary conditions for the model for the calibration/verification phase as well as for short term simulations were provided through tidal records at the lower boundary and by discharge at the upper boundary. The results of the calibration show that the match between computed and actual water elevations is not perfect. Considering, however, that prognostic runs to be carried out are based on a system comparison and 'artificial' tides are being used for model control the estuary is simulated with a satisfactory similitude. The same applies to the comparison of tidal currents as shown
in Fig. 9.

The strongly structured bathymetry of the investigation area required a high resolution in various parts. Particularly well known deposition and erosion areas, more important small tidal gullies and side branches were to be overlaid by a finite element grid with element lengths down to 15 m. The diversity of the grid is demonstrated in Fig. 10.

Generally, this pilot study for the deployment of a morphodynamic model was initiated to determine its capability to simulate short-term and long-term sediment processes as a result of man-made changes to the system. This would include

- the effects of dredging operations on the channel
- the selection of dump sites for dredged spoil to prevent backdrift into the channel
- the design of access channels in areas of heavy sedimentation, and

![Fig. 9 Water Levels and Current Velocities - Verification Runs](image-url)
To achieve this, the evolution of the investigated stretch of the estuary was simulated for a period of twelve and twenty-two years with and without the usual maintenance by dredging. In a pre-run and to generate an initial situation a period of two years was simulated to allow for the necessary morphodynamic adjustment of the bathymetry created from echo soundings. Fig. 11 shows the initial bathymetry and the changes after these two years without and with man-made changes (dredging). The difference after 12 years would give an indication of the trend in the natural development of the system. The difference after 22 years gives clues as to where the changes occur and at what order of magnitude they will occur. Hence, the given time frames cannot be taken as absolute. A more accurate information can be given only after intensive calibration of the model with historical developments or long-term morphological comparisons. The difficulties of obtaining continuous environmental data for the same period is well known. Fig. 12 finally shows the difference of 22 years of morphodynamic development with and without maintenance dredging.
Fig. 11 Evolution of Bathymetry After 2 Years
Fig. 12 Development of the Investigation Area in 22 Years Without (Top Graph) and With Maintenance Dredging
Even though the grey shading in the graph cannot well reproduce the differences between the two stages of development as the original coloured graph could the effect of maintenance can well be detected. Without going into detail here one can interpret the results of the investigation in a way to show

- the effects of dredging activities for the channel and adjacent areas,
- the effect of dumping operations on the bathymetry,
- possibilities to change dredging strategies, and
- the imminent danger of meandering of the system if maintenance is not carried out on a regular basis.

Fig. 13 Investigation Area of the Ferry Access Channel - Alternatives
In a more detailed analysis of short term changes for the ferry access channel a morphodynamic development period of one year was simulated. This included the existing situation and various alternatives which theoretically should improve the situation (Fig. 13).

The investigation showed clearly that none of the proposed alternatives would improve the existing set-up. This is demonstrated through the graph in Fig. 13 showing the quantities to be dredged annually according to the numerical simulation. These quantities are in accord with the actually dredged material.

![Graph showing quantities to be dredged for alternatives A - D](image)

**Fig. 14 Quantities of Dredged Spoil for Alternatives A - D**

5. CONCLUSIONS

The investigations with a morphodynamic model set up to simulate the short-term and long-term sediment processes in an estuarine environment revealed that

- the model can be used as an economical engineering tool to plan and/or optimize dredging operations and river training measures,
- with a suitable hardware basis the calibrated model can even be deployed as a case-to-case-tool for maintenance dredging when changing tidal patterns required an immediate decision for dump sites,
- the comparison between the one-grain-model and the multi-layered system clearly
points towards the latter. However, for cheap and fast analysis, the simple model may be sufficient.

A major conclusion from this model study is, that the set-up, calibration, verification and running of a morphodynamic model requires the cooperation and functioning-as-a-team of experts from various disciplines. The interaction of these experts who seldom can be united at the same location is a major basis for the economic and successful conclusion of studies of larger extent. Therefore, a project has been initiated which combines the expertise from various fields in a 'virtual institute'. Utilizing modern information and communication technology on the basis of the INTERNET these experts collaborate form various locations in the same project. RANDOM WAVE MODELLING APPROACH INCLUDED
IN A BEACH DEFORMATION MODEL

Ioan Nistor¹ and Tomoya Shibayama²

Abstract

The paper presents the results of a study dealing with the inclusion of wave randomness into a beach deformation and a sand transport model developed for the regular wave input. The effect of wave irregularity is considered by employing the significant wave characteristics method and a joint distribution of wave heights and wave periods. The theoretical framework and the practical method for obtaining the joint distribution together with its application procedure are presented. The validity of the random wave approach modelling is verified by applying it for two different models: a time-averaged beach deformation model and a time-dependent sand transport model. The time-averaged model is capable of computing the beach deformation profiles while the time-dependent turbulent sand transport model is capable of computing the total sand transport rate over the entire surf zone. The simulation results for both numerical models are compared with laboratory data in order to verify, analyze and discuss the validity of the random wave approach as presented.

1. Introduction

Over the last years, numerous studies have been carried out for modeling beach profiles evolution under various wave conditions. Most of these efforts, whether physical or numerical, have been conducted for regular waves. Since the theoretical assumptions for many of the regular wave input models are reasonable and based on detailed physical and numerical assumptions, it is therefore necessary to try to extend the results of such models for the case of random waves. In natural conditions, the state of the sea is irregular. The present theoretical models, with a few exceptions, are considering the wave input as a regular one. Despite their usually good results, when compared to laboratory

¹Doctoral Student, Dept. of Civil Engineering, Yokohama National University, 79-5 Tokiwadai, Hodogaya-ku, Yokohama 240-8501, JAPAN.
²Professor, ditto.

3008
data dealing with regular waves, the practical purpose of such models is limited when it comes to practical applications since wave randomness, the true state of the ocean waves, is not included. The irregularity of the waves should be included in a theoretical model whose aim is - beyond its theoretical value - some level of practical application. Researchers opinioned that the relatively low level of understanding the sediment transport problems considerably slowed the introduction of the wave irregularity concept within sediment transport models. However, at this point, it is still difficult to incorporate a complicated random wave model coupled with the Navier-Stokes equations (even in their Reynolds averaged form) due to the very large computational effort required.

2. Random Wave Modelling

Random waves should be taken into account for a realistic modelling of the surf zone phenomena. For the practical application, Wu et al. (1994) discussed three basic approaches for the treatment of the random wave transformation in shoaling water and through the surf zone.

(1) Using a deepwater random wave time series as input and transforming each individual wave in the series as if it were a regular wave component with a distinct wave amplitude and period. The input deepwater time series could be generated from (a) real-time data series, (b) simulated from a given spectrum or (c) simulated from a given distribution function.

(2) Carrying out a spectral transformation, first from deepwater into shallow water. A time series is then created from the shallow water spectrum for further shoaling and surf zone transformation of each individual wave. The first step is equivalent to the transformation of Fourier components under the constraint of energy conservation. Some numerical models were used to accomplish this transformation.

(3) Conducting a “parametric” type transformation of deepwater random wave directly into the surf zone. The surf zone wave properties are then expressed as significant wave parameters and, sometimes, associated with distribution functions.

Each approach presented above can be considered as random wave input information. Approach (1) and (2) are conceptually the same. The third approach yields local wave information inside the surf zone but is difficult to reconstruct a continuous spatial variation of each wave which is required in some of the sand transport models. Many surf zone hydrodynamic or sand transport models focus on using individual wave analysis since this was proved to be more suitable for the surf zone. The probabilistic approach, which considers individual waves in the time domain, can be used to predict the distribution of wave heights and wave periods. In the surf zone, energy dissipation produces a strong coupling between components of the spectrum that is not well known. Therefore, a detailed description of the wave spectrum is not needed - in most of the practical cases - to compute wave-driven currents and sand transport. As a result, the researchers proposed simpler parametric approaches, which seek to reduce the computational effort - implicit in a fully discrete spectral model - by expressing the wave action balance in terms of a small number of characteristic parameters.
For the present case, a joint distribution of wave heights and wave periods is proposed. The method and theoretical framework for obtaining this distribution is further on presented.

**Joint Distribution of Wave Heights and Wave Periods**

In the last few years, few reliable experiments involving irregular wave action were performed in different laboratories around the world. In spite of the fact that not all-complete data parameters are available to public use (sometimes they are still being processed or incompletely reported), part of them can be used for the kind of analysis which the present work is dealing with.

The experiment involving irregular waves which is used for the present study is the Beach Deformation Research Project - BDRP - which was performed at the Central Research Institute for Electric Power Industry (CRIEPI), Japan in October 1995. All the cases involved in the BDRP experiment have several common features:

- were performed in Large Wave Flumes;
- all involved random waves action on a sloping sandy beach;
- all cases investigated the cross-shore hydrodynamics, sand transport and beach profile changes processes;

Two approaches were considered for including the irregularity of the input wave data (1) using significant wave parameters such as the significant wave height, $H_{1/3}$, and significant wave period, $T_{1/3}$, and (2) using a joint distribution of wave heights and wave periods.

![Wave Randomness Input](image)

Fig. 1: Wave randomness input for the present study.

In order to obtain the above-mentioned elements, the time-history of water surface elevation was necessary. For the case of the BDRP, Japan, the time-history of water surface elevation was available, so that it was possible to calculate the joint distribution of wave heights and wave periods. The details of the experimental set-up are not described in detail in the present material. A full description of the experimental facility and of the three cases analyzed in the present paper can be found in the paper of Shimizu et al. (1996).

The time-history of the water surface elevation throughout the entire surf zone was available for the case of the present experiment as recorded by a number of wave gages. For this latter case, the zero-down crossing method was employed, obtaining thus the time series of waves which were generated for all the three cases performed during the
laboratory experiments. For all cases, the number of raw data from the time-history of water surface elevation was 16384 (approximately 13.6 minutes duration) while the sampling frequency was 20 Hz. A Fortran program was developed to smooth the raw water surface data by using a low passing filter with a cut frequency of 5 Hz. Then, the zero-down crossing method was employed. The final outputs of zero-down crossing method were the wave characteristics (wave heights and periods) for all the waves in the series. Figure 2 explains the procedure used to obtain the joint distribution of wave heights and wave periods.

**Figure 2: Calculation of the joint distribution of wave heights and wave periods.**

The columns represented equal wave period intervals ($\Delta T = 1.0$ sec) while the rows represented wave height intervals ($\Delta H = 0.13$ cm). The size of the intervals was defined in correlation with the maximum recorded wave height, $H_{\text{max}}$, and maximum recorded wave period, $T_{\text{max}}$. Then, all waves in the three series were considered in order to
determine the number (or percentage of the total number of waves) of waves corresponded to each matrix location (e.g., what number (or percentage) of the total number of waves have the period in the interval between 5.0 and 6.0 seconds and the height in the interval between 0.40 and 0.53 m). All the waves in the time series were thus analyzed so that a particular distribution was obtained for all the three cases.

For these cases, 1a, 1b and 2 of the BRDP experiment, the wave series were analyzed and the results of the joint distribution are presented in Figs. 3, 4 and 5.

Fig. 3: Joint distribution of wave heights and wave periods for Case 1a (BDRP, Japan).

Fig. 4: Joint distribution of wave heights and wave periods for Case 1b (BDRP, Japan).
Fig. 5: Joint distribution of wave heights and wave periods for Case 2 (BDRP, Japan).

Basically, the irregularity of the wave series is reduced to a number of regular waves having their characteristics (heights and periods) comprised within certain selected intervals. As a result, it is possible to input the joint distribution output to any numerical model, which was developed for the regular wave input.

The values \( N_{i,j} \) represented on the vertical axes of the Figs. 3, 4 and 5 are the numbers of waves having the wave height comprised between \((H_i, H_{i+1})\) and the wave period within the interval \((T_j, T_{j+1})\). For each matrix element, \( N_{i,j} \), the mean value of wave height and wave period, \((\bar{H}_i, \bar{T}_j)\) is calculated as

\[
\bar{H}_i = \frac{H_{i+1} - H_i}{2}, \quad \bar{T}_j = \frac{T_{j+1} - T_j}{2} \tag{1}
\]

The pairs of wave characteristics, \((\bar{H}_i, \bar{T}_j)\), are taken as input data for the beach deformation model. The total duration of action for each of the pairs was obtained as

\[
T_{ij} = N_{ij} \times \bar{T}_j \tag{3}
\]

However, the input data for the duration of the simulation is the entire duration of the experiment, \(T_d\). The corresponding weight for each of the matrix elements is then calculated as

\[
p_{ij} = \frac{T_{ij}}{\sum_{i=1}^{m} \sum_{j=1}^{n} T_{ij}} = \frac{T_{ij}}{T_d} \tag{4}
\]
The number of output data - i.e., final beach deformation profiles or sand transport rates - is thus equal to the number of matrix elements. The elements are characterized by each combination of wave heights and wave periods. Then, the values of water depth in each location, \( h_{ij} \), (the vertical distance between the bottom and the mean water level which reflects the changes in the beach profile) are multiplied with the value of each weight, \( p_{ij} \), obtaining thus the final beach profile. A Fortran program was developed to compute the final beach profile.

\[
h = \sum_{i=1}^{m} \sum_{j=1}^{n} \left( h_{ij} p_{ij} \right)
\]  

The joint distribution is further verified using a numerical beach deformation model initially developed by Winyu and Shibayama (1996) and a turbulent sand transport model developed by the authors of the present paper. The beach deformation model is based on the time-averaged concept when computing the flow field and sediment concentration and the final output is represented by the beach profile change. The turbulent sand transport model is based on the time-dependent calculation of the hydrodynamic and sand concentration fields and its final result is the sand transport rate integrated over the entire water thickness and also, over one wave period. Further on, a brief description of the framework of the numerical models and their output as a result of applying the random wave approaches is presented.

3. Time-averaged Beach Deformation Model (Winyu and Shibayama, 1996)

The modified time-averaged beach deformation model of Winyu and Shibayama (1996) is composed of a sand transport model driven by a hydrodynamic model. The cross-shore change of local water depth, \( h \), can be calculated by solving the equation of conservation of sediment mass.

Assuming a steady concentration above the bed within the control volume, conservation of sand mass can be expressed as

\[
\frac{\partial h}{\partial t} = - \frac{1}{1 - \lambda} \frac{\partial q_T}{\partial x}
\]  

where \( t \): the time, \( x \): the horizontal coordinate in cross-shore direction, \( \lambda \): the sand porosity and \( q_T \): the total sand transport rate per unit width. In order to estimate the water depth change, the sand transport rate has to be evaluated at each local point.

A two-layer sand transport model is considered. In the upper layer, the transport rate is computed as a product of time-averaged suspended sand concentrations and time-averaged particle velocities at respective elevations. Integrating the product over the upper layer one can obtain the suspended load. The transport rate in the bottom boundary layer (bedload) is calculated in the form of an empirical formula. Therefore, the total load at the local point of the cross-shore sand transport rate, \( q_T \), is expressed as

\[
q_T = q_s + q_B
\]  

where \( q_s \): the suspended sand transport rate and \( q_B \): the bedload transport rate. In order to compute the total sand transport rate, \( q_T \), the sand concentration, fluid velocity and
bed load should be known first. Figure 6 shows the functional diagram of the 2-DV time-averaged beach deformation model.

![Flowchart diagram](image)

**Fig. 6: Beach deformation model - functional diagram.**

**The Wave Model**

In order to calculate the sand transport rate and beach profile change, wave height at each location must be computed. Wave height transformation in cross-shore direction is calculated using the energy flux conservation method in the form

\[ \frac{\partial Ec_s}{\partial x} = -D_b \]  

where, \( E \): the wave energy density, \( c_s \): the wave group velocity and \( D_b \): the energy dissipation rate which is zero outside of the surf zone. The energy dissipation rate is
calculated assuming its proportionality with the difference between the local energy flux and the stable energy flux.

\[ D_h = \frac{K_d}{h} \left[ E_{c_s} - \left( E_{c_s} \right)_s \right] \]  

(9)

where all the variables are computed using linear wave theory, so that \( E = \rho g H^2 / 8 \): the wave energy, \( K_d = 0.15 \): a constant, \( h \): the local water depth while subscript \( s \) means “stable”. The advantage of this procedure is that it is able to reproduce the pause (or stop) in the wave breaking process at a finite wave height on a horizontal bed or in the recovery zone.

The Sand Model

A two-layer sand transport model is considered. The upper layer includes the suspended sand while the lower one defines the bedload. The transport mechanisms for the two layers are essentially different concerning all phases of sand transport: initial movement, displacement of sand particles and deposition.

For calculating the sand transport rate in the case of suspended load, the employed approach is the \textit{time-averaged concept}. That is, calculating the time-averaged sand concentration and velocity profiles for each section of the beach in cross-shore direction, multiplying their values and integrating the product over the time and space. The time-averaged concentration profiles are calculated using the simplified diffusion equation, neglecting the horizontal convection and diffusion.

\[ \bar{c} w_s + \varepsilon_s \frac{\partial c}{\partial z} = 0 \]  

(10)

where \( \bar{c} \): the time-averaged sand concentration, \( w_s \): the falling velocity of the sand grain and \( \varepsilon_s \): the diffusion coefficient. To solve the diffusion equation, the concentration at the reference level should be given as boundary condition and the distribution of the diffusion coefficient should also be known. The reference concentration is calculated for both the cases of breaking and non-breaking waves. The diffusion coefficient is calculated using a new empirical formula developed by Winyu and Shibayama (1996), based on a large number of laboratory data and is given as

\[ \varepsilon_s = 0.21 u_* a_b \left( \frac{w_s}{u_*} \right)^2 \left( \frac{\eta}{d} \right) d_*^{-1.5} \]  

(11)

where \( u_* \): the maximum bed shear velocity, \( a_b \): the orbital amplitude of fluid particle just above the bottom boundary layer, \( w_s \): the falling velocity of the sand grain, \( \eta \): the ripple height, \( d \): the mean sand particle diameter and \( d_* \): the dimensionless parameter of sand grain diameter.

The vertical distribution of time-averaged velocity profiles is calculated based on the assumption of the eddy viscosity model. By considering the time-averaged values, the eddy viscosity model can be expressed as

\[ \bar{\tau} = \rho v \frac{\partial u}{\partial z} \]  

(12)
where $\bar{\tau}$: the time-averaged shear stress, $\rho$: the fluid density, $v$: the eddy viscosity coefficient, $\bar{u}$: the time-averaged velocity and $z$: the upward coordinate from the bed. Finally, the suspended sand transport rate is

$$q_s = \frac{1}{T} \int_0^T \int_{z_m}^{z} c(z) \bar{u}_s(z) dz dt$$

where $\bar{c}(z)$: the time-averaged vertical distribution of sand concentration, $\bar{u}_s(z)$: the time-averaged vertical distribution of sand grain velocity, $T$: the wave period, $z_m$: the level below which there is no movement of suspended sand particles, $z$: the vertical coordinate measured upward from the bed. The bedload is calculated using an empirical formula calibrated with a large set of experimental data.

4. Time-dependent Turbulent Sand Transport Model (Integrated Model)

The present numerical model is a 2-DV (two-dimensional vertical) model, named here as “Integrated Model”, which is divided into two distinct parts: (1) the upper model comprising the description of the upper layer (suspended sediment) and (2) the lower model (sediment as bedload), concerned with the bottom boundary layer.

The structure of the numerical model ensures continuity in the final calculation of the sediment transport rate over the entire water depth. Also, the hydrodynamic field and the sand concentration values are also obtained as equi-phase mean values. At first, the upper hydrodynamic model of Shibayama and Duy (1994), which is based on the averaged form of the Navier-Stokes equations (Reynolds equations), is used to calculate the velocity field in the area above the boundary layer. At the same time, the free stream velocity at the upper edge of the bottom boundary layer is obtained. The model assumes a time-dependent eddy viscosity coefficient depending on the wave breaking characteristics. The time series of the horizontal and vertical velocity at the upper limit of the bottom boundary layer which represent the “forcing factor” driving the flow inside the area close to the bed are the output of the upper hydrodynamic model. These values are imposed to the next model, which is the hydrodynamic and sediment model for the bottom boundary layer. This model is also based on the averaged Navier-Stokes equations (computing the velocity vector) and on the two-dimensional convection-diffusion equation (computing sand concentration). The output of the model include the equi-phase mean values of the horizontal and vertical velocity, of the sediment concentration and the sediment transport rate integrated over one wave period and over the thickness of the bottom boundary layer is calculated. The last element of the “Integrated Model” is the suspended sediment model for the area above the bottom boundary layer. This is a modified version of the suspended sediment model of Duy and Shibayama (1997) based on the same mechanism of diffusion combined with convection. Unlike the original model, which included a time-dependent pick-up function as bottom boundary condition, the modified model uses the time series of the concentration at the upper edge of the bottom boundary layer as the lower boundary condition. Then, the sediment transport rate is calculated for the upper layer using the time series of velocities and the time series of suspended sand concentration. Finally, the total sediment transport rate averaged over the entire surf zone and over one wave period is the summation of the
sediment transport rate in the upper and lower layer. The diagram of the “Integrated Model” is presented in Fig. 7.

![Diagram of the Integrated Model](image)

**5. Comparison with Laboratory Data**

Since the random wave input is the first step for the research processes of the present paper, it is necessary to evaluate the ideas proposed. The validity of the random wave input (as presented here) is evaluated by verifying it with laboratory data.

**The Time-averaged Beach Deformation Model**

The computed final beach profiles and the laboratory measured ones are shown in Fig. 8 (a, b and c). The calculated beach profile for all the three cases (Case 1a, 1b and 2) were determined using as input data both the significant wave characteristics and the joint distribution of wave heights and wave periods. As shown in the previously mentioned figures, each case involved different input data in terms of either the significant wave characteristics or the experiments duration. Using the joint distribution of wave heights and wave periods led to better results comparing to using the significant wave characteristics, both in terms of the horizontal location and vertical amplitude of beach profile deformations. For all the three cases shown in Fig. 8, using the significant wave height and wave period as wave input led to an overestimation of the beach deformation patterns. For a short duration of the experiment, using the joint distribution of wave heights and wave periods underestimates the laboratory data.
Concluding, the comparisons of the numerical and laboratory data seem to show a better performance when using the joint distribution compared to the use of the significant wave characteristics.

More than that, the differences between laboratory data and the computation using the significant wave characteristics are increasing with the duration of the experiment. The differences between computation and laboratory data for the case of the joint distribution have an opposite trend and tend to get closer in terms of deformation pattern and location.
The Time-dependent Turbulent Sand Transport Model (Integrated Model)

The measured sand transport rates (calculated from the beach profile change) are
compared with the sand transport rates as computed by the Integrated Model. For the case
of the Integrated Model, the sand transport rate is computed after a relatively small
number of waves (6-8 waves for stable computational conditions), assuming a uniform
beach profile without any small structure. Therefore, the computed sand transport rate
does not take into consideration any change of the beach profile and remains uniform for
any duration of the wave action. At the same time, it does not include the slope effect on
the transported sand.

In Fig. 9 (a, b and c), the total measured sand transport rates together with the
computed ones for both irregular wave approaches are compared. For all the three cases,
a general characteristic is that the total sand transport rate computed by using significant
wave characteristics has similar magnitude and space location as the ones resulted from
the application of the joint distribution of wave heights and wave periods.

For Case 1a and Case 1b and to some extent for Case 2, the volume of sand
transported as a result of applying the joint distribution of wave heights and wave periods
appears to be smaller than the volume of sand computed by using the significant wave.
The observation confirms previous conclusion of other studies, which suggested that, the

Fig. 9: Total sand transport rate for BDRP – Japan (using joint distribution of wave
heights and wave periods and significant wave characteristics).
volume of sand transported under the effect of an irregular wave train, is smaller than the one transported by a regular wave train having the same significant dimensions (wave height and wave period) as the irregular wave train.

7. Concluding Remarks

The aim of the present study is to analyze the inclusion of wave irregularity through two approaches: (1) the significant wave characteristics and (2) the joint distribution of wave heights and wave periods. The two approaches were applied for two different models: (1) a time-averaged beach deformation model, based on the linear wave theory, which is capable of simulating the beach profile changes for the entire duration of wave action and (2) a time-dependent, high computationally demanding turbulent sand transport model, based on the Navier-Stokes equations and on the in turbulent convection-diffusion equation, which is capable of computing the sand transport rate for a relatively short duration of the wave action.

For both models, using the joint distribution of wave heights and wave periods led to better results than for the case of using the significant wave characteristics. For the case of the beach deformation model, the advantage of using the joint distribution becomes clearer with a longer duration of the irregular wave action. For the case of the turbulent sand transport model, the application of the joint distribution of wave heights and wave periods reflects into slightly reduced sediment transport rates than when employing the significant wave heights and periods. At the same time, the sand transport rate is more uniformly distributed over the surf zone area when applying the joint distribution.

Yet, the results found for the present stage are not evident enough to draw a clear-cut conclusion so that more experimental and numerical results should be analyzed before a well-endorsed and solid statement to be made.

Geomorphological Modelling in Coastal Waters

Morteza Kolahdoozan¹, Roger A. Falconer² (Fellow), Yiping Chen³

Abstract

Details are given herein of the development and application of a three dimensional layer integrated numerical model to predict geomorphological changes in estuarine and coastal waters. An Alternating Direction Implicit finite difference scheme has been used for solving the governing differential equations, which include the conservation of mass and momentum for flow, the transport equation for suspended sediment fluxes and mass conservation for bed level changes. Model predictions have been compared to predictions using other existing models and against laboratory measurements. A series of experiments have been carried out for a laboratory model harbour, with the model predictions being compared to laboratory measurements.

1. Introduction

Rivers, lakes, estuaries and coastal zones have been used as a means of navigation, disposal of waste, fishing and many commercial and economic activities for centuries. One of the most important phenomenon in these regions is the transport of sediments, which may cause erosion and deposition and produce problems for navigation and marine economic activities. In recent years there has been a growing interest in long term geomorphological processes in estuarine and coastal waters, which are related to the transport of sediment particles.

In modelling the geomorphological changes in coastal waters the main processes are the flow, sediment transport and bed level changes. These three independent processes also depend upon each other. The current structure causes sediment particles to erode from the bed and settle out through the water column, thereby causing bed level changes. The changed bed elevation can in-turn then effect the current structure and hence the sediment transport rate etc. Therefore, a complete numerical model to predict the geomorphological processes should contain a set of

³ Lecturer, Department of Civil & Environmental Engineering, University of Bradford, UK
coupled equations, solving for the flow and sediment transport processes and bed level changes in the region of interest.

Rivers, estuaries and coastal zones are continually undergoing geomorphological development, including sudden changes due to tectonic movement or human interference and gradual evolution as a natural process. In this study, geomorphological processes by means of gradual changes have been studied. Mathematical models now provide an efficient and relatively accurate method for studying many phenomena relating coastal and estuarine engineering problems, including geomorphological processes. Different models have been developed and used for predicting bed level changes. The theoretical aspects of one-dimensional geomorphological models were studied by de Vries, 1981. De Vriend (1986) worked on the theoretical basis of the behaviour of two-dimensional models. Van Rijn (1987) developed a two dimensional vertical model for predicting geomorphological changes in laboratory channels. Following a two-dimensional depth averaged asymptotic solution for the advective-diffusion equation, introduced by Galappatti and Vreugdenhil (1985), Wang (1989) developed a two-dimensional geomorphological model for tidal basins. Van Rijn (1987) used a two-dimensional depth integrated model, together with a logarithmic velocity profile in the vertical direction, to provide a quasi three-dimensional geomorphological model and applied it to steady state flows in straight channels.

In this paper details are given of the development and application of a three-dimensional layer integrated geomorphological model for coastal water studies, with the model predicting bed level changes as a result of both suspended and bed load transport. The hydrodynamic field has been modelled by using a combined layer integrated and depth integrated set of equations [see Falconer et al. (1991) and Lin and Falconer (1997a)]. The suspended sediment transport equation was solved using an operator splitting algorithm, as the ratio of the vertical to the horizontal length scale was generally very small in coastal waters [Lin and Falconer, 1996]. A depth integrated mass balance equation has been used for predicting bed and suspended load fluxes, and subsequently predictions in bed level changes. An Alternating Direction Implicit finite difference method has been used to solve the governing equation for bed level changes.

2. Mathematical Formulation

In order to simulate the geomorphological processes occurring in estuarine and coastal waters, the governing equations were divided into three categories, representing the hydrodynamic, sediment transport and bed level changes. The governing hydrodynamic equations include the continuity and momentum equations in three dimensions, together with a turbulence closure equation for the determination of the eddy viscosity and diffusivities. In the sediment transport model, the advective-diffusion equation for suspended sediment transport is solved. The bed load transport is determined using a box model originally developed by van Rijn (1984). With the velocity and sediment concentration fields predicted, and by using the mass balance equation for the bed material, then bed level changes can be determined accordingly.
Governing Hydrodynamic Equations

The governing equations used to describe the velocity distribution in estuarine and coastal waters are generally based on the 3-D Reynolds equations for incompressible, unsteady turbulent flows. Usually in 3-D tidal models the assumption of a vertical hydrostatic pressure distribution is assumed, as is the case in the current model. According to this assumption the vertical acceleration of the flow must be much smaller than gravitational acceleration. As the water can be assumed to be well mixed in many estuarine and coastal zones, the water density can often be assumed to be constant throughout the domain. In applying these approximations, the governing three dimensional differential equations of mass and momentum can be written in their conservative form as follows [Lin and Falconer, 1997a]:

\[
\frac{\partial u}{\partial t} + \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0
\]  
(1)

\[
\frac{\partial u}{\partial x} + \frac{\partial u}{\partial t} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = f v - \frac{1}{\rho} \frac{\partial P}{\partial x} + \frac{1}{\rho} \left( \frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} + \frac{\partial \tau_{xz}}{\partial z} \right)
\]  
(2)

\[
\frac{\partial v}{\partial y} + \frac{\partial u}{\partial t} + \frac{\partial v}{\partial x} + \frac{\partial w}{\partial z} = -f u - \frac{1}{\rho} \frac{\partial P}{\partial y} + \frac{1}{\rho} \left( \frac{\partial \tau_{yx}}{\partial x} + \frac{\partial \tau_{yy}}{\partial y} + \frac{\partial \tau_{yz}}{\partial z} \right)
\]  
(3)

\[
\frac{\partial P}{\partial z} + \rho g = 0
\]  
(4)

where: \( t = \) time, \( x, y, z \) = Cartesian co-ordinates, \( u, v, w \) = components of velocity in \( x, y \) and \( z \) directions respectively, \( P \) = pressure, \( \rho \) = density of water, \( f \) = coriolis parameter, \( g \) = acceleration due to gravity and \( \sigma_{xx}, \tau_{xy}, \tau_{xz}, \sigma_{yy}, \tau_{yz} \) = components of stress tensor in \( x-z \) and \( y-z \) planes respectively.

Sediment Transport Equations

For the sediment transport sub-model both suspended load and bed load transport have been considered, with the sediment type depending upon the size and density of the bed material and the flow conditions. For predicting the suspended sediment concentration in estuarine and coastal waters, the advective-diffusion equation is usually used and which can be written as:

\[
\frac{\partial s}{\partial t} + \frac{\partial (us)}{\partial x} + \frac{\partial (vs)}{\partial y} + \frac{\partial ((w-w_*)s)}{\partial z} - \frac{\partial (e_x \frac{\partial s}{\partial x})}{\partial x} - \frac{\partial (e_y \frac{\partial s}{\partial y})}{\partial y} - \frac{\partial (e_z \frac{\partial s}{\partial z})}{\partial z} = 0
\]  
(5)

where: \( s \) = sediment concentration, \( w_* \) = particle settling velocity and \( e_x, e_y, e_z \) = sediment mixing coefficients in \( x, y \) and \( z \) directions respectively. For the case of bed load transport a box model, originally developed by van Rijn (1984), has been used giving:

\[
q_b = 0.053 T^{2.1} (\Delta g) D_s^{1.1} D_r^{-1}
\]  
(6)
where: \( T = \) transport stage parameter = \( \frac{(u_*)^2 - (u_{*,cr})^2}{(u_{*,cr})^2} \), \( D_* = \) particle diameter = \( D_{50} \left[ \frac{(s-1)g}{u^2} \right]^{1/2} \), \( \Delta = \) relative density and \( u_{*,cr} = \) critical bed shear velocity = \( (\theta_{cr} (s-1) g D_{50})^{1/2} \).

For the critical mobility parameter \( (\theta_{cr}) \), a novel unsteady criteria for the initiation of motion has been introduced and used in this study. Based on this hypothesis, the forces acting on a sediment particle can be divided into steady and unsteady flow forces. For unsteady flow effects, the significance of time dependency of the hydrodynamic parameters on the motion of sediment particles has been considered.

Assuming a sediment particle rests on a horizontal bed as shown in Fig. (1), then the fluid forces acting on this particle are the pressure force and the skin friction. These forces can be divided into drag and lift forces, in the vertical and horizontal plane, and in the Cartesian co-ordinate system. For unsteady tidal flow the drag and lift forces consist of two components, i.e. steady state flow effects and time dependency effects of the fluid parameters. Therefore these drag and lift forces can be represented as follows:

\[
F_D = F_{DST} + F_{DUST}
\]

(7)

\[
F_L = F_{LST} + F_{LUST}
\]

(8)

where: \( F_{DST} = \) steady drag force effect, \( F_{LST} = \) steady lift force effect, \( F_{DUST} = \) unsteady drag force effect and \( F_{LUST} = \) unsteady lift force effect. For steady state flows the drag and lift forces can be shown to be:
\[ F_{\text{DST}} = \frac{1}{2} C_D A \rho u^2 \]  
(9)

\[ F_{\text{LST}} = \frac{1}{2} C_L A \rho u^2 \]  
(10)

Similarly, for unsteady flows the force due to the time dependency of hydrodynamic parameters can be shown to be:

\[ F_{\text{UST}} = m \left( -\frac{A_w}{\omega^2} \sin(\omega t + \varphi) + u \frac{\partial u}{\partial x} \right) \]  
(11)

where: \( m = \) mass of sediment particle, \( A_w = \) amplitude of tidal wave, \( \omega = \) angular velocity and \( \varphi = \) tidal phase. Combining equations (9), (10) and (11), the critical mobility parameter for unsteady tidal flows can be shown to be:

\[ \theta_c = \frac{4}{3} \frac{1}{C^2 \left( L_1 C_D + L_2 C_L \right)} \left\{ - \left( -\frac{A_w}{\omega^2} \sin(\omega t + \varphi) + u \frac{\partial u}{\partial x} \right) (\sin \psi + \cos \psi) + g L_3 \right\} \]  
(12)

where the coefficients \( L_1, L_2 \) and \( L_3 \) are distances from the contact point of the particle, as shown in Fig. (1).

**Bed Level Changes Equation**

Bed level changes can be described mathematically using the mass balance equation for sediment fluxes. In the three dimensional computational domain a control volume is assumed in the vertical direction of the water column as shown in Fig. (2). The depth integrated mass balance equation for sediment in this case can be shown to be given as:

![Fig. (2) A control volume in the water body](image)
\[
\frac{\partial h_z}{\partial t} + \frac{1}{1 - p} \left( \frac{\partial}{\partial x} (h\bar{s}) + \frac{\partial}{\partial x} (S_{t,x}) + \frac{\partial}{\partial y} (S_{t,y}) \right) = 0
\]

where: \(z_b\) = bed level above datum, \(\bar{s}\) = depth averaged concentration, \(S_t\) = total transport = \(s_s + s_b\) and \(s_s\) = depth integrated suspended load flux which given as:

\[
s_{s,x} = \int_a^b \left( u_s - e_{s,x} \frac{\partial \bar{s}}{\partial x} \right) dz
\]

\[
s_{s,y} = \int_a^b \left( v_s - e_{s,y} \frac{\partial \bar{s}}{\partial y} \right) dz
\]

3. Numerical Procedure

The 3-D layer integrated TRIVAST model, originally developed by Falconer et al. (1991) and refined by Lin and Falconer (1997b), has been used for both the hydrodynamic and sediment transport part of the model. For the hydrodynamic model the depth integrated continuity and momentum equations are first solved to define the water elevations across the domain. Then the three dimensional continuity and momentum equations are solved for each layer giving the velocity components in three dimensions. In solving the to the above set of equations the Alternating Direction Implicit (ADI) finite difference method was used.

For the sediment transport sub-model an operator splitting algorithm was used to solve the advective-diffusion equation for suspended load transport. The basic principle of this method is to split the advective-diffusion equation into several smaller and simpler sub-equations, with each sub-equation being solved using the most efficient numerical algorithm (Lin and Falconer 1996). For more details about the solution procedure of this part of the model see Lin and Falconer (1997b). As the accuracy of the sediment flux predictions is significant in the bed level change predictions, it is therefore important to use a highly accurate scheme for solving the sediment transport equation. Since the advection terms (of order \(\Delta x^{-1}\)) are likely to dominate over the diffusion terms (of order \(\Delta x^{-2}\)) in estuarine and coastal waters, then for this part of the equation it was particularly important that an accurate scheme was used to discretize the advective-diffusion equation. Based on a study carried out by Cahyono (1992), the ULTIMATE scheme, originally proposed by Leonard (1991), was particularly attractive since it was more general than the other schemes considered and easier to apply. Lin and Falconer (1996) in their 2-D depth integrated estuarine model, used both splitting and non-splitting methods for the third order QUICKEST scheme, combined with the ULTIMATE limiter, to produce solute and sediment flux predictions [see Lin and Falconer, 1997b]. In this study, the ULTIMATE QUICKEST scheme was used to represent the advective terms in the sediment transport sub-model given by equation (5).
For the bed level sub-model, the depth integrated mass balance equation was solved using an Alternating Direction Implicit finite difference method. It is assumed that in the three-dimensional computational domain the sediment flux is integrated over each layer and then over the whole water depth, to calculate the depth integrated suspended sediment flux. These three sets of equations have been solved together in an uncoupled model resulting in predictions of the geomorphological changes occurring in coastal waters.

4. Experimental Set-up

For the validation of the model a laboratory experimental programme was carried out in the tidal flume [Falconer and Chapman, 1996] at the University of Bradford. This model was first set-up to study the tidal currents and flushing characteristics within a rectangular harbour. The overall working area of the tidal basin was $5.34 \times 3.68 \text{ m}$, with the square harbour being positioned on a level platform covering the full width of the tank and extending $3 \text{ m}$ out from the rear wall of the basin, as illustrated in Fig. (3). The square harbour had a plan-area of $1.08 \times 1.08 \text{ m}$ with varying entrance widths being considered in this study. Tides were generated using a variable elevation waste weir driven by a computer and producing a sinusoidal wave for this study. The flat bed of the harbour was first covered with a uniform depth of non-cohesive bed material. After 24 repetitive model tides, the bed level changes inside the harbour were measured. These changes mainly occurred along the entrance.

Fig. (3) Schematic illustration of the tidal basin
centreline of the harbour, where a strong jet-flow was produced due to the narrow harbour entrance. Measurements were taken for a number of parameters, including: the depth inside the harbour and the tidal range. A comparison of the results for different tidal ranges is shown in Fig. (4), with increased erosion occurring as the tidal range increased and the mean water depth decreased.

5. Model Application and Verification

In verifying the mathematical model for the case with suspended sediment transport, a straight channel, 3 km long and 1 km wide, under uni-directional and steady state flow conditions was chosen [van Rijn, 1987 and Wang, 1989]. A 400 m long headland was sited in the middle of the channel as illustrated in Fig. (5). The upstream and downstream boundary conditions were set to a constant discharge of 4000 cumecs and a flow depth of 6 m respectively. In the three-dimensional numerical model the water column was divided into 10 layers in the vertical. The predicted velocity and streamline fields are shown in Figs. (6) and (7) respectively. The predicted depth averaged
velocity field has been compared with predictions from the SUTRENCH and ESMOR models, developed by Delft Hydraulics (van Rijn, 1987 and Wang, 1989). The results obtained from these two models were compared along streamlines B and C with the current model, with the comparisons being shown in Figs. (8) and (9) respectively. As can be seen from Figs. (8) and (9), the depth averaged velocity prediction obtained from the three-dimensional model were in good agreement with the Delft Hydraulic model predictions.
A comparison of the depth averaged suspended sediment fluxes for five different numerical model predictions are shown in Figs. (10) and (11) along streamlines B and C respectively. As can be seen from the results, the current model predictions are again in good agreement with the other models. Finally, the sediment concentration patterns using this model are shown in Fig. (12), with the rate of bed level changes being predicted as shown in Fig. (13).
The maximum erosion rate near the tip of the headland was predicted to be 44.6 mm/hr and the maximum deposition rate was 6.9 mm/hr. In contrast, the results using a 2-D model gave lower values for the erosion and deposition rates. The values reported by Wang and van Rijn for maximum erosion were 43 and 100 mm/hr respectively, and the maximum deposition rates were 10.5 and 25 mm/hr respectively. A comparison of the above results shows that the results using the current 3-D model were in close agreement with the results of Wang (1989).

In terms of bed load transport, the model was then set-up to predict the bed level changes in the laboratory model harbour. A tidal period of 300s, with a tidal range of 10cm and an entrance width of 60mm gave rise to the predicted depth averaged velocity distribution for different tidal phases and using a no-slip boundary condition as shown in Fig. (14).

By including the sediment transport part of the model in predicting the bed load transport in the tidal basin, it was found that the Shield's criterion for the initiation of motion—which is based on extrapolation of the bed shear stresses obtained from experimental measurements for steady state flow conditions in flumes—failed to predict any changes in the bed level for the laboratory model harbour. Therefore a new criterion for the initiation of motion under unsteady flow conditions had to be
developed and used in this model. Results from the refined model for the bed level changes along the harbour entrance centreline are shown in Fig. (15), together with the experimentally measured results. As can be seen from this comparison, the refined model was capable of accurately predicting the bed level changes in the laboratory model harbour.

6. Conclusion

A three-dimensional layer integrated geomorphological model has been developed to predict bed level changes in coastal and estuarine waters. As the accuracy of the bed level predictions highly depends upon the accuracy of the sediment transport predictions, an accurate finite difference scheme - named the ULTIMATE QUICKEST scheme - was used to predict the suspended sediment fluxes. For bed load transport, the criterion for the initiation of motion for steady and unsteady flow conditions has been investigated. A comparison between laboratory measurements and the predictions obtained from the numerical model, for both steady and unsteady initiation of motion, was undertaken. These comparisons showed that a new criterion for the initiation of motion, based on a tidal flow, was capable of predicting bed level changes accurately in comparison with the physical model measurements.

Beach Recharge Design and Bi-modal Wave Spectra

T T Coates and P J Hawkes

Abstract

Recent field and laboratory research indicates the potential importance of complex wave spectra (combining swell and wind sea) in the design of gravel beach recharge schemes. The paper discusses the research and introduces a swell wave atlas as an aid to understanding the occurrence probability of complex wave conditions around England and Wales.

Introduction

Gravel beaches are found on the shores of many parts of the world, and are of particular importance along stretches of the heavily populated south coast of England where they are known as shingle beaches. Fully developed shingle beaches provide an excellent barrier against erosion or flooding. Unfortunately they are becoming depleted due to a lack of natural sediment supply and modifications to natural processes caused by coastal works (harbour construction, dredging, beach control structures). Shoreline managers are increasingly using beach recharge as a method of improving beaches for coastal defence purposes.

Design of shingle beach recharge schemes in the UK over the past ten years has relied heavily on a parametric beach profile model developed at HR Wallingford (Powell, 1988). The model was developed from an extensive mobile bed wave flume study using waves defined by JONSWAP spectra; effects on wave height and period, water level, sediment size and underlying impermeable layers are all considered.

Results from three recent research projects indicate a possible weakness in the model, and in all other beach or structure response models that are driven by simple wave conditions, whether numerical or physical. These results provide evidence of the potential importance of complex wave conditions that combine wind sea and swell, forming a wide spectral distribution that can separate into two distinct peaks or a bi-modal spectrum. These conditions arise when locally generated storm seas occur in conjunction with longer period swell waves.
The projects discussed in this paper include:

- Field work that recognised the occurrence and potential importance of bi-modal wave conditions.
- Development of a swell wave atlas for England and Wales that identifies the coastal areas likely to be affected by bi-modal conditions.
- A wave flume study that investigated the response of beaches under laboratory conditions.

The paper also touches briefly on further flume studies that looked at the impact of bi-modal waves overtopping seawalls and the stability of armour stone revetments.

The research projects were all funded by the UK Ministry of Agriculture, Fisheries and Food under their Flood and Coast Defence programme. Detailed descriptions of the work and the full results are presented in Coates et al (1998), whilst discussions and conclusions are presented in Hawkes et al (1998).

Field study

The response of shingle beaches to long period wave conditions has been noted and observed many times, but quantitative data regarding sea conditions and beach profiles are not generally available. An exception to this is the data set collected at a recharged beach at Highcliffe in Christchurch Bay on the UK south coast (Coates & Bona, 1997).

The Christchurch Bay field site is within an embayment and is partially protected from wave attack by headlands and an offshore reef. The steeply sloping upper beach is formed of shingle (5mm-50mm), while the lower beach comprises a wide sand platform. A three year study was commissioned to record the post-construction development of the recharged beach and to determine the effectiveness of the design process. Measurements were taken of beach profiles, sediment distribution, wave conditions and water levels.

Over the first two years the beach crest remained relatively stable, with variations of +/- 0.1m from the design elevation of 3.9mOD. This apparent equilibrium situation changed during a storm in late December 1994. The post-storm survey showed a distinct rise of the crest elevation to 4.3mOD. Initial analysis of the field data showed that the storm event was not unusual in terms of pre-storm beach profile, storm sequence and duration, peak water levels or maximum significant wave height. In most respects it was apparently similar to the previous storm in early December 1994, during which the beach crest had shown no increase in elevation. As there was no obvious reason for the difference in beach response a more detailed analysis of the wave record was undertaken.

The maximum recorded significant wave height was 3.17m for the 7-8 December and 3.14 for the 29-30 December. Plots of the wave spectra for these two events (Figure 1) show that the headline wave heights were misleading. The early December storm gave a typical wind sea spectra with a single peaked energy distribution (dashed line). The post-Christmas storm shows a distinctly different
The bi-modal shape comprises a less severe wind sea overlying a 15-20 second swell. The swell accounts for about 20% of the total energy and gives an estimated 1.15m wave height.

Figure 1  Storm wave spectra: 7-8 Dec and 29-30 Dec, 1994

Although these field records of beach response and wave spectra did not form conclusive evidence, they did suggest that bi-modal wave conditions could be important to beach recharge designs. Schemes designed using simple wave conditions could under estimate the equilibrium beach crest elevation and therefore the total volume of material required to provide coast protection. The field results were of sufficient interest to justify further work, first on the occurrence probability of complex wave conditions and second on a wave flume study to extend the beach response investigation under laboratory conditions.

Swell wave atlas

An atlas of offshore swell wave conditions around England and Wales has been developed (Hawkes et al, 1997), based on the UK Meteorological Office (UKMO) wave model for European waters. The UKMO model predicts both wind sea and swell waves at three hourly intervals for points on a 25-30k grid around Europe. Five years of data from the grid points around England and Wales were analysed to estimate extremes and were then presented as representative conditions for twenty five coastal areas. The atlas information is broken down by swell wave period and probability of occurrence. Figure 2 shows the distribution of UKMO grid points and the coastal areas. Figure 3 presents the swell wave distribution ($H_s$ vs $T_m$) for the area of the field study over the five year analysis period.
From the basis of this new swell wave information and an existing knowledge of wind sea climates the authors were able to consider their joint probability of occurrence. The interdependence of swell and wind sea were considered and correlation coefficients were proposed for each of the twenty five coastal areas. The results are presented as a series of tables of the range of wave combinations that have return periods from 1 to 100 years. In most locations the wave energy for a given return period is greatest for the wind sea only condition, while the swell wave only condition has the lowest energy; bi-modal conditions of combined wind sea and swell fit between these two limits. The shape of the energy curve for different wave combinations is critical in determining the potential importance of bi-modal conditions at any given site.
Figure 4 presents the energy distribution curve for Lyme Bay on a moderately exposed part of the south-west coast of England. The energy level drops away with increasing percentages of swell energy, but the rate is dependent on the swell wave period. Interestingly, for the same return period the total energy for wind sea only is approximately equal to wind sea plus a small percentage of swell; this observation is of importance in relation to the non-linear wave flume results presented below.

The shape of the energy curves is dependent on exposure to swell, exposure to storms and on local bathymetry. Further information on the development of the swell atlas is presented in Hawkes et al (1997).

Wave flume study

A physical model study was commissioned to investigate shingle beach response to varying combinations of swell and wind sea under laboratory conditions. The model was built in a 45m flume with a working water depth of 800mm. The required ranges of simple and bi-modal spectra were generated by an electro-hydraulic piston paddle to a notional scale of 1:20. Equipment included camera, video, automatic profiler and wave probes. The mobile beach simulated a typical UK shingle beach. It was formed of crushed and graded anthracite coal scaled according to well established and field validated principles that reproduce threshold of motion, fall velocity and beach permeability (Powell, 1988).

The test programme looked at beach response under six sequences of wave conditions. The five tests comprising each sequence had a constant total wave energy but varying proportions of swell and wind sea. The tests did not consider the probabilities of occurrence that can be derived from the swell atlas for specific sites.

Initial tests in each sequence used wind sea only. These were followed by three bi-modal spectra tests with an increasing percentage of swell energy relative to total energy. The final test used swell only. Figure 5 presents the spectra for one of the test sequences. Energy levels and peak swell periods for all of the sequences are presented in Table 1.

Figure 3  Sample swell wave distribution plot (central south coast of England)

Figure 4  Wave energy curve for a range of swell/wind sea combinations with an equal return period (Lyme Bay)
Figure 5  Typical wave energy spectra for test sequences

Complete cross-shore beach profiles were measured after each test using the automatic profiler. Analysis concentrated on the elevation and cross-shore location of the crest relative to the initial beach water line. These two parameters are considered critical indicators of shingle beach response under storm conditions and are important to beach nourishment design.

Figure 6 shows the variation in crest elevation with increasing percentages of swell at periods ranging from 11s to 19s. The wind sea only condition has an $H_s$ of 2.83m and is taken as the reference against which the other conditions are compared. The crest elevations have been non-dimensionalised to a percentage increase relative to the wind sea only result.

The elevation response to increasing amounts of swell energy and swell period are non-linear. The rate of elevation change decreases when swell accounts for more than 50% of total energy and when swell period increases above 14s.
Figure 6  Relative shingle beach crest elevations under bi-modal sea conditions

Figure 7 shows a similar pattern of results for the change in crest cut back with percentage and period of swell energy. The non-linearity is much more pronounced for percentage swell with the greatest change occurring up to 20%. Change with period appears to increase significantly between 14s and 19s.

Figure 7  Relative shingle beach crest cut back under bi-modal sea conditions

These results confirm the field observation that relatively small levels of swell energy in combination with wind waves can cause greater beach response than an equal amount of energy in the wind sea only frequencies. This conclusion has importance in the design of shingle beach recharge schemes in those areas identified by the swell atlas as being subject to significant bi-modal wave conditions.
Other flume studies

A series of additional studies were undertaken in the wave flume to determine the importance of bi-modal wave conditions to structure design. Work concentrated on wave overtopping of simple sloping walls, but some tests of rock armour stability were also completed.

Overtopping tests considered seawall slopes of 1:2 and 1:4, foreshore slopes of 1:7, 1:10, 1:20 and 1:50, and crest freeboards of 2m and 4m. Wave conditions included those used for shingle beaches, plus some additional heights and periods to provide a larger data set for analysis.

Measured overtopping rates varied with each structural parameter and with wave conditions. Bi-modal and swell only waves were shown to be most significant for the 1:4 wall slope with a 4m freeboard. Foreshore slopes made little difference.

Figure 8 shows the results for a 1:50 approach slope. Unlike the beach response results discussed earlier, the overtopping curves tend to be linear, apart from an apparent steepening towards the 100% swell conditions.

![Figure 8: Relative change in overtopping rates under bi-modal sea conditions](image)

The overtopping test programme showed conclusively that sloping seawall design should consider complex wave spectra in areas exposed to even moderate swell. Failure to do so could result in a significant underestimation of risks during storms.

A brief series of tests were run to determine the potential significance of bi-modal waves in determining armour rock stability. The damage results were inconclusive but suggested that complex sea states could be important to structural design.
Conclusions

The important influences of bi-modal wave conditions (combining wind sea with an underlying long period swell) have been observed in the field and in a large scale wave flume model. The probabilities of occurrence of these wave conditions around England and Wales have been estimated and published as part of a wave atlas (Hawkes, et al, 1997).

These conditions are believed to be important to the design of shingle beach recharge schemes and to some coastal structures. As yet little work has been done on defining the physical processes involved in the interaction between complex sea conditions and beaches. The results of this study can be used by coastal engineers to improve beach design, but no formal design tools have yet been developed.

MANAGEMENT OF BEACH NOURISHMENT
IN AN OPEN SAND SYSTEM

Hans H. Dette

Abstract

The nourishment of beaches is an environmentally friendly method of shore protection but the annual sand requirement may lead to substantial expenditure. Therefore the annual sand demand should be minimized. Factors which affect the sand demand along a sandy coastline in order retain the shoreline at a given position will be discussed. A wide normally dry beach on which waves can dissipate their energy at raised water levels without substantial reshaping of the underwater profile is desirable. Where such a beach cannot be created measures have to be taken to minimize sand losses from dunes during extreme events into the everyday surf zone. Furthermore the sand requirement for an open sand system, like the Island Sylt/North Sea, can be obtained by a reduction of the amount of sand from longshore transport which is carried over the ends of the island and is lost from the system.

Introduction

The west coast of Sylt (Fig. 1) is fully exposed to the North Sea waves from westerly directions and subjected to ca. 2 m high tides. Due to the geometry of the German Bight the coast is also affected by storm tides which lead to a rise in MHW level of up to 3.5 m. A maximum wave height $H_{m0} = 6$ m in 13 m depth of water (approx. 5 km off the coast) has been recorded so far.

The nearshore area is characterized by a longshore bar which is located approximately 300 m seaward of the shoreline. There high waves break as plunging breakers. During storm surges with a water level rise of more than 2 m the protective effect of the bar (crest height approx. MSL - 3 m) is lost and the waves pass over the bar without breaking (Fig. 2).

According to geological estimates the west coast of Sylt has been receding approximately 13 km over a period of 7,000 years (1.8 m per year). During all these

---

years the underwater profile has been translated eastward, probably without much change in shape. The eroded material established spits to north and south of the core of the island. These are now curtailed by major tidal channels. The tidal currents carry the sand that arrives at the ends of the spits away from the island. Thus, Sylt is a typical example of an open sand system, because eroded material is not returned to the island.

Figure 1. Open sand system: Island Sylt/North Sea
The 36 km long west coast consists mainly of unprotected dunes and an up to 25 m high cliff (Fig. 1). Only 10% of the coastline are protected by heavy coastal structures (city of Westerland). Since 1950 the mean yearly recession has increased from 0.9 m/year (1870 - 1950) to 1.5 m/year (1950 - 1985) due to an increased storm surge frequency (Dette, 1997). This is equivalent to an annual sand loss of $1.5 \times 10^6$ m$^3$ (1/3 to the south and 2/3 to the north). As a consequence of this accelerated recession a coastal protection concept for a period of 35 years (1985 - 2020) was initiated. This was done on the supposition that the increased storm surge frequency would continue and with it the erosion, which would endanger the island if no counter-measures were undertaken. The consideration of all possible alternatives of future coastal protection, their technical, economic and environmental aspects indicated that repeated beach replenishments appeared to be the most favourable solution. These repeated nourishments aim to replace the mean yearly loss of sand off the coast. A Sylt-specific masterplan based on the above considerations was introduced in 1985. It includes the task of monitoring, especially land and sea surveys before, during and after the individual nourishment schemes.

The first experiences gained from monitoring led to modifications of the initial profile of the berm nourishment to a lower and broader shape in 1988 (Fig. 3). Fig. 4 shows that the initial fill geometry (1992) has been altered considerably by a single storm surge within one year after the fill. The storm surge established an equilibrium profile for its raised water level (1993), which remained fairly stable even during a following storm surge of comparable strength (1994). Attempts to optimize the current design practice have been made since the beginning of the 90's.
Figure 3. Change of initial berm nourishment profile (above) to a lower and broader shape (below)

Figure 4. Changes of beach fill geometry (Sylt) during major storm surges in two consecutive years
Boundary Conditions on Nourishment Optimization

Having beautiful beaches and sea ambience Sylt developed into the primary recreational area in the North Sea since the middle of the last century. Any method of optimizing the coastal protection has to take into account the following boundary conditions:

- retention of the shoreline and the surf zone in its present form
- prevention of negative impacts on the near- and farfield coastline and islands
- minimization of any environmental impacts
- retention of a sandy beach
- acceptability for tourism

In addition protection has to meet the policy decision by the government that: "As a general principle hard structures should be avoided on sandy beaches."

These requirements basically predetermine beach nourishment as the best method of coastal protection. The normal longshore transport along the west coast of Sylt which is necessary to maintain the present appearance of the surf zone should not be influenced. The minimization of transport along the coast into the tidal channels can only be focussed on surplus sand masses exceeding the normal demand of sand in the surf zone. That is the uncontrolled transfer of sand from unprotected dunes or fills in front of dunes into the everyday surf zone at raised water level.

Under these premisses the following alternatives will be discussed:

- reduction of sand losses into the surf zone by design of nourishment techniques
- reduction of sand losses into the surf zone by measures that reduce the losses by storm surges
- reduction of sand losses from the island into the tidal channel by structural means

Protection by Exclusive Nourishment

Since 1972 repeated beach nourishments have been carried out for the protection of a seawall and revetment (length: 3 km) at Westerland (Fig. 1) against underscouring of the structures (Fuhrböter, 1974 and Dette, 1977). On the basis of the masterplan the nourishments were extended to the so far unprotected dune and cliff sites (length: 33 km) in order to maintain the shoreline in its natural appearance. The nourishments are nowadays aimed at the retention of the 1992-position which was legally introduced as the reference. Up to 1996 the total volume of beach fills amounted to $25 \times 10^6$ m$^3$ of sand from offshore borrow areas (Fig. 5). Practical experiences with the placement of beach fill, its effectiveness and life span have been gathered over a period of more than 25 years (Dette et al., 1994).

In the case of exclusive nourishment an optimization of the necessary amount of sand for the everyday surf zone is not possible because the longshore transport potential remains unaltered by an ordinary fill. As mentioned before in case of an exclusive nourishment, that is without any additional constructive measures, the supply of the surf zone from the high beach is uncontrolled (Newe and Dette, 1995).
It depends on the occurrence of storm tides. An optimization of sand requirement is restricted to the following alternatives:

- shaping of the fill geometry on the dry beach
- control of replenishment frequency
Shaping of Beach Fill Geometry

The day-to-day processes occur in the surf zone. The erosion during storm surges affects the normally dry beach and dune. The material is carried cross-shore into the everyday surf zone. On the basis of detailed profile surveys before and after a storm tide it was calculated that two major storm tides in 1990 caused a loss of $1.8 \times 10^6 \text{ m}^3$ of sand from the 36 km long west coast of Sylt. This is equivalent to 60 m$^3$/m shoreline. This large volume of sand in the everyday surf zone leads to a profile which is out of equilibrium with the everyday wave conditions. During the following normal weather conditions waves start to reshape the profile left after the storm into an equilibrium profile. This is associated with an increased mobilization of sediment and an increased longshore transport. Consequently, increased sediment volumes are transported by superimposed wave and tide-induced currents to the ends of the island during the reestablishment of the equilibrium profile. That means increased losses of sand. Only a minor part of the sand dumped into the surf zone by the storm will be returned to the beach, because the wave climate off Sylt contains only a small portion of long and swell waves. However, at times appreciable accretion of the beach does occur, as illustrated in Fig. 6 (12/73 - 12/74).

Figure 6. Appreciable accretion of the beach (Sylt) during occasional environmental conditions (seaward winds)

The shaping of beach fill geometry should be focussed on the creation of an as broad as possible dry beach with a flat slope which would suffer minimal sand losses during minor storm surges.

In case of raised water levels the flat slope of the usually dry beach (ca. 1:15) will lead to wave runup without creating an erosion escarpment. The amount of sand required for the reestablishment of an equilibrium profile, corresponding to the raised water level, is small (Fig. 7). The initial establishment of a broad beach along the west coast of Sylt would, however, requires a very substantial amount of sand (Fig. 4, similar to 2/93 profile).
Even with this solution losses from the fill geometry at all storm tides would occur, and by these means nourish the everyday surf zone. This process is an uncontrolled one and associated with occurrence of storm surge tides.

**Controlled Beach Nourishment**

Controlled beach nourishment is considered under the aspect of the establishment of a flat and as broad a beach as possible without attempting to "relocate" the surf zone seaward. This can be achieved by protecting the dune with a built-in membrane (Fig. 8). The membrane limits the amount of sand lost from the dune during a storm tide to the volume of sand cover on the membrane, i.e. the membrane serves as a limitation measure (Dette and Raudkivi, 1994). The membrane does not affect the appearance of the beach. If the membrane is exposed during a storm tide the sand cover has to be restored.
If the dry beach is very narrow the frequency of the membrane being exposed can be reduced by installing a stone wall at its toe. It limits the frequency of storm tides which overtop the wall to ten or more year intervals (Fig. 9). The maintenance of the surf zone by means of sufficient longshore transport in this case is from the beach which has to replenished at required intervals.

![Diagram](image)

**Figure 9.** Dune and flood protection on a narrow beach (schematic)

**Reduction of Sand Requirements**

The sand requirement can only be reduced by reduction of the sand loss from the western shoreline. That is the reduction of the amount of sand carried into the main tidal channels at the ends of the island. The installation of underwater sills at the ends of the island will counteract the concentration of the longshore currents at the island's ends and the development of deep channels. The sills will spread and slow down the longshore current and lead to accretion of sand. This will reduce the slope of the underwater beach and induce it to assume more the plan shape of a half moon bay. The reduction of the slope leads to wave energy conversion over a broader surf zone and reduce the energy loading per unit area.

The non-erodible sills will reduce the sand loss into the main tidal channels but will not stop it. That means that a supply to the adjacent areas will continue. Such a sill existed as a natural ridge at the northern end some 50 years ago, linking the end of the island to the larger offshore sand bank. Today the ridge is been eroded down to a 6 m deep channel with concentrated high velocities. At the northern end the installation of the sill means restoration of the ridge which was there before. It is schematically shown in Fig. 10.
Figure 10. Layout of an underwater sill at the northern end of Sylt to reduce longshore transport into the tidal channel (schematic)

At the southern end the installation of a sill involves a substantial effort. The dynamic equilibrium of the southern end of the island was disturbed by the construction of the large tetrapod groyne at Hörnum in the 70's. It deflected seaward the southerly longshore transport and it continued offshore to the main tidal channel (Fig. 11). The shoreline south of the groyne suffered by lee erosion and the southern end has retreated nearly 1 km. The ridge along the tidal channel to the offshore sand bar has increased in length from 800 m to 1750 m and the depth over it by 2 m (Fig. 12).
Figure 11. Accelerated shoreline recession after construction of a Tetrapod groyne in the 70-ties (ALR Husum)
Figure 12. Extension of the ridge along the tidal channel from the shoreline to the offshore shoal and lowering of the depth contour by 2 m in the average
A sill at the southern end would stabilize that end. It would involve some "reconstruction" of the end and a sill as illustrated schematically in Fig. 13.

Figure 13. Restoration of former island's shape and its fixing at the southern end of Sylt (schematic)

Conclusions and Recommendations

In order to protect an open sand system the entire coastline should be considered as one single unit, i.e. it should not be splitted into sectors with different protection standards. The most favorable solution for the management of an open sand system like the westcoast of Sylt would be the minimization of the everyday longshore transport to that magnitude which just is necessary to preserve the present appearance of a wide beach and surf zone.
The required minimization of sand loss can be achieved by a barrier inside the dune or inside a berm nourishment profile that limits uncontrolled erosion by extreme storm tides. In case of a narrow beach the barrier, e.g. a geotextile membrane, can be protected by an additional stone wall at its toe. Sand deficits to the everyday longshore transport due to this measure could be compensated by additional sand supply (nourishment) to the beach in the middle of the island, from where the sand will be moved alongshore to the ends of the island.

Underwater sills at the ends of the island will reduce the concentrated longshore flux into the tidal channels and by these means extend the residence time of sand in the open system.

The realisation of such an overall solution, with the aspect of changing philosophy from shortterm, mostly remedial measures to a longterm preventive strategy, necessitates persuasive power and last not least the availability of substantial funds.

BEACH FILLS IN EUROPE -
PROJECTS, PRACTICES, AND OBJECTIVES

L Hamm1, H Hanson2, M Capobianco3, H H Dette4, A Lechuga5, and R Spanhoff6

ABSTRACT: The beach fill situation in five European countries is highlighted and discussed with respect to the general situation, project type and objectives, design and evaluation procedures, legal framework, and financial aspects. As expected, significant differences were found between the investigated countries. In general, the study shows that it would be very profitable for south European countries to learn about the Dutch and German practices, particularly regarding the long-term coastal management and the regular monitoring of the coastal morphology. On the other hand, recent Dutch experience has shown that their legal system is a bit too rigid leading to automatic local renourishments that are unnecessary to reach the global objective.

INTRODUCTION

The present study is a part of a project called SAFE (Performance of Soft Beach Systems and Nourishment Measures for European Coasts), sponsored by the European Commission. The overall objective of the SAFE project is to develop a sound and improved methodology to predict the medium and long-term performance of artificial nourishment schemes by introducing reliable and validated numerical modeling tools (Hamm 1998). As a part of this project, an inventory of and a comparison between the major nourishment countries involved in the SAFE project was performed.

The objective of this particular study is to compile, disseminate and exchange national information on a European level concerning beach fill operations for coastal protection, projects involved, and practices used. Below follows a tour through the participating countries in Europe, in no particular order, to reveal the present situation. For each country, the general situation is briefly discussed together with an overall description of

project types, objectives, design, and evaluation. In the concluding section at the end of this paper, a comparison between the different countries is presented, where common features as well as differences are discussed. This includes the more detailed design aspects - methods, considerations, constraints, and fill types, methodologies, and equipment.

BEACH FILLS IN GERMANY (DE)

Up until 1950, shore protection in Germany was mainly achieved through hard structures. The first fill in modern times was performed in 1951 on the Island of Norderney. Since then, there has been a gradual change from hard to soft protection measures in sandy coastal zones. After the first fill, more than 130 fills have been performed at 60 different sites (Figure 1) adding up to a total fill volume of about 50-10^6 m^3.

The mainland of the German North Sea coast is protected by seadikes. Beach fills are carried out at sandy beaches which are predominant on the Eastfrisian and Northfrisian Islands in the North Sea and along the coastline of the Baltic Sea. The islands have to be maintained, because their existence is considered as large scale-natural barriers which protect the mainland.

Project Types and Objectives

Because the federal states in Germany have different protection policies, the project objectives may vary depending on location: 1. Soft protection of seawalls and revetments against local scour through toe nourishments. 2. Strengthening of dunes and beaches in order to keep shorelines at their 1992 positions (Dette 1987). 3. Preserve at all times a minimum natural dune width of 40-45 m. 4. Erosion mitigation. 5. Compensation of lee-erosion caused by coastal structures. These five types of projects are carried out in the framework of legal coastal protection by coastal authorities. In addition, local communities take initiatives to improve their beaches for recreational purposes.

Design and Evaluation

The design methods to meet the various objectives can all be classified into the category of generic templates. Refined design stage methods are at the very beginning of being considered as design tools. For the protection of the Westerland seawall on Sylt three unusual design types were developed (Dette and Gärtnner 1987) including 1. a successful spit-type fill which extended seawards more than 350 m from the seawall, 2. a less successful, linear, 1.0-km long fill up to 3 m above MHW, and 3. the combination of both previous designs called a "girland-type" fill with satisfying results.

In general, coastal protection in Germany is done within a well-developed longterm strategy for actions along the coast. For most projects the responsible authorities are implementing follow-up programs. However, serious overall performance evaluation programs are still not used to any extent, but only in some special cases.
Legal and Financial Aspects

German coastal protection is regulated by the Constitutional Law in terms of a Conflicting Legislation Act. The national Government may apply this right, if a matter is not regulated effectively by federal law or if the legislation of one state interferes with the legislation of other states or that of the entire nation. The five coastal federal states have formulated special regulations for coastal protection in their federal legislation. Although these regulations differ in certain aspects, the national Government has not yet made any use of the Conflicting Legislation Act.

The national Government, being aware of its overall responsibility, financially supports the coastal protection works of the coastal federal states. This support is subsidiary, i.e., national funds are only granted if matched by funds from the concerned federal states.

In 1969, Article 91a was amended to the Constitutional Law of 1949. In this Article the co-operation between the national Government and the federal states was legally established by means of "Joint Tasks". Such tasks have to be classified as being of national importance and as being necessary for improving the standard of living. Coastal protection has been identified as such a Joint Task and, thus, included in article 91a. The national financial share in these tasks was fixed at 70 per cent.

The protection of sandy coastlines against storm surges and erosion by means of repeated beach fills and nourishments is handled individually by the coastal federal states in terms of "General Protection Guidelines" or site specific master plans. Since 1950 more than 95 % of all nourishment sites in Germany have been benefitting from those regulations. The rest, e.g. small fill projects for mostly recreational purposes, are financed by local authorities on the basis of their own interest. Within this legal scheme, the economy of coastal protection projects is not dealt with. Until this day economic justification of such projects is not obligatory.

BEACH FILLS IN ITALY (IT)

In Italy, modern beach fills have been practiced since 1969. During this period about 50 fills have been performed at 36 sites (Zaggia, 1998) adding up to a total fill volume of about 15·10^6 m^3 (Figure 2). A large majority of these fills are small-size interventions around 100 - 150·10^3 m^3. The exceptions are four large interventions at Cavallino and Pellestrina near Venice (7.6·10^6 m^3), Ravenna in the Po river delta (1.4·10^7 m^3), Ostia close to Rome (1.4·10^7 m^3), and Bergeggi on the Italian Riviera (2·10^7 m^3).
Project Types and Objectives

Almost all projects comprise of a combination of sand nourishment and hard structures (Benassai et al. 1997). These different projects may be attributed to one of the following general objectives: 1. Erosion mitigation at local scale. 2. Enhanced recreation at very small scale. 3. In southern Italy there is often the need to safeguard the coastal railway. These interventions may, almost generally, be regarded as remedial (counter-active) rather than preventive (pro-active) measures, i.e., emergency-type actions are taken as problems are identified along the coast without any long-term planning or overall strategy.

Design and Evaluation

Most projects are based on a generic design with a combination of hard and soft structures. Most minor projects are designed by simple scoping methods utilizing crude evaluations of shoreline retreat rate together with an evaluation of the equilibrium slope. In larger projects, somewhat more refined design methods are used, where a crude evaluation of the longshore sediment transport rate is combined with detailed computations of the volume budget. In addition, the Dutch CUR (1987) manual is consulted for determining longterm trends, renourishment intervals, etc.

Physical model tests are quite common in larger projects. However, numerical models are not used, with the exception of the Pellestrina and Cavallino projects where, to some extent, such models were used. These projects were, however, undertaken in the particular framework of the Special Law for the Safeguard of Venice. In general, monitoring is only limited or not done at all. Also, there is no established methodology for maintenance schemes and no actual performance evaluation is made for the projects.

Legal and Financial Aspects

In Italy, coastal waters and beaches are State owned. This means that initial costs have generally been attributed to the State, while the regional Governments are responsible for maintenance and associated costs, at least formally. Exceptions to the attribution of the maintenance costs are the rule, typically based on the occurrence of extreme events which require the support of emergency measures (with funds coming from the State). Revenues go to the Municipalities. In the past there were hardly any cost-benefit analyses of
projects. What is most evident is, thus, the discrepancy between who is paying and who is receiving the benefits. The situation is anticipated to change in the future.

The Law of 1907 distinguished between two types of coastal defenses, those to protect built-up areas and those to halt beach erosion. Concerning the former, the local planning authority is in charge and can obtain financial support from the Ministry of Public Works, once its operative sections have considered the works to be technically feasible. In the second case, both the Municipality and the Port Authority can apply for financial supports from the Ministry of Public Works in order to build up the defenses.

The Decree Law of 1985 restricted development to 300 m inland from the high water mark. The regions were requested to issue territorial and landscape plans aimed at regulating the uses of these areas and at ensuring their sustainable exploitation. Stabilization of the dunes in order to protect the hinterland is now being considered.

New legislative developments are expected by the application of the so-called "Coastal Plan", currently under preparation by the Ministry of the Environment. Other new legislative developments, that could eventually go in the direction of "Coastal Zone Management" are also expected following the possible adoption of the Strategic Environmental Assessment for the coastal zone and the transfer of competence from the State to the Regions (Law of 1997).

BEACH FILLS IN THE NETHERLANDS (NL)

In the Netherlands, modern beach fills have been practiced since 1970. During this period about 150 fills and refills have been performed at about 30 sites adding up to a total fill volume of about $110 \times 10^6$ m$^3$ (Figure 3). Since 1991 the average fill volume amounts to about $6 \times 10^6$ m$^3$ per year.

The Netherlands have struggled for many centuries to safeguard its territory from flooding. The western part of the country is below mean sea level. Large portions of the Dutch coast are receding since long. Historically, this recession has been stopped at some places with dikes, whereas at various other places no strict measures have been taken, or the recession has merely been slowed down with groins and fences. Thus, in general, the policy was previously one of selective retreat. The disastrous flooding in 1953 of large parts of the south-western part of the Netherlands led to a change of this policy. New legislation concerning minimal safety standards for the coast against flooding was adopted.

Figure 3. Documented beach nourishment sites in the Netherlands.
A further step in this direction was taken in 1990 when the policy of Dynamic Preservation was adopted. This was based on the presumption that it is technically and economically possible to compensate natural erosion of sandy coasts by nourishment. Prior to this policy, most nourishments were done for reinforcing dunes against breaching.

**Project Types and Objectives**

After adopting the Dynamic Preservation policy, the overall objective has been to preserve the 1990 coastline location through nourishments on a national scale. Thus, policy implies that the future coastline should nowhere be landward of the 1990 position. When required, sand is nourished to warrant the latter.

**Design and Evaluation**

The responsibility for coastal protection in the Netherlands is divided between national (Rijkswaterstaat which also have local offices) and regional authorities, so-called Water Boards. A local Rijkswaterstaat’s body designs the nourishment and produces a blue print covering all aspects to be taken into account by a contractor, such as place of sand mining, shape of the nourished profile, i.e., how much sand has to be placed in each profile, in which time-frame the work should be performed, etc. Thus, the design is very strict and with little variation from site to site (CUR 1987).

The principal design parameters are nourishment volume, depending on the rate of autonomous erosion and the requested lifetime and the effectiveness factor of nourished sand. The latter is defined as the ratio of the autonomous erosion rate before to the actual erosion after implementation of the nourishment. Beach nourishments are designed to compensate for the natural loss of sand in a coastal stretch for a defined period of time to come. The amount of sand is, thus, calculated by multiplying the design lifetime with the annual loss derived with the regression over the previous 10 years. The amount is then corrected with a site-dependent effectiveness factor (10%-20%) to account for the possible slightly increased erosion rate after the nourishment, compared to the autonomous one.

The coastline is obtained from a measured sand volume rather than from an observed horizontal line such as the MLW. This volume is contained in a horizontal layer and is bounded by the profile and a fixed vertical reference line. For some places one has deliberately defined another position, more seaward, to ensure that the safety or a required beach width is automatically warranted as long as the coast line meets the 1990 criterion. In addition, the safety against flooding is checked every year, on the basis of the measured profiles. The evaluation of nourishments is based on annual surveys, performed along the entire Dutch coast since 1965, with cross-shore profiles 200 to 250 m apart. During the operations the treated sections of the nourishment site are surveyed before and soon after their treatment, in order to achieve proper nourishment volume values.

**Legal and Financial Aspects**

The Sea Defense Law of 1996 regulates the responsibility for maintaining the safety against flooding and the division of tasks between Government and regional authorities. Maintenance of the primary sea defenses is handled at a regional level, through the Water Boards who are supervised by the provinces. Because of the national interest of safety, the
Minister of Transport, Public Works, and Water Management has the overall supervision. For dune systems, a large part of the profile is considered to make up the primary defense, from the shoreface to the landward side of the first dune. The local Water Boards are in first instance responsible for the dunes while the Government has to maintain the coast line. This approach obviously requires close collaboration between the two levels, which takes place on a provincial level in the so-called Provincial Consultative Bodies (POK's), each consisting of representatives from the province Government, the local Water Board(s), and the Rijkswaterstaat. The provincial authorities chair the POK's to ensure that the coastal management is in line with the regional planning policy. According to the Sea Defense Law, the dune profiles are measured each year and whenever the standards are not met, measures will be taken with a high priority.

The local Rijkswaterstaat's authority is also responsible for numerous permits needed. They have to be granted by local municipalities, Water Boards, etc. They concern amongst other things permission to work in the areas, such as installing pipelines and pumping stations. There may be regional differences. For example, in one province the beach has remained under the jurisdiction of Rijkswaterstaat, for the specific reason of controlling the permits to work there, while in another it has become part of the Water Board's responsibility. Fortunately, with the present day experience, obtaining these permits is a routine operation.

In the policy of Dynamic Preservation the Minister of Transport, Public Works, and Water Management has to inform parliament every 5 years about the results of this policy. A first (interim) report was provided in 1993, a first full report in 1995, while the next one is foreseen for the year 2000. The policy will be continued for the time being. With the maintenance scheme built into the legal structure, little economic justification is necessary for individual projects.

**BEACH FILLS IN FRANCE (FR)**

In France coastal defense works are quite significant but nourishment is only a marginal technique adopted to control the erosion. A recent inventory (Hamm et al. 1998) showed that modern beach fills have been practiced since 1962. During this period about 115 fills and refills have been performed at 26 sites adding up to a total fill volume of about $12 \times 10^6$ m$^3$ (Figure 4). This very limited quantity reflects that most coastal defense works in France still comprise the construction of groins, seawalls and detached breakwaters.

**Project Types and Objectives**

The French approach of beach nourishment is traditionally to couple it with hard structures as supporting measures to minimize sand losses and maintenance. In addition, in the most important nourishment projects, the nourishment option was chosen on the basis of the desire to get rid of available sand dredged to maintain navigable depths in a nearby harbor. A slight change of policy may possibly be reflected in two recent projects representing a new approach with much less supporting measures and allowance of an annual loss of material (implying some periodic renourishment).
Project motivations include the creation of recreational beaches, coastal defense, dune restoration, and, as mentioned above, the use of dredged sand from harbor extensions or maintenance. No difference is made in practice between protection against flooding and stabilization of the shoreline. In general - as in Italy - the measures may be classified as remedial rather than preventive.

**Design and Evaluation**

Design methods of coastal defense works are rather well developed in France. The survey of the completed projects has shown that detailed design studies have been performed for 15 cases. Typical design is based on classical coastal engineering concepts (SPM 1984) but includes also environmental considerations.

The movable bed scale model is the traditional tool in France to perform morphodynamic impact investigations since 1950's. Shoreline numerical models are also being used in recent years to study large-scale evolutions. In several cases, *in situ* tests have been performed to check the design. However, the monitoring after nourishment is in most cases not systematic. The monitoring program is not planned in advance and is often not comprehensive. Topographic surveys are quite frequent for dune and beach nourishments. However, they are typically not complemented by bathymetric surveys. The wave climate is seldom recorded but international databases (synopships, satellite data) as well as hindcast techniques are used.

**Legal and Financial Aspects**

The Law of 1807 specifies that the Ministry of Public Works shall certify the necessity of coastal defense works. All costs incurred for coastal defense works shall be borne by the protected landowners in proportion to their interests, except in cases where the Government decides that subsidies from public funds would be advisable or merited. In practice, such subsidies have usually been extremely small, owing to the limited financial resources generally devoted to coastal defense works. This law also sets out guidelines for the so-called "compulsory" associations that are responsible for having these works carried out and maintained. It has always been difficult to put these laws into effect, which has
given rise to the saying that "France has no coastal defense system, only expenses". (De Rouville, 1954).

Since 1970, the certification is now provided by the local representative of the Government with possible funding (10 to 30%) in cases of the defense of urbanized areas. Such funding is, however, exceptional. The Law of 1973 allows local communities to take initiatives in this area when common interests are threatened. In practice, local municipalities are nowadays in charge of coastal defense works with possible partial financial support of regional authorities. As a consequence, there is no national coastal management in France and no national standard for doing beach fill design and evaluation. Each project is managed according to prevailing and local conditions. On the other hand, mentalities are slowly changing and many regional funders are now becoming aware of the necessity to think regionally before funding locally.

The Law of 1977 was aiming at the protection of nature and institutes an environmental impact assessment study when the budget of works exceeds 1 million ECU. Further legal texts improved the accreditation procedure including public inquiries, concertation and administrative procedures when the works occupy a surface over 2,000m². In practice, the financial threshold is not reached and the surface area threshold is difficult to define. Thus, nourishment projects escape to this law. So, in practice, accreditation procedures are seldom in effect for nourishment operations in France.

The so-called Littoral Law of 1986 extends the concept of coastal defense works to natural sites with an accreditation procedure when the budget of works exceeds 0.15 million ECU. It also forbids new artificial beach developments and protects the natural state of the coastline. Furthermore, the coherence between the earlier laws and the new environmental laws needs improvements which are reported to be in progress.

BEACH FILLS IN SPAIN (ES)

Practically the entire Spanish Mediterranean coast is a sandy coast (Lechuga 1994). The principal causes of erosion along this coast is the interruption of the sand transport by numerous harbor installations. Modern beach fills have been practiced only since 1983. During the last five years alone more than 600 fills and refills have been performed at about 400 sites adding up to a total fill volume of about 110·10⁶ m³ (Figure 5). The vast majority of the projects are along the Mediterranean coast.

Project Types & Objectives

Beach fills are usually done without any supporting structures. In some cases detached breakwaters are used. In quite a few cases existing detached breakwaters have been removed in connection with the nourishment project. Being a nation with a significant portion of its income based on tourism, the overall objective of these nourishments is connected to recreational space rather than the exact position of the shoreline or concerns about flooding. Thus, the objective may be stated as: "The dry beach width must exceed 60 m at all times for recreational reasons". As for the French and Italian cases the measures are mostly remedial rather than preventive.
Design and Evaluation

The overall Spanish design type may be classified as profile translation. Numerical or physical models have only been used in a few important projects. Similarly, follow-up studies, including annual bathymetry and grain size studies, are only performed for these major projects. In the design process, environmental concerns seem more important than engineering aspects.

Legal and Financial Aspects

The financial processes involved in beach nourishment are regulated by The Shores Act of 1989, according to which all beaches in Spain are State owned. This Act states that works within the jurisdictions of the central Government shall be financed by proper budgetary appropriations and, if applicable, with contributions from the regional Governments, local Governments, international organizations, and private parties. The Shores Act imposes severe restrictions to build and develop in a "protection zone" 100 to 200 m inland from the beach.

In practice, almost all nourishments are financed by the central Government, because, according to the Shores Act, the coastal defense is strictly its responsibility. In some projects, with a more infrastructural rather than protective character, such as beachfront promenades, regional and local Governments may contribute financially jointly with the central Government. In the near future, more of the coastal works are going to be considered as parts of an integrated coastal zone management process. A first example of this could be seen in the management of the Castellon coastal zone project.

COMPARATIVE RESULTS

Rates and Volumes

There are big differences in nourishment fill rates and volumes between the investigated countries. Table 1 shows number of fills, fill rates and volumes for the respective countries together with the year when beach modern nourishments were introduced on a more regular basis. As seen from the Table, Spain and the Netherlands are by far the biggest nourishing countries in Europe. The most distinguishing difference between the two is that the sand in the Netherlands is placed on a few locations, while in Spain the
sand is portioned out over a large number of smaller sites. Table 2 shows the present annual fill rates for the above countries together with estimations of the corresponding numbers for some other countries around the world.

<table>
<thead>

</table>

Thus, the total annual rate of the European countries adds up to about \(28 \times 10^6 \text{ m}^3\), which is about the same volume as that for the USA.

**Design Parameters**

The Tables below show a first attempt to classify the design parameters taken into account in the respective countries. Table 3 indicates which wave and sediment related conditions that are included in the design process where the parameters listed are: Storm = storm surge levels, \(Q_L\) = longshore sediment transport rates, Run-up = run-up levels, \(D_c\) = depth of closure, Waves = wave height (and direction), Sed. dist. = spatial distribution of sediment grain size, and Aeolian trp. = losses of sediment due to aeolian transport. Table 4 shows which fill properties and procedures that are explicitly taken into account in the nourishment design.

where $H_B$ = berm height, $W_B$ = berm width, Overfill = the use of overfills, Vol./m = volume of fill per m of beach, Transition = the use of transitions at the lateral ends, $D_b/D_n$ = grain size of borrow material relative to the natural sediment grain size, Structures = the use of supporting structures, Ren. period = calculated renourishment period, Follow-up = the use of follow-up programs, and Perf. eval. = the use of performance evaluation programs.
OVERALL CONCLUSIONS

The Tables above are hard to evaluate as they still only present which parameters that are taken into account, not how. Countries, such as Italy, that consider more parameters may seem to perform a more thorough design than others. However, it could also indicate that these countries improvise more from cases to case than others, such as the Netherlands, that has a more consistent design. Also, the number of parameters needed to be taken into account certainly reflects the degree of varying conditions from site to site, which is of course smaller in the Netherlands than in Italy.

Beach Fill Practice

There are - as expected - significant differences between the investigated countries regarding 1. Engineering methods and evaluation procedures, 2. Overall coastal management strategies (which are very developed in some countries and virtually non-existing in others), and 3. Legal and financial framework. The following more specific remarks can be made concerning the different national characteristics:

- NL is the only country that has a serious overall performance evaluation program integrated into their legal framework.
- NL and DE have developed a long-term strategy for actions along the coast and are implementing thorough follow-up programs.
- ES has a fairly well-developed organization and a long term philosophy for their actions, but anticipate to run into problems of finding suitable borrow areas in the near future.
- ES, IT and FR all apply a strategy of remedial rather than preventive measures and seem to suffer from a lack of overall long-term strategy, coastal management, regular monitoring of the coastline, as well as a comprehensive survey of available borrow areas.
- IT and FR suffer from a lack of financial support for regular renourishments.
- IT experiences unclear commitments and sharing of responsibilities between the Ministry of Environment and the Ministry of Public Works.
- All investigated countries foresee a continued transfer from hard to soft measures and regard beach nourishments a an effective means of coastline preservation.
- Nourishments are expected to continue over foreseeable future in all participating countries.

The SAFE project is contributing to disseminate the experience of each of the participating countries in Europe and to promote an integrated and large-scale approach of these problems. The present study shows that it would be very profitable for south European countries to learn about the Dutch and German practices, particularly regarding
the long-term coastal management and the regular monitoring of the coastal morphology. On the other hand, the recent Dutch experience has shown that their legal system is a bit too rigid leading to automatic local renourishments that are unnecessary to reach the global objective.

ACKNOWLEDGMENTS

This work is undertaken as part of the SAFE project partly funded by the European Commission/Directorate of Science, Research and Development (DG-XII), contract N° MAS3-CT95-0004 and by Ministère de l'Equipement, des Transports et du Logement/Direction de la Recherche et des Affaires Scientifiques et Techniques/Service Technique des Ports Maritimes et des Voies Navigables (France), subvention N° 97 M/3.

Evaluation of the Effect of 20 Years of Nourishment
Christian Laustrup\textsuperscript{1} and Holger Toxvig Madsen\textsuperscript{2}

Abstract
Since 1982, large-scale coastal protection works have taken place on the Danish North Sea coast. The subject of the first part of this paper is the coastal protection policy, the engineering approaches to erosion and flood control and the results achieved. An important tool for coastal protection has always been and still is nourishment. In the second part of the paper, the effect of the nourishment will be evaluated with focus on the positioning of the nourishment in the profile and on the use of coarse materials.

1. Introduction

The Danish coastline is 7000 km long. Roughly speaking, there are four different types of coast:

1 Deputy Director
2 Senior Coastal Engineer
Danish Coastal Authority, Box 100, DK7620 Lemvig, Denmark, E-mail: ki@kyst.dk
- A tidal coast with a tidal range of 1.5 – 2 m where the low hinterland is protected against flooding by dikes.
- The southern part of the North Sea coast with sandy beaches where dunes protect the low hinterland against flooding.
- The northern part of the North Sea coast with sand and clay cliffs.
- The Baltic Sea coasts mainly with clay cliffs.

Figure 3 illustrates the different degrees of exposure.

2. The coastal protection policy

2.1 Regulations and funding

In Denmark, we do not have a basic coastline defined by law as it is the case in for example the Netherlands. For the two major dikes in the tidal region, the dike safety level was decided by the government to be a 200-year return period. Apart from that, there are no national rules for safety assessment of dikes or dunes. The actual policy for safety assessment and the erosion control policy are established as an agreement between local authorities and the government based on Danish Coastal Authority recommendations. There are probably a number of reasons for the lack of national regulations but the main reason is that apart from the land protected by the two main dikes, the danger to human life is small and “only” land is damaged by erosion and flooding.

The costs of coastal protection on the North Sea coast are shared between the government and the local authorities. The government typically pays 50 to 70 %. In some cases the government pays 100 %.

On the Baltic Sea coasts, coastal protection is regulated by an act passed in 1988. According to this act, the counties are responsible for the administration of coastal protection projects. Since the counties do not have any coastal engineering expertise, the Coastal Authority provides assistance at the planning stage and the consultants provide assistance at the project
stage. The general practise is that there is no public funding of coastal protection in the Baltic Sea area. Here the individual landowner has to bear all the costs.

2.2 The situation and strategy in 1982

The following chapters deal with the problems on the North Sea coast, especially on the southern part of the coast.

Figure 4 shows the coastline retreat rate before 1977 for the southern part of the North Sea coast. There are very high rates of leeside erosion caused by harbour breakwaters and large groyne groups. Besides the loss of valuable recreational areas, the high erosion rates had the effect of significantly reducing the protection against flooding provided by the dunes.

About 100 years ago, the dunes were stabilized by marram grass planting. At the same time, harbours and groyne groups were built which resulted in serious downdrift erosion. The combined result of the stabilization of the dunes and the erosion was that in 1982, the dunes had disappeared or were weak along 50 km of the coast. So in 1982, it was decided to implement a coastal protection scheme.

Figure 5 shows the areas below +2.5 m and the safety level against flooding below a 100-year return period.
The headlines of this policy were:
- To re-establish a safety level against flooding to a 100-year return period minimum.
- To stop the erosion where towns were situated close to the beach.
- To reduce erosion on parts of the coast where erosion in the near future would reduce the safety against flooding to less than 100 years.

The dunes were reinforced and new dunes were built to re-establish the safety against flooding to a 100-year return period. However, in many cases it was not possible to reach the safety level required because there was not enough land between the beach and the houses or the road to build a sufficient dune volume. In this case, the dunes were protected by a revetment.

Placed concrete block revetment

To stop or slow down the general erosion of the coastal profile, the following approach was used:
- On highly exposed stretches where erosion should be stopped, low detached breakwaters were used in combination with nourishment. One reason for the use of breakwaters was that for historical reasons, local politicians trusted in hard structures like groynes and breakwaters. Another reason was the high price of the nourishment sand.
- Nourishment was applied but on a small scale. The main reason for this was that the principle of beach nourishment was new to the politicians. It was difficult to convince the politicians that “the erosion of the nourishment sand during storms is part of the plan”. This meant that volumes were small and unit costs were high which was one reason for stabilizing the nourishment by means of breakwaters.
2.3 Important developments since 1982

Figure 6 shows the coastline retreat rate in 1998 for the southern part of the North Sea coast. The very high erosion rates are no longer a fact. We do not have an absolute zero erosion but the erosion has been stopped where it is important for the dune safety and on average, the coastal erosion rate is 0.1 m/year.
The safety level of the dunes has been re-established to a level of at least 100 years which was the goal in 1982.

Figure 7 shows the development in the use of structures and beach nourishment for the period, including costs.

The effect of using low detached breakwaters has been studied (Laustrup and Toxvig Madsen, 1994). The results were based on 10 years of monitoring of a group of breakwaters. The purpose of the study was to confirm the design theory which had been used and which was based on theoretical computations. The paper confirmed that the use of breakwaters in this group had reduced the need for nourishment landward of the breakwaters by 50%.

Since 1982, the engineering solutions have changed from a hard to a soft approach. There is a number of reasons for this development of which the most important are:

- A growing awareness among the general public and among politicians of environmental issues.
- The problems which required hard solutions have been solved.
- The budgets have been raised dramatically rendering soft solutions more competitive.

Because of the small volumes and the lack of experience of the Danish contractors regarding pumping of sand directly on shore on the North Sea coast, the mobilization costs were quite high and consequently, the unit costs were high. With increasing volumes and experience, a better approach for nourishing the different parts of the profile has been developed. Today, three methods are used. The methods are pumping onshore through a submerged steel pipe, pumping over the bow and dumping from split barges.

3. Evaluation of the effect of the beach nourishment

Some effects of the nourishment have now been evaluated. In this chapter, some of the aspects concerning a steepening of the coastal profile, positioning of the nourishment sand in the profile and the effect of using coarse sand will be discussed.

3.1 Profile steepening

The retreat rates shown in figure 6 have been calculated for the profile section from -6 to +4 m. For nourishment we only use a volume equivalent to the erosion on this part of the profile. As it could be expected, this policy leads to a steepening of the profiles. Figure 8 shows a number of bars each representing a number of profiles on a part of the coast. The length of the bars represents the difference between erosion velocity of the profile seaward of -6 m and landward of -6 m. This difference represents the steepening of the profiles. Before 1986, the steepening took place on parts of the coast where groyne groups had been built (sections 3, 4 and 5 in figure 8). After 1986, the steepening mainly took place where the nourishment projects were carried out (sections 1–5 in figure 8).

Figure 8. Difference between retreat rates seaward and landward of -6 m
3.2 Positioning the nourishment in the profile

In 1993–96, the European Union MAST project Nourtec was carried out with participation from the Netherlands, Germany and Denmark. In the Danish case, a nourishment project on the longshore bar and a project on the beach were studied (Laustrup and Madsen, 1996).

Figure 9. The Nourtec general location plan

The main results were:
- In the first year, the beach nourishment gives the better stabilization of the beach.
- At the end of the period, the shoreface nourishment is the better option for the stabilization of the beach.
- The shoreface nourishment is more stable than the beach nourishment. The main reason is that the shoreface nourishment sand was coarse, \( D_{50} = 0.57 \text{ mm} \). The effect of the beach nourishment is that of a feeder berm and the effect of the shoreface nourishment is that of a breaker berm. The effect of the shoreface nourishment on the outer part of the profile is that of a feeder berm.

The conclusion was that the profile from the bar and out should be nourished by dumping sand on the bar. This is also cheaper than placing the sand on the beach. There was nearly no migration of sand from the bar to the beach so for the inner part of the profile it was recommended to place the sand on the beach. Figure 10 shows the principles of positioning the sand in the profile that we are going to implement in the future. Part of the nourishment on the beach is used as a buffer to prevent erosion of the dunes during storms.
3.3 The effectiveness of coarse sand

We are now studying the relationship between the $D_{50}$ and the effectiveness of the sand. For that purpose, we have evaluated nine projects involving annual nourishment during the period 1986–96. The length of the project stretches are 3–5 km and the volume per metre is $10^{-50}$ m$^3$.

![Diagram of principles of calculating the nourishment effect](image)

The principle used for the study is shown in figure 11. We know the 1986 and the 1996 profile. However, the effect of the nourishment is the shaded area between the 1996 profile and...
the autonomous 1996 profile (the profile without nourishment). Since we do not know the theoretical profile and since this profile is important for the result, we have estimated it in three different ways.

1. Natural erosion on section X, 66–96 =

2. Natural erosion on section X, 66–96 = erosion on section X, 67–86 • erosion on reference stretches, 67–86

3. Natural erosion on section X, 66–96 = CERC-transport, 86–96
   erosion on section X, 67–86

Figure 12. Methods for calculation of the natural erosion rates

Figure 12 illustrates the three methods used to estimate the natural erosion. We are looking for the natural erosion in the nourishment period 1986–96 on each of the nourished stretches. Method 1 and 2 use the erosion on stretches of the coast which developed naturally and which have the same degree of exposure as the nourished stretches (reference stretches). In method 1, the difference between the period 1986–96 and 1967–86 is used. In method 2, the ratio between the erosion of the two periods is used. In method 3, the ratio between transport capacities calculated by use of the CERC formula in the two periods is used.

| Profile erosion 1967–86 | 79.4 m³/ year |
| Difference 1967–86 to 1986–96 | -3.2 m³/ year |
| Natural erosion 1986–96 | 76.2 m³/ year |
| Effect of breakwaters | -10.1 m³/ year |
| Anticipated erosion 1986–96 without the effect of nourishment included | 66.1 m³/ year |
| Monitored erosion 1986–96 | 6.2 m³/ year |
| Effect of nourishment | 59.9 m³/ year |
| Nourishment volume | 40.3 m³/ year |
| Effectiveness of nourishment | 59.9/40.3 |

Figure 13. Example of the calculation of the effectiveness

Figure 13 shows an example of a calculation of the effectiveness. The effect of the nourishment is the shaded area in figure 11. The nourishment volume is known so the effectiveness is the effect divided by the volume. In this case, it is greater than one. The effectiveness can also be defined as the ratio between erosion velocity in native and borrow material. Since the renourishment factor (James, 1975) is the ratio of erosion velocity in borrow material to native material, this is the inverse of the effectiveness.
Figure 14. Results of the calculation of the effectiveness using method 1

Figure 14 shows the effectiveness as a function of the $D_{50}$ for the nourishment sand, if we use method 1 to estimate the theoretical profile in 1996. The area of the individual dots is proportional to the nourishment volume. The total volume represented by the dots is 10 mill. m$^3$. The curve is a weighted best fit curve.

Figure 15. Results of the calculation of the effectiveness using method 2

Figure 15 shows the same relationship if we use the ratio between erosion on reference stretches in the two periods.

Figure 16. Results of the calculation of the effectiveness using method 3

Figure 16 shows the relationship if we use the ratio between CERC transport capacities for the two periods.
Figure 17 shows method 1, 2 and 3 and the inverse renourishment factor. To improve the results we are going to work on getting better sediment characteristics and to improve the method to calculate the theoretical erosion. Besides, the comparison with the inverse renourishment factor is not correct if there has been some erosion in the native material in a project. We know that is the case at the beginning of the period 1986-96 because at that time, we did not have enough money to stop the erosion completely, so we are going to do some more work along that line.

4. Conclusions

Erosion control with a combination of nourishment and low detached breakwaters has reduced the retreat rate to average zero for the depth range from -6 m to +4 m. The policy of only nourishing this part of the profile has resulted in a steepening. The safety against flooding has been raised to a return period of more than 100 years by building new dunes and by protecting the dune foot with a revetment.

Based on monitoring of nine nourishment projects with a total volume of 10 mill. m$^3$ for a period of 11 years, guidelines for positioning of nourishment sand in the profile and for the use of coarse sand in nourishment projects have been developed. Better quality information about the native and borrow sand characteristics is needed.

ZURRIOLA BEACH EVOLUTION TWO YEARS AFTER NOURISHMENT

José C.Santas¹, José M.Medina², Alejandro Caballero³, Adolfo Uriarte⁴ and Vicente Esteban⁵

Abstract

First results about the behaviour of the nourishment done at Zurriola beach, Vasc Country, Spain, have been obtained, by means of the data acquired during 2 years monitoring. The general conclusion appoint to a good agreement with the previous physical model results: in spite of a small percentage of sand is lost, the beach is "self kept ". A rough evaluation of losses has been done, helping us to predict the future maintenance to do. The topography and bathymetry of the beach do not help to a easy modelling by means of mathematical models.

Introduction: The Nourishment Project

Zurriola beach, located in Gros neighbourhood of San Sebastian, in the North of Spain, has been progressively disappearing along this century, mainly due to the advance of the city over the beach. Its reconstruction project, tested at 1992-93, was based on the construction of the prolongation of the embankment Urumea river breakwater and a nourishment of the beach, with an urban promenade of 1100m. on the interface with the city.

The project begun at 1993(1), and 1*10⁶ m³ of sand were used, that was borrowed form a submarine area close the 15 Kms from the beach. The grain size was .33mm. and the final slope was 0.013.

It ended at March-95, with a total cost of 13.3*10⁶ ECUS(1996). After this moment the evolution of this new beach is being studied. Directional waves, tide and currents data are recorded simultaneously with monthly bathymetry,
Field data acquisition survey:

The information acquisition survey incorporated data of directional waves, tides, currents, bathymetry and topography for both submerged and emerged areas of the beach, completed by remote sensing of the dry beach. Since July-1995 the monitoring is being carried out. Four control profiles have been measured to obtain the beach evolution, employing DGPS. The closure depth for the noticeable sand movements was initially estimated at 15 metres depth but due to discrepancies between successive surveys, the number of control profiles and its final depth were modified adding other 4 with a total length prolonged till 25m. depth (May97).

The sea weather conditions have been studied with 2 in situ systems:

1. First at all a S4DW EMCM that was deployed at a point located on the
T3 control profile, 1.5 metre over the bottom which is 11 metre deep.

2. At May-97 a Directional Waverider Buoy (DWB) has been deployed at 37 metres depth outside the Zurriola Bay.

Estimation of deep water storm conditions was done using the information provided by a Wavescan Ocean - Meteorological Directional Buoy (named EMOD-1) located at 600 metres depth, 40 miles north-west away.

The characteristics of Wave data acquisition survey were as follows (2):

EMOD1: Time series of 2048 points, 0.5 seconds sampling period, every 3 hours. Spectral process with 32 freedom degrees, without overlapping.

DWB: Time series of 1536 points, 0.78 seconds sampling period, every 1 hour. Spectral process with 24 freedom degrees, without overlapping.

S4DW: Time series of 4096 data points, 0.5 seconds sampling period, every 3 hours. Spectral process with 64 freedom degrees, without overlapping.

Equipment S4DW provides the tidal data, that have been used for the bathymetry data corrections, and the current data.

The coverage of data during all the monitoring duration that began at June-1995, reaches more that the 80%. Specially the amount of information of the DWB is done better that the 95% since its installation at 19th-June/1997.

Bathymetry and topography data surveys were initially scheduled as monthly but the rough sea conditions do not enable to be realised every month.
The chosen methodology that is based on measurements only along same previous selected control profiles to optimise the balance between cheaper total costs and better knowledge of the short term temporal evolution, has allowed us to reach a big total amount of data of the 81% (36 monthly surveys done over 37 possible) tacking into account the temporal coverage. This point allows us to get a good base to estimate the beach evolution.

The selection of the closure depth (CD) was obtained from the Harllemeier’s criteria (CERC, Shore Protection Manual, 1984):

$$d_1=2.H_s(p=0.50).12.\sigma(H_s) \quad \text{and} \quad d_2=2.H_s(p=0.137) \quad [1]$$

The data taken from the EMOD-1 Data Base allow us to propagated the selected sea conditions from deep waters to 30 metres depth, obtaining $d_1=27.2$ m and $d_2=12$ m for the Zurriola Bay external border. Due to that a CD of 15 m. was initially taken, but the successive comparisons of volumes for summer conditions evidenced that it should be greater. At May-97 it was enhanced till CD=25 m.

By other way it was added 4 control profiles more in order minimise the errors produced by the interpolation between them. All the features are produced because the extreme roughness of the bottom as its mobility. As a test point it was observed visually that the depth for the installation point of the S4DW varies 1.2 metres on 1 month at the moment to be done the monthly maintenance operations.

The grain size surveys were done every 3 months and they also reflected the high mobility of the bottom, specially along the river moth area and the extreme of the breakwater due to the currents created by waves diffraction.

Finally the remote optically observation of dry beach by means of a PC controlled camera allow us to contrast the results obtained from topography surveys as estimate the greater effects done by storms on the sandy and promenade areas.

Physical and mathematical modelling

First at all the Zurriola Regeneration Project was previously studied by REF-DIF propagation numerical model (3) to evaluate the best solution. At 1993 it was modelled by means a movable bed physical model to study the best choice for the groin to be constructed (4). The input data for deep water conditions, obtained from EMOD-1 buoy was $H_s=9.3$, $T_p=16$ s, $\gamma=7$, $s_{\max}(\text{Mitsuyasu})=20$, $\Theta_m(\text{incoming})=\text{NW}$.

Evolution of control profiles in their swash and surf zones shows appreciable variations as it is presented on the picture 4. The behaviour of the beach + groin system was enough satisfactory but appointed a lost of sand that would appear in the future.
The area is too difficult to be mathematically modelled in order to employ shoreline and cross shore evolution models. But it was studied the the local behaviour of the beach, appearing a very active zone with big rip-current effects after storms, corresponding with the T3 control profile.

Figure 4: Experimented evolution of the T1 control profile by means the Physical model under storm conditions

Beach evolution: Shoreline position and width of dry beach

The shoreline evolution has been estimated taking into account data from the measured control profiles and its crossing point with zero level. The figure 5 shows the evolution along the monitoring period, from August-95 to February-98.

Figure 5: Monthly evolution of dry beach width (reference: August-95)
Maximum variations of 130 metres appear on T2 profile, while the minimum is on the T3 profile. The evolution along the year looks like the general rules, but it is dominated by other effects that masks it; the more important could be the movement of sand done by the local authorities focussed on the aesthetic aspect and leisure use purposes. This conclusion has been obtained doing the comparison with Monthly Averaged Waves, estimated at the no - surpassing levels of 50%, 84%, 97.7% and 99.87%, figure 6.

![Figure 6](image_url)

**Figure 6: Time evolution during 1997 of Sea Wave conditions close to the beach. Data from S4DW equipment. Values corresponding to no - surpassing probability for Significant Wave Height Hzs, averaged along every month.**

The more active zone, Profile T2, coincides with those that exhibit the rip currents effects after storms. This events fit well to the results from the numerical wave propagation model.

**Beach evolution: Volumetric variation of wedge sand**

Due to the two different used schemes of control profiles there are 2 zones to establish the evolution of the sand wedge (figure 7):

-Reduced area: comprised between the -15 metres bathymetric line, the breakwater and the cost line, that includes the zero depth contour line of the beach and the cliff of Ulia Mountain.

-Enhanced area: comprising from 25 metres depth contour line, the river mouth and the cost line.
Figure 7: Enhanced area used to study the evolution of the wedge sand, after May-97. The reduced area is constraint to the inner part of the beach located between the breakwater, the 15 meters depth contour line and the coast line.

The evolution recorded along the 2-years monitoring is presented on the figure 8 for the period between January97 to February98.

Figure 8: A) Relative evolution of Sand wedge, referenced to Reduced area (continuous line) and enhanced (dashed line).

B) Absolute variation from the beginning of monitoring (narrow line) corresponding to 2-years and for Ag96-Ag97 period.
Estimate of sand balance and tendencies

The evolution is not continuous during all the monitoring period. For the reduced area, where the information volume is greater, it was recorded an accretion of 46,000 m$^3$ during the period Ag95 to Ag96, while the lost of sand from Ag96 to Ag97 has been evaluated as 110,000 m$^3$. The general tendency could be assumed is about -60,000 m$^3$ for the 2-years period.

The enhanced area shows greater variations due to the inclusion of the river mouth. For the period between the beginning of working with this area, May97, to February98 the total amount of lost sand has been about 124,000 m$^3$ but the maximum sand losses, located between September and October 1997, has been about 312,000 m$^3$, while the maximum accretion is about 227,000 m$^3$ (dated between January to February 1998) after the biggest storm recorded since last 5 years (5).

These data show the high degree of mobility that the bottom has in this area. The factors that do that are:

1) The existence of the river mouth that acts as a sand reservoir. This fact is also proved because the relative high grain size that has been measured in this area:

   Average: 2.6 mm, Sorting : 1.43 mm (October 97)
   " : 0.14 mm, " : 0.4 mm (July-97).

2) The layout of this area that provides losses of sand from the studied area toward the east, outside of the Zurriola Bay.

Estimate of errors of the used control profiles schemes

The magnitude of figures before mentioned drive us to do an estimate of the errors that the methodology employed could have.

One of the source of errors to eliminate is the consideration of extrapolated areas, far of data. It produces extra data added by the working program, that have to be eliminated. These areas have been previously "blanked", as it can be appreciated on the picture 7, between the more external control profiles and the cost line.

First at all keeping in mind the wave data obtained by the buoys, we can assume that the movement of sediment during summer must be very short, specifically for the period from June to August, 1997. Due to that the variation recorded must be errors of the methodology. The evaluation of that are about 22,000 m$^3$ for the reduced area and about 45,000 m$^3$ for the enhanced one.

Secondly the gap between the control profiles can produce a source of
errors directly proportional to that gap. Due to that it have to be greater for the used scheme with 4 profiles (before May97) than the used after, but it must increase with the area size. After May 98 it has been done a big density survey, with separation between points less than 10 metres along tracks (perpendicular to the cost) and less than 20 metres laterally to the track. The 3-D surface obtained has been cut by the control profiles and the new surface has been compare to the previous one. The estimated errors are about the following figures:

- Reduced area scheme (with 200 metres gaps and CD=15m): 10,000 m$^3$
- Enhanced area scheme (with more profiles, 100 metres gap, CD=25m): 16,500 m$^3$

It is clear to deduce that the figures obtained by the reduced scheme are not so good to obtained an accurate estimate of sand balance, although the tendency could be taken as a draft conclusion. In opposite the figures deduced by the enhanced area and its scheme are more accurate and show an more approximated reality of the evolution.

Conclusions

- The main objective of the nourishment done was to recover an open space for social and leisure uses that the citizens had lost. This objective has been achieved with this reconstruction and opens new possibilities to the city.

- The control profiles scheme previously used with gap close to 200 metres, is not enough dense and wide to produce good estimation because the rough conditions of the sea, the mobility of the bottom and the quality of abruptness of the bottom surface. In the opposite the second scheme is enough good to produce a draft estimation of nourishment evolution.

- The order of the errors on the evaluation are about 35,000 m$^3$. If all the volume of the wedge sand is taken in mind (13,000,000 m$^3$), it is about 3 °/100.

- The beach experiences a little tendency to loss sand as it was predicted by the physical model. The evaluation of this tendency is about 30,000 m$^3$ per year, but it is a primary draft estimation because of factors like the amplitude of time dependent variations, with very high excursion during the year, and the errors.

- There are zones with high tendency to loss sand in the middle of the beach, profile T3, where rip currents happen after storms. In the same way the area close to the end of breakwater shows high mobility due to diffraction effects.

- Because aesthetic questions the layout of the beach, and specially the coast line contour and the dry beach surface, is man-made modified in order to obtain a good aspect for citizen uses. This character must be kept into consideration for all the urban beaches, and this disables to employ these to
calibrate numerical models.

- The presence of a river mouth modifies the evolution, doing an "open" character to the ensemble.

MODEL TESTS FOR EVALUATING
BEACH NOURISHMENT PERFORMANCE

Massimo Tondello¹, Piero Ruol², Mauro Sclavo³ and Michele Capobianco⁴

Abstract

After having shortly discussed about the nourishment fundamentals, focussing the attention on the benefits and on the factors promoting the beach fills, some specific questions on fill design, on related processes and on the temporal aspects of such beach-protecting intervention were addressed and tentatively answered.

In the second part, the physical-model tool, as a way for answering to the suggested questions is presented and three different case studies are discussed.

Introduction

In the last decades the use in coastal protection of soft intervention schemes such as beach nourishment has largely substituted the use of “hard” intervention approaches like seawalls and groins, because of economic reasons and mostly because of the lower impact on coastal resources and activities.

Nowadays the first task of a project manager is the quantification of the on-going beach erosion phenomenon. This involves the identification of the relevant morphological processes and the consideration of the aspects related to local interests such as safety, recreation, environment and economy.

Once the problem has been defined, the protective measures must be carefully

selected. The increasing need of solutions at low environmental impact suggests the choice of soft intervention schemes, which may be integrated with some supporting hard structure. However, "soft" projects need some additional experience in order to derive consistent evaluation criteria for technical problems, economic matters and public policy issues. A beach nourishment project, in fact, includes design considerations on the following aspects: frequency and duration of the fills, pre- and post-fill erosion rates, post-fill profile equilibrium, project length, volumetric requirements, grain size compatibility, protective dunes, long-term sand resources, placement location, "hybrid" projects and downdrift impacts. Because of its relatively short design life, a beach nourishment project needs to be periodically refinanced for maintenance, rehabilitation and environmental permitting.

The first part of this work deals with the choice of the "most suitable" solution. A general framework for comparing the possible solutions is presented in terms of morphological impact and economic aspects that define a number of "objective evaluation criteria".

The determination of the design life is important because it gives the designer the chance of a long term management of the interventions. The long-term evaluation of beach nourishment performance can be obtained by means of numerical or physical modelling. We focus here on the physical modelling approach, which will be proven to be valuable when mutually interacting physical processes are to be taken into account.

The second part of the paper presents the results of three sets of model tests, performed referring to different beach nourishment projects in Italy.

Basic considerations on beach nourishment

For a number of reasons, not lastly historical and legislative, the coastal zone was seen as a "low cost" resource. The adoption of hard engineering practices, heavily based on concrete and steel structures, results in a completely artificial set of forcing factors and boundary conditions, further exacerbating the problem. This has led to the present tendency of developing "soft defence techniques" as a tool to be used in Integrated Coastal Zone Management (ICZM). Among these techniques, periodic artificial nourishment is widely regarded today as an environmentally acceptable method of beach and dune protection and restoration for short-term urgencies (viz. storm-induced erosion) as well as long-term issues (i.e. structural erosion and relative sea-level rise).

Beach nourishment or fill can generally be defined as the artificial addition of suitable (in terms of beach quality) sediment to a coastal area that has a sediment deficiency in order to rebuild and maintain that beach at a certain width and height which provides storm protection and/or a recreation area (CBNP, 1995; Delft Hydraulics, 1987). This definition encompasses restoration (an initial and major sediment contribution to widen the beach) and periodic renourishment (an additional, usually smaller, sediment contribution necessary for the preservation of project integrity). Frequently, nourishment projects include an artificial dune for additional protection against storm surge and waves.

The most important benefits of beach nourishment can be summarised as follows:

- reduction of erosion and flood damage;
resetting of the long-term erosion trend;
- enhance of recreation and tourism;
- spreading of cost outlays over time;
- reduction of downdrift impact of coastal protections;
- increasing of sand budget for global coastal stability;
- project reversibility.

For these reasons, over the past several decades the beach nourishment has become a preferred coastal hazards management tool. In the future, this reliance is expected to increase mainly for the following reasons:
- increasing of coastal populations
- increasing use of beach for recreational purposes
- increasing public awareness of coastal hazards
- increasing concern about the impact of hard structures.

Technical issues in beach nourishment planning

The technical issues in nourishment planning have been in depth analysed in a previous paper of the authors (Ruol et al, 1997; Capobianco and Stive, 1997) which discusses the beach fill management, focussing on the requirements of fill-design, the correct definition of active processes and the planning of a beach-fill timing strategy. For the benefit of the further discussion, some results are summarised in tables 1-3.

Physical model tests as a tool for beach nourishment behaviour evaluation

Physical model tests represent a technique to answer to those questions in tables 1 to 3. This technique is used most appropriately when a decision problem under analysis is too complex to be solved by analytical models. Simulation through physical models is a quantitative procedure that describes morphodynamics process by constructing a model and then observing how the model behaves in order to learn how the process itself might behave. As a general rule, physical simulation should be used only as a last resort and never as the first option. There may be theory or analytical techniques available to solve a problem. When there are, they should be used.

We should also not forget that "communication and involvement" increasingly play a fundamental role in environmental protection activities in general and nourishment interventions in particular. The adoption of physical model tests have a strong potential also because can be immediately understood (even if only partially) by a large audience. The advantages of physical model tests are:

- The effect of interaction between the different forcing agents can be taken into account;
- complex boundaries can be reproduced;
- wave conditions vary continuously according to seabed modifications;
- up to now, other modelling techniques are not as useful as physical models in morphological analysis where cross-shore and longshore sediment transport together must be taken into account,

while the limits of physical model tests are:

- they are expensive and time consuming;
- the analysis of different situations or the repetition of tests often implies a new setup of the model;
- scale effects are not always assessable.
As a general approach, fixed bed models are suitable for the study of:

- wave propagation;
- sediment transport patterns (particle tracks);
- armour stability;
- forces on structures,

while movable bed models are suitable for the study of:

- planform beach evolution;
- longshore sediment transport;
- beach profile evolution;
- cross-shore sediment transport;
- scour.

Where physical models are probably giving signs of their limits is in the context of long-term and large scale modelling. Such limitation is however still largely compensated by their intrinsic ability to handle complex situations.

In many practical situations, while waiting for the latest developments in the field of morphological modelling and particularly long term morphological modelling, the contribution that physical model tests can give is still of paramount importance, being implicitly integrative of all the (scaled and complex) processes that determine the evolution of the nourishment interventions. In particular they can when the validity of numerical models is limited by large uncertainty in the relevant input parameters which propagates to the model output.

Case studies

The following paragraphs describe how physical model tests have been applied for evaluating the performance of three beach nourishment projects.

The general purpose of physical modelling was to assess if the planned interventions were able to protect the infrastructures located on and behind the beaches and if the beach fill maintenance cost was acceptable.

The projects hereafter presented (fig.1) deal with two protected beach nourishments located close to Rome (Ostia) and in Northern Sicily (Capo d'Orlando), and with a "self nourishment" induced by a coastal protection intervention located in the Po river delta (Barbamarco).

Beach nourishment at Capo d'Orlando (Sicily)

The first application of physical modelling is a protected beach nourishment designed for a 1200 m long beach located close to Capo d'Orlando and facing the Southern Thyrrenian Sea.

The project area is today characterised by an increasing beach erosion caused by an unbalanced longshore sediment transport condition. This erosion is exposing the street and the buildings to the wave attacks; the picture in fig. 2 shows the present condition of the village and underlines the need of a quick intervention.
The design requirements for this project were mainly:

- safety of infrastructures behind the beach;
- availability of a larger beach area for recreational activities.

Figure 1. Project sites.

Figure 2. Capo d'Orlando beach.
The design solution of the 1200 meters long protected beach nourishment prescribes a sand fill of about 205 m$^3$/m of sand operated by means of building 39 sand groins (fig. 3) followed by the placement of 6 quarry groins spaced about 200m.

The general interest was to evaluate whether the designed project was suitable to protect the urban area behind the beach and if the beach fill technique (sand groynes) was really effective. These questions have been answered using mobile bed physical models: a number of tests have been planned to study the two- and three-dimensional sand transport phenomena occurring on the beach.

The models have been designed according to the Froude criterion, whereas the bed material has been scaled according to the Dean criterion (in the model and in the prototype a constant ratio between the wave height and the fall velocity times the wave period has been imposed).

The specific questions on the beach fill design for Capo d'Orlando project can be summarised as follows:

- which short term evolution of the Capo d'Orlando littoral without any additional beach protection is expected?
- is it the beach fill technique effective?
- does the designed construction sequence optimise the effectiveness of the beach fill?
- is it possible to define a construction schedule that does not interfere with the tourist activities?

The physical modelling program designed for the study of Capo d'Orlando beach erosion phenomena included:

- 2D model 1:25 (cross-shore profile)
- 3D model 1:25 (representative cell reproducing the beach delimited by two rubble mound groynes)
- 3D model 1:60 (whole project area);

The waves used for modelling the local climate have been selected from local wave hind-
casting by the UKMO (United Kingdom Meteorological Office). In particular, the waves to be reproduced in the 3D models were obtained respecting the energy flux criterion.

The study of the cross-shore profile (2D-model) started with the simulation of beach evolution from the present condition; the results clearly demonstrated that the surveyed profile are indeed in critical condition and can not be maintained without adding new sediments. The nourished profile and the erosion rate related to cross-shore sand transport have been studied through the simulation of the two nourishment phases planned in the project.

The first phase of the nourishment consisted in building-up a first series of sand groines and in placing a certain amount of sand directly on the beach (fig. 4). A three-month long (all time data are referred to prototype units) wave attack (simulating an average wave climate) has been simulated on this artificial beach and a first nourished profile has been obtained; in the second phase, again sand groins have been built on the new cross-shore profile and a second 3 months long wave attack has been simulated.

In order to compare the final condition (fig. 5) with the surveyed starting profile (summer profile), a new 1.5 months long mild wave attack has been performed to simulate the summer wave conditions. The summer profile obtained after this test is shown in figure 6.

Figure 4. Beach nourishment 2D – Phase 1 (sand groynes and beach fill)

Figure 5. Beach profile after beach nourishment and wave attacks
The results of the 2D modelling can be summarised as follows:

- beach profile is indeed in critical condition: after having simulated 1.5 months of waves, the retreat of the shoreline (cross-shore transport) was about 8 m;
- after the nourishment a quasi-equilibrium profile was reached, with the shoreline moved about 12 m seaward;
- since the existing profile is far from an equilibrium condition, most of the sand supplied from the sand groins moved offshore, without significant contribution to shoreline advance.

Both the 3D models (the "cell-model", scaled 1:25 and the global one scaled 1:60) followed the wave schedule already used for the 2D model; the longshore energy flux has been analysed in order to obtain a set of 4 wave spectra reproducing the existing sand transport conditions. Figure 7 shows the experimental layout for the 3D "cell model".

In figg. 8 and 9 the final results obtained after the construction of the quarry groins built up after the reshaping of the beach operated by the wave attacks.

The results of the 3D-models can be summarised as follows:

- the three-month long simulation from the present condition (without additional protections) shows that the shoreline position reaches the seawall, endangering houses and infrastructures;
the beach fill forces the shoreline to move 15 m (average displacement) seaward, even if in critical points the shoreline advance appears negligible;

- the late construction of the rubble mound groins allows beach fill material to move downdrift before being protected;

- the model results show that the reshaping of the sand groins will occur in a very short time (e.g. 1 day, if a 2.5 m high wave is used). The beach fill does not need to be ended long time before summer. If operated in wintertime, it is very likely that the wave action will destroy the groins before the end of their construction.

Figure 8. Final beach condition 3D

Figure 9. Shoreline beach evolution 3D – Phase 1 (sand groynes and beach fill)
Beach nourishment at Ostia (Lazio)

The project consists of the build up of a submerged breakwater, distant some 80 m from the shoreline, located in a water depth of about 4 m, with the top at -0.5 m from m.w.l.; the area delimited by this parallel-to-the-shoreline structure and the shoreline is going to be filled with an amount of 250 m$^3$/m of sand (fig. 10, upper panel).

The specific questions on the beach fill design tried to be answered by means of physical model tests were:

- is it the hard structure suitable for beach fill protection?
- is it the hard structure suitable for recreational purposes?
- are there any alternative solution that suits both beach protection and recreational purposes?
- which is the life expectancy of the beach fill (or the expected maintenance schedule)?

Based upon the waves recording of the site, it was possible to reproduce a morphological period corresponding to about 3 months in nature; the sequence of waves: summer, autumn, winter, spring was used.

The results obtained by mean of 2D-physical model tests can be outlined in the following list:

- the model tests demonstrated a good stability of the nourished beach (upper panel of fig. 10), with only small variations from the initial beach profile;
- a considerable increase of the water level in the region between the submerged breakwater and the shoreline (ranging between 13 to 43 cm, referred to prototype) was measured and, as a consequence,
- very “dangerous” return currents have arisen over the top of the submerged structure (this behaviour seems not to be acceptable in the framework of a safe utilisation of the beach).

As a consequence of the described results, a different solution (fig. 10, lower panel), with the top of the structure protecting the “perched beach”, placed at -2.0 m from m.w.l.
was reproduced and studied in the 2D-model. In particular with the analysed solution the stability of the artificial nourishment was increased using a double layer fill (lower coarse-quarry-sand covered with fine sand, suitable for beach activities). The results of this second round of tests is outlined in the following:

- the model tests demonstrated a lower effectiveness of the structure in protecting the beach fill (fig. 11);
- the coarse-quarry-sand layer was not reshaped by the wave action;
- an initial sand loss of about 25 m$^3$/m was evaluated in a 3 months period, with a retreat of 10 m, but further simulations showed that the beach profile is close to equilibrium (expected retreat 5 m/year);
- return currents over the breakwater are much lower than in the previous case and seem to be acceptable in the framework of a safe utilisation of the beach;

![Figure 11. Beach profile evolution after the wave attacks](image)

**Beach reshaping and inlet stabilisation at Barbamarco (Po delta)**

This project (located at Barbamarco, Northern Adriatic Sea) deals with the stabilisation and reshaping of a deltaic lagoon inlet. This stabilisation, obtained placing sand filled geosynthetic tubes for limiting the inlet fill up, induces the accretion of the updrift beach. The beaches adjacent to the inlet have also been nourished using the sand dredged from the channel, which has been dredged up to -3.0 m. The investigation area is sketched in fig. 12.

The specific questions on beach fill design to be answered using physical modelling were the following:

- is it the longshore sediment transport able to fill the area close to the geosynthetic tubes?
- how long will it take to reshape the beach?
- what will be the filling rate of the dredged channel?
The physical modelling programme designed to answer the previously mentioned questions implied the construction of a 3D model in a 1:100 scale, reproducing the whole project area. The 3D physical model tests designed to evaluate the performance and the time schedule of the project were carried out using light bed material (anionic resin CPN80-bayer\textsuperscript{®}, see tab. 4 for a detailed characterisation). This bed material allows to reproduce the prototype sediments behaviour with respect to the Dean criterion also using very small scale models.

Table 4. CPN80-bayer\textsuperscript{®} characteristics (w: fall velocity; s: specific weight)

The model has been calibrated using field data obtained by means of a successive bathymetric campaigns and allowed to determine a morphological model time scale.

The rate of sand bypassing the tubes and filling the dredged channel has been evaluated in the physical model using sand traps located within the channel; a value of about 2000 m\textsuperscript{3}/year was found.

The calibrated model has been used also for evaluating the beach accretion rate updrift the inlet; it was determined that, by the end of 1997, the coastline south of the inlet should have reached the edge of the tube groin (a recent inspection confirmed this forecast).

![Figure 12. Barbamarco inlet (tubes are sketched with solid lines).](image-url)
Final remarks

After a brief survey of the still open questions related to the beach nourishment performance evaluation, three cases studies has been presented and analysed by means of physical model tests. This methodology allowed to give satisfactory answers to some practical questions not easily manageable with numerical techniques.

The experimental study of the nourishment design of Capo d‘Orlando allowed to point out some useful information concerning the temporal aspects of sand groins remodelling phenomenon induced by the wave attacks.

From the tests on the Ostia littoral nourishment, it was possible to obtain interesting results concerning both the most suitable design of the submerged detached breakwaters and the behaviour of a double-layer supply of material.

Finally, the Barbamarco study evidenced the effectiveness of light bed material in describing transport phenomena when using very small model scale.

As a final remark, it can be stressed that the contribution of physical model tests is still of paramount importance, being implicitly integrative of all the (scaled and complex) processes that determine the evolution of the nourishment interventions.

Assessment of Depth of Closure on a Nourished Beach:
Terschelling, The Netherlands

S. W. Marsh*, R. J. Nicholls*, A. Kroon** and P. Hoekstra**

Abstract

Depth of closure is studied on a nourished beach in the light of its autonomous behaviour over long temporal and large spatial scales. Long term data show that depth of closure is variable alongshore, being shallower to the west and deeper to the east. Following placement of a shore nourishment along the middle section of the coast, the spatial variation of depth of closure changes. Initially the depth of closure is shallowest where the fill was placed. With time after the placement of the fill, this effect diminishes. Depth of closure observed in this study is influenced by bar behaviour. The fill material affects the observed depths of closure by reducing offshore bar migration. Maximum depths of closure for any particular timescale observed in this study are well predicted by the Hallermeier (1981) formulation for the depth limit to the active profile. In conclusion, pre-fill observations and Hallermeier (1981) provide a useful limit to the observed post-fill depth of closure. Similar analysis of other beach nourishment projects would be useful.

Introduction

Beach or shore nourishment is increasingly the preferred engineering solution when eroding coastlines require protection (Davison et al, 1992; Khabidov et al, 1996; Cooper, 1998). When designing a nourishment project it is important to have a detailed understanding of how the nourished coast will respond to the local hydrodynamic and morphodynamic regime. Furthermore it would also be useful to know whether placement of fill material will affect the local morphodynamic regime, even if the hydrodynamic conditions do not change. One fundamental aspect of the morphodynamic regime that has received increasing attention in recent years is depth of closure (Hallermeier, 1981; Nicholls et al, 1998).

If a series of beach and nearshore profiles are collected at a given location, the profile will change through time. In any normal set of profiles, it will be clear that bed elevation is highly variable within the littoral zone. Moving offshore this variability decreases; consequently a plot showing several profiles collected over time will have a depth at which the profiles "close" within the accuracy of the data. In other words, the depth of closure represents the seaward limit of the profile envelope. Depth of closure is a morphodynamic boundary which separates a landward, morphodynamically active zone from a seaward, morphodynamically inactive zone over the period defined by the observations (Nicholls et al., 1996). Depth of closure does not represent a barrier to cross-shore sediment transport.

Depth of closure is a key design parameter in the design of beach or shore nourishments (Davison et al., 1992). Depth of closure allows coastal engineers to estimate how far offshore morphological change is likely to extend, and hence, calculate the volume of sediment required to nourish a section of coast. However it remains unclear if placing nourishment material influences depth of closure. To investigate this question, depth of closure on a nourished shoreline will be compared to depth of closure on the same shoreline prior to nourishment. Any changes that occur because of the placement of nourishment material can then be investigated. The study will also include an examination of the validity of the Hallermeier (1981) formulation for the depth limit to the active profile.

**Study Area**

This work focuses on data collected at the Dutch barrier island of Terschelling, figure 1. Two morphological data sets covering this site will be analysed; these are the JARKUS data set and the NOURTEC data set. The combined data sets cover a longshore distance of 12 km and span a time period of 30 years from 1965 to 1995.

The JARKUS data set is comprised of annual surveys along the whole of the Dutch coast. Data collection began in 1963 with annual surveys extending seaward 1200 m. Since 1965 there have been five-yearly surveys extending to 2500 m. Depth of closure tends to occur seaward of 1200 m, so in this study only the five yearly extended JARKUS data are used. The central section of Terschelling has suffered from severe shoreline erosion. In an attempt to overcome this problem, 2.1 million cubic metres of sand were placed in the nearshore zone, between the middle and outer bars of the triple barred system, figure 2. The nourishment sand was slightly coarser ($D_{50} = 200 \mu m$) than the native sand ($D_{50} = 180 \mu m$) at the point where the fill was placed. The sand grain size decreases across the profile from 220–260 $\mu m$ on the beach to 150–160 $\mu m$ on the lower shoreface, (Hoekstra et al., 1994).

The nourishment was placed by RWS-RIKZ, the Dutch National Institute for Coastal and Marine Management and was monitored under the European Community Marine Science and Technology (MAST), Innovative Nourishment Techniques Evaluation (NOURTEC) programme. The length of the nourishment was 4.4 km (from 13.7 km to 18.1 km). Its placement depth ranged from -5 to -7 m NAP (NAP is Dutch Ordnance Datum; zero NAP is approximately mean sea level), Hoekstra et al (1996). Many previous nourishment projects have been criticised for failing to
monitor the fill response adequately after placement; see Davison et al. (1992). The Terschelling nourishment has been surveyed in considerable detail following its placement. Ten surveys were carried out with one in spring 1993, immediately prior to the fill placement and nine after placement of the fill between autumn 1993 and winter 1995. Dates of surveys and survey reference numbers are shown in table 1.

The survey area is approximately 25 km², and surveys extend from the top of the dunes backing the beach to 2 km offshore, at a water depth of 9 to 10 metres. The spring tidal range is 2.8 m, and the average annual significant wave height is approximately 1.5 m (associated wave period 8 seconds). Severe winter storms can generate waves up to 6 m high (period 10 - 15 seconds); the highest waves are typically from the northwest.

Previous studies (Ruessink and Kroon, 1994; Ruessink, 1998) show that the bars normally migrate offshore and similar morphology recurs about every 12 to 15 years. Ruessink (1998) shows that ebb tidal shoals are present at the eastern and western ends of Terschelling and it is possible that tidal inlets influence the profiles at the eastern end of the study area.

Figure 1. Location map showing the barrier island of Terschelling on the Northern Holland coast and the location of the study area.
The NOURTEC profiles were collected along the same transect lines as the JARKUS profiles. The combined use of JARKUS data and NOURTEC data means that depth of closure in an artificially forced situation can be compared with the autonomous behaviour of closure over the preceding 25 years.

**Quantifying Depth of Closure**

Closure occurs at a depth below which there is no measurable change in bed elevation, so measurement accuracy defines the criteria used to recognise closure in field data. In this study two techniques for determining depth of closure will be used; these are the standard deviation of depth change (SDDC) technique and a fixed criteria technique.

**Standard Deviation of Depth Change (SDDC) Technique**

For any given point that has been repetitively surveyed, it is possible to calculate the standard deviation of depth through time. When these standard deviation values are plotted along surveyed lines it is possible to discriminate between variability due to true changes in depth and variability that is due to measurement error (Kraus and Harikai, 1983). When the variability is due to measurement error alone, the profiles can be considered closed for the time period concerned. In the JARKUS data set, the standard deviation of depth typically falls to a non-zero tail with a value of approximately 0.25 m for profiles which exhibit closure. The mean depth at the beginning of the non-zero tail is defined as the depth of closure.

**Fixed Criteria Technique**

When two profiles are taken at the same location at different times it is possible to calculate the difference between the profiles along their length. When the difference falls below some value (determined by the accuracy of the data) then the profiles can be considered closed. We can assume that the JARKUS data
measurement errors are normally distributed, and as stated above, these errors have a
standard deviation of about 0.25 m. This means that if we observe a depth change of
0.25 m and 0.50 m between two profiles, then we can be 66% and 95% confident that
a real change has occurred, respectively. In this study a fixed criteria of 0.50 m will be
used when calculating fixed criteria depths of closure (cf. Nicholls et al., 1998). The
depth of closure is then calculated by moving up the profiles from the seaward end,
with closure being the mean depth where the difference between the profiles exceeds
50 cm.

Results

Pre-Fill Behaviour

Firstly, depth of closure for the whole JARKUS period will be examined using
SDDC and fixed criteria techniques. SDDC profiles were constructed for lines 10 to
variation in depth of closure is shown in figure 3.

![Figure 3. Observed longshore variation in depth of closure from 1965 to 1990, calculated using the SDDC method.](image)

At the west of the island (lines 10, 11 and 12) the observed depth of closure is
in the region of 7.5 to 8 m. This increases to the east as far as line 19, where the
observed depth of closure is 10 to 10.5 m. Lines 20, 21 and 22 do not exhibit closure.
This is attributed to the profiles ending before the depth of closure is reached. The
depth limit of the profiles is indicated on figure 3, and we infer that if closure occurs it
is deeper than the maximum depth of the profiles. A tidal channel is also present at
the east of the island, and this is likely to extend into the study area. The migration of
this tidal channel may affect depth of closure, and hence morphological change is
occurring which is not simply wave driven.
Depths of closure using the fixed criteria technique were calculated for each five year interval between JARKUS surveys, for each line in the study area. These are shown in figure 4. Again there is a trend for depth of closure to become deeper to the east of the island. The trend is significant at the 95% level for three periods: 1965-1970, 1970-1975 and 1975-1980.

Figure 4. Observed depths of closure determined using a fixed criteria depth change criterion of 50 cm for five-year time intervals.

Figure 5. Observed depth of closure determined using a fixed criteria depth change criterion of 50 cm for an expanding time window for 5 to 25 years (relative to 1965).
If the timescale is increased the trend is similar, with deeper closure to the east. Figure 5 shows depth of closure for 5, 10, 15, 20 and 25 year time intervals using 1965 as the reference profile; the alongshore variation is significant at the 95% level for all of these time intervals. Depth of closure also tends to increase with timescale as has been observed at other sites, such as Duck, NC (Nicholls et al, 1998).

Post-Fill Behaviour

Using data collected as part of the NOURTEC project, post-fill depths of closure were calculated using the SDDC and fixed criteria techniques. The first pre-fill NOURTEC survey is excluded. Depths of closure calculated using the SDDC technique for the post-fill period are shown in figure 6.

![Figure 6](image)

Figure 6. Observed longshore variation in depth of closure determined using the SDDC technique for the post-fill period (17th November 1993 to 13th December 1995).

The profiles for lines 10, 12 and 13 did not exhibit closure during the NOURTEC period. To give some representation of depth of closure at these locations, the depth limit of the profile data is shown. It is inferred that if closure does occur on these lines then it would be deeper than this depth. Interestingly the shallowest depth of closure occurs along the nourished section of the coast, which is quite different to the pre-fill behaviour (figure 3).

The depths of closure calculated using the fixed criteria method for each of the time intervals between NOURTEC surveys begin to explain the observed “average” behaviour shown using the SDDC method. Using the fixed criteria method, depth of closure still varies along the coast, but in general this variation does not show the systematic deepening to the east seen for the longer JARKUS periods which show shallow closure to the west and deeper closure to the east.
Figure 7. Time-expanding envelope, post-fill depths of closure. Intervals refer to survey numbers shown in Table 1. Each interval is offset by 2 m, and the dashed line indicates -5 m on each transect. The vertical lines mark the fill boundaries.
Depths of closure using a time-expanding envelope analysis were calculated to give a representation of the cumulative post-fill evolution of depth of closure. For these calculations the second NOURTEC survey (immediately after placement of the nourishment) was used as the reference.

The results of this analysis are shown in figure 7; the data are offset by 2 m for each survey to allow spatial patterns to be seen more clearly. Cases where no closure is observed are left blank. For most of the post fill period, there is a tendency for the shallowest depths of closure to occur in the nourished area, or just east of the nourished area. Westlake (1995) shows that sediment moved to the east following placement of the fill, and it is possible that this movement of sediment has an effect on the depths of closure observed.

Predicting the Depth Limit of the Active Profile

The depth limit to the active profile has been examined by Hallermeier (1981). Hallermeier proposed a predictive formula for the active depth limit which can be generalised to

\[ d_{t,t} = 2.28H_{e,t} - 68.5(H_{e,t}^2 / gT_{e,t}^2) \]  

where \( H_{e,t} \) is the significant wave height exceeded for 12 hours per t years and, \( T_{e,t} \) is the associated wave period; \( g \) is acceleration due to gravity.

Evaluation of this method suggests that it provides a limit to actual closure during storms and for annual periods on wave-dominated, microtidal sandy coasts (Nicholls et al., 1996, 1998).

The wave data available in this study cover the end of the JARKUS monitoring period and the whole of the NOURTEC monitoring period. Wave data collection began at Schiermonnikoog (the Son buoy in figure 1) in 1979. The offshore buoy at this location is exposed to similar wave conditions to Terschelling (van Beek, 1995), and the wave data from Schiermonnikoog are used to calculate the depth limit predicted by equation 1 for the JARKUS data. The time intervals used for this calculation were 1980-1985, 1985-1990 and 1980 to 1990.

The depth limits predicted by Equation 1 for the NOURTEC data were calculated using wave data from the buoy located offshore of Terschelling (in 15 m water depth), and extend the analysis of Westlake (1995). The predicted depth limit, for each time interval between surveys, is compared with the observed depth of closure for each of the profile lines.

Figure 8a shows observed depths of closure plotted against the predicted depth limit for all data. The JARKUS data have a deeper predicted depth of closure than the NOURTEC data because they are based on a longer time interval. However, for both short and long timescales, the predicted depth limit based on a 12-hour exceedance wave height, acts as a good limit to the observed depths of closure. The range of
Figure 8. Observed depths of closure versus predicted depth limit of active profile. a) shows all data, b) shows average values for the western, central and eastern sections of the study area.
observed depths of closure for any measurement period is roughly constant at 4 metres. Hallermeier (1981) suggests that equation 1 approximates a yearly closeout of about 0.15 m using field data available in 1981. Nicholls et al. (1998) show that equation 1 is a limit to annual closure at Duck using a closure criteria of 6 cm. Therefore, using a 50 cm closure criteria, we would expect the observed depths of closure to be significantly shallower than equation 1 predicts (see figure 1, in Capobianco et al, 1997).

Figure 8b shows how the observed depths of closure vary in space, using the average observed depths of closure in the western, eastern and central sections of the study area (western is west of the fill boundary, the eastern section is to the east of the fill boundary; and the central section is the nourished section). It reinforces the observation of alongshore variation in the observed depths of closure.

Discussion

Equation 1 provides a limit to the closure observations which suggests that wave breaking is a fundamental control on the observed depth of closure (cf. Hallermeier, 1981; Nicholls et al, 1998). However it is also clear that depth of closure is variable alongshore. Assuming that the whole length of the shore is exposed to similar waves, then if the incident wave field were the only control over depth of closure we would expect depth of closure to be the similar along the whole coast. It is therefore likely that there are other controls on depth of closure along the Terschelling coast. In this study, the relatively large depth change criteria that has been used to define closure means that we may observe a depth of closure which is largely influenced by the outer bar position; it is the offshore migration of the outer bar that controls depth of closure. The depth change criteria of 50 cm used here would be expected to give shallower depths of closure than a 15-cm or 6-cm closure criteria, and we do not resolve some sub-50-cm morphodynamics in the profile that occurs deeper than our observed closures. However, using the data available gives us some understanding of how closure behaves over longer timescales than previous studies have investigated. This in turn allows more robust conclusions to be drawn regarding the influence that the nourishment has on the observed depth of closure.

Previous studies have shown that the migration of bars at Terschelling involves both longshore and cross-shore components of movement. The largest waves approach from the northwest and generate longshore currents to the east. Morphological studies (Ruessink and Kroon, 1994; Ruessink, 1998) show that bars propagate alongshore towards the east. There are ebb tidal shoals to the west of the island, and these are likely to protect the western section of the study area from the largest waves, hence the shallower depth of closure at the west of the island. In the centre of the island, the dominant process that is likely to affect the depths of closure observed in this study is cross-shore movement of the outer bar. Ruessink and Kroon (1994) show that the natural bar cycle involves a degeneration of the outer bar, and subsequent seaward migration of the middle bar. The return period of this cycle is approximately 12 to 15 years. An analysis of the furthest offshore position of the outer bar for the JARKUS data and the position of closure during the same time intervals shows that the position of closure is closely associated with the position of
the outer bar as illustrated in figure 9. The observation of deeper closure to the east of
the study area may be attributed to the presence of tidal channels which extend from
the tidal inlets at the eastern end of the island, and hence produce tidally driven
morphological change.

Given these observations, we are still faced with the question posed initially:

"What effect does the nourishment have on depth of closure?"

The long-term data suggest that depth of closure does vary alongshore, under
natural conditions. However, the longshore variation of depth of closure is different in
the post-fill period. In particular the mean behaviour, observed using the SDDC
method, and the post-fill cumulative evolution of depth of closure, show that depth of
closure is shallower than we would expect in the nourished area for the two year
interval following placement of the fill. It appears that as the timescale considered
increased, so the effect that the fill has on closure may diminish.

It has been suggested above that the closure we observe is influenced by bar
migration. Assuming this is true, we then seek to explain how the fill has affected bar
migration. The nourishment appears to have suppressed the offshore migration of the
bar system, which might make the depth of closure we observe shallower than we
might otherwise expect. Kroon et al. (1994) show that placement of the nourishment
has decreased bar morphodynamics by making the middle bar stable in a position
where it would have been expected to migrate offshore, based on observations before
the fill.

Ruessink and Kroon (1994) argue that if the outer crest height is greater than
about 5.5 m then on- and off-shore bar driving forces are balanced. Placing the fill
between two crests effectively provided a much broader area to dissipate wave energy.
It also means that much more sediment had to be moved before cross-shore movement of bars could occur.

Westlake (1995) shows that after the nourishment sediment moved to the east and towards the land at the eastern end of the fill. Figure 7 shows that the section of coast with the shallowest closures migrates eastwards for much of the two-year period following fill placement. It is likely that the buffering effect that the fill has on bar migration also moves eastwards because of this *en masse* transport of material. However, the outer bar height is not diminished sufficiently for the middle bar to move offshore and take up the outer bar position in the time period for which we have observations.

The observation of shallower closure in the fill area in the short time period following placement of the fill is surprising. Based on first principles, the opposite behaviour would be expected because the fill would be expected to oversteepen the profile. In this case, the fill doesn’t oversteepen the profile because it was placed in a trough between bars. On the basis of the observations of shallower closure in the nourished area, it is possible that placing the fill between the bars reduces the rate of loss of sediment from the nourishment site to the offshore zone in the period following placement of the fill. To assess the impact of the fill over long time periods, it will be necessary to examine data from the study area for at least one natural bar cycle period, approximately 12 years (Ruessink and Kroon, 1994).

**Conclusions and Engineering Implications**

Depth of closure is observed using SDDC and fixed criteria techniques over short and long time periods off the coast of Terschelling. Depth of closure observed in this study tends to vary systematically alongshore. Over long periods of time (5 years to 25 years), depth of closure is in the range 4 to 10 m, and is shallower to the west of the island, and deeper to the east.

Our ability to predict depth of closure remains relatively poor, but for both long and short time intervals, the depth limit to the active profile suggested by Hallermeier (1981) is a good upper limit to the observed depths of closure for both the nourished and un-nourished profiles. The terminology as used by Hallermeier (1981) is deliberate; formulations such as Equation 1 should be considered as a limit to the depth of closure, and not as a prediction of depth of closure. In this study, the autonomous variation below the limit predicted by Equation 1 is attributed to large scale morphological features.

This analysis shows that closure is influenced by beach nourishment but in this case, the closure depth was reduced by the placement of the fill. Therefore, the historical perspective of the extended JARKUS data, or Equation 1 are both useful to determine a limit to the actual closure. However, they do not allow prediction of the actual closure in the post-fill period. It will be interesting to continue to monitor the profile development at this site over a complete bar cycle (12 years), to see if the placement of the fill has a lasting effect on the bar behaviour and depth of closure.
This study gives some confidence in using the depth of closure concept as part of beach nourishment design. However, it represents one site and systematic monitoring of beach fills should be encouraged to extend our understanding of a wider range of situations (e.g., Stauble and Grosskopf, 1993). As technology improves we look forward to more accurate vertical resolution, and the ability to resolve closure using smaller depth change criteria.

Abstract

The behavior of Oregon Inlet, located north of Cape Hatteras, North Carolina, on the Pamlico Sound estuary, and its commercial, ecological, and recreational importance have been the subject of much study and controversy. The construction of a terminal groin on the southern shoulder of the inlet in 1990 served to heighten this interest. Both the U.S. Army Corps of Engineers (USACE) and the NC Department of Transportation (NCDOT) have maintained monitoring programs since that time to study the impact of the terminal groin on the morphology of the inlet and the adjacent shorelines. This paper utilizes data from the USACE and NCDOT programs to examine the relationship between the growth of the Bodie Island spit and the resulting bathymetric changes in the inlet. Data collected are compared with results from the literature.

The morphology of Oregon Inlet exhibited changes expected with the stabilization of a single shoulder of a tidal inlet. In contrast, the cross-sectional area of the channel at the minimum inlet width changed little. When analyzed in light of empirical equilibrium conditions reported in the literature, the results supported the conclusion that the inlet had achieved a new equilibrium configuration due to the presence of the terminal groin.

1. Introduction and Location of Study Area

Since the construction of a terminal groin at Oregon Inlet, NC, both the U.S. Army Corps of Engineers (USACE) and the NC Department of Transportation (NCDOT) have maintained programs to monitor the morphology of the inlet and the adjacent shorelines. This paper utilizes data from the USACE and NCDOT programs to examine changes in inlet width and orientation due to migration of the non-stabilized northern inlet shoulder (Bodie Island); also discussed are associated changes in the bathymetric configuration of the inlet. The results of the measurements are analyzed for consistency with empirical equilibrium indicators reported in previous studies of inlet behavior.

Oregon Inlet is located on the Outer Banks of North Carolina, just south of Nags Head and north of Cape Hatteras. It is the only inlet in the Outer Banks between Cape Hatteras and Cape Henry, VA, providing an exchange for Pamlico, Currituck, and Albemarle.
Sounds with the Atlantic Ocean. Figure 1 shows the location of the inlet in relation to the United States and, on a smaller scale, to the North Carolina coastline and coastal waters. The inlet is the site of the only bridge currently spanning a major inlet in North Carolina, the Herbert C. Bonner Bridge, completed in 1964.

![Figure 1. Location of study area, Oregon Inlet, NC.](image)

The mean ocean tidal range at Oregon Inlet is 2.0 ft, with a spring range of 2.4 ft (Moffatt and Nichol, 1990). The average significant wave height at Oregon Inlet is approximately 3 ft, with an extreme height of approximately 10 ft (Moffatt and Nichol, 1990). Wind effects on tidal flow at Oregon Inlet may be very dramatic, especially in cases of rapid wind reversals over Pamlico Sound (Inman and Dolan, 1989). Winds from severe storms have caused differences in water levels in excess of 9 ft across the inlet (Moffatt and Nichol, 1990). Gross longshore sediment transport has been estimated to be $5.8 \times 10^7$ ft$^3$/yr in the vicinity of Oregon Inlet (Inman and Dolan, 1989). Hollyfield, et al. (Inman and Dolan, 1989) and Dennis (1997) have reported values for the tidal prism of Oregon Inlet of $3 \times 10^9$ ft$^3$ and $2.3 \times 10^9$ ft$^3$, respectively. The tidal prism values were both determined from pre-terminal groin measurements and will be used in later sections of this paper.

At Oregon Inlet, the net longshore sediment drift is in a southerly direction, resulting in a predominant southward inlet migration. Between 1846 and 1989, Oregon Inlet migrated approximately 2.2 miles southward and 2,070 feet landward. By the late 1980s, the southern approach to the Bonner Bridge had become endangered by inlet migration, and the NCDOT sponsored construction of a terminal groin to stabilize the southern (Pea Island) shoulder. Construction was begun in October 1989 and was completed early in 1991. The present study considered data gathered from October 1989 until April 1997.
2. Data and Methods

The purpose of the present research was to characterize the migration and equilibrium condition of Oregon Inlet since the terminal groin was constructed. The study was accomplished using time series of shoreline positions and bathymetric data taken between October 1989 to April 1997. Using these data, changes in inlet geometry were analyzed in light of empirical equilibrium indicators reported in the literature, specifically in studies by O'Brien (1931, 1969) and Jarrett (1976).

The primary sources of data for this study included a database of shoreline positions and hydrographic surveys of the inlet area. The shoreline database was generated as part of a shoreline erosion monitoring project conducted by the NCSU-Kenan Natural Hazards Mapping Program at North Carolina State University (Overton and Fisher, 1997), in conjunction with the NCDOT. The shoreline positions were digitized by the NCDOT from rectified aerial photographs, taken at a bimonthly frequency beginning in October 1989.

Morphological parameters observed from the shoreline database include minimum inlet width, planimetric accretion and erosion of the Bodie Island shoulder, and location and orientation of the minimum width section. The majority of definitions for this study are consistent with work done by Vincent and Corson on inlet geometry (1981); detailed definitions for the parameters follow this section.

The hydrographic surveys were obtained from the U.S. Army Corps of Engineers, Wilmington district (USACE, 1990a, 1990b, 1994, 1995, 1996, 1997). The dates of the surveys and the related shoreline positions are listed in Table 1. Three full-inlet, bank-to-bank surveys were available; the remaining surveys covered only the channel section through the inlet. The data were processed to create contours, grids, and profiles of the submerged inlet area from which subsequent measurements were made. Parameters measured included cross-sectional area, maximum channel depths, and ebb delta area.

Data were collected from the shoreline positions and hydrographic data sets by the measurement of several geometric parameters of inlet configuration. All measurements were made using the MicroStation CADD software in conjunction with Intergraph’s Terrain Analyst software for profile creation and contouring of the bathymetric data. The contours were used to determine channel position, which was digitized by following the deepest contiguous contours through the inlet. An example of channel delineation is
shown in Figure 2. Unless otherwise noted, all measurements of depth were taken from Mean Sea Level 1929 (referred to hereafter as “mean sea level”). The following is a list of the parameters and the working definitions:

1. Minimum inlet width \( (W) \) is defined as the narrowest point between the inlet shoulders, as shown by the shoreline data set. The location of the minimum width section was determined by constructing the minimum distance line between the digital shoreline shoulders using the CADD software. An example of width delineation is displayed in Figure 2. The section of minimum width may also be referred to as the gorge or throat section.

2. Maximum channel depth \( (d_m) \) is defined as the maximum depth occurring at the section of minimum inlet width. Maximum depth and all other bathymetric measurements were determined from computer-generated digital profile plots of the bathymetric data. Figure 3 graphically portrays gorge profile definitions.

3. Cross-sectional area \( (A_c) \) was taken at minimum width by digitally measuring the area bounded by the profile, the water surface at 0.0 ft on the plot (mean sea level), and the vertical axes of the plot. The vertical axes represent the locations of the Bodie and Pea Island shoulders of the inlet; see Figure 3.

4. Ebb tidal delta area \( (A_E) \) was defined, again following Vincent and Corson (1980), as the area of the region bounded by the inlet shoulders, the minimum width line, the contour of controlling depth, and a set of boundary lines marking the point on either side of the inlet where the controlling depth contour became approximately shore-parallel (Figure 2). The area was measured by an application of the CADD software.

3. Graphical Presentation of Data and Discussion of Results

This section documents the results of the analysis of the shoreline and bathymetric time series. The results are presented in three parts. First, the observed trends in planimetric inlet morphology are discussed, followed by a description of changes observed in the bathymetric configuration of the inlet. Finally, Table 2 summarizes the results of the measurements of inlet minimum width, maximum depth, cross-sectional area, and ebb tidal delta area.

**Planimetric inlet morphology**

While the construction of the terminal groin has effectively halted the migration of the southern (Pea Island) shoulder of the inlet, the northern (Bodie Island) shoulder exhibited both alongshore and cross-shore migration over the study period. Inlet migration has resulted in changes in inlet width and orientation.
Figure 2. Parameter definition sketch, planimetric view.

Figure 3. Parameter definition sketch, bathymetric view.
A progression of semi-annual shoreline positions is shown in Figure 4, beginning with April 1990 and ending with April 1997. The October 1989 position is included in each frame to provide a reference from which changes may be observed. In each frame, the dated shoreline position is marked by a dotted pattern fill. The solid lines crossing the inlet mark the gorge section for both the October 1989 and the designated positions; the most bayward solid line marks the location of the highway and bridge over the inlet.

The Bodie Island spit accreted bayward over the study period, reaching and crossing the location of the bridge. The beginning of this movement is noticeable from the figure as early as April 1991. This date marks the approximate completion of the terminal groin, which becomes a permanent reference point in the remaining frames. The spit continued to accrete bayward, with some migration into the inlet, until October 1993. At this point, the spit began to show more dramatic accretion toward Pea Island. From this date through the end of the study period, the spit continued to migrate toward Pea Island, with accretion taking place at the northern portion of the bridge as the end of the spit widened.

Trends in inlet width may be observed from Figure 5, a plot of minimum inlet width vs. time since construction of the terminal groin. The narrowing between the April 1990 and October 1990 positions was due primarily to the encroachment of the terminal groin into the inlet. After this date, the terminal groin stabilized and defined the location of the southern shoulder, and changes in width were due to the migration of the Bodie Island spit. Following the initial decrease in width, the inlet continued to show a slight narrowing trend, with short-lived minor widenings observed. The inlet reached its narrowest width of the present study period, 2,732 ft, on February 11, 1996. Since that time, the data showed a relatively short but distinct trend toward widening, with the latest measured value at 3,017 ft in April 1997.

Accretion of the spit was also responsible for a change in location and orientation of the gorge section. The shifting of the gorge became most noticeable beginning in April 1995, which coincided with the beginning of significant widening of the spit at the bridge. The shift of the gorge bayward required a rotation of the section, since the terminal groin remained as the southern extent of the inlet. The gorge continued to move bayward and orient itself in a more northerly direction through the remainder of the study period.

Bathymetric inlet morphology

Changes in the inlet's bathymetric configuration were observed coincident with the changes in inlet width and orientation. Using data from the hydrographic surveys, profiles were created to measure changes in channel location and shape. The profiles, shown in Figure 6, were taken across the gorge section, using the minimum width line as a transect. The plots are aligned using the axis representing Pea Island as a reference point. This alignment was chosen because the terminal groin has stabilized this shoulder of the inlet, so that its position is constant. The plots show the bottom elevations, relative to mean sea level, of the gorge section from Bodie Island to Pea Island (left to right).
Figure 5. Oregon Inlet minimum width, October 1989 to April 1997.

The channel at the gorge section showed lateral migration toward the terminal groin (Pea Island). This is evident between the January 1990 and December 1990 profiles. A more visible migration was noticed between December 1990 and December 1996, as the channel shifted 2,160 ft toward Pea Island. In contrast, the position of the channel relative to the Bodie Island axis has remained relatively constant, at a distance of 700 to 900 ft.

Along with its lateral migration, the channel deepened, with maximum depths increasing from approximately 27 feet below mean sea level in January 1990 to 50 feet in December 1996, then slightly decreasing to 46 feet in April 1997. The deepening trend was dominant over the study period, except for the April 1995 survey, which showed a maximum channel depth of only 26 feet.

A second set of profiles was constructed along the lines marking the channel locations from bayward of the bridge to seaward of the ebb delta. The profiles are displayed in Figure 7, and show the bottom elevations along the channel from the sound toward the ocean entrance (left to right). The bridge location was chosen as an alignment reference point for these profiles; its position is marked on the figure by a solid vertical line. The dashed vertical lines mark the location of the minimum inlet width.

As the inlet width decreased through December 1996, the maximum depth of the channel at the gorge increased. While these changes took place, the cross-sectional area of the gorge remained relatively constant, hovering around 50,000 ft$^2$. A constant cross-sectional area suggests that a state of equilibrium exists, as do the changes in depth coincident with changes in width. From inspection of the profiles in Figure 6, the
Figure 6. Gorge cross-section bathymetric profiles.

Figure 7. Channel lengthwise bathymetric profiles
channel itself became narrower as the inlet width decreased. In order to maintain a constant cross-sectional area, a narrowing inlet must become deeper to accommodate the same discharge volume, or tidal prism. The data show that this has been the case at Oregon Inlet since the terminal groin was constructed.

Summary of results

A summary of observed planimetric and bathymetric parameter measurements is displayed in Table 2. Measurements of bathymetric parameters were taken from the channel profile plots previously described. The three bank-to-bank surveys contained sufficient data for the measurement of all parameters under study; at least one parameter was not measurable for the remaining profiles, due to insufficient data. All vertical measurements were made relative to mean sea level.

Table 2. Summary of data measured from shoreline positions and hydrographic surveys.

*I/D denotes insufficient data for measurement.

A note should be made about the measurement of A_c for the April 1997 data. As can be seen from the profile in Figure 6, the survey did not span the entire inlet, so that the area could not be measured exactly as defined. However, it was judged that enough information was present to allow the reasonable measurement of cross-sectional area by extending the profile on either side of the channel to the vertical axes. It is believed that, though the measurement is not as exact as those for the bank-to-bank surveys, the area determined in this way is reasonably close to what would actually be measured from a full survey, if it existed. Any error in the measurement from the actual value should be an underestimate, since most of the profiles showed some deepening on either side of the channel banks which would not be accounted for in the profile extrapolation. This method of measuring cross-sectional area was considered for the August 1994 and April 1995 surveys, but it was judged that insufficient information existed for any reasonable extrapolation to the vertical axes of the plots.

A second aspect of the analysis that deserves comment is the fact that the shoreline position dates do not exactly coincide with the dates of the hydrographic surveys. Since inlet parameters may adjust themselves rapidly to existing wave and tidal current conditions, the difference in time between a hydrographic survey and its corresponding shoreline position may be a significant source of error. Unfortunately, it is a source of error that could not be quantified or known for certain. However, since most of the
survey/shoreline position sets were collected within two to three weeks of each other, it was assumed for the sake of the study that the shoreline data was representative of the actual shoreline position at the times of the surveys.

The changes in inlet width became smaller in magnitude, or "slower" in rate, as the study period progressed. Small changes from a certain state were described by van de Kreeke (1992) as an indication of inlet equilibrium. Though it was not clear whether the inlet would continue to widen or remain more constant in width, the data suggested that the hydraulic forcing factors at Oregon Inlet are currently sufficient to maintain an inlet width greater than 2,732 feet. The inlet has been narrower, at 2,100 feet in 1975 (Moffatt & Nichol, 1990), so that the narrowing was no indication in itself of progression toward inlet closure due to the presence of the terminal groin. Conversely, the combination of small changes in inlet width and small variance in cross-sectional area supported the hypothesis that the inlet had reached equilibrium since terminal groin construction. An analysis of the data using empirical results from previous researchers on equilibrium inlet geometry was conducted to further test the hypothesis; Section 4 of this paper describes the comparative analysis.

4. Comparison of results with reported empirical equations

The relationship between tidal prism and cross-sectional gorge area is a commonly studied and used empirical description of inlet equilibrium (Escoffier, 1940; van de Kreeke, 1992; O'Brien, 1931, 1969; Jarrett, 1976). Since the results of this study showed small variance in cross-sectional area, it was believed that the data would fit one of the classic tidal prism-flow area relationships. This section documents the results of a comparison of empirical equations from studies by O'Brien (1931, 1969) and Jarrett (1976) with the measured cross-sectional area data and reported tidal prism values for Oregon Inlet.

The empirical equations describing the equilibrium relationship between tidal prism and cross-sectional area take the form $A_c = C \times P^n$, where $A_c$ is cross-sectional area in ft$^2$ and $P$ is tidal prism in ft$^3$, and $C$ and $n$ are empirically determined constants. Table 3 lists the specific equations of this form considered for the present study, along with the geographic locations and stabilization status of the inlets considered in the development of each equation.

The cross-sectional areas measured by this study were compared with calculated results from Equations (1) through (6). Equation (7) was not included in this analysis, because it was intended to describe Pacific coast, dual-jettied inlets, and it agrees closely with Equation (1) from O'Brien (1931). For the analysis, tidal prisms were calculated using Equations (1) through (6) with the measured values of \( A_c \). The results are reported in Table 4. The calculated tidal prisms were compared with values reported for Oregon Inlet by Hollyfield, et al. (Inman and Dolan, 1989) and Dennis (1997), also included in Table 4. The reported values for Oregon Inlet’s tidal prism fell within 95% confidence limits determined by Jarrett for reliability of his equations.

The best prediction of Oregon Inlet’s tidal prism was obtained using Equation (2), O’Brien’s 1969 result for inlets without jetties. Equation (1) consistently underestimated tidal prism values, as did Equation (6). Equations (3), (4), and (5) tended to overestimate. Since the reported tidal prisms fall within the confidence limits of Jarrett’s data, it is reasonable to believe that Equations (3), (4), (5) and (6) may be used to generally
describe Oregon Inlet’s behavior. From this analysis it appears that the relationship between post-groin cross-sectional gorge areas and tidal prism at Oregon Inlet is similar to those determined by O’Brien and Jarrett. This information supports the hypothesis that the inlet has exhibited an equilibrium condition over the study period.

The values reported for Oregon Inlet’s tidal prism were calculated using pre-terminal groin data. To the author’s knowledge, post-terminal groin data for calculation of the tidal prism were not available, though the data would be helpful in accurately understanding changes that have occurred since the construction of the terminal groin.

5. Conclusions

This report documented a study of morphological changes observed at Oregon Inlet, NC. The study period was from October 1989 to April 1997, the time since the construction of a terminal groin on the downdrift shoulder of the inlet. It was hypothesized that the hydraulic and sedimentary environment of the inlet had approached or reached a state of equilibrium since the construction of the terminal groin, and that the groin had not negatively affected the stability of the inlet. To test the hypothesis, shoreline position and bathymetric data were analyzed to examine changes in inlet geometry. The results of the analyses supported the hypothesis.

Further study of the morphology and hydraulic and sedimentary conditions of Oregon Inlet is necessary to more fully understand its behavior, particularly as it relates to future engineering works for transportation safety and reliability. Specifically, an accurate hydraulic model of the inlet and adjacent waters it affects would be helpful in determining a post-groin tidal prism as well as predicting effects of winds, waves, and engineering efforts on flows through the inlet. Furthermore, the application of a sediment transport model with a hydraulic model of the inlet would provide means for determining the effects of influencing factors on inlet morphology and stability.

PREDICTIVE MODEL OF THREE-DIMENSIONAL DEVELOPMENT AND DEFORMATION OF A RIVER MOUTH DELTA BY APPLYING CONTOUR LINE CHANGE MODEL

Takaaki UDA¹, Hiroshi YAMAGATA², Ken-ichi KATOH² and Naohiro AKAMATSU²

Abstract

A predictive model of the three-dimensional development and deformation of a river mouth delta is developed. This model enables the prediction of not only the shoreline change but also the three-dimensional, long-term topographic changes around a river mouth, and offshore sand transport can be taken into account when the sea bottom slope exceeds a critical value given by the angle of repose of sand. Numerical simulation of three cases of initial beach slopes is carried out and compared. The calculated and actual beach changes measured around the Fuji and Tenryu River mouths are compared. It is concluded that calculated results can reproduce real phenomena measured around river mouths qualitatively.

I. INTRODUCTION

In order to evaluate the influence of the construction of a dam in a large river basin on coastlines, since the river supplies a large amount of sand to the surrounding coastline, the impact of a decrease in fluvial sand supply should be predicted quantitatively. In past studies, the shoreline change model has been widely used for this purpose (Hashimoto, 1975; Rafaat and Tsuchiya, 1991; Tsuchiya et al., 1995). This model is very simple and can be applied under any kind of practical conditions, but it cannot be used to predict profile changes caused by longshore sand transport and offshore discharge of sand. Recently, Uda and Kawano (1996) developed a new model called the “contour line change (CLC) model” which can be used to predict successive changes in each contour line position through numerical solution of the continuity equation of sand and longshore sand transport, with assumed values of depth change in the longshore sand transport rate. This model was applied to the prediction of the movement of a sand body on the Shizuoka coast in Japan, and it well reproduced this phenomenon quantitatively (Uda et al., 1997). This study is aimed at developing a new model to predict three-dimensional deformation of a river mouth delta.

II. NUMERICAL MODEL OF DEVELOPMENT OF A RIVER MOUTH DELTA

2.1 Contour Line Change Model

Uda and Kawano (1996) and Uda et al. (1997) developed a model which enables the prediction of the spatial and temporal changes in contour line positions by assuming the depth distribution of the longshore sand transport rate. This model is designed for a coast with a steep slope near the shoreline, without bar/trough topography. It was originally developed as one of the applications of the analytical method in which temporal and spatial changes in offshore distance to some reference contours are investigated in place of simple comparison of sounding maps based on beach survey data collected on actual coasts. The fundamental idea of this model is as follows: on a steep coast without bar/trough topography the change in offshore distance to contours located between wave run-up height and the critical depth for beach changes is very closely related to the change in shoreline position if the beach changes are caused by longshore sand transport. This suggests predictability of subsequent locations of each contour due to longshore sand transport, if the relation between the changes in those contours can be determined. As schematically shown in Fig.1, this model can be used to predict the subsequent locations of contours \( y_1, y_2, \ldots \), including the changes in longitudinal profile of the beach, by dividing the beach profile between \( h_R \) and \(-h_c\) into thin layers and assuming the depth distribution of the longshore sand transport rate. Here, \( h_R \) and \( h_c \) are the wave run-up height and the critical depth for beach changes, respectively.

The introduction of a cross-shore distribution of longshore sand transport can be performed similar to the present model, but in this case, the cross-shore distribution must be transferred every time the shoreline changes its location, and in addition, even if the change in depth is calculated, complicated transformation is required to calculate the change in contours from the change in depth. For these reasons, in the present study we assume the depth distribution of longshore sand transport instead of the cross-shore distribution. In the CLC model the distribution of longshore sand transport...
ranges between $h_R$ and $-h_c$, as shown in Fig.1. Longshore change in wave height can easily be taken into account since $h_c$ and $h_R$ are assumed to be a function of breaker height $H_b$.

If the incident angle at the breaking point is assumed to be sufficiently small, Eq.(1) is satisfied using the Savage formula for longshore sand transport.

\[ Q = F_0 (\tan \alpha_0 - \frac{\partial y_s}{\partial x}) \]  

(1)

where $Q$ : littoral transport rate, $F_0$ : a coefficient depending on wave energy flux, $\alpha_0$ : incident angle at breaking point, $x$ : longshore distance, and $y_s$ : shoreline position measured normal to $x$ axis. Eq.(1) is satisfied only if the beach profile undergoes parallel movement in time and space, and the rate of longshore sand transport is determined by the relationship between the shoreline and the incident angle of waves.

Now, for a region divided by $n$ contour lines, and if the longshore sand transport at a water depth corresponding to $k = 1 \ldots n$ is assumed to be $q_k$ and if it is also assumed that a similar relationship is established between the contour line distance $y_k$ and $q_k$ in analogy with Eq.(1), the following equation is obtained.

\[ I = F_{ok} (\tan \alpha_0 - \frac{\partial y_k}{\partial x}) \]  

(2)

where $F_{ok} = F_0 \cdot \mu_k$, $\sum \mu_k = 1$. Eq.(2) assumes that the longshore sand transport in each layer is governed by the relationship between the location of each contour line and incident wave direction. This model, therefore, does not require parallel movement, unlike the shoreline change model.

$\mu_k$ is a coefficient to give the longshore sand transport rate at each water depth and is calculated using Eq.(3) by giving the depth change of the longshore sand transport rate.

\[ \mu_k = \int_{z_k}^{z_{k+1}} \frac{\xi(z)dz}{\int_{-h_c}^{h} \xi(z)dz} \]  

(3)

$z$ is the vertical distance with the still water level as the reference. The continuity equation of the longshore sand transport is given as

\[ \frac{\partial q_k}{\partial x} + h_k \frac{\partial y_k}{\partial t} = 0, \quad k = 1 \ldots n \]  

(4)

where $h_k (k = 1 \ldots n)$ is the characteristic height of beach changes related to the topographic change represented by the contour lines, and is given by

\[ h_k = z_k - z_{k-1} \]  

(5)

If the functional form of $\xi(z)$ is given, $\mu_k$ is calculated using Eq. (3), and so the change in contour for each water depth is calculated by simultaneously solving Eqs.
(2) and (4). If the vertical distribution of the longshore sand transport rate is assumed to be between the wave run-up height on the foreshore and beach changes, the following relation can be assumed based on the field observation.

\[
z^* = \frac{z}{H_b}, \quad h^*_c = \frac{h_c}{H_b}
\]

When \(-h_c < z < h_R\),

\[
\xi(z) = \frac{2}{h_c^*} \left( \frac{1}{2} - z^* \right) (z^* + h_c^*)^2
\]

When \(z < -h_c\) and \(z > h_R\),

\[
\xi(z) = 0
\]

Uda and Kawano (1996) showed a correction method for the overhanging state of contours, namely, the state that the offshore distance to some reference contour becomes larger than that to a deeper contour. This induces offshore sand movement due to the gravity effect, and the sea bottom slope becomes more stable. Accordingly, the physical meaning of this correction is equivalent to the profile adjustment in order for the local sea bottom slope to maintain this critical value if the sea bottom slope exceeds a critical value, and eroded and accreted areas in the profile are always equivalent, while satisfying the continuity of sand volume per unit distance. Figure 2 shows a schematic of this process.

Assuming that the local sea bottom with a slope exceeding the critical value is equivalent to the critical slope and the point of intersection between BC and B'C' is set to be M, a procedure for transformation from point B to B' and from C to C' is carried out so as to satisfy the equivalence of areas ABMB' and DCMC'. Since this mechanism is included in the model, sand movement to a far-offshore zone deeper than the critical depth for beach

2.2 Conditions of Numerical Simulation

Six cases of numerical simulation of the development and deformation of a river mouth delta were investigated as shown in Table 1. The effect of the initial sea bottom slope on the formation of a foreset slope is investigated first for three different sea bottom slopes of 1/5, 1/10 and 1/20. The initial sea bottom slope is a key parameter because it influences the amount of accumulation space of fluvial sand supplied from the river mouth. Cases ①, ② and ③ aim at the investigation of this point. In each case a constant sand supply of 5.0x10⁵ m³/yr from a river mouth is assumed from the initial stage up to two years, and thereafter, sand supply from the river is stopped completely (cases ①～③) and in another three cases, ④, ⑤ and ⑥, prediction is carried out for an additional 2 years after sand supply from the river was cut to half, in order to study the topographic changes around the river mouth due to the decrease in fluvial sand supply. Accordingly, the conditions in cases ①, ② and ③ are the same as those in ④, ⑤ and ⑥, except for the boundary condition at the river mouth after two years.

As a calculation domain, a 3km stretch, in the longshore direction, of uniform sandy beach is considered, and this domain is divided into 61 points at 0.05km intervals alongshore. A river is located at the center of this region and the open-boundary condition is set at both ends of the calculation domain. In the model, landward and offshore limits are given by the maximum run-up height, $h_R$ and the critical depth for beach changes, $h_c$, respectively. Furthermore, the critical slopes of the beach on land and in the sea are assumed to be 1/1.7 and 1/2, respectively. As the wave condition, a simple condition of a constant breaker height of 3m alongshore is selected as an example, and the wave direction is assumed to be perpendicular to the initial shoreline in order to facilitate the understanding of the mechanism of the development and deformation of a river mouth delta. Furthermore, $h_R$ and $h_c$ are set to be 4m and -7m, respectively. The calculation period is four years, which requires the total number of time steps of around 4.15x10⁵, because one time step is set to be 300s.

Sand is supplied from three points located at the distance of 2Δx in the longshore direction and the amount of supplied sand per unit time is divided into three portions; 0.6$Q_0$ at the central point and 0.2$Q_0$ at a point on either side, where $Q_0$ is the amount of fluvial sand supply from the river per unit time. The supplied sand is assumed to be rapidly divided in each layer separated vertically in correspond to the depth change in longshore sand transport by wave action.

III. RESULTS OF NUMERICAL SIMULATION

(1) Initial sea bottom slope of 1/5 (cases ① & ④)

Figures 3 (a), (b), (c) and (d) show the results of the calculations, for case ①, in which a river supplies sand at a rate of $Q_0=5.0x10^5$ m³/yr to the surrounding sandy coast with the initial sea bottom slope of 1/5 and parallel contours. Under the condition of a constant sand supply, the development of a river mouth delta continues for two years. As the river mouth delta protrudes, the sea bottom slope gradually exceeds the critical slope given by the angle of repose of sand, leading to the discharge of sand into a deeper zone. As a result, the interval of contours in the deep
(a) 1 year (Q = Q₀)  
(b) 2 years (Q = Q₀)  
(c) 3 years (Q = 0)  
(d) 4 years (Q = 0)  
(e) 3 years (Q = 1/2Q₀)  
(f) 4 years (Q = 1/2Q₀)

Fig. 3 Results of calculation for development and deformation of a river mouth delta (initial beach slope 1/5: cases ① & ④).

The zone is greatly narrowed. In the two years after sediment supply from the river is totally cut off, the protruding contours of a triangular shape in the zone shallower than \(-h_c\) become milder. In this case the redistribution of sand due to longshore sand transport is impossible in the zone deeper than \(-h_c\), and therefore a gentle slope is formed by erosion in the zone shallower than \(-h_c\) with the formation of a mildly protruding shoreline. In case ④, as shown in Figs. 3 (e) and (f), where sediment supply had been cut in half, sand further accumulates to build a river mouth delta while crutosis of the protruding contours in the vicinity of the center of the river mouth delta decreases gradually.

(2) Initial sea bottom slope of 1/10 (cases ② & ⑤)

Figure 4 shows the results of the calculation for cases ② and ⑤ with initial sea bottom slope of 1/10. The only difference between cases ① and ④, and cases ② and ⑤ is the initial sea bottom slope. Figures 4 (a) ~ 4 (d) show that the aerial range, in which offshore sand movement is observed with the formation of a very
steep angle of repose of sand, is narrowed, since the sea bottom slope in cases 2 and 5 becomes gentler than that in cases 1 and 4. Therefore the area expressed by dense contours in the offshore zone decreased. The rate of protrusion of the river mouth delta, however, is increased with a decrease in the average water depth of the accumulation zone of sand in cases 2 and 5, as shown in Fig.4, compared with that in cases 1 and 4, as shown in Fig.3. Furthermore, in case 4, in which sediment supply from the river is cut in half, as shown in Figs.4 (e) and (f), sand further accumulates to build a river mouth delta, while crutosis of the protruding contours in the vicinity of the center of the river mouth delta decreases gradually.

(3) Initial sea bottom slope of 1/20 (cases 3 & 6)

Figure 5 shows the results of the calculations for cases 3 and 6 with initial sea bottom slope of 1/20. The width of the region, where offshore sand movement is observed with the formation of a very steep angle of repose of sand, is greatly narrowed, since the sea bottom slope in cases 3 and 6 becomes much gentler.
than that in cases ① and ④. For example, the foot depth of the foreset slope, which was formed by the successive deposition of fluvial sand, increases to 8m, 14m and 26m in cases ③, ② and ①, respectively, as shown in Figs.5 (b), 4 (b) and 3 (b).

Figure 6 shows the relation between the reciprocal of the initial beach slope and the foot depth of the foreset slope. The gentler the initial beach slope is, the shallower this foot depth becomes.

Here consider the case
where sand is supplied to a coast with a gentle initial slope, as in case 3 shown in Fig.5. After cut-off of the fluvial sand supply, deposited sand will be carried away by longshore sand transport, resulting in less protruding contours, since a large portion of the sand had been deposited in a zone shallower than the critical depth for beach changes. In contrast, in case 6, as shown in Figs.5(c) and (f), the development of a river mouth delta further continues, although crutosis of the river mouth contours are decreased.

(4) Comparison of beach profiles along the centerline of the river mouth delta

Figures 7 (a), (b) and (c) show the profile changes along the centerline of the river mouth delta. After the sand supply from the river was cut off 0, a gentle slope is formed in the zone shallower than \(-h_c\) in each case. In the case of the slope of 1/5, as shown in Fig.7 (a), a large portion of the sand carried into the sea is deposited at a depth where sand movement is impossible due to wave action, so that the nourishment effect to the surrounding coastline of fluvial sand is minimum. In the case of the slope of 1/10, as shown in Fig.7 (b), a large portion of fluvial sand can be redistributed by longshore sand transport, since the water depth of the accumulation zone is sufficiently small. In the case of the slope of 1/20, as shown in Fig.7 (c), a large portion of the supplied sand is eroded due to wave action, since almost all the sand is deposited in the zone shallower than \(-h_c\). It is concluded that if the initial sea bottom slope is sufficiently gentle, the protrusion of the river mouth delta, and therefore shoreline advance, will be large with a constant sand supply from the river. On the contrary the influence of a decrease in fluvial sand supply to the surrounding coastline becomes strong in terms of shoreline recession.

Figure 8 shows the temporal change in shoreline position along the centerline crossing the river mouth delta, where Figs.8 (a) and (b) are for cases in which sand supply from the river is totally cut off and reduced to half over two years, respectively.

The results in both cases are the same up to two years; the advancement rate of the shoreline position gradually decreases, though the change in shoreline position monotonically increases. This is because the water depth in the deposition zone of

![Fig.7 Temporal change in beach profile along centerline crossing the river Mouth delta.](image-url)
sand gradually increases with the seaward advance of the river mouth, and sand supplied from the river mouth is carried offshoreward and deposited in a deeper zone. In the case that the sand supply from the river is cut off over two years, shoreline recession starts immediately, and this response is expressed by an exponential curve. In contrast, in the case that the sand supply from the river is reduced to half, the shoreline initially retreats but later gradually advances.

Consider the case in which the river mouth delta being accretive for a long time is eroded due to a decrease in the fluvial sediment supply. In this case, a steep sea bottom slope formed by the successive deposition of sand is distinguished very well from the very gentle slope reformed by erosion upon a sudden change of slope, as shown in Fig.7. Figure 9 shows the offshore distance from the shoreline position to the location of the sudden change in slope at each time. This offshore distance gradually increases with time after the sand supply from the river is totally cut off over two years, whereas it increases immediately after the sand supply from the river is reduced to half but then changes to a gradual decrease with time. These findings indicate that the offshore distance from the shoreline position at each time to the location of sudden change of the slope is a useful index for expressing the elapsed period of erosion of the river mouth delta. This point shows the importance of fluvial sand supply to nourish the surrounding shoreline even if the sand supply rate has been decreased.

IV. DISCUSSION

In the present study, the topographic changes around a river mouth delta were
On 400m

Fig. 10  Sea bottom contours around Fuji River mouth measured in 1989.

Fig. 11  Comparison of beach profiles around Fuji River mouth.

predicted under the conditions that sand supply from a river is totally cut off and reduced to half over two years, after a constant supply of sand for two years. For actual rivers it is generally considered that a large amount of sand is supplied to the sea by infrequent, large floods through the river mouth and thereafter, sand supply to the sea decreases for a considerably long period. Taking this into account, it is considered that for an actual river mouth, a cyclic mode of topographic change is induced from the stage shown in Fig. 3 (b) via the stage shown in Fig. 3 (c) or Fig. 3 (e), depending on the decrease rate of sand supply, back to the stage shown in Fig. 3 (b), if a large amount of sand is supplied from the river mouth.

An example of a case river mouth is the Fuji River discharging at the Fuji coast in Suruga Bay facing the Pacific Ocean. The median diameter of river bed materials at the river mouth is around 75mm and the riverbed slope near the river mouth is very steep at 1/400. Figure 10 shows the beach topography around the Fuji River mouth measured in 1989. Close examination of contours between the shoreline and -20m depth reveals that the contour line intervals between the shoreline and -12m depth are very wide, whereas the contour intervals in the zone deeper than -12m are abruptly narrowed west of the mouth. Inversely, there is a very gentle slope near the depth of -4m east of the mouth, but beyond this gentle slope, the seabed slope becomes very steep. In short, contours around this river mouth show remarkable asymmetry between the east and west directions with respect to the centerline of the river mouth as well as the eastward extension of the river mouth barrier. All these findings indicate that over the long term, eastward longshore sand transport is
Fig. 12  Sea bottom contours around Tenryu River mouth measured in 1984.

Fig. 13  Comparison of deformation process of the terrace topography off Tenryu River mouth.

predominant at the Fuji River mouth with waves obliquely incident from the south. Profiles along the three crosssections shown in Fig.10 are shown in Fig.11 by superimposing crosssections off the critical depth for beach changes given at around -8m (Uda, 1997). There is a terrace with a gentle slope and a very steep seabed with a slope of 1/4 off this terrace. Profiles of the east and west crosssections of the river mouth are approximately the same, whereas the sea bottom elevation along the centerline crossing the mouth is higher than those along both sides, and the profile is upward convex, implying excess sand deposition from the river in front of the river mouth. These topographic characteristics are very similar to the results of the calculation for case ①, although temporal changes in profiles are not known in field data.

An example of a case ③ river mouth is the Tenryu River discharging at the Enshu coast facing the Pacific Ocean. The riverbed slope near the mouth of this river is 1/1,230, the median diameter of riverbed materials is around 13.9mm and the mean sea bed slope of this coast is 1/90.

Figure 12 shows river mouth topography around the Tenryu River measured in 1984. There is a flat terrace at -2m depth west of the river mouth. The contour of -10m shows that the western area is concave and the eastern area convex with respect to the centerline of the river mouth. This asymmetry of the contours in the two directions is the same as that observed at the Fuji River mouth, and implies the predominance of an oblique wave incidence from clockwise direction.

Figure 13 shows profile changes along the centerline of the river mouth. In
September 1970, the water depth at the flat river mouth terrace was about 2m and the terrace was as wide as around 400m from the shoreline. In July 1984, the offshore slope of the terrace retreated to a large extent compared with the one in September, 1970. In July 1986, the river mouth terrace was eroded and narrowed. These changes are considered to be caused by the imbalance between the longshore sand transport flowing away from the river mouth and sand supply from the Tenryu River which was decreased due to river bed excavation before 1967. These results agree well qualitatively with the topographic changes shown in Fig.5.

V. CONCLUSIONS

A predictive model of the three-dimensional development and deformation of a river mouth delta was developed. This model enables the prediction of not only the shoreline change but also the three-dimensional topographic changes around a river mouth. In this model, offshore sand movement is taken into account, with constant critical slope, when the sea bottom slope exceeds a critical slope given by the angle of repose. This has the advantage that the shoreline change, the progression rate of which gradually decreases with time can be simulated, since the depth of the sand deposition zone increases with the progression of the shoreline position.

Field Investigation on Sediment Transport into the Submarine Canyon in the Fuji Coast with the New Type Tracers

Shigenobu Tanaka¹, Koji Yamamoto², Hitoshi Ito³, Toshiharu Arisawa⁴, and Toshimitsu Takagi⁵

Abstract

The Fuji coast in Japan is one of the beaches which is suffering from coastal erosion. One reason for erosion is seemed to be the offshore sediment transport through the submarine canyon in front of eroded area. The present paper concerns the field investigation in order to confirm the sediment transport into the submarine canyon with two new type tracers. One tracer is the artificial sand and gravel made of the hard plastic. The other is the tracer with an ultrasonic transmitter. These tracers are very effective for tracking the sediment.

1. Introduction

The Fuji coast, facing on the Suruga bay in Japan which has the Suruga trough over 2,000 m depth, is known for one of the most beautiful coast where Mt. Fuji is seen behind (Figs. 1 and 2). The coast is 19 km long between the estuary of Fuji River and Numazu harbor. The coast is made of sand and gravel and the sea bottom has a steep slope, close to 1/2 over 20m depth. In this coast, the longshore sand transport toward east is dominant, which amounts to almost 100,000 m³/year. The western side of the coast has been suffering from erosion since 1970 as shown in Fig. 3. These reasons are partly reduction of discharged sediment from the Fuji river and stopping the longshore sediment transport by the breakwater of Tagonoura harbor. Since the coastal erosion

started, the wave dissipating breakwater has been constructed along the shore. Because of the effect, the backward movement of shoreline stopped. However, the erosion has been spread to the downdrift side of longshore sediment transport. The wave dispersion breakwater might cause the decrease of sediment transport. Recently the erosion occurs from the Outlet 1 to east where is the end of the wave dissipating concrete block. Therefore, the countermeasure is necessary for protection of the eroded beach. To make a plan for countermeasure, the mechanism of sediment movement must be clarified. In this coast the sand transport is dominant toward not only longshore but also offshore because the sediment budget is not maintained along the coast with 15 m or less in depth according to the analysis of topography maps. Particularly a large submarine canyon exists in front of the eroded beach, and its entrance (20m depth) is close to the shoreline (Fig. 3). Therefore, there is a possibility of offshore sediment transport through this canyon. Thus, the field investigation on sediment transport was carried out around the submarine canyon with the two types of new tracers.

![Figure 1 Location map of the Fuji Coast](image)
Figure 2  Map of the Fuji coast

Figure 3  History of the shoreline change
2. **Topography around the Submarine Canyon and Characteristics of Sediment**

The study coast has very steep bottom, approximately 1/10 from the shore to 20m depth and approximately 1/2 offshore from 20m depth. Especially in front of the Outlet 1 the 20m contour is close to shoreline. These characteristics of topography of Fuji coast are found obviously from the variation of depth contours as shown in Fig.4. According to the topography analysis, the critical depth of topography change is about 14m depth (Fig. 5). The distribution of sediment grain size around the submarine canyon shows in Fig. 6. It is found that the variation of the grain distribution in 50m depth of the canyon from No.48 to 49 is much more than that out of the canyon. This fact shows the movement of sediment even in 50m depth of the canyon.

**Figure 4.** Distribution of topography

**Figure 5.** Variations of depth contours
3. Field Investigation Using New Type Tracers

3.1 Artificial gravel tracer (Type A tracer)

The artificial sand and gravel, which are made of the hard plastic, colored pink, with approximately the same density and grain size distribution as the field, were put on the bottom in 16 m depth offshore No.49+125m(Fig.7). Three different sizes of gravel, 1 mm, 10 mm and 50 mm, which are taken as the representative sizes for the field sediment were made (Fig.8, Photo 1). The 100mm tracers as the maximum size in the field were also made. The tracers with 1mm and 10 mm mean diameters were made by crush of the hard plastic panels. The tracers with 50 and 100mm diameter were cast in cup-shaped mold. After mixing these tracers as almost same distribution of grain size as that in the field (Fig.8), three ton of these were put on the bottom in 16m depth offshore to No.49+125 m (Fig.7). On three times tracks including immediately after typhoon, divers collected the sediments of approximately five kilograms weight on the several places of the bottom around the injection place of tracers. The weight of tracers included in the collected sediment was measured in each grain size group.

3.2 Small ultrasonic transmitter (Type B tracer)

The other tracer is the artificial gravel with a small ultrasonic transmitter (Photo 2) that has approximately five months of life (Table 1 and Fig.9). The small ultrasonic transmitter is often used in trace of fish. Three pieces of tracers that have the different
Photo 1  Artificial sand and gravel for tracers

Photo 2  An ultrasonic transmitter
frequency transmitters were separately put on the bottom each in 10 m and 15 m depth (Fig. 7). By using an ultrasonic receiver fixed on a boat, the position of the tracer with the small ultrasonic transmitter can be searched.

the investigation. Especially the typhoon 9617 caused big waves, about 3.5m height of significant wave and a period of 15 second. Although the velocity of mean current was below 10 cm/s, the orbital velocity of wave was about 1.0 m/s in significant value and 2.0 m/s in maximum value when the maximum wave height 5.25m was recorded. During the tracking of the tracer, type B, the big waves attacked as shown in Table.2. According to the wave data, the wave was coming to the shore from SSW dominantly, which is about 5.0 degree clockwise from the normal direction of shoreline.

4.2 Tracking results of artificial sand and gravel

The artificial tracers of the type A were put on 12 Sept. and the tracking of them was carried out three times, 27 Sept. immediately after the typhoon 9617, 9 Oct. and 7 Nov.. The results of tracking of tracers are shown in Fig.11. After the typhoon 9617 the tracers moved toward south along the steepest bottom slope of the canyon. In particular, 100mm tracers were found even in the bottom of 40m depth. Although the sediment could not be collected in 50m depth, divers confirmed the existence of some tracers in it. In addition, any tracer was not found in onshore and longshore from the injection point. The movement of each grain size group of tracers is shown in Fig.12. According to this result, the different movement due to the grain size was not confirmed.

4.3 Tracking result of tracer with an ultrasonic transmitter

The tracers with ultrasonic transmitter (Type B) were put on 12 Oct. 1996. The tracking was carried out on 9 Nov. 1996 and 23 Jan. of the next year. The tracking result is shown in Fig.13. On the first tracking, the movement of them was not

confirmed. However on the second time, the tracers put on the bottom in 15m depth moved toward offshore about 30m away, and those put on the bottom in 10m depth moved toward both longshore and offshore about 20m far away. The movements of tracers Type A and B injected on 15m depth were toward offshore. However, the movement of tracer type B injected on 10m depth had a longshore component more than that on 15m depth.
5. Mechanism of Sediment Movement on the Steep Bottom

According to the result of the field investigation, it was found that the sediment in 15 m depth where is the entrance of the submarine canyon, moved toward the offshore during the typhoon. The force of the sediment movement is seemed to be the orbital velocity due to wave and gravity because the mean current velocity is not dominant toward offshore. Then using the Shields parameter obtained by the orbital velocity, the stability of sediment was analyzed. On this analysis the critical Shields parameter was revised using Lane's equation (Lane, 1955),

\[ K = \frac{\Psi_{cr}}{\Psi_c} = \cos\theta \sqrt{1 - (\tan\theta / \tan\phi)^2} \]  

(1)

where \( \Psi_{cr} \) is the critical Shield parameter on a slope, \( \Psi_c \) is the critical Shield parameter on a flat bottom, \( \theta \) is the angle of bottom slope, and \( \phi \) is the stable angle of bottom slope. Fig. 14 shows the influence of the bottom slope to the critical Shields parameter with respect to the sediment grain sizes. From this figure, the sediment with 4mm on 1/2 slope starts moving by the half of the critical force at the flat bottom. Fig. 15 shows the histories of the Shields parameters during typhoon 9617 over a range of the grain sizes from 1mm to 100mm. In this case the critical Shields parameter on the flat bottom is 0.05 that is obtained by Madsen and Grant (1976). The bottom slope is 1/6 at the injection point of tracers (Type A). It is found that the sediment with grain size less than 100mm has the possibility of movement at the attack of typhoon. It can be estimated that due to the gravity, the direction of movement is inclined to the offshore with the steep bottom slope.

6. Conclusions

It is found in this investigation that the sediment transport around the 15m depth, partly made of the gravel with 100mm diameter, move toward the submarine canyon when the big waves generated by the typhoons attacked. The force of the sediment movement could be the wave orbital velocities up to 2.0 m/s in typhoon and gravity according to the Shields parameter analysis. By the fact that the averaged offshore velocities are weak, the steep bottom slope determines dominantly the direction of the sediment movement even deeper than 15m around the submarine canyon. Furthermore, the effect of the new type tracers was confirmed in this investigation.

Figure 15 History of Shield parameters during the typhoon 9617
Sea Breeze Climatology and Nearshore Processes along the Perth Metropolitan coastline, Western Australia

G. Masselink¹ and C.B. Pattiaratchi²

Abstract

The Perth metropolitan coastline is characterised by one of the strongest and most consistent sea breeze systems in the world. In contrast to the 'classic' sea breeze system, characterised by sea breezes blowing in the onshore direction, the sea breeze in Perth blows in a predominantly alongshore direction. Each year, around 200 sea breezes are experienced with an average wind speed of 5.7 m/s. Sea breezes in summer are stronger and more persistent than in winter. The importance of the sea breeze is clearly indicated by wind spectra showing significant spectral peaks at the diurnal frequency. The sea breeze system directly forces the incident wave field and induces a diurnal cycle of nearshore change by causing: (1) an increase in wave height; (2) a decrease in wave period; (3) an intensification of the nearshore currents; and (4) an increase in suspended sediment levels and suspended sediment transport. In addition, the seasonal variation in sea breeze activity, with frequent and strong sea breezes in summer and infrequent and weaker sea breezes in winter, is responsible for a seasonal change in the littoral drift direction. In summer, longshore sediment transport is towards the north and causes beaches located south of structures or headlands to widen considerably. In winter, when littoral drift is towards the south due to northwesterly storms, beaches located north of structures or headlands will become wider. It is further demonstrated that strong sea breeze activity is common along the entire Western Australian coastline, implying that the results obtained for the Perth metropolitan coastline can be applied to some extent to the entire state.

¹ Research Fellow, Department of Environmental Engineering, Centre for Water Research, University of Western Australia, Nedlands, WA 6907, Australia.
² Head, Department of Environmental Engineering, Centre for Water Research, University of Western Australia, Nedlands, WA 6907, Australia.
Introduction

The Perth Metropolitan coastline experiences mixed, microtidal tides with a mean spring tidal range of 0.9 m (Department of Defence, 1996). Because of the relatively low range of the tide, it is frequently over-ridden by barometric pressure effects on sea level (storm surge and shelf waves), wind/wave set-up and seiching (Eliot and Clarke, 1986). The offshore wave climate is dominated by a low to moderate energy, deep water wave regime characterised by persistent south to southwest swell and an average significant wave height of 1.5–2.5 m (Lemm, 1996; Fig. 1). Closer to shore, the swell is refracted and diffracted by several offshore reef systems and greatly attenuated by shoaling across the inner continental shelf. As a result, the inshore wave height is about 40% of that outside the reef system (Steedman, 1993). A highly variable wind wave climate is superimposed on the swell regime, dominated by northwesterly to westerly storm waves during winter and by the wave field associated with strong south to southwesterly summer sea breezes.

Fig. 1 - Offshore wave climate of Perth (data from Lemm, 1996).

The coastline of Perth is subject to one of the most energetic and consistent sea breeze systems in the world. A typical sea breeze cycle is characterised by offshore winds from an easterly direction (80–100°) in the morning, switching to shore-parallel southerly (180–200°) winds in the afternoon (Fig. 2). A significant feature of the sea breeze system along the Perth coast is that it blows parallel to the shoreline, in contrast to the "classic" onshore sea breeze. The shore-parallel sea breeze system in Perth, and in fact along most of Western Australian coastline, is attributed to the interaction between the sea breeze system and synoptic weather patterns (Pattiaratchi et al., 1997).

The impact of sea breeze activity on surf zone processes and morphology along the Perth metropolitan coastline has been extensively discussed by Masselink (1996), Pattiaratchi et al. (1997) and Masselink and Pattiaratchi (1998a, b). These studies indicate that the energy levels in the surf zone increase dramatically during the sea breeze, and suggest that the effect of a strong sea breeze on nearshore processes is similar to that of a small storm. The objective of this paper is put these previous
morphodynamic investigations in a wider perspective by characterising the Perth sea breeze climate using more than 50 years of wind data collected at Perth airport. The wind analysis is extended to nine other Western Australian coastal locations to demonstrate that strong sea breeze activity is common along the entire Western Australian coastline, implying that the results obtained for the Perth metropolitan coastline can be applied to some extent to the entire state.

![Wind speed and direction time series](image)

**Fig. 2 - A typical 1-week time series of wind speed and direction collected at Ocean Reef, 2–9 January, 1993 (data from Pattiaratchi et al., 1997).**

**Time-Domain Analysis of Sea Breezes in Perth**

Three-hourly wind data collected at Perth Airport from 1948–1997 were used to determine the sea breeze climate of Perth. The data were subjected to an algorithm that selected the days during which sea breezes occurred. A day was considered a “sea breeze day” if: (1) the wind direction in the afternoon (15:00 hrs) was from the sea breeze direction (190°–300°), but the wind in the morning (09:00 hrs) was not from that direction; or (2) The wind direction in the morning and afternoon were both from the sea breeze direction, but the afternoon wind speed was larger than during the morning. Using these selection criteria the number of sea breezes per month and the mean sea breeze speed and direction were determined.

A strong seasonal variation in sea breeze activity is apparent (Fig. 3). In the summer months, more than 20 sea breezes are experienced per month with speeds (at 15:00 hrs) of 6–7 m/s. In the winter, only 10–15 sea breezes occur per month with speeds of around 5 m/s. On average, each year 197 sea breezes are experienced with a mean wind speed of 5.7 m/s. The direction of the sea breeze is consistently from the WSW throughout the year. However, the summer sea breeze blows from a slightly more southerly direction (240°) than the winter sea breeze (250°).
Fig. 3 - Seasonal variation in the number of sea breezes (upper panel) and the wind speed (middle panel) and direction during the sea breeze (lower panel) from three-hourly data collected at Perth Airport from 1948–1997. The vertical lines indicate the standard deviations associated with the averages.

Frequency-Domain Analysis of Sea Breezes in Perth

The Perth wind data was also subjected to spectral analysis. For each year, spectra were computed for the periods December–February (summer), March–May (autumn), June–August (winter) and September–November (spring). Subsequently, an average spectra was determined for each of the seasons (Fig. 4). All spectra show three main characteristics. Firstly, a large amount of energy is present at the low-frequency end of the spectrum (periods longer than 1.5 days). This corresponds to the time scale of synoptic weather patterns, such as storms. Secondly, a pronounced peak can be found at the diurnal frequency (period of one day). This peak represent sea breeze activity. Thirdly, complementary peaks occur at the first and second harmonics of the diurnal frequency (periods of 12 and 6 hours, respectively). These are primarily due to the non-linear (non-sinusoidal) nature of the sea breeze signal. However, the occurrence of strong land breezes during night may also have contributed to the first harmonic frequency (refer Fig. 2). The diurnal peak is present in all the seasonal spectra, but is widest in the summer spectrum and narrowest in the winter spectrum.

Using the same data set, monthly wind spectra were computed and an average spectra was determined for each month. The total spectral energy was then partitioned into a low-frequency band (period larger than 1.5 days; ‘synoptic band’) and a high-frequency band (period smaller than 1.5 days; ‘sea breeze band’) to allow investigation of the seasonal variation in the importance of these components (Fig. 5). The spectral energy of the synoptic band and the sea breeze band show an anti-phase relationship; the synoptic band reaches its maximum energy levels in June/July when storm activity is prevalent, whereas the sea breeze band dominates from November–January when sea breeze are at their strongest and most abundant. In the summer months, the sea breeze band accounts for 60–70% of the total variance in the wind record.
Fig. 4 - Average wind spectra for summer, autumn, winter and spring from three-hourly data collected at Perth Airport from 1948–1997.

Fig. 5 - Monthly variation in spectral energy in the synoptic (solid line) and sea breeze (dashed line) frequency band (upper panel) and relative contribution of the sea breeze band to the total wind variance (lower panel). Based on three-hourly data collected at Perth Airport from 1948–1997.
Effect of Sea Breeze Activity on Nearshore Processes

Offshore wave conditions are significantly affected by the sea breeze and this is clearly illustrated by seasonal offshore wave spectra (Fig. 6). All spectra show a peak around the diurnal frequency, similar to that of the wind spectra (refer Fig. 4). However, in contrast to the wind spectra, the synoptic band in the wave spectra is of greater importance than the sea breeze band. This simply indicates that the variability in wave conditions due to storm activity is greater than that generated by sea breezes.

![Wave spectra for summer (Jan-Feb 1995), autumn (Mar-Apr 1995), winter (Jun-Jul 1995) and spring (Sep-Oct 1995) from data collected off the coast of Perth in 48 m water depth. The spectra were computed from 20-min wave summary statistics.](image)

Sea breeze activity has a pronounced effect on coastal processes. Pattiaratchi et al. (1997) and Masselink and Pattiaratchi (1998a) report on the results of a field experiment conducted on City Beach in Perth that monitored the effect of a strong sea breeze on the nearshore environment (Fig. 7). Prior to the onset of the sea breeze, offshore winds with speeds less than 5 m/s prevailed. During the sea breeze, alongshore winds with speeds higher than 10 m/s were experienced. The sea breeze induced pronounced changes to the nearshore morphodynamics which were similar to that of a storm event: (1) root mean square wave height increased from 0.3 to 0.5 m; (2) zero-upcrossing wave period decreased from 8 to 4 s; (3) mean cross-shore flows reached velocities of 0.2 m/s directed offshore; and (4) the longshore current increased in strength from 0.05 to 1.0 m/s. As a result of the increase in longshore current velocity and suspended sediment concentration during the sea breeze, the suspended
sediment flux increased by two order of magnitude. In addition, pronounced beach cusp morphology that was present on the beachface prior to the sea breeze, was completely destroyed during the sea breeze.

Fig. 7 - Wind speed ($W$), wind direction ($\text{dir}$), significant wave height ($H_s$), zero-crossing wave period ($T_z$), cross-shore current velocity ($U$), longshore current velocity ($V$), suspended sediment concentration measured 0.275 m above the bed ($c$) and longshore suspended sediment transport averaged across the surf zone ($Q$). The start of the sea breeze is indicated by the dotted line. The data were collected on City Beach, Perth on the 23rd of January 1992.

Masselink and Pattiaratchi (1998b) discuss the effect of weak sea breeze activity on nearshore processes. They demonstrate that even weak sea breezes with wind speeds of around 6 m/s induce pronounced changes to the surf zone hydrodynamics. A three-day time series of wind speed, direction, offshore wave height and nearshore current spectra illustrates clearly that the impact of sea breeze activity extends significantly longer than the duration of the sea breeze (Fig. 8). Over the three-day period, the narrow-banded swell peak remained at a constant frequency of around 0.085 Hz. Wind-wave energy starts appearing immediately after the onset of the sea breeze and remained present long after the cessation of the sea breeze. The presence of wind wave energy long after the sea breeze had ceased to blow is attributed to the alongshore component of the sea breeze (Masselink and Pattiaratchi (1998b)).
Fig. 8 - Three-day time series of wind speed (upper panel), wind direction (middle panel) and spectral shape of cross-shore current velocity data collected just outside the surf zone (lower panel). The contour lines represent an energy level of 0.25 m$^2$/s. All three sea breezes started at 14:45 hrs. The data were collected on City Beach (Perth) during three successive sea breeze cycles from the 6th to the 9th of March 1995.

Seasonal Variation in Beach Morphology

A number of Perth metropolitan beaches have been monitored weekly to two-weekly since November 1995. All display a strong seasonal variation in beach width (Fig. 9). Three of the beaches display a widening trend during summer (City, Brighton and Triggs Beaches), one becomes narrower over summer (Floreat Park) and one displays a hybrid behavior (Port Beach). These dissimilar trends are somewhat at odds with the strong seasonal variation in the incident wave conditions (refer Fig. 1) on the basis of which one would expect all beaches to behave in a similar manner. In addition, the amplitude of the beach width cycle varies substantially between the different beaches.

To explain the observed trends in beach width one needs to take into consideration the seasonal change in the direction of littoral drift. In the summer, when the southerly sea breeze prevails, longshore transport is towards the north. As a result, beaches that are located south of coastal structures (City Beach) or headlands (Triggs Beach) become wider during summer due to the accumulation of sediment against the structure/headland. These beaches will erode in winter when the longshore sediment transport is towards the south due to northwesterly storm waves. In contrast, beaches located to the north of coastal structures (Floreat Park) or headlands will become narrower during summer and wider during winter. Beaches located at
relatively "straight" coasts (Brighton Beach) will conform to the wave-induced seasonal cycle of beach change by widening during summer and narrowing during winter. The amplitude of the straight beach cycle, however, will be smaller than those beaches affected by the seasonal reversal in the littoral drift direction.

![Graph showing temporal variation in beach width for five Perth metropolitan beaches from 1995 to 1998.](image)

Fig. 9 - Temporal variation in beach width for five Perth metropolitan beaches for the period November 1995 to September 1998. The data were collected weekly or two-weekly.

The profile behavior of Port Beach is complicated and shows only two beach cycles in the 3-year monitoring period. During the first part of the time series, the beach width decreased in summer as well as in winter. From mid-1996 to mid-1997, the width of the beach remained constant. During the last part of the time series, Port Beach has been widening from mid-winter to early summer 1997, narrowing from mid-summer to early winter 1998 and widening again from mid-winter 1998. The complex behavior of Port Beach is attributed to anthropogenic influences (Masselink and Pattiaratchi, 1997). Prior to 1996, Port Beach was located about 500 m north of a small groyne. The beach behaved like a straight beach, attaining its maximum width just prior to the start of the winter storm season (cf., Brighton Beach). At the end of 1995, however, the groyne was significantly extended to accommodate for a marina development. As a result, Port Beach is now acting like a beach located north of a coastal structure, attaining its maximum width early-summer (cf., Floreat Park).
Analysis of Coastal Stations along Western Australian Coastline

The analysis of the wind data was extended to include nine additional coastal meteorological stations spread out along the coast of Western Australia (Fig. 10). Most of these stations were located some distance inland of the coastline at local airports, except for Ocean Reef and Cape Leeuwin which were directly located on the coast and Abrolhos, which was located on an island. One year of data (1995) were analyzed. Prior to analysis, all data were converted to hourly data for reasons of consistency.

![Map of Western Australia with ten coastal meteorological stations.](image)

Table 1 summarises the time and frequency domain analysis of the ten Western Australian coastal weather stations. In the northern region (Derby, Broome, Karratha, Learmonth), the sea breeze mainly blows from an offshore and northwesterly direction. In the central region (Carnarvon, Abrolhos, Ocean Reef, Perth), alongshore and southeasterly sea breezes prevail. In the southern region (Cape Leeuwin and Esperance), the sea breeze blows from a predominantly onshore and southeasterly direction. The data were subjected to the same analysis as the long-term Perth wind data and the number of sea breezes and the mean sea breeze wind speed were determined. Excepting Cape Leeuwin, the mean annual wind speed for all coastal stations is significantly less than the wind speed associated with the sea.
breeze. This indicates that at all locations, the sea breeze represents a condition that is more energetic than normal. The number of sea breezes that occurred in 1995 ranges from 137 (Cape Leeuwin) to 304 (Karratha).

Table 1 - Summary of time and frequency domain analysis of 1995 wind data collected at ten coastal meteorological stations in Western Australia. $W =$ mean annual wind speed; $N =$ number of sea breezes; $W_{sb}$ = mean wind speed during sea breeze at 15:00 hrs.

</table>

The importance of sea breeze activity is somewhat underestimated in Table 1 because most meteorological stations are located some distance landward of the coastline. A comparison between the characteristics of the sea breeze measured at Ocean Reef (on the coast) and Perth (about 20 km inland) indicates a reduction in the wind speed by about 20%. In addition, the direction of the sea breeze becomes more onshore with distance from the coastline. The number of sea breezes at Ocean Reef and Perth, however, are very similar.

Wind spectra were computed for all coastal stations and except Cape Leeuwin, all exhibit a pronounced diurnal peak with associated harmonics (Fig. 11). Partitioning the total spectral energy into the low-frequency synoptic band and the high-frequency sea breeze band (period smaller than 1.5 days; 'sea breeze band') further demonstrated the dominance of the sea breeze for most of the coastal stations. In general, more than 50% of the total variability in the wind record can be attributed to the sea breeze band. The only exceptions are Cape Leeuwin and the Abrolhos Islands. The former is one of the stormiest locations on the Western Australian coastline and winds at this site are expected to be dominated by storm activity. At the latter site, strong southerly winds prevail throughout the year, with the sea breeze only inducing a modest increase in the wind speed and a slight change in the direction.

Discussion and Conclusions

The diurnal sea-breeze system in Perth, Western Australia, is a very important contributor to the overall wind climate. Around 200 sea breezes are experienced per year with an average wind velocity at 15:00 hrs of 5.7 m/s. In summer, more than 20 sea breezes occur on a monthly basis, whereas in winter between 10 and 15 sea-breeze cycles are experienced each month. Throughout the year, more than half the variance in
the wind speed record can be attributed to the sea breeze frequency band (period less than 1.5 days). Analysis of wind data collected at nine other coastal meteorological stations in Western Australia indicated similar results, demonstrating that the sea breeze system is highly significant state-wide.

![Wind spectra](image)

**Fig. 11 - Wind spectra for ten Western Australian coastal stations. The data represent hourly data collected in 1995.**

The strength and persistence of the sea breezes has important implications for the offshore wave climate and nearshore processes and morphology in the area. Spectral analysis of wave data collected off the coast of Perth revealed significant amounts of spectral energy present within the sea breeze band, in particular during summer when the sea breeze system is best developed. In the nearshore zone, the sea breeze generates energetic, obliquely-incident wind waves. In turn, theses waves generate strong longshore currents and sediment transport.
The wind climate along the Perth metropolitan coastline displays a pronounced seasonality characterised by strong and persistent southerly sea breezes in the summer and infrequent northwesterlies associated with the passage of mid-latitude storms. As a consequence, the dominant direction of the littoral drift is towards the north in the summer and towards the south in winter. In the vicinity of coastal structures or natural headlands, the seasonal variation in littoral drift direction induces a seasonal cycle of beach change that is different from the classic transition from summer to winter profile. During summer, a beach located south of an obstacle becomes progressively wider due to the piling up of sediment against the obstacle. At the same time, the beach located north of the obstacle becomes narrower. The opposite will occur during winter.

FIELD OBSERVATION OF EROSION AND ACCRETION WAVES ON SHIZUOKA AND SHIMIZU COASTS IN SURUGA BAY IN JAPAN

Itabashi, Naoki¹ and Takaaki Uda²

ABSTRACT

A distinct propagation of erosion and accretion waves was discovered along the Shizuoka and Shimizu coasts facing Suruga Bay in Japan. Their propagation velocities were 270m/yr and 250m/yr. "Hagoromo-no-matsu", a scenic beach famous in Japan, where, along the shoreline, people can see Mt. Fuji in the distance, sandy beaches and pine trees, will be eroded in two years, whereas it takes 30 years for longshore sand supply to reach this beach. Countermeasures must be taken, without relying on natural sand supply from the upcoast by longshore sand transport which will take for at least 30 years. Severe beach erosion began at the time of large-scale river bed excavation conducted before 1967 in the Abe River which is the source of littoral sand, and beach erosion has a propagation mode of erosion waves. Measures combining the construction of headlands to stabilize the natural sandy beach with beach nourishment should be taken immediately.

I. INTRODUCTION

In recent years, shoreline change of a wavy mode has been extensively studied. Such shoreline changes are classified into the longshore sand waves discussed by Thevenot and Kraus (1995) and a type in which the wavelike shoreline propagates alongshore while keeping its form. In addition, there are various names for the longshore sand waves. Sonu (1968) called them cusp-type sand waves, Bruun (1954) and Grove et al. (1987) migrating sand humps, Inman (1987) accretion and erosion waves, and Verhagen (1989) simply sand waves. In particular, the accretion and erosion waves reported by Inman (1987) are produced when a coastal structure such as a groin is installed or the sediment supply from a river or the source of littoral drift is sharply increased due to flooding, and they propagate along the coastline, accompanied by weak diffusion. Uda and Yamamoto (1994) and Uda et al. (1996) investigated this phenomenon of a longshore movement of a large mass of sediment (hereinafter called sand body), analogous to a soliton, along the Shizuoka coast in Japan and concluded that this sand body movement was triggered by the trapping effect of sand supplied from the Abe River by detached

breakwaters built along this coast, by using a contour line change model.

On the other hand, before the propagation of this positive wave along the Shizuoka coast, it was also found that an erosion wave with the phase velocity of 0.5-0.8 km/yr propagated (Uda and Yamamoto, 1994). Presently, this erosion wave is approaching the northeastern end of the Shimizu coast, the famous viewpoint called "Hagoromo-no-matsu" where a sandy beach with pine trees and a backdrop of Mt. Fuji provides a scenic view. "Hagoromo-no-matsu" means a pine tree on which a young lady has draped her clothes. This study is aimed at investigating beach changes associated with the propagation of these erosion and accretion waves occurring along the Shizuoka and Shimizu coasts, with special attention paid to the preservation of this beach.

II. FIELD OBSERVATION OF EROSION AND ACCRETION WAVES ALONG SHIZUOKA AND SHIMIZU COASTS

(1) General

Figure 1 shows the location of the Shizuoka and Shimizu coasts situated on the outer margin of the Mihono-matsubara sand spit on the west shore of Suruga Bay. Suruga Bay opens south to the Pacific Ocean and rough waves are incident from the south. Since the coastline runs southwest to northeast, as shown in Fig.1,

![Fig.1 Location of the Shizuoka and Shimizu coasts in Suruga Bay facing the Pacific Ocean.](image)
northeastward longshore sand transport prevails along these coasts. The Shizuoka coast extends 7.8km northeastward from the Abe River mouth to the mouth of the Takigahara River and the 9.8km coastline from this river mouth to the tip of the sand spit is called the Shimizu coast. Figure 2 shows the sea bottom contours off the Shizuoka and Shimizu coasts. Here, the beach slope near the shoreline is as steep as 1/10. A continental shelf of mild slope of 1/150 is spread along the offshore zone ranging from 10m to 30m in depth, but the sea bottom slope at the tip of the Mihono-matsubara sand spit is steep at about 1/5.

It is considered that during the Jomon Transgression of the sea level about 6,000 years ago, erosion of the side of Mt. Kuno, as shown in Fig.2, supplied sediment to the Mihono-matsubara sand spit, but at the present sea level, the only source of sediment to the sand spit is the Abe River. River bed excavation was carried out extensively before 1968 in the Abe River, causing a sharp decrease in fluvial sand supply from this river, and the dynamic balance of longshore sand transport was lost, giving rise to the northeastward extension of the eroded area from the river mouth. Uda and Yamamoto (1994) revealed that the erosion wave propagated at 0.8km/yr in the period between 1975 and 1983 and 0.5km/yr between 1983 and 1988 along the Shizuoka coast. At present, the most severely eroded portion of the beach is near the tip of the Mihono-matsubara sand spit at the northeastern end of the Shimizu coast. Most of the sediment transported by northeastward longshore sand transport discharges into the submarine canyon located at the northeastern end of the Shimizu coast.
Figure 3 shows the sea bottom topography around the tip of the Mihono-matsubara sand spit, as well as the alignment of measuring lines on the Shimizu coast. In this area, sea bottom surveys have been conducted once a year in March since 1988. The interval of measuring lines is 100m. The origin of the measuring lines is located at a point No.0 at Mazaki at the tip of the sand spit and measuring lines are set alongshore southwestward. In Fig.3 the turning point of the shoreline is located at a point No.12, and there exists a submarine canyon between points No.12 and No.30. The beach slope is very steep around this submarine canyon. Hagoromo-no-matsu, as shown in Photograph 1, is located at a point No.35. According to the sampling test of bottom materials conducted at nine points at 1km intervals alongshore from the Abe River mouth on February 20, 1989, the median diameter of beach materials near the shoreline of the Shizuoka coast is around 7.5mm.
(2) Changes in Shoreline Configuration and Sand Volume of Shizuoka and Shimizu Coasts

Figure 4 shows the shoreline change of the Shizuoka and Shimizu coasts with reference to the shoreline position in 1983 obtained from the sea bottom surveys. The Abe River mouth is located at the right end of the figure, and the left end is the tip of Mihono-matsubara sand spit called Masaki Point. The Shizuoka and Shimizu coasts are separated by the mouth of the Takigahara River. Along the Shizuoka coast, a sand body formed by sand accumulation moves northward (leftward in the figure) with time and its propagation velocity is around 250 m/yr, as shown in Fig.4. Uda et al. (1996) showed that the propagation velocity of the leading edge of this sand body between 1984 and 1993 was 233 m/yr. The value obtained in the present study is slightly larger due to the selection of a longer comparison period.

The shoreline of the Shizuoka coast was totally covered by concrete armor units before the propagation of the sand body and there existed no sandy beaches, which means an absence of littoral sand to be transported alongshore. The sand body was considered to be moving northeastward, while sand was also covering the concrete armor units set along the shoreline, since a large amount of sediment was supplied from the mouth of the Abe River located at the southwestern boundary of the coast. Furthermore, Uda et al. (1996) revealed, by numerical simulation using "the contour line change model", that the movement of the sand body was triggered by

---

Fig.4 Shoreline changes along the Shizuoka and Shimizu coasts showing the propagation of erosion and accretion waves. The propagation velocities of erosion and accretion waves are around 270 m/yr and 250 m/yr, respectively.
Photo.2 Coastline totally covered by seawall and concrete armor units on the Shimizu coast. This picture was taken in July, 1995. The river flowing into the sea is the Takigahara River, which separates the Shizuoka and Shimizu coasts. These coastal structures were built to protect farmland just behind the seawall.

Photo.3 Coastline protected by a continuous seawall, concrete armor units and a number of detached breakwaters further north of the location shown in Photograph 2 on the Shimizu coast.

the blocking effect of longshore sand transport due to the presence of a number of detached breakwaters constructed off the coastline.

Along the coast between the location of longshore distance of around 12.5km, which the leading edge of the sand body reached in 1996, and the location around 0.5km north of the mouth of the Takigahara River, no shoreline change is observed because this area is totally covered by concrete armor units, as shown in Photographs 2 and 3.

Along the Shimizu coast, beach erosion has clearly occurred since 1983. Shoreline recession first began from the location of around 9km and extended northeastward with time, approaching Hagoromo-no-matsu in 1996. Beach erosion along the Shizuoka coast was originally triggered by a sharp decrease in fluvial sand supply from the Abe River due to large-scale river bed excavation to obtain construction materials in the period around 1970, and it propagated from the Shizuoka coast to the Shimizu coast (Uda and Yamamoto, 1994). Presently it is approaching the tip of the Mihono-matsubara sand spit. Shoreline change of a zigzag type have occurred after the construction of headlands using two sets of detached breakwaters built as a countermeasure against beach erosion, as shown in Photographs 4, 5 and 6. The eroded zone is monotonously extending northward and its propagation velocity is around 270 m/yr. This propagation velocity is comparable to the propagation velocity (250m/yr) of the sand body on the
Photo.4 The shoreline around detached breakwaters I. A couple of detached breakwaters were built alongshore. The offshore distance of the detached breakwater downcoast is close to the original shoreline. Large cuspate foreland was formed behind the upcoast detached breakwater.

Photo.5 The shoreline downcoast of detached breakwaters II. Downcoast erosion was so severe that beach nourishment is being conducted, as shown in the photograph of the most severely eroded location.

Photo.6 The shoreline around detached breakwaters III. In this area, the foreshore is still fairly wide.

Shizuoka coast, but with an excess of about 8%. Since the distance between the tip of the eroded zone (No.40) and Hagoromo-no-matsu (No.35) was only 500m in 1996, only two years remain before severe beach erosion reaches Hagoromo-no-matsu, if the propagation velocity of the erosion zone remains unchanged. Uda et al. (1994) determined that the rate of extension of the erosion zone was about 271m/yr on an average in the period between March 1990 and March 1993; this means that the same propagation velocity of the erosive zone has been maintained thereafter.
The change in foreshore area in the accretion area of the Shizuoka coast and erosion area of the Shimizu coast compared to that in 1983 was calculated and is shown in Fig.5. Along the Shizuoka coast, the rates of increase of the accretion area during each of the three periods shown in Fig.5 differ; the rate of increase was $1.42 \times 10^3 \text{ m}^2/\text{yr}$ in the first period between 1983 and 1987, which decreased by one order of magnitude to $0.44 \times 10^3 \text{ m}^2/\text{yr}$ in the second period between 1987 and 1992, and in the last period between 1992 and 1995, the rate increased to $1.98 \times 10^3 \text{ m}^2/\text{yr}$, larger than that in the first period. The only sand supply to the Shizuoka coast is from the Abe River. In addition, the shoreline north of the tip of the sand deposition zone is covered by a large number of concrete armor units and there are no sandy beaches. This means that this artificially protected coast suffers from a shortage of sand before the arrival of the tip of sand body. Accordingly the only reason for the accretion zone increase as shown in Fig.5 must be due to the sand supplied from the Abe River mouth. Table 1 shows the records of large floods since 1980 at location 4.7 km upstream from the river mouth. Daily average flood discharges of $1,000 \text{ m}^3/\text{s}$ or

larger occurred seven times between 1980 and 1993, as shown in Table 1, and particularly, on September 12, 1982 the flood with the largest discharge of 3,857 m$^3$/s occurred, but thereafter, large-scale floods have rarely occurred. This indicates that the variation in the rate of increase of the foreshore area in the accretion zone of the Shizuoka coast mainly corresponds to the occurrence of large floods that supply large amounts of sediment to the coast.

Along the Shimizu coast, the eroded area monotonously increased from 1983 to 1996 at the rate of 1.42x10$^3$ m$^2$/yr, as shown in Fig.5. This rate is approximately equal to that in the first period along the Shizuoka coast. The long-term rate of increase of the foreshore area of the Shizuoka coast between 1983 and 1996 became 1.21x10$^3$ m$^2$/yr, although there are short-term variations in this rate, as shown in Fig.5. This value is only 14% smaller than that obtained on the Shimizu coast. This indicates that the foreshore area exhibits a large variation along the Shizuoka coast in the area next to the river mouth depending on the variation in the amount of river sediment discharge, but along the Shimizu coast located far from the river mouth, such a variation is minimal and monotonous change is dominant, resulting in a smooth shoreline change.

Along the Shizuoka and Shimizu coasts, the shoreline change correlates well with the change in cross-sectional area of the beaches, and the regression coefficient between these parameters gives characteristic heights of beach changes of 7.7m and 7.2m on the Shizuoka and Shimizu coasts, respectively (Uda and Yamamoto, 1994). The changes in foreshore area were multiplied by the characteristic height of beach changes to calculate the change in sand volume due to erosion and accretion. Since the coast near the boundary between the Shizuoka and Shimizu coasts is totally covered by concrete armor units and there exists no sandy foreshore as shown in Photographs 3 and 4, longshore sand transport passing this location is assumed to be 0. Accordingly, calculated change in sand volume is approximately equal to the inflow or outflow rate of longshore sand transport to the examination zone from the continuity condition of sand mass. Table 2 is the results of the calculation in each period. Inflow rate of longshore sand transport to the Shizuoka coast has a considerably large variation and it varies from 3.4x10$^4$ m$^3$/yr to 15.2x10$^4$ m$^3$/yr. Average rate of longshore sand transport is found to be 10.1x10$^4$ m$^3$/yr. In contrast, the rate of longshore sand transport on the Shimizu coast has an approximately constant value of 10.2x10$^4$ m$^3$/yr.

Figure 6 shows temporal change in sand volume calculated by multiplying the decrease of the foreshore area in the region between No.55 and No.85 by the characteristic height of beach changes of 7.2m. The reference year is taken in 1983 the same as that in Fig.5.
Fig. 6 Change in sand volume with time in the regions between No.55 and No.85, and between No.44 and No.55 along the Shimizu coast.

Fig. 5 it was clear that total volume of sand in the erosion zone on the Shimizu coast had increased monotonously since 1983. However, precise examination of the change in sand volume in each zone in Fig. 6 gives another features. Eroded sand volume in the region between No. 55 and No. 85 attains to an equilibrium state after it increased up to 1991, whereas the eroded sand volume in the zone between No. 40 and No. 55 increased after 1991 at a rate of increase equal to the increase rate of the eroded area along the entire Shimizu coast. This means that the construction of a headland using a couple of detached breakwaters prevents further beach erosion at the site but instead, the erosion zone extends further downwards.

In short, accretion and erosion waves were triggered by the imbalance in these longshore sand transport rates. In Fig. 4, Hagoromo-no-matsu was about 7.9 km from the tip of the sand body (x=12.5 km) in 1996 and therefore it should take 30 years for the tip of the sand body to reach the most severely eroded location of Hagoromo-no-matsu, if the movement of the sand body takes place in an unchanging manner. During this period, natural sand supply by longshore sand transport cannot be expected along the Shimizu coast and therefore, it is necessary to effectively utilize the sand existing along the coast. This period is a long time compared with that required for erosion waves to reach north tip of the Shimizu coast. During this period, measures to stabilize the shoreline must be taken without relying on sand supply from upcoast. Beach nourishment is one of the possible measures, but the longshore sand transport along this coast is around $10^{10}$ m$^3$/yr, with ultimate discharge into the deep ocean through the submarine canyon located at the tip of sand spit, implying that beach nourishment only is not a sufficient measure.
III. BEACH PROFILE CHANGES ALONG SHIMIZU COAST

Beach profile changes are investigated in detail along several measuring lines where large shoreline recession was observed in Fig.4. As typical measuring lines, four lines are selected: No.44 located north of the group of detached breakwaters III very close to Hagoromo-no-matsu, No.50 located between detached breakwaters II and II', No.55 located north of detached breakwaters II, and No.62 to the north of detached breakwaters I which was built the earliest.

Figure 7 shows the beach profile changes along No.44. The beach profile in 1985 is selected as a reference and beach profiles after this year are shifted along the vertical axis. At this location, accretion prevailed until 1995, corresponding to the shoreline advance in comparison with the beach profile in 1985, but beach erosion became dominant in 1996 in the zone shallower than -4m. At No.50 0.6km south of survey line No.44, intense beach erosion has taken place since 1992, as shown in Fig.8. In this case it should be noted that the beach profile change at around 1994, as shown in Fig.8, is very similar to that in 1996 in Fig.7, implying that recession of the beach extended gradually alongshore while maintaining almost the same profile.

Figure 9 shows the beach profile changes along No.55. As shown in Fig.4, the shoreline retreated considerably until 1994 in the vicinity of this measuring line (No.55) because detached breakwaters II' were constructed between detached breakwaters II and III. Depending on this shoreline change, the beach was eroded until 1994 but thereafter, sand accumulated again until 1996 and almost the same beach profile as in 1993 was recovered. Re-accretion occurred at No.55 due to the sand accumulation effect of the detached breakwaters constructed immediately downcoast.

Figure 10 shows the beach profile changes at No.62. Severe beach erosion can be observed in the profile after 1989, corresponding to the extensive shoreline recession shown in Fig.4. It is noted that the time when beach erosion became dominant at this location was 8 years before the initiation of beach erosion at No.44 located 1.8km north of No.62. In addition, it is found that an upward convex profile near the shoreline reduced to a concave profile, because the sea bed in the zone shallower than -6m was eroded as a result of beach erosion.

The beach profile changes mentioned above are similar to each other except in terms of the initiation time of beach erosion. As mentioned earlier, only two years remain before the shoreline recession zone reaches Hagoromo-no-matsu. After that, the shoreline profile is predicted to become steep, as shown in Figs.8, 9 and 10.
Fig. 7 Profile changes along No. 44.

Fig. 8 Profile changes along No. 50.

Fig. 9 Profile changes along No. 55.

Fig. 10 Profile changes along No. 62.
IV. TOPOGRAPHIC CHANGES AROUND DETACHED BREAKWATERS

Since dominant beach changes along the Shimizu coast can be observed in the area between No.40 and No.60, as shown in Fig.4, beach changes in this area from March 1992 to March 1996 are investigated in detail through a comparison of bathymetric survey maps. Figure 11(a) shows the sea bottom topography in March 1992. At this time, northeastward longshore sand transport was partly blocked by detached breakwaters II located at around No.57 and No.58 and therefore, sea bottom contours shallower than -3m became concave at the northeast end of the detached breakwaters, whereas the contours far from this area were straight. In contrast, on the southwest side of the detached breakwaters, the shoreline connects smoothly to the detached breakwaters and offshore contours between -4m and -6m protrude off the detached breakwaters, implying that some longshore sand transport is discharged downdriftward while passing around the detached breakwaters, since longshore sand transport is blocked by the detached breakwaters.

In March 1993, as shown in Fig.11(b), sea bottom contours in the vicinity of No.55 became further concave and the foot depth in front of the seawall considerably increased. In March 1994, as shown in Fig.11(c), according to the dense contours near the shoreline, the seawall was directly exposed to sea waves in the vicinity of No.55, and also, a steep scarp between No.55 and No.51 was formed. Beach erosion near No.55 was so severe as to cause the failure of the seawall such that not only the detached breakwaters III were set in the vicinity of No.46 but detached breakwaters II' were also constructed at No.53 to prevent further beach erosion. As a result, the foreshore was widened near No.53, as shown in Fig.11(d) and the seawall was protected against scouring. The shoreline north of detached breakwaters II' is considerably stable because the shoreline is fixed at detached
breakwaters III. By contrast, shoreline recession has begun northeast of detached breakwaters III.

Figure 11(e) shows the sea bottom topography in March 1996. A stepped shoreline was formed due to the construction of detached breakwaters. However, the contours northeast of detached breakwaters III are still unstable because of the open boundary condition and therefore, urgent measures to stabilize the shoreline in front of this area should be adopted by constructing a facility to stabilize the shoreline, such as a groin or detached breakwaters downcoast of this point. As shown in Photograph 1 taken at a point No.35, a snowcapped Mt. Fuji in the distance beyond the sandy beach and pine trees produce a beautiful scene, so that the disappearance of the sandy beach is considered to be a definite damage to this coast.

V. CONCLUSIONS

Distinct propagation of erosion and accretion waves was revealed along the Shizuoka and Shimizu coasts facing Suruga Bay. Their propagation velocities are 270m/yr and 250m/yr, respectively. It was found that the famous scenic beach called "Hagoromo-no-matsu" will be eroded in two years, whereas it takes 30 years for longshore sand supply to reach this beach. Therefore, countermeasures must be taken without relying on natural sand supply from upcoast by longshore sand transport for at least 30 years. Furthermore, taking into consideration that such severe beach erosion dates from the large-scale river bed excavation of the Abe River conducted before 1968 and that it has a propagation mode of an erosion wave, it can be said that beach erosion along the Shimizu coast is inevitable. Measures combining the construction of headlands to stabilize the natural sandy beach, with beach nourishment should be adopted immediately.

Coastal Erosion at Keta Lagoon, Ghana
- Large Scale Solution to a Large Scale Problem

R.B. Nairn¹, K.J. Macintosh¹, M. O. Hayes², G. Nai³, S.L. Anthonio⁴ and W.S. Valley⁵

Abstract

This paper describes the development of a solution to a large scale, long term erosion process along the Atlantic coast of eastern Ghana in West Africa. The understanding of the erosion process was developed through a combination of geomorphic investigations and numerical and physical modeling of coastal processes. Key aspects of the investigations are described in this paper. The performance of the adopted sea defence system, consisting of rubblemound structures and beach nourishment, was evaluated using the GENESIS and COSMOS numerical models of shoreline change. The numerical models were also used to modify the sea defence system such that an acceptable level of downdrift impact was confined within the study area.

Introduction

This paper describes the development of a solution to address a large scale erosion problem along the Atlantic Coast of Ghana, West Africa. A background of the problem is presented followed by a summary of some of the more important design investigations. Finally, the various components of the sea defence system are described. The overall project also includes an 8.5 km causeway across Keta Lagoon for the coastal highway, a flood relief system to address lagoon flooding and land reclamation. The sea defence system is the focus of this paper.

This paper presents a brief summary of some of the key aspects of the Keta Sea Defence Project. Full details are presented in the Final Report on the technical aspects of the Keta Sea Defence Project (Great Lakes Dredge & Dock and Baird & Associates, 1997).

Background

Keta Lagoon is located immediately east of the Volta River mouth along the east coast of Ghana in West Africa (refer to Figure 1). The Volta River historically carried large quantities of sediment, including coarse-grained sand, to the sea and this sediment was deposited at the river mouth, forming the modern (Holocene) delta. Several thousand years ago, at a lower sea level stage, and when the river mouth was located further to the east, another large delta lobe was formed. This old delta is now a large offshore shoal in depths of 10 to 20 m below sea level.

Figure 1 – Regional Study Area – The Volta Delta
Wave action from the South Atlantic is incessant along this section of the West African coast and invariably originates from the south to southwest sectors resulting in continuous eastward directed sand transport with rates in the range of 500,000 to 1,500,000 m$^3$/yr at most locations. As a result, the shape of the existing delta and the older submerged delta are skewed towards the east. The present eastward migrating delta features a zone of rapid deposition near its eastern leading edge, which is now located immediately southwest of the town of Keta (see Figure 2). This zone is sheltered from wave action by a large depositional protuberance located 20 km east of the river mouth and by the older submerged delta located offshore. As a result, potential sediment transport rates are low.

An apparent repositioning of the river mouth to the west and a decrease in sediment supply, to the area east of Keta, have resulted in erosion and realignment of the delta front east of the present river mouth (see Figure 3). This realignment is thought to be at least partially responsible for the initiation of the depositional protuberance on the delta front.

**Figure 2 – Project Area and Recession Rates**
Figure 3 – Proposed changes of the Volta River Delta shoreline as a result of river mouth switching and shoreline realignment.

This large scale, long term process of sediment deposition on the deltaic protuberance is directly responsible for the shoreline recession in the study area, which is located immediately downdrift of the protuberance. The study area consists of a narrow 7 km long washover terrace separating Keta Lagoon from the sea (see Figures 4a and b). The terrace sits on lagoonal sediments, which are presently being transgressed. Annual average recession rates along the narrow section of beach range from 8 m/yr at the southwest end to less than 2 m/yr at the northeast end (refer to Figure 2). In addition, the coastline features migrating sand waves from 10 m long beach cusps to 300 m long tongues of sand. The migration of these features results in fluctuations in shoreline position of 50 m or more over a period of several weeks. These large sand waves appear to be generated by the creation and release of sand spits at beach bends along the leading edge of the delta front protuberance. Small changes in wave direction may initiate the break away of the spits to form migrating sand waves.

The erosion problem at Keta has been the focus of many investigations dating back to the first published engineering report by Coode (1929). This report concluded that the erosion problem had existed for at least 50 to 60 years prior to 1929 and relocation was proposed as the only practical solution. A series of reports by Batley between 1947 and 1950 suggested that the erosion problem at Keta was diminishing and that changes in erosion trends in the Keta area are related to dynamics of the Volta River mouth (including long term changes in the position of the mouth). Halcrow (1954) investigated the potential impact of the Akosombo Dam (which resulted in the creation of Lake Volta) on the coastal erosion at Keta. That study concluded that the regulated flow conditions
would result in a reduction of the rate of deposition in the vicinity of Cape St. Paul, and therefore, alleviation of the erosion problem at Keta. Freedman (1955) disagreed with Batley's conclusion that the erosion problem at Keta was coming to an end. Emphasis was placed on seepage from the lagoon through the beach face during low tide conditions as an important factor in the erosion process. Groynes were rejected as a viable solution while the construction of a continuous seawall was endorsed as a practical but costly solution, relocation was proposed for further consideration. In 1960 a recommendation in a report by the Hydrological Branch of the Public Works Department of Ghana resulted in the construction of 1600 m long steel sheet pile wall at Keta (the remains of this can be seen offshore of Keta in Figure 4a). Following construction of the wall serious erosion occurred at the northeast (downdrift) end of the wall. NEDECO (1964, 1976 and 1980) and Delft Hydraulics (1993) have prepared several reports on the flooding and erosion problem at Keta. These reports agree with the view that the erosion problem is slowly shifting northeastwards. In the 1980 report a series of groynes was proposed to protect the shoreline between Keta and Horvi. Most recently, Anthonio and Valentine (1995) developed a numerical nearshore wave transformation model to describe the variability in alongshore transport passing Keta depending on the direction of wave attack.

Design Investigations

Geomorphic investigations consisted of air photo and satellite imagery analysis, mapping historic beach ridges; hydrographic surveys; subsurface investigations including vibracores, augers, boreholes, sediment sampling, seismic profiling and radiocarbon dating; and monitoring of 10 permanent beach profile stations (some of which have been monitored since the early 1970’s). The key findings of these investigations are listed below:

- Earlier during the present Holocene high-stand of sea level, the mouth of the Volta River was located further to the east and the leading edge of the delta probably consisted of spits curving into an open bay which is now the enclosed Keta Lagoon (see Figure 3);
- The northeastward migration of the leading edge of the Volta River delta has been occurring in an episodic manner at the existing location for a period of centuries and will continue to do so (see Figure 5);
- The section of eroding shoreline is a washover terrace consisting of a wedge of sand migrating into the lagoon through overwash processes and through shoreface erosion of underlying lagoonal sediments (see Figure 6).
Figure 5 – Beach–ridge development. (A) Overlay tracing of the beach ridge margins seen on aerial photographs taken in October 1993. (B) Interpretation of episodes of beach-ridge growth (1=oldest; 6=youngest).

Figure 6 – Section of Washover Terrace
The findings of the geomorphic investigations were corroborated or refined based on the coastal engineering analyses described below.

Coastal process investigations included prediction of the deepwater wave conditions with the U.K Global Wave Model calibrated by satellite data by Oceanor (1997) and verified against wave measurements with pressure sensors deployed by Baird. Nearshore wave transformation was completed using the Nearshore Spectral Wave model of the MIKE21 package developed by DHI. The nearshore wave transformation results showed that the degree of sheltering at Keta varies significantly with only a small change in incident wave angle. For a typical 12 s wave period, the wave height in the vicinity of Keta is reduced to 20% of the incident wave height for SW incident wave attack, 50% for SSW wave attack and 70% for S wave attack.

An overtopping analysis was completed to simulate serious flooding events that occurred during the course of the design investigations. The findings of this analysis demonstrated the importance of washover in the retreat of the beach terrace. Samples of the underlying lagoonal sediment (peat and clay) were found to contain little or no beach sand. Therefore, once the underlying lagoonal sediment was exposed in the surfzone, it was readily and irreversibly eroded, with little or no contribution of sand to the littoral system.

Prediction of longshore and cross-shore currents and sand transport rates (including in the vicinity of the headlands) were completed using the COSMOS model (see Nairn and Southgate, 1993). There were two purposes of these estimates: 1) to quantify the geomorphic findings and specifically to develop a sediment budget to provide the basis for a solution; and 2) to assess the potential performance of the proposed solution.

In summary, the sediment budget found that between Cape St. Paul and just southwest of Keta, the net eastward transport rate decreases from nearly 1,000,000 m$^3$/year to less than 50,000 m$^3$/year. The result is deposition of sand and the migration of the leading edge of the delta. The rate of shoreline progradation is greatest at Keta where the depths of water are shallow (owing to the fact that this area was recently eroded). Northeast of Keta the potential sand transport rate increases from 50,000 to 200,000 m$^3$/year towards the east at the northeast end of the study area near Horvi. The deficit in the potential transport rate of approximately 150,000 m$^3$/year compares well to the estimated average annual loss of 164,000 m$^3$ of sand sized sediment from this reach of coastline (determined from historic recession rates and a consideration of the thickness of sand eroded - accounting for the fact that the washover terrace material is conserved and that the lagoonal muds do not produce sand sized material).

The GENESIS model (Hanson and Kraus, 1989) was used to assess the potential performance of large headlands in protecting the shoreline from erosion and regulating the rate of alongshore transport. Two key aspects of the GENESIS model that required calibration to address specific site and project conditions are: 1) the potential sand transport rate; and 2) the rate of bypassing at each headland (referred to as the permeability of the structure in the GENESIS input). The transport rate was established by the COSMOS model and the sediment budget findings discussed above. The rate of
bypassing, or groyne permeability, is a critical factor as it establishes the offset of the shoreline from the tip of the downdrift groin with a groin cell. This setback distance must be determined to assess the required groin or headland spacing to optimize the transport rate through the study area and to avoid flanking erosion on the downdrift side of the headlands. The setback distance was determined for a given alongshore transport rate (i.e. associated with a given shoreline orientation) by finding the position that resulted in equilibrium between alongshore and offshore transport just updrift of the headland (see Figure 7). It was determined that the shoreline must advance to within 50 m of the end of the headland before the offshore transport rate matches the alongshore transport rate of 150,000 m$^3$/year. However, for an alongshore transport rate of 50,000 m$^3$/year, the setback distance increases to 120 m. The prediction of setback distances was corroborated by a review of setback distances for many existing groin and headland structures.

Physical modelling was completed to examine the impact of the headlands on the beach orientation and the bypassing process as well as the stability and constructability of the rubblemound structures. One of the key findings of the mobile bed modelling was that the advantages of implementing T-head, L-head or angled groins or headlands at this location did not justify the additional cost compared to a straight, shore perpendicular headland. The finding that the T and L head layouts did not add significantly to the length of protected beach (and the required spacing between headlands) may be a function of the narrow window of wave attack at this site (i.e. all significant waves approach from the SW to SSE sectors). The model test results for beach planform compared well to empirical predictions from expressions developed by Hsu et al (1989).

Figure 7 – Estimating bypassing at the headlands

![Diagram of headland and beach planform](image)
The Sea Defence System

The objectives of the sea defence system are:

- stabilize areas of existing and planned development;
- prevent flooding of the coastal communities;
- minimize disruption to human activities associated with the coastline, particularly seine netting and the launching of fishing canoes; and
- avoid transferring the erosion problem to developed areas downdrift and northeast of the study area.

In order to stabilize the study shoreline and meet the above objectives, it is necessary to address a deficit of approximately 150,000 m$^3$/yr of sand between the updrift and downdrift limits of the developed area (a distance of 5 km). It is also necessary to protect the erosion susceptible lagoonal sediments underlying the beach.

Prior to developing a solution to the erosion problem, the “do nothing” scenario was considered in detail. Based on the results of the geomorphic investigation, the coastal process modelling and the sediment budget analysis, projections of shoreline position for the next 75 years were made (see Figure 8). It is evident that perhaps within 25 years time, erosion will no longer be a threat to the community of Keta. However, the communities of Vodza and Kedzi will suffer severe erosion. Relocation of these communities was not an acceptable option as there are no remaining suitable locations for ocean seine netting — the primary occupation of the communities. In addition, it is possible that the erosion may result in the breach of the narrow washover terrace separating the lagoon from the sea. The introduction of seawater into fresh/brackish water of Keta Lagoon would have disastrous effects on local drinking water, lagoon fishing and irrigation of adjacent agricultural land. Therefore, the “do nothing” option was considered to be unacceptable.

The adopted large scale solution consists of constructing one breakwater and 7 rubblemound headlands, prefilled with 2.5 million cubic metres of sand dredged from the lagoon bed. The breakwater (not shown on Figure 8) will protect the town of Keta from erosion until this area is naturally protected by the migrating delta front. One of the reasons a breakwater was preferred to a headland at this location was to minimize the disruption to alongshore transport between the depositional area at the leading edge of the delta and the downdrift erosion area. On average, the headlands are approximately 200 m long and extend out to a depth of 5 m. The average spacing between the headlands is 750 m. The function of the headlands is to extend the longevity of the beach nourishment and to protect the underlying lagoonal sediments from erosion. The purpose of the beach nourishment is to act as a feeder beach to address the potential transport deficit within the study area. Figure 9 illustrates the solution in terms of its performance relative to the sediment budget. It is noted that Figure 9 shows eight headlands, the design was recently modified to eliminate the most northerly headland (reducing the total number to 7).
Figure 8 - Projections of future shoreline change under the 'Do Nothing' scenario
Figure 9 – Proposed Sea Defence Scheme

(Note: The proposed breakwater is located along the alignment of the old sheet pile wall and the most northerly headland has been removed from the latest design revision.)
Another important aspect of the sea defence system is the 2 km section of unprotected shoreline at the downdrift end of the project. This undeveloped area will erode to make up the remaining 60,000 m$^3$/yr deficit between the transport through the project area and the potential rate downdrift of the sea defence system.

Based on the COSMOS and GENESIS numerical modeling, it was determined that the feeder beach area will have to be renourished every 10 to 15 years. Model simulations showed that failure to renourish the feeder beach would result in flanking erosion at the base of the headlands and accelerated downdrift erosion, to the extent that downdrift communities may eventually be affected.

A range of other possible solutions was considered in detail. These included the use of rubblemound structures without beach nourishment, and beach nourishment without structures. In the former case it was determined that twelve headlands would be required and that five more headlands would have to be added every 10 to 15 years to address downdrift erosion. This solution would simply transfer the problem downdrift. One alternative that consisted exclusively of beachfill was a "sand bridge" extending from updrift of Keta to Vodza. The purpose of the sand bridge was to link updrift and downdrift locations with similar potential transport rates (eliminating some of the deposition updrift and alleviating the downdrift supply deficit). The net present value of this solution was similar to the adopted solution of the feeder beach and headlands, however, it was not selected owing to the higher risk associated with estimating the performance of the sand bridge.

**Conclusions**

The combined investigation of coastal processes, geology and geomorphology was utilized to develop an understanding of the coastal morphodynamics across a wide range of temporal and spatial scales. This understanding was used to predict future shoreline change in order to develop a coastal management solution to the ongoing impact of the shoreline recession on the coastal communities in the study area. The solution addresses the erosion problem within the limits of the study area and avoids the downdrift transfer of the problem.

Construction is planned to commence in early 1999. An extensive monitoring program through the four year construction period will assess the waves, shoreline change, scour and stability of structures in addition to environmental conditions as part of the environmental impact assessment requirements.

Morphological vulnerability index: A simple way of determining beach behaviour

Óscar Ferreira¹, Rui Taborda² and J. Alveirinho Dias¹

Abstract

A simple morphological based index to determine beach vulnerability is proposed in this paper. The presented morphological vulnerability index ($I_v$) relates maximum annual volumetric difference and average beach volume for each particular site. High index values are representative of coastlines vulnerable to erosion.

After the index application to 15 Portuguese sites it was possible to determine empirical threshold values, defining limits between beach stages. Based on these limits the beaches can be classified as: robust beaches, for $I_v < 0.35$; fragile beaches, for $0.35 < I_v < 0.9$; and extremely fragile beaches, for $I_v > 0.9$. The index validation tests against field observations and recent shoreline evolution gave good results, indicating that the $I_v$ has a strong potential application to characterise medium to long-term beach evolution.

Introduction

A successful approach to characterise large-scale sediment transport, including cross-shore rates, must use information on the principles underlying key features of the larger scale morphology (Larson and Kraus, 1995). However, to our knowledge there are no simple morphological based indexes available in literature describing beach behaviour at macro and megascale timescales (year to decades).

The main goal of this study was to develop an index capable of determining the morphological vulnerability of a given beach or coastal stretch. For the purpose of this study a beach with high morphological vulnerability is defined as having a small ability to support high energy conditions without strong morphological changes. Thus, a

¹ UCTRA, Universidade do Algarve, Campus de Gambelas, 8000 Faro, Portugal.
² Departamento de Geologia, Faculdade de Ciências, Universidade de Lisboa, Campo Grande, 1700 Lisboa, Portugal.
beach with high vulnerability can also be referred as a fragile beach, due to the possibility of effective shoreline or dune retreat to occur. Conversely, a low vulnerability beach can also be referred as a robust one, meaning that even facing some erosion during high energy conditions the beach will not show effective shoreline or dune retreat. It is meant by effective shoreline or dune retreat the total remotion of the upper beach (foreshore and backshore) sedimentary stock with erosion of the dune or cliff.

In order to introduce an index of this kind studies were carried out on 15 Portuguese beaches. Two different coastal sectors were surveyed including; 10 sites from Aveiro - Cape Mondego (figure 1), Northwest of Portugal (surveys from September 1992 until June 1993) and 5 sites from Praia de Faro (figure 2), Algarve (surveys from May 1995 until May 1997). The 10 sites of the Northwest coast belong to a coastal stretch with about 50km length and include beaches updrift and downdrift of groins as well as beaches without human intervention. On the Algarve coast three of the surveyed beaches are backed by human occupation (sites A to C) and two of them by a dune ridge (sites D and E). The surveys were made during low spring tides, once a month in Praia de Faro and every two months at Aveiro - Cape Mondego. All these sites were intermediate to reflective Atlantic facing sandy beaches with moderate (Algarve) to high wave (Aveiro - Cape Mondego) energy. Both coastal areas are mesotidal with maximum tidal ranges reaching about 3.6m-3.8m.

Figure 1. Location of the study sites from Aveiro - Cape Mondego coastal stretch.
Vulnerability index

Concepts

The main concept underlying the proposed vulnerability index is that the annual beach variability can be an indicator of its future evolution. The index application assumes that the beach variability is mainly dependent on cross-shore exchanges and that after an annual cycle the upper beach morphology becomes similar to the initial one, even if there was effective dune or shoreline retreat. Thus, this index can only be used in beaches where a seasonal behaviour exists.

To obtain the morphological vulnerability index ($I_v$) it was necessary to compute the beach volume above mean sea level for each obtained profile (figure 3). The landward limit for these calculations was taken to be the "non-mobility point" of the site (the inland point at which no sand movement due to wave action was observed). Using the obtained volumes, mean profile volumes ($V_{mean}$) were calculated for each beach and for the desired periods.

The morphological vulnerability index ($I_v$) is then given by the relationship,

$$I_v = \frac{V_{max} - V_{min}}{V_{mean}}$$  \hspace{1cm} (1)

where $V_{max}$ and $V_{min}$ are the maximum and the minimum volumes computed for the chosen survey period. A high index indicates a high range in beach volume (a dynamic site) and low mean values. Thus, high indexes will be indicative of coastlines vulnerable to erosion while low index values will be representative of shorelines without evident retreat.
From the available data and after some application tests, it was found that the index only shows stable results if survey data is included for a full seasonal (Summer/Winter) cycle, with a period between successive surveys no longer than 2 months. Figure 4 illustrates the index evolution \( (I_{vn} / I_{vn-1}) \) with an increasing number of profiles \( (n) \) used in the calculation of \( I_v \). This figure shows that the index variation tends to be small or nule \( (I_{vn} / I_{vn-1} \approx 1) \) when the number of used profiles \( (n) \) is higher than 12/13 (one year of monthly observations). On the basis of these results \( I_v \) is computed at each site using one full year of survey data, and thus indicating the beach behaviour of that period.

Application to Praia de Faro

By the application of equation (1) to the Praia de Faro data set 13 indexes were obtained for each site, from months 1-13 (first year of surveys) until months 13-25 (last year of surveys). The minimum, maximum and mean values, obtained to each site, are expressed in Table I. It is apparent from Table I that site B (parking place at Praia de Faro) is the most vulnerable to erosion or overwash. This is in agreement with field observations of frequent overwashes at this site. Dune erosion is impossible to occur at this site since the parking area was built over the former dunes, destroying them. From field observations it is also evident that sites A and C are less robust than
sites D and E, since the dune at site A and the seawall at site C have been eroded and damaged by the sea. Conversely, at sites D and E the dunes remained unaffected by the swash. The conclusions obtained by the analysis of Table I agree with those reached by previous studies at Praia de Faro (Martins et al., 1996; Ferreira et al., 1997), using different evaluation methods.

Figure 5 shows the mean values and the index variability at sites B and E, for the observed period. The difference between sites is evident, with site B having a significantly higher vulnerability index than E. With the knowledge that the dunes at sites D and E did not experience erosion or overwash, which occurred on sites A to C, it is possible to infer a robustness limit of approximately 0.35. Above this limit coastal erosion will be frequent. Figure 6 shows the relationship between the computed index values at the different sites together with this empirical limit.

Figure 5. Index variation for sites B and E, along the surveyed period.

Figure 6. Determined index variability for the studied period, at each site, and its relation with the empirical limit.
Application to the Aveiro - Cape Mondego data

By the application of this index to the data resulting from the Aveiro - Cape Mondego monitoring program, it was only possible to obtain one set of $I_v$ values, since the survey period was only 10 months in duration. From these observations two distinct groups of beaches were identified (figure 7). Three of the surveyed sites (white symbols) exhibited very high index values, and thus may be classified as extremely fragile (prone to overwash and erosion). These 3 sites (PMS, PA and VS) are placed downdrift of groins, facing strong dune retreat.

![Figure 7. $I_v$ values for the Aveiro - Cape Mondego coastal stretch.](image)

In figure 8 the observed beach/dune retreat or accretion, for the 1980/90 period, was plotted against the computed $I_v$ for each site. A strong correlation was observed between $I_v$ and beach/dune evolution. These data indicate that $I_v$ values greater than 0.9 denote extreme beach vulnerability (effective shoreline retreat higher than 2m/year).

![Figure 8. Relation between $I_v$ and beach/dune evolution at Aveiro - Cape Mondego (negative values represent erosion).](image)

Combining the results obtained by the analysis of the two coastal sectors, the following limits are proposed: $I_v < 0.35$, Robust beach; $0.35 \leq I_v < 0.9$, Fragile beach; $I_v \geq 0.9$, Extremely fragile beach.
The obtained limits are based on a restrict number of data, being necessary a future confirmation of the thresholds for other coastal areas with different wave energy and morphodynamic conditions.

Index validation

In order to confirm the results obtained by the application of the morphological vulnerability index, a validation test was performed. For this test nine beach profiles, obtained in April 1995 on the same sites of the 1992/93 surveys for the Aveiro - Cape Mondego coastal stretch, were used. The new profiles were compared with the previous ones, by measuring the observed dune retreat and computing the volumetric difference between each new profile and the corresponding average volume for the 1992/93 surveys. Table II shows the volumetric differences and the maximum observed dune retreat at each site.

<sup>a</sup> Retreat due to seawall reconstruction.

A high volumetric difference occurred at most sites, showing a global erosional trend from 1992/93 to April 1995. However, an effective dune retreat only occurred at beaches where the $I_R$ value was higher than 0.9 (PMS, PA and VS). At the other sites the dune was not reached by the sea, even if the volumetric difference was very high (e.g. PMN, where a volume change of -182.6 m$^3$/m was measured). This observation confirms that the robustness of a beach is not only given by the sedimentary volume exchange but mainly by the relationship between that volume and the available sand stock. Two examples of profiles from the same coastal stretch (Aveiro - Cape Mondego) showing high volumetric changes, with and without dune retreat, are presented in figure 9.

According with the obtained results, the index proved to give a good discrimination of the fragile sites, being able to point out the beaches where an effective retreat could occur.
In this paper a new and simple index to determine morphological vulnerability of sandy beaches is proposed. This index was applied to 15 different Portuguese sites showing that it is possible to use simple morphological parameters to characterise the beach behaviour as well as the medium to large-scale beach evolution. For the available data sets three classes of beach behaviour are proposed: robust, fragile and extremely fragile. The morphological vulnerability index can be easily applied on beach monitoring programs, providing coastal managers a clear and simple indicator of beach stability. However, future work is required, namely in the determination of the $I_V$ limits with larger data sets and testing the index validation to different beach types (dissipative and extremely dissipative beaches, pocket beaches, shingle beaches, etc.).

Homogeneity aspects in statistical analysis of coastal engineering data

P.H.A.J.M. van Gelder\textsuperscript{1} and J.K. Vrijling\textsuperscript{2}

Abstract

In this paper, the problem of (in)homogeneous data in coastal engineering applications is studied. Statistical analysis of coastal engineering data such as flood data, wind data, wave height data, etc., is essentially a problem of information scarcity. Records are usually too short to ensure reliable estimates of low-exceedance probability quantiles in many practical problems. Determination of quantiles is needed for the design, construction and operation of hydraulic structures, insurance studies and protection of populated areas. To perform a frequency analysis of data from coastal engineering practice, the data first has to be tested for homogeneity. Non-homogeneous data may lead to wrong quantiles. A homogeneity test must be able to separate data sets that do not come from the same distribution. In this paper statistical and physical-based homogeneity tests will be presented.

Introduction

Statistical analysis of coastal engineering data is a problem of information scarcity. Usually records are very short. Datasets with 100 years of water levels may seem much, but when one is interested in the $10^{-4}$ quantile, 100 years of data is very little. Apart from the data scarcity problem, there is also a data homogeneity (or rather data inhomogeneity) problem. A basic assumption is that data is coming from one and the same process. Or in mathematical terms: the data are realisations from one and the same probability distribution function. Statistical procedures are available to check the homogeneity of a dataset. A short overview of these procedures will be given in the paper. However their weakness will appear quickly, since these procedures are not very

powerful to reject inhomogeneous- or accept homogeneous data. A Monte Carlo experiment will illustrate this. A second method to judge the homogeneity of a dataset is more physically based. It will be shown that this way is more powerfull than the statistical procedures. A case study will be presented in order to show the physical based judgement of a coastal engineering dataset. Other physical based techniques will be reviewed in the paper. The paper will end with some conclusions and a list of references in the area of homogeneity analysis.

Homogeneity

Statistical distribution functions play an important role in coastal engineering. In the design of coastal structures they are used to determine the so-called p-quantiles. A p-quantile of a random variable is the value of that variable which is exceeded with a probability p. In coastal engineering p-quantiles in the order of $10^{-4}$ for small-scale defence structures to $10^{-3}$ for important coastal defence structures are commonly applied. In the Netherlands the seadikes for instance are designed with p-values of $10^{-4}$ and river dikes with p-values of $1.25 \times 10^{-3}$. The reason for the difference is that a possible inundation from the rivers is not so disasterous as an inundation from the sea.

The importance to estimate the correct p-quantile is quite high. A too low estimate may lead to an unsafe structure, whereas a too high estimate may lead to a conservative overdesigned structures which costs unnecessarily too much. Lots of research has been carried out for finding the best p-quantile estimation method. Well known methods are for example Maximum Likelihood (ML), Method of Moments, Least Squares (LS), Weighted Least Squares (WLS), Method of L-Moments, Bayesian methods, and many more. Methods to select the optimal distribution function are also available. Various goodness-of-fit criteria such as $\chi^2$, Kolmogorov-Smirnov (KS), etc. can be used for that purpose. All these p-quantile estimation techniques and distribution selection methods have one important assumption in common, and that is that the data under consideration must be homogeneous. To verify the homogeneity assumption, statistical procedures have been developed.

Homogeneity analysis has been carried out a lot in the field of flood frequency analysis (FFA). FFA tries to combine data from other sites in order to improve the accuracy of the p-quantile estimate. However, combining data from different sites may only be done when the sites can be considered homogeneous. Therefore numerous papers have appeared dealing with this problem. We mention Dalrymple's test and the L-moment X10 test (Fill et al., 1995). Homogeneity tests based on L-moment ratios have received quite some attention lately (Rao et al., 1994, Zrinji et al., 1996). Sample L-moments are less biased than traditional moment estimators.

Not only homogeneity tests have been developed in the field of FFA. Also literature is available from the behavioural sciences such as sociology and psychology. Well known statistical tests are for example the Mann-Whitney test, and the Wald Wolfowitz test (Harnett, 1970). The Mann-Whitney test is a non-parametric homogeneity test which can test the nul-hypothesis that two independent datasets are
coming from the same distribution. The performance of this test can be studied with help of Monte Carlo simulations. A dataset 1 with a given size can be simulated from a given distribution function. Also a dataset 2 can be generated and the two datasets can be compared with each other from a homogeneity point of view. Under the null-hypothesis that the datasets come from the same distribution, the test statistic should be normally distributed with mean 0 and standard deviation 1. If the Mann-Whitney test is analyzed in this way, it will appear that the test is not so powerful for small sample sizes. Only for large sample sizes in the order of 100 or more, the test may reject or accept the null-hypothesis with high reliability. Also the recently developed L-Moment techniques have difficulties to judge the homogeneity of a dataset. A Monte Carlo experiment was designed for that purpose. A sample of size 40 is generated from a certain extreme value distribution (Gumbel$^{10}$). From this sample the ordinary moments and the L-moments are calculated. Another sample of size 40 is generated from a quite different extreme value distribution (Normal$^{10}$) with the same mean and standard deviation however. Its ordinary and L-moments are calculated. The experiment is repeated 100 times and the moments and L-moments values of each sample are depicted in figure 1. Note that as well as the ordinary moments graphic as the L-moments graphic show a non-distinguishable behaviour between the Gumbel$^{10}$ and Normal$^{10}$ distribution. In other words: it is impossible to separate the two distribution functions with the traditional and newly developed L-moment techniques.

![Figure 1. Homogeneity analysis with L-moments techniques. Data from Gumbel$^{10}$ are indicated with x; data from Normal$^{10}$ with o.](image)

COASTAL ENGINEERING 1998
The before mentioned homogeneity tests do not include any physical arguments to judge the data. In the following part we will propose procedures in order to examine the homogeneity of a data set on basis of physical arguments.

**Physical based homogeneity analysis**

Rather than a statistical analysis of the data, the data is examined on basis of its physical origin.

Physical arguments to judge the homogeneity of a data set are for instance:
1. Type of spectrum (swell, wind, single or double peaked wave height spectrum);
2. Season, calendar period of the data set (sea level data in the winter or summer);
3. Physical characteristics of the phenomena (breaking, non-breaking waves).

Combining statistical tests with physical arguments leads to more homogeneous data than only applying the statistical tests. This will be shown in a case of wave height and peak period data measured in the Bay of Bengal near the city of Madras.

**Case study**

In this case study registrations of the wave rider campaigns in the Bay of Bengal near the city of Madras during the south-west monsoon from mid-April to mid-August 1993 were used for analysis. A set of peaks over threshold values is available with significant wave heights. The set consists of 144 values and the threshold is given by 39cm. A statistical data analysis gives the following figure 2.
A statistical homogeneity check on the data set with 144 values as described in the previous section does not lead to a rejection of the data set. Also a visual inspection of figure 2 does not suspect inhomogeneous data.

An investigation on the origins of wave generation in the Bay of Bengal however leads to:
1. Locally generated waves; these waves are generated in the Bay of Bengal either by the north-east or south-west monsoon or by hurricanes.
2. Swell; these waves are generated in the Roaring Forties, south of Cape Town. They reach the southern point of India from the south-west in approximately three days.

From the given data set with 144 significant wave heights, also the corresponding peak periods were available. A visual inspection of the data set with the peak periods immediately leads to the conclusion of inhomogeneity (figure 3). The waves can be separated into two classes. The first class contains waves with periods of about 5 sec. The second class contains waves of about 12 sec.
Figure 3. Probability distribution of Tp

Trying to model the probability distribution of the peak periods by one single distribution function leads to unacceptable deviations, as can be seen from figure 3. Therefore the inhomogeneous data set had to be split up into two sub sets. Each sub set is modeled by its own distribution and the probability model of the total data set is obtained by combining both sub models (figure 3).

Returning to the original goal: a probability distribution for the significant wave height, the following result is obtained (figure 4). The significant wave height with exceedance probability of $10^{-3}$ is 1.55m in stead of 1.90m; a difference of about 30%. This might have lead to an overdesigned coastal structure. However, the multivariate analysis of the data (including wave period in the analysis together with wave heights) had shown the inhomogeneous behaviour of the second tuple.
Figure 4. Comparison of in-/homogeneous fit.

North-European climate

Coastal engineering data from Northern European seas differ from the data presented above. Monsoons and hurricanes are not present in Northern Europe. However, strong winds can occur during the winter months November, December and January. These winds may yield extreme wave heights and water levels along the coasts. The analysis of such datasets also requires homogeneity studies. One of the first extensive homogeneity studies of the water levels along the Dutch coast was performed in 1960 by the Delta Committee. They homogenize the dataset of water levels by looking at the trajectory of the depression that caused the high water level. Extreme water levels can only occur when the depression follows a trajectory through a certain area. From the meteorological archive the area could be confined to:

At 10° W between 51° N and 62° N;

at 0° W between 52° N and 61° N;

at 7° E between 52° N and 61° N.

The cause of an extreme water level is found in the trajectory of the depression combined with the behaviour of the body of water in the North Sea basin. Therefore
the statistics of the water level data is confined to those water levels that were caused by the dangerous trajectories. Such a physically based homogeneity selection method can also be successfully applied at other locations.

Multivariate analysis

What was seen in the case study was that the homogeneity of a univariate dataset can be judged by extending the univariate set to a multivariate dataset and analyzing the other tuples of the dataset. This principle can be applied to all kinds of studies and appears to be very powerful. Consider for example the total yearly precipitation in the Netherlands (figure 5).

![Graph of precipitation in the Netherlands](image)

Figure 5. Total yearly precipitation with high variation coefficient.

Although the total yearly precipitation might be expected to be a stable quantity, a variation coefficient of 15% is observed. The univariate dataset of precipitation at each year can be extended to a multivariate dataset with (precipitation, dominant wind direction). Due to the geographic location of the Netherlands, winds from the west are very humid and bring a lot of rain; winds from the east however are very dry. Therefore two different processes can be distinguished and the precipitation dataset should be split into at least two subsets.
Conclusions

Homogeneity aspects in the statistical analysis of coastal engineering data have been discussed in this paper. Apart from statistical tests to judge the homogeneity of a data set, also physical arguments have to be included in the judgement. A case study of significant wave height data has been presented to illustrate the differences between the tails of distributions when the homogeneity aspects are left out of consideration.

A simple method to predict long-term morphological changes

Dano Roelvink¹,², Alain Boutmy² and Jean-Marie Stam³,⁴

¹) WL | Delft Hydraulics
²) Delft University of Technology
³) Netherlands Institute for Marine and Coastal Management (RIKZ)
⁴) Netherlands Centre for Coastal Research.

Abstract

A method is presented to obtain a first estimate of long-term bathymetric changes based on an initial transport field obtained from a 2DH process model. The results are compared with full morphodynamic simulations and measured bottom developments after extension of the harbour moles at IJmuiden, the Netherlands.

Introduction

Over the past decade, process-based morphodynamic models based on depth-averaged two-dimensional equations for wave action, flow, sediment transport and bed level change have been developed at several institutes and have now become generally available for application in practical model studies (for a review see De Vriend et al., 1993; Nicholson et al., 1993).

The strength of these models lies within their ability to represent the various processes simultaneously, and to evaluate the changes in these processes due to human interference in the form of structures, nourishments or dredging. The outcome of the model is often not very accurate and expertise is needed to calibrate it for a given situation. Even then, absolute predictions are often difficult to make, but a comparison of simulations with and without various scenarios of interference usually yields useful and objective results, based on which an overall advice can be given.
A major problem still lies in the fact that the time-scale of interest in many cases is in the order of decades, whereas the simulation period that can be feasibly covered is usually not much longer than some years. In this paper a simple method will be presented which reduces the computational effort by an order of magnitude, while maintaining an acceptable accuracy. This clears the way for simulations over periods in the order of decades. The simple method will be compared with the full morphodynamic method, and both will be tested against measured bathymetric changes after construction of a large extension of the harbour of IJmuiden in the Netherlands.

‘Standard’ morphodynamic method

The ‘standard’ morphodynamic method applied by various institutes (e.g. de Vriend et al. (1993), Nicholson et al., 1997) involves a coupled simulation of waves, currents, transport and bottom changes. The Delft3D-MOR system, developed by WL | Delft Hydraulics, is one of the systems designed to apply this method in consulting practice. The details are outlined in Roelvink and Van Banning (1994) and Roelvink et al. (1994). Here we present the main features.

The model structure consists of a steering module and four computational modules, as outlined in Figure 1. The steering module calls the computational modules in any prescribed order, and arranges the time-progress of each module. It allows iterations between modules. The computational modules are:

- Wave module based on HISWA (Holthuijzen et al, 1989). Refraction and dissipation of directionally spread random waves. Several computations through a tidal cycle in one call.
- Flow module solves non-steady, 2DH or 3D shallow water equations on a curvilinear finite difference grid, using ADI scheme. Wave effects on flow through bottom friction and driving terms.
- Transport module solves quasi-3D advection-diffusion equation for sediment. Equilibrium concentrations in this study based on Bijker with wave effects. Recently added cross-shore transport terms using Bailard approach.
- Bottom update module solves sediment balance using explicit scheme of Lax-Wendroff type, with automatic timestep.
A simulation in Delft3D-MOR is built up like a hierarchical tree structure, a so-called process tree. In Figure 2 a typical tree is given. A morphological process is built up from morphological time steps, which consist of a simulation of wave-current interaction over a tidal cycle, followed by a number of intermediate steps where transport is computed and averaged over a tidal cycle, and the bottom is updated. The transport and bottom computations are repeated a number of times using "continuity correction" (see below), until bottom changes are so large that a full hydrodynamics computation is required.

**Sediment balance**

The sediment balance equation reads:

$$\frac{\partial z}{\partial t_{\text{mor}}} - \frac{\partial S_x}{\partial x} + \frac{\partial S_y}{\partial y} = 0$$

(1)

Here, $z$ is the bed level (positive downward), $S_x$ and $S_y$ the components of the tide-averaged sediment transport vector, and $t_{\text{mor}}$ the time; the subscript refers to the fact that the time scale of bottom changes is generally much larger than the tidal period.

**Continuity Correction**

The sediment transport field is generally a function of the velocity field $\bar{u}$ and the orbital velocity $u_{\text{orb}}$:

$$\bar{S} = f(\bar{u}, u_{\text{orb}})$$

(2)

When the bathymetry changes, the flow field and orbital velocity change, and have to be recomputed. The "continuity correction" is a frequently applied method to adjust
the flow field after small changes in the bathymetry. The flow pattern is assumed not
to vary for small bottom changes:

\[ \bar{q} \neq f(t_{\text{mor}}) \quad (3) \]

where \( \bar{q} = h \bar{u} \) is the flow rate vector and \( h \) is the water depth. The same goes for wave
pattern: wave height, period and direction are kept constant, and only the orbital
velocity is adapted for the local water depth:

\[ H_{\text{rms}} \neq f(t_{\text{mor}}) \]
\[ T_p \neq f(t_{\text{mor}}) \quad (4) \]
\[ (5) \]

Since \( \bar{u} = \bar{q} / h \) and \( u_{\text{orb}} = f(H_{\text{rms}}, T_p, h) \), adaptation of the sediment transport field is
now simply a matter of adjusting the velocity and orbital velocity and recomputing the
sediment transport using eq. (2).

In case of a tidal flow situation, a number of velocity and wave fields based on the
original bathymetry are stored, and when the depth changes, the adapted transport
field is computed for a number of time points in the tidal cycle and subsequently
averaged. This averaged transport field is then used in the sediment balance (1).

The method still requires full transport computations through tidal cycle, which
can be time-consuming when suspended-load transport is to be accounted for. The
morphological time step is often dominated by some shallow points, which are usually
not of interest. This means that typically after some 10-20 continuity correction steps,
the full hydrodynamic model has to be run on the updated bathymetry.

Rapid Assessment of Morphology (Delft3D-RAM)

In practical consultancy projects there is often a need to interpret the outcome of
initial transport computations without having to resort to full morphodynamic
simulations. One way of doing this is looking at initial sedimentation/erosion rates,
but this method is flawed in many respects. Initial disturbances of the bathymetry lead
to a very scattered pattern, and, as De Vriend et al. (1993) point out,
sedimentation/erosion patterns tend to migrate in the direction of transport, a
behaviour which is not represented in the initial sedimentation/erosion patterns.

What we propose in this paper is a simple method which overcomes these
disadvantages. In the previous section, we have seen that under the assumptions used
in the "continuity correction", the tide-averaged transport rates are a function of flow
and wave patterns which do not vary on the morphological time-scale, and the local
depth, which does vary on this time-scale. In other words: given a certain set of
currents and waves, the transport at a given location is only a function of the water depth.

If we can now approximate this function by some simple expression with coefficients which vary from place to place, we end up with a very simple set of two equations: the sediment balance (1) which expresses bottom change in terms of sediment transport gradients, and:

$$\bar{S} = \frac{\bar{S}_{x=0}}{\bar{S}_{y=0}} f(z)$$  \hspace{1cm} (6)

This equation describes the reaction of sediment transport to bottom changes. The form of the function $f(z)$ can be estimated by considering that transport usually is proportional to the velocity to some power $b$:

$$|\bar{S}| \propto |\vec{q}|^b \propto \left( \frac{|\vec{q}|}{h} \right)^b \propto |\vec{q}|^b h^{-b}$$  \hspace{1cm} (7)

Since a similar relationship with the orbital velocity can be assumed, a suitable function is:

$$|\bar{S}| = A(x,y) h^{-b(x,y)}$$  \hspace{1cm} (8)

where the water depth $h$ is taken as $h = z + HW$, and $HW$ is the high water level, which ensures that water depth is always positive.

As a further simplification $b$ can be assumed constant throughout the field. In this case, the value of $A$ in each point can be derived directly from the local water depth and the initial transport rate, which may be computed using a sophisticated transport model.

The combination of equations (1) and (8) can be solved using the same bottom update scheme as in the full morphodynamic model and requires very little computational effort (in the order of minutes on a PC).

In De Vriend et al. (1993), a steady-state version of this concept, aiming at a direct estimate of the equilibrium bathymetry, was presented for the case of a schematised river outflow. In this case, the solution is governed by the upstream boundary condition. In real life, such a condition cannot be found; by using a time-dependent approach as given here and choosing weak boundary conditions far from the area of interest, this problem is avoided.
Applications

RAM is applicable where the flow- and wave patterns are restricted by the geometry, so small bottom changes do not change the overall pattern. This is typically the case near river outflows, around harbour moles and near river training works. In these cases the behaviour simulated by RAM is similar to that using a full morphodynamic model. At the beginning of a simulation, the RAM simulation matches the full solution exactly: the simplified transport equation is made to fit the full model and the bottom update scheme is the same. As time progresses, the two models will deviate as the flow pattern starts to react to the bottom changes.

Test case: IJmuiden harbour

The harbour moles of IJmuiden, the sea port of Amsterdam (see Figure 3), were extended by approx. 2500 m in the period of 1962-1968. A large scour hole has since developed near the tip of the longest, southern harbour mole, and the coast line has accreted more than 500 m since then, especially on the southern side. Further away from the harbour, the coast has suffered erosion.

Regular surveys of the area have been performed and dredging data collected routinely, apart from the yearly sounding of coastal profiles which takes place along the whole of the Dutch coast. In the framework of this study, these data have been compiled, digitised where necessary and tailored for model validation. Data have been collected over a period of 28 years; in this paper we focus on the first 8 years of this period, from 1968 to 1976. Directional wave data are available from stations in approx. 20 m water depth.

Figure 3. Location map

The full data set and details of simulations are described in Boutmy (1998).
The tidal motion in the area is well documented and several operational models exist which can be used to generate boundary conditions for a detailed model of the vicinity of the harbour.

In Figure 3 the detailed model area is shown. A curvilinear grid was constructed with a good resolution near the harbour entrance and near the coast, but gradually coarsening towards the model boundaries, which were put some 10-15 km from the harbour. A single representative tide was chosen with an amplitude of 1.1 times the average amplitude. Simulations were carried out without waves, with waves perpendicular to the coast, and with two wave conditions representing south-westerly (245° N) and north-westerly (335° N) wave directions. This coarse schematisation was (for the time being) thought to be good enough to represent most of the important processes in this comparative study, and allows an insight into the importance of:

- tide only
- waves acting as stirring agent for sediment
- wave-driven currents and
- other wave-induced processes.

**Tide only**

In Figure 4, the measured sedimentation and erosion is shown for the period 1968-1973. Clearly a scour hole develops in front of the southern harbour mole. The coast southward of the moles accretes strongly, as does the foreshore to the north of the moles. In Figure 5, the same period is simulated with the full morphological model, but taking into account only the tidal flow. Due to contraction around the moles, a scour hole develops; the eroded sand is deposited on either side of the harbour, in deep water. Near the coast and in other areas, nothing happens at all.

Figure 4. Measured bottom change 1968-1973
In Figure 6, the results are shown for a simulation with RAM based on the first computed transport field. As could be expected for this situation where RAM is clearly applicable, the results are quite similar to the full model. Both runs simulate the development of the scour hole reasonably well.

Figure 5. MOR computation '68-'73
Figure 6. RAM computation '68-'73

Tide plus wave stirring

In the next simulations, waves incident perpendicular to the coast have been introduced in the sediment transport module. The effect of the waves is merely to stir up the sediment which is transported by the tidal current. A representative significant wave height of 1.68 m was derived from the available wave data.

The first simulation with standard settings revealed a rather surprising result (Figure 7): there was a small scour hole some distance from the southern mole, but the dominant feature is the accretion at the entrance. The area near the coast is now eroded, which can be attributed to the large eddies downstream of the moles which transport sand towards the harbour mole and outwards; there, the stirring by waves decreases and the sediment is dropped. This also explains the reduced scour hole in this simulation.

One way to reduce the somewhat exaggerated effect of waves on the stirring of sediment is to reduce the wave-related roughness applied in the Bijker formulation from 5 cm (standard run, Figure 7) to 1 cm. The results are shown in Figure 8. The development of the scour hole and the accretion areas near the harbour is much more
in line with the measurements, and the scour hole develops to much greater depth. The interesting conclusion here is, that decreasing the transport rates (by reducing the roughness) has the effect of increasing the scour.

In Figure 9, the results are shown for RAM, based on the same initial transport field as in Figure 8. The agreement is still quite good, albeit that the changes in RAM are sharper, since it lacks the smoothing effects of a free water surface and spatial lag in the suspended transport.

In none of these simulations the accretion of the shoreline is represented.

The results so far show that for a case where the flow pattern is severely restricted by the geometry, the RAM model is able to reproduce the pattern of sedimentation and erosion over a number of years with reasonable accuracy. The computational cost of the RAM simulation is in the order of minutes on a PC. Obviously, the outcome is
very much determined by the quality of the initial sediment transport field provided by the Delft3D process model.

The nearshore area is dominated by wave-driven currents and cross-shore transport phenomena: the longshore current will deposit sand near both sides of the moles, which will be redistributed across the profile. As a result of this, the coastline moves in seaward direction, while the coastal profiles keep more or less the same shape.

In the final set of simulations, we will review the effect of processes not yet introduced in RAM, in order to see how much further a full process modelling approach will take us.

Tide plus waves

In the final scenarios the simulations were run with alternating wave directions; since we are only interested in the long-term evolution, the wave direction is switched each half year of simulation. Figure 10 shows a detail of the initial tide-averaged sediment transport field for southwesterly wave conditions.

Figure 10. Initial transport field, SW waves.
The northward longshore current is stopped and diverted seaward near the southern mole. At the tip of this mole we see an area with accelerating transports, responsible for the scour hole in that region. Near the tip of the northern mole, the eddy during northward tidal flow and the contraction of the southward ebb current combine to generate a southward nett transport in the direction of the harbour entrance, responsible for considerable accretion. North of the northern breakwater, the longshore current is first directed towards the harbour, due to shielding of the southern waves, but further northward the full transport capacity is restored.

These simulations have been carried out over a somewhat longer period, from 1968-1976. The measured depth changes are shown in Figure 11. In Figure 12, the simulated development is shown. There is now clearly accretion of the coast due to the effect of the longshore current. The developments near the tip of the breakwaters are quite similar to the simulations without wave-driven currents, so that we may conclude that the two systems can be looked at separately, at least for the first decade.

The accretion near the southern breakwater takes place about one kilometre from the coast, therefore the coastline itself does not move seaward at all.

Figure 11. Measured depth changes
Figure 12. MOR with wave-driven currents
1968-1976, roughness 1 cm
This is due to the fact that in these simulations redistribution of sand across the profile by cross-shore transport is not taken into account. In a final simulation, this effect was investigated.

The Bailard formula (Bailard, 1981) was used to account for the effect of bed slope and wave asymmetry. The contributions of these terms to transport were simply added to the total transport during each morphological step. Calibration coefficients were applied to both terms in order to make the model produce reasonable equilibrium profiles and adaptation time scales. The results for a first test run are shown in Figure 13. Also in this run, a realistic dredging scenario was applied in the simulation, to avoid a build-up of sediment in the harbour entrance. The results appear to be more realistic, and show a clear accretion at the beach. The present settings of the cross-shore transport model are not ideal yet, and lead to profiles which are somewhat too steep;

this explains the erosion of the foreshore in areas outside the direct influence of the harbour.

Finally, the measured 1976 bathymetry is compared with the last simulation in Fig 14 and 15, respectively. This shows that the cross-shore transport module generates too steep profiles, on the other hand, it has the effect of shifting the coastal profiles in seaward direction in a more or less uniform way; this has important benefits in longer-term simulations. The overall shape of the coastal evolution is qualitatively in line with the observed shape.

All simulations shown so far underestimate the depth of the scour hole which develops in front of the harbour. A likely explanation for this is the lack of large-scale 2D turbulence generated near the breakwaters in the model. This is a point of further study at the moment.
Conclusions and recommendations

A method has been presented to estimate long-term bathymetric changes based on a single initial transport field. The results over a 5-year period show good agreement between the full morphodynamic MOR model and the simplified RAM approach.

For the present test case, the developments around the harbour entrance can be seen as separated from the coast, and can be modelled well using the RAM approach. This approach means a significant improvement over initial sedimentation/erosion models.

The quality of the initial transport field dominates the outcome; inaccurate modelling of the transport due to combined currents and waves can lead to completely wrong morphological developments. The large-scale 2D turbulence generated near the tips of the breakwaters is likely to be important and must be incorporated in the model.

The simulations with the full model taking into account more wave-related processes show much better predictions in the nearshore area. The processes active in this area cannot be represented in the RAM module for the moment. Further work should be done on implementing these processes in a simplified way.

Coastal Morphologic Variability of High Energy Dissipative Beaches

Peter Ruggiero1, George Kaminsky1 and Nathaniel Plant2

Abstract
A beach morphology monitoring program was initiated in the Columbia River littoral cell along the coasts of Oregon and Washington, USA, during the summer of 1997. The field program is designed to document short- to medium-term morphologic variability of the high-energy dissipative beaches within the littoral cell over a variety of spatial scales. Following the installation of a dense network of geodetic control monuments, a nested sampling scheme of cross-shore beach profiling, 3-dimensional beach surface mapping and shoreline reference feature surveying was devised. Monitoring is being conducted using RTK DGPS survey methods that combine both high accuracy and speed of measurement. Sampling methods resolve alongshore length scales of O(100 m) to O(100 km) and cross-shore length scales of O(1 m) to O(1 km). Long-term beach profile evolution, estimated via a comparison with surveys collected in the 1940s, feature regional variability. Some beach profiles revealed remarkably little change over the last 50 years. Although this study is in its infancy, large signals in both forcing and response have yielded exciting results. During the 1997/1998 winter, the littoral cell was influenced by one of the most significant El Niño events on record. Steeper than typical southerly wave angles forced alongshore sediment transport gradients that were evident in seasonal morphology on a regional scale. The morphologic data from the monitoring program are being integrated with other geophysical data sets to develop a conceptual model of the region and to begin shoreline change modeling to predict coastal evolution at a management scale (ie., decades and tens of kilometers). The magnitudes of both the environmental forcing and morphologic variability of the beaches along the Columbia River littoral cell are greater than the better understood, lower energy and more reflective beaches of, for example, Duck, North Carolina and the central Dutch coast (Holland). These differences in scale raise questions regarding the validity of directly applying morphologic change models developed from these coasts to the Columbia River littoral cell.

Introduction

A regional study of long-term coastal evolution and shoreline response has been initiated for a 160 km long littoral cell in the Pacific Northwest of the United States extending from Tillamook Head, Oregon to Point Grenville, Washington (Kaminsky et al., 1997). The Columbia River littoral cell (CRLC) is characterized by wide dissipative beaches of fine sand, ranging between 0.13 and 0.23 mm in mean diameter, typically backed by broad dune fields or sea cliffs. Beaches in the region have 3-dimensional multiple bar systems with infragravity energy dominating the inner surf zone. Four sub-cells exist within the region separated by three large estuaries, the Columbia River, Willapa Bay and Grays Harbor. Although this region is well known for the severity of its wave climate, most of the littoral cell has historically been accretionary. Recently, however, episodes of severe erosion throughout the cell (Figure 1) have resulted in lost or damaged infrastructure, threatening local economies. To date, millions of Federal and State dollars have been spent on erosion mitigation efforts. In many areas the long-term accretion appears to have slowed or even reversed, indicating a regional trend of erosion. Both anthropogenic influence and variability in large-scale environmental forcing may be causing these changes in morphologic behaviour.

Figure 1. The Columbia River littoral cell with erosion hot spots and the locations of long-term wave and tide measurements.
This paper discusses the variety of survey techniques being applied to and the initial results from a regional beach morphology monitoring program designed to quantify morphologic variability within the CRLC at a variety of spatial and temporal scales. The objectives of the monitoring program include: the quantification of short- to medium-term (event-seasonal-interannual) morphologic variability; development of data sets for beach profile modeling; shoreline change and coastal flooding predictions; and the comparison of variability scales with other coastlines. These objectives are aligned with a primary goal of the Southwest Washington Coastal Erosion Study, predicting coastal behaviour of the CRLC at a management scale. Several existing long-term monitoring programs, specifically the beach profiling done at the US Army Corps of Engineers Field Research Facility (FRF) in Duck, North Carolina and the Jarkus data base of the Dutch Department of Public Works (Rijkswaterstaat), provide guidance for designing sampling schemes. Since 1981, bi-monthly beach surveys have been collected at the FRF over a 1 km alongshore reach with the Coastal Research Amphibious Buggy (CRAB). Utilizing this dense data set, many researchers have examined long-term beach profile evolution and sand bar migration patterns to develop valuable engineering models of coastal morphology (eg., Larson and Kraus, 1994 and Plant, 1998). The Jarkus data set, which consists of 30 years of annual profiles spaced every 250 meters along the Dutch coast, has also led to advances in understanding temporal profile evolution and the spatial variability in morphologic behaviour. Components of these programs, particularly observations of meso- to large-scale fluctuations and alongshore inhomegenity, were considered in the design of the CRLC beach morphology monitoring program. The program has been established to acquire regional coverage of the littoral cell that is dense enough to resolve short-term change of kilometer scale evolution of the coastal planform. Results from this study are being used to develop a conceptual model of coastal morphologic variability on high-energy dissipative beaches.

**Monitoring Program Components**

Beach morphology monitoring is being conducted using Real Time Kinematic Differential Global Positioning System (RTK DGPS) surveying techniques, widely accepted as an accurate and efficient means to collect coastal morphology data (Morton *et al.*, 1993). The following sections describe the techniques associated with each component of the monitoring program.

**Geodetic Control**

In order to reference all monitoring program data to consistent horizontal and vertical datums, a dense network of 77 geodetic control monuments was established during the summer of 1997 (Figure 2a). After an inventory of existing monuments within the littoral cell, 13 additional monuments were installed to ensure consistent spacing of 3 to 4 km along the coast. A two-week field campaign was then conducted using 8 dual-frequency full-wavelength GPS receivers to establish a 2 cm-level vertical control network in accordance with the most recent guidelines provided by the National Geodetic Survey. The network has been referenced to the Washington State Plane (South) North American Datum of 1983 (NAD 83) and the land-based North American Vertical Datum of 1988 (NAVD 88).
Figure 2. a) Locations of geodetic control monuments and b) locations of beach profiles and 3 dimensional surface maps.
**Cross-shore beach profiles**

The high-energy dissipative beaches of the Pacific Northwest have been studied less intensely than the lower energy, more reflective beaches typical of the US East Coast. Initial attempts at creating a regional database (Peterson et al., 1994) and scattered work by resource management agencies, comprised the only beach morphology data for the Columbia River littoral cell before the onset of the Southwest Washington Coastal Erosion Study (Kaminsky et al., 1997). The first comprehensive regional morphology monitoring program began in the summer of 1997. In an effort to quantify seasonal morphologic change, cross-shore beach profiles are being collected bi-annually at 47 locations, spaced approximately 3-4 km throughout the littoral cell (Figure 2b). Profile locations are typically coincident with the locations of control network survey monuments. The beach profiles are obtained by walking from the landward edge of the primary dune to wading depth at spring low tides with a GPS receiver and antenna mounted to a backpack. Although the manufacturer's reported 3-dimensional error of the RTK GPS receiver is less than 2 cm, the vertical RMS error of this technique compared to surveying with a leveled pole and bipod is typically 4 cm. While not as accurate as standard terrestrial surveying, this technique is justified by both the reduction in survey time and the large morphologic change signals observed on these beaches. A field experiment scheduled to begin in spring 1999 will begin to examine beach profile evolution on even shorter (processes) time scales via bi-weekly surveys at a number of locations.

Due to the difficulty of surveying in the Pacific Northwest's dissipative, yet energetic nearshore environment (mean annual significant wave height is 2.0 m), most beach profiles do not extend beyond the inner surf zone. Willard Bascom and associates, in conjunction with the Wave Project of the University of California at Berkeley, collected the only set of nearshore bathymetric surveys in the region prior to the onset of this study (Komar, 1978 and Kraus et al., 1996). In an attempt to document long-term morphologic change, these profiles are now being re-occupied utilizing a new technique, the Coastal Profiling System (CPS), developed at Oregon State University (Beach et al., 1996, Cote et al., in press). The system consists of a Yamaha Waverunner III equipped with an RTK GPS receiver, an echo sounder and onboard data storage capabilities. The system was extensively tested during the SandyDuck field experiment at the FRF in the fall of 1997 with results indicating an RMS error ranging from 10 to 20 cm. A reconnaissance level, nearshore bathymetric survey campaign was initiated in the CRLC in April 1998. Beach profiles, spaced at 150 m over 2-3 km long sections, from the beach to the 12 m depth contour, have been collected in the approximate center of each of the four sub-cells. These study sites were chosen to overlap with beach surface mapping sites (described in the next section) and include Ocean City, Grayland, Oysterville, Rilea, and Fort Canby (Figure 2b). A series of seasonal surveys in April, July, and October 1998 is underway at the northern most site, Ocean City, WA, in an attempt to document seasonal bar migration patterns.

**Beach Surface Maps**

Although analysis of beach profiles can reveal both cross-shore variability in beach elevation and volumetric change over an individual profile, little information about the
longshore component of morphologic change can be obtained. In lieu of multiple closely-spaced cross-shore transects, three-dimensional surface maps are being generated by mapping the beach surface with a GPS antenna mounted to a six-wheel drive amphibious all-terrain vehicle called the CLAMMER (CoastaL All-terrain Morphology Monitoring and Erosion Research vehicle). Alongshore reaches, approximately 4 km in length, are being mapped between the toe of the primary dune and the swash zone (typically 100's of meters in the cross-shore direction due to mild sloping beaches). To determine both the alongshore and cross-shore morphologic variability at a variety of spatial scales, 16 sites (Figure 2b), totaling more than 60 km of alongshore distance, are being surveyed bi-annually.

Individual measurements are densely spaced in the alongshore direction, O(5-10 m), to resolve relatively small-scale features such as beach cusps, and are over long enough distances to resolve larger scale, potentially migrating features such as mega-cusps, rip-current embayments, sand waves and regional gradients. The cross-shore distance between alongshore transects is typically 20 - 30 m but is determined in the field based on cross-shore breaks in beach slope such as at swash bar crests and troughs. The non-uniformly spaced raw data (typically 5,000 to 10,000 points) is mapped onto a surface via triangle-based, weighted linear interpolation. The model surface is then interpolated on a uniform 2-dimensional grid for comparing subsequent data sets. Although individual model elevations feature sub-decimeter accuracy, the RMS error of the interpolated surface compared to detailed surveying using a leveled pole is typically 5 cm. Surface maps are collected bi-annually at all 16 sites to determine seasonal fluctuations, however, in areas that are eroding rapidly, survey frequency has been increased in an attempt to determine shorter scale temporal changes, eg. mega-cusp migration.

Other Monitoring Components
Four surface sediment samples are collected at each beach profile location, within the dune, at the dune toe, at mid-beach and within the swash zone at low tide. Sand grain size distributions are being determined by using ASTM approved dry sieves at quarter phi intervals following current EPA protocols for sediment analysis in the state of Washington. Modern shorelines are being mapped on rapidly eroding beaches by walking erosion reference features, such as scarps or driftlines, with a GPS backpack. This shoreline position data is being used to complement the historical shoreline change analyses being conducted by digitizing historical NOS topographic sheets and aerial photography (Kaminsky et al., in press, a). Shoreline change reference features also serve to expand the regional coverage between cross-shore profiles and provide a definite shoreline boundary to the beach surface maps. Several remote sensing techniques have also been applied within the CRLC as part of the Southwest Washington Coastal Erosion Study including airborne laser mapping and remote video technology. Lidar coverage, as part of a NASA/NOAA/USGS cooperative, will be used to create a high resolution Digital Elevation Model of the littoral cell. A video station (Argus camera) has been installed at Cape Shoalwater and a second station is scheduled for deployment at Ocean Shores in October 1998 for processes scale (e.g., mega-cusp migration) studies.
Waves and Water Levels

Coupled with the beach monitoring program is the long-term analysis of environmental data, e.g., waves and water levels. The locations of long-term wave (both NOAA and CDIP gages) and tide measurements are shown in Figure 1. Mean annual significant wave height along the CRLC is approximately 2.0 m with a peak period of 10 s with winter storms generating waves greater than 8.0 m with 20 s periods (Ruggiero et al., 1997). There is a distinct seasonality in wave height, period and direction with increased wave heights and periods propagating from the south in the winter and lower waves and periods arriving from the north in the summer. The littoral cell is meso-tidal with a 2.0 to 4.0 m range and winter water levels as much as 0.3 m higher than the summer water levels. Figure 3 illustrates the seasonality of both the water levels measured at Toke Point, WA, and the wave parameters taken from the Grays Harbor directional waverider buoy.

![Figure 3](image)

Figure 3. Monthly mean a) water levels, WL, for the Toke Point tide gage (NAVD 88), b) significant wave heights, Hs, c) periods, T, and d) direction, Ø, from the Grays Harbor buoy. Values from the 1997/1998 El Niño event are shown with darker lines and asterisks.

1997/98 El Niño

The winter of 1997/1998, the first winter of the monitoring program, coincided with one of the largest El Niño events of the 20th century. In the Pacific Northwest, strong El Niños are decadal scale forcing anomalies featuring increased frequency of extreme waves from the south-southwest and higher than normal sea levels (Komar and Good, 1989). During the previous major El Niño, 1982/1983, large wave heights and acute wave angles forced excessive offshore and northerly sand transport, causing severe beach erosion and shoreline orientation change that persisted for several years (Peterson et al., 1990). The 1997/1998 El Niño fit this pattern by generating some of the highest water levels on record in the Pacific Northwest (Figure 3a). Monthly mean water levels were
typically 10-15 cm higher than usual for much of 1997 with the main increase in elevation occurring in January and February 1998.

Wave conditions were also more intense than typical during the 1997/1998 winter. Figures 3b and 3c show the increase in monthly mean values for both significant wave height and period. The most intense month, February, featured wave heights on average of 1 m higher than normal with wave periods over 2 s greater than normal. During the months of January and February 1998 there were 13 storm events in which the significant wave height reached or exceeded 6 m, approximately the 1 year event (Ruggiero et al., 1997). Figure 3c shows that in January 1998 waves approached the coast from a more acute southerly angle than typical, as derived from monthly mean calculations since 1993, when the gage became directional.

**Initial Results**

Like any long-term monitoring program, the data collected as part of this study will increase in value over time. Although limited to one year of data at the time of this publication, the monitoring program is beginning to reveal scales of morphologic change within the littoral cell for comparison with lower energy reflective beaches. Results from other monitoring components, *i.e.*, Argus remote sensing techniques and shoreline change analyses will be provided in subsequent publications.

**Cross-Shore Beach Profiles**

The 47 beach profiles in the monitoring program provide a regional inventory of the variability of beach slope, elevation and volume change during the seasonal exchange from summer (calm or berm profile) to winter (storm or barred profile). In order to extract comparable quantitative statistics from beach profiles ranging over the 160 km long littoral cell, standard methods need to be adopted. Many predictive runup models depend on foreshore beach slopes, (Ruggiero et al., 1996). Therefore, slopes have been computed for each of the profiles between the 1.0 m and 3.0 m contour elevations. This definition of beach slope coincides with the Bascom (1951) definition of a "reference point" for comparison of profiles taken at a variety of locations, *i.e.*, the "part of the beach face subject to wave action at mid-tide elevation." The elevation of MSL varies along the length of the cell between approximately 0.9 and 1.4 m NAVD 88. Foreshore beach slopes vary between 1:100 and 1:10 while a mean slope for this dissipative cell is approximately 1:75.

Volume change between subsequent profiles has been calculated between the 1.0 m and 4.0 m contour elevations. Although many of the summer profiles extend to lower contours, the winter profiles were taken during periods of high wave conditions when both wave setup and swash limited the depth to which profiles could be safely obtained. The volume calculations have been further standardized, reducing the effect of beach slope variability, by normalizing by the cross-shore length between contours. Regional scale volume change is thus presented as an average vertical change across subsequent profiles between the 1.0 m and 4.0 m contours for each of the 47 profiles in Figure 4a. As anticipated, the southern ends of sub-cells, Ft. Canby, Cape Shoalwater and Ocean
Shores, experienced high levels of erosion during the El Niño winter of 1997/1998. The accretion at Tillamook Head (profile Seaside RM2) is associated with the northerly migration of a small creek, consistent with the expected pattern of El Niño influenced sediment transport. Remarkably, erosion hotspots at the northern ends of sub-cells, Clatsop Spit and Westport, showed net accretion during the winter. The three northern most sub-cells each reveal a trend of decreasing erosion from south to north, however erosion volumes are not balanced between erosion and accretion indicating substantial...
offshore sediment transport. A detailed description of other El Niño related observations can be found in Kaminsky et al. (in press, b). Initial analyses of profile data from the summer of 1998 reveal a surprisingly rapid recovery of many of the beaches within the cell. More data will be necessary to identify anomalous morphologic change signals in response to this decadal scale forcing event.

The Coastal Profiling System was utilized to extend the cross-shore beach profiles and surface maps beyond the swash zone at 5 locations during summer 1998, including 3 of the 9 Bascom profiles. A simple Hallemeir-type calculation based on the 1-year return wave height and period gives an estimated profile closure depth of 12 m. It was not always possible to survey to this depth during the field campaign due to high waves and fog. Figure 5 provides sample profiles, Ocean City (a) and Oysterville (b), in which CLAMMER and CPS data have been merged and compared to Bascom's data collected in the 1940s. The large gap in the Ocean City profile (approximately 300 m) is due to the CPS not resolving the bathymetry in the surf zone under relatively high wave conditions (approximately 3 m in April 1998). The origin of the coordinate system has been set at the cross-shore position of the 4.0 m NAVD 88 contour in the 1945 profile. The Bascom data was originally collected and reported in MLLW and has been adjusted to the land based vertical datum. Corrections for the horizontal offset between subsequent profiles were determined via historical aerial photographs and shoreline change rates.

![Figure 5](image-url)

**Figure 5.** Beach profiles at a) Ocean City and b) Oysterville comparing data collected by Bascom and associates in the 1940s with modern profiles collected with the Coastal Profiling System and the CLAMMER.

The example profiles illustrated in Figure 5 suggest that recent beach slopes are similar to those of Bascom's profiles collected over a half century ago. However, dramatic shoreline change has occurred during this period, with approximately 2 m of beach
elevation gain along most of the profile. The earlier surveys show substantial short-term fluctuations of the upper beach profile associated with either seasonal variability or alongshore sediment transport gradients. The modern Ocean City profile is different than the Bascom data in that the sand bar is broader and contains more sediment volume. The Oysterville data is remarkable, as the form of the profiles, separated by over 50 years, is almost identical with 3 distinguishable bars of similar magnitudes in the same cross-shore position. All sites where nearshore bathymetry has been collected are characterized by multiple barred profiles with varying levels of 3-dimensionality. Two offshore sand bars can be identified at each survey site between the 2.0 m and 7.0 m depth contours with vertical relief O(2 m). An additional bar in the swash zone at the 0.0 m contour was resolved in some cross-shore profiles. Sand bar formation and migration patterns will be determined from the series of quarterly surveys at Ocean City, WA.

**Beach Surface Maps**

Surface maps have been collected at 16 sites throughout the littoral cell in order to resolve 3-dimensional morphologic features and changes and to eliminate the alongshore aliasing problem of single cross-shore beach profiles. Figure 6 shows the difference between surface maps collected at Ocean Shores, WA, on 18 August 1997 and 27 February 1998. The patterns of alternating accretion and erosion represent the migration of morphologic features such as megacusps and rip current embayments. A series of monthly surface maps has been collected at this site since summer 1997 generating a 1-year time series of morphodynamic change. Superimposed on the map are the 1.0 m, 2.0 m and 3.0 m contour elevations over the 4 km stretch of beach. The average horizontal retreat of these contours has been calculated for each of the 16 surface maps. Flatter beaches will experience greater contour recession than steeper beaches for a similar forcing. For inter-comparison, the horizontal retreat has been normalized by multiplying the average beach slope along the length of the mapped region. This calculation gives a proxy for the average vertical change between the position of the elevation contours. Figure 4b illustrates this quantity for the 2.0 m contour between the summer 1997 and winter 1998 surface maps. These results show the regional gradient in erosion from south to north along each of the sub-cells. The southern boundaries at each sub-cell, Seaside, Fort Canby, North Cove and Ocean Shores, exhibited severe erosion, while the northern sub-cell boundaries all showed nearly the minimum elevation change for the sub-cell. Most of these areas are erosion hot spots, therefore it will be important for future monitoring to distinguish the El Niño signal from typical seasonal changes and long term trends.

**Engineering Applications of Morphology Data**

Beach morphology monitoring data is being directly applied to a variety of existing coastal processes models with the ultimate goal of predicting shoreline evolution. The Dutch model UNIBEST (Delft Hydraulics, 1995) is currently being applied to the northern sub-cell to model decadal scale shoreline evolution. Nearshore bathymetric surveys will be used in attempts to determine closure depths within the cell, a critical parameter in one-line shoreline change models such as UNIBEST. Engineering profiles such as the Dean equilibrium profile (Dean, 1977) and exponential profiles (Komar and McDougal, 1994) are being fitted to the measured cross-shore bathymetry for input into
these processes models. The tuning parameters for each model have been determined by minimizing the RMS error between the measured profile and the modeled profile in a least squares sense. The Dean profile typically has a slightly lower RMS error which better models the inner-surf zone, while the exponential profile performs better in deeper water.

Beach slopes and intersection elevations of the beach face and backing dune are being used in a probabilistic model (Ruggiero et al., 1996), developed specifically for high-energy dissipative beaches. The model evaluates the relative susceptibility of coastal properties to flooding and erosion based on extreme water levels and wave conditions. Model results will be used to enable coastal planners to make informed, long-term coastal management decisions. Surface mapping data, coupled with nearshore bathymetric surveys, are being used to quantify seasonal and long-term adjustments of the entire nearshore planform. Following a spring 1999 experiment, event driven cross-shore beach profile response will be correlated with environmental forcing data in efforts to calibrate cross-shore beach and dune erosion models for Pacific Northwest beaches.

Figure 6. Surface difference map for Ocean Shores, WA from 18 August 1997 to 27 February 1998. The grayscale bar to the right of the figure represents the vertical change over the mapped area with darker shades indicating erosion and lighter shades indicating accretion. The 1.0 m, 2.0 m and 3.0 m contour positions are shown for both the summer 1997 data, light lines, and the winter 1998 data, darker lines. Also shown in the diagram is horizontal retreat of the erosion scarp backing this site, dashed to solid line, and the location of a rock revetment (solid lines show the stepped revetment at the 400 m alongshore distance) designed to slow this shoreline retreat at one location.
Conclusions

A morphology monitoring program has been initiated in the CRLC, consisting of 47 cross-shore beach profiles and over 60 km of beach surface topography, documenting short- to medium-term morphologic variability. This program is beginning to provide regional scale quantitative data on high-energy dissipative beaches for the first time in the Pacific Northwest. The 1997/1998 seasonal response was very large, in part due to a major El Niño event. Gradients in sediment transport are evident in the regional morphologic response to this decadal-scale forcing event.

High quality long-term data sets exist in other locations, with two of the most comprehensive collected at Duck, NC and the Dutch coast. Much has been learned about morphologic behaviour at these sites and many models have been formulated from the data. In order to determine the applicability of these morphodynamic models to the CRLC, the scales of environmental forcing and morphologic response need to be compared. Table 1 lists several parameters and gives ranges and mean values from the CRLC as well as typical values for Duck and the central Dutch coast (Plant, 1998; Wijnberg, 1995). The CRLC features higher energy than the other two coastlines and the morphology is more dissipative with finer sediment sizes and lower beach slopes, β, both on the foreshore and within the surf zone (from the +1 m contour to 750 m seaward). At least for the winter of 1997/1998, the seasonal morphologic variability (average change in elevation across a profile, ΔZ, and the average 2.0 m contour recession, ΔX) appears to be greater in the CRLC than at Duck or in Holland. Future work will include the collection of data to improve the temporal resolution of morphologic variability and existing models will continue to be tested, identifying modifications necessary for application to the CRLC.

EFFECT RESONANCE ON MORPHOLOGY OF TIDAL CHANNELS

Willem T. Bakker

Abstract

Tidal basins with a length of the order of 1/4 of a wave length of the dominant tide, susceptible to resonance, occur on many sites on the world. This paper will show, that these basins can become morphologically unstable. The most primitive schematization possible has been investigated: a prismatic channel, closed at one end. Under some circumstances (for which dimensionless criteria are given), small increments in depth intensify the vertical tidal amplitude at the landward side of the basin, which in turn triggers increased erosion of the basin. Knowledge on this subject can lead to redirect sand fluxes in the basin by taking small measures just in time.

Starting from the assumption of a power-law sand transport formula, it is found, that for prismatic channels, morphodynamic instabilities occur when a small increment \( dh \) of depth generates a larger value \( 2 \) of \( Z_0/h \), where \( Z_0 \) is the amplitude of the vertical tide at the landward end of the channel. This criterion can be translated in relative length of the basin and in bottom roughness (fig.2).

Method

Only the Eulerian resultant current and the first harmonic of the tidal motion have been taken into account. The morphological model consists of 3 parts: "hydraulics"; "accretion/erosion" and "morphodynamic stability".

a. hydraulic computation (the water motion in the channel):
- The first harmonic is calculated analytically with the harmonical method of LORENTZ et al. (1926). If friction would have been neglected, the incoming tidal wave and the corresponding reflected wave would have resulted in a standing wave. However, friction makes the reflected wave much weaker than the incoming wave. Thus, the character of the wave shifts from "propagating" at the entrance of the basin (vertical tide and velocity are nearly in phase) to

2 I.e.: the generated relative increase of \( Z_0 \) should be larger than the assumed relative increase of \( h \)
"standing" at the closed end (90° phase difference between vertical and horizontal tide). The analytical computations can be presented in a dimensionless way. Results depend on angle $\theta$, indicating the rate of bottom friction: $\theta = 0^\circ$ for zero- and $\theta = 45^\circ$ for infinitely large friction.

- The tide-averaged Eulerian current below the LW-level is calculated in the following way. The harmonic Eulerian horizontal velocity in each point of the vertical cross-section above the LW-line is tide-averaged. During the part of the tide, when the level considered lies above the actual water level the velocity is taken equal to zero.

Next, these values are integrated over the height (between the LW- and HW-line), thus giving a tide-averaged residual flow rate above the LW-level. The magnitude of this Eulerian residual strongly depends on phase difference between vertical and horizontal tide.

- At the (seaward) end of the channel, the tide-averaged flux of water above LW will be relatively large and landward-directed: velocities there are high anyway and the horizontal and vertical tides are approximately in phase. At the closed end, all velocities are zero. Continuity requests a seaward-directed tide-averaged velocity below LW, increasing towards the entrance. Hence, all along the channel there must be a tide-averaged flux from the upper to the lower level, down through the LW-line (fig. 1).

BARKER & DE VRIEND (1995), consider a network instead of a single channel. They concentrate this flux in the nodes of the network and call it: "rain in the drain", because of the analogy with a drain system: water flushing in above the "pavement" (at LW-level) flushes out through the drain system, i.e. the tidal channels below LW. In the case presently considered, the "rain in the drain" is a continuous function of the horizontal co-ordinate $x$; its dimension is $(m^3/s)/m^2$. So it degenerates to a tide-averaged downward velocity (fig.1), called "w".

- the model has been checked (BARKER & DE VRIEND (1995); fig.6) with the fully non-linear DUFLOW computer model (SPAANS et al., 1989).

b. calculation accretion/erosion rate:
- The sand transport rate is assumed proportional to the third power of the velocity, the latter being represented by its zeroth and first harmonic. Thus the tide-averaged gradient of the sand transport (=erosion/accretion rate) is calculated analytically as a function of those zero- and first harmonics and their gradients in x-direction. The gradients in the tide-averaged current are caused by the rain in the drain. Dimensionless presentation is possible again.

c. Morphodynamic stability analysis:
- The stability analysis reveals, how hydraulic conditions change, when the water depth changes and whether this can be a reason for enhanced erosion. Rate of change of depth $dh/dt$ as function of depth $h$ (cf.ad "b") renders a differential equation, resulting in depth as function of time. Thus (in)stability can be determined.
Results

For derivations refer to "Details". Morphodynamic stability depends on the ratio $L^* = L/L_0$, where $L$ is the length of the channel and $L_0 = T \sqrt{gh}$ would be the tidal wave length, if friction would be neglected. Criterium for instability appears to be (cf.eqn. (9)) that a small increase of depth $dh$ increases $Z_0/h$, where $Z_0$ is the amplitude of the vertical tide at the closed end of the channel. Relative growth of $Z_0$ should surpass the one of $h$. If friction is very low ($\theta = 7.5^\circ$) instability would occur for values of $\frac{3}{4} < L^* < \frac{1}{4}$ and $\frac{3}{4} < L^* < \frac{1}{4}$ (standing-wave effects). If friction is higher, near the entrance no effect of reflection is found: here the tidal wave is a propagating, attenuating wave. After some initial deepening, reflection may reach the entrance: this will increase the tidal motion and trigger further deepening. This kind of instability occurs for $L^* > \frac{1}{2}$ ($\theta = 30^\circ$) or $L^* > \frac{1}{4}$ ($\theta = 37.5^\circ$).

Figure 2, Explanation:
The following criterion will be derived for instability of the channel (cf. eqn.(12)):
\[
\frac{d(\log Z)}{dx^*} \bigg|_{x=L} > 2L^* \tag{1}
\]
where $x$ is the horizontal coordinate of the prismatic channel, starting at the closed end of the channel and pointing seaward; $\xi$ is the local amplitude of the vertical tidal wave related to its value at the closed end.
The figure depicts the lefthand side of equation (1) as function of $x/T\sqrt{gh}$. Thus, for a given case, determined by $L^*$ and friction factor $\theta$ the value of the lefthand side of (1) is determined by a point in the plot of the figure. If this point is in the gray area, the case is unstable.

Relation to other investigations: discussion of assumptions

Classifying estuary models as empirical models, semi-empirical models and dynamical models, the present model should be earmarked as a one-dimensional analytical dynamical initial morphological model. Equilibrium conditions are not assumed a priori, contrarily to many morphological models, like BRUUN & GERRITSEN, 1960, which start from assumptions that a profile adjusts itself until a certain maximum shear stress is reached.

It is a core model with a large mathematical rigidity, aiming at the demonstration of easy to understand input-output relations. Where on one hand matters as (for instance) interaction between shoal-channel interaction remain (as yet) out of scope, on the other hand no further unknowns like diffusion coefficients are introduced.

The present model is "initial": difference between absolute instability and metastability is not made. The present investigation is a part of a joint Dutch effort to improve the insight in the morphodynamics of Wadden Sea and estuaries. This concerns as well the tidal basins itself as its interaction with the adjacent outer delta's.
BAKKER & DE VRIEND, 1995 report on the general approach of this problem. One of the constituents is: modeling the behaviour of the outer delta under the influence of a combination of sources and sinks (DE VRIEND et al., 1994). Source is the sand output of ebb-channels in the outer delta, a sink (for the outer delta) is the influx of sand in the tidal basin through a flood channel.

Another constituent (one of the other subjects of BAKKER & DE VRIEND, 1995) is the quantification of such a "source": an embouching ebb-channel as most seaward channel of a network of channels in the tidal basin. Furthermore, BAKKER & DE VRIEND (1995) treat the morphological behaviour of those tidal channels itself, using the results of the present paper.

The power-law transport formula presumes immediate adjustment of sand transport to bed shear; the transport rate equals the transport capacity. In the present model all sediment is transported below LW. This excludes the effect of fines, which explains why near the closed end of the estuary hardly any bottom change is found; partly because of low velocities, partly because horizontal and vertical tide are 90° out of phase. In practice, those areas will silt up quickly. Possibly, combination of present theory with the theory of KROL (1990), assuming a uniform sediment concentration over the depth, could shed any light on this matter. Water motion being investigated only up to first order of accuracy, effects of imported or internally generated higher harmonics are overlooked. In practice, those might lead to sedimentation of (short) basins (VAN DONGEREN & De VRIEND, 1994). On the other hand, V.D.KREEKE & ROBACZEWSKA (1993), investigating for the Ems estuary interactions of $M_0 - M_2$, find the tide-averaged sediment transport dominated by interactions between $M_0$ and $M_2$. Thus, for longer channels the used schematization might be appropriate.

BLIEK points out (cf. BARKER et al. (1998)) that also in well-mixed estuaries mostly a longitudinal salt gradient will counteract the rain in the drain. At a smaller space scale the horizontal tide-averaged circulation in ebb- and flood channels will interact with the "rain in the drain" effect. The "closed" end of the channel does not have to be strictly "closed". An extensive underwater sill (artificial? sand? silt?) with (about) the same reflection coefficient for the tide as the closure dam could react morphodynamically about in the same way. Refer furthermore to ch.7 ("Discussion") of BAKKER & de VRIEND (1995).

Details.

**Hydraulic calculation**

Concerning the first harmonic of the vertical and horizontal tidal motion, the relevant equations of the Lorentz method are summarized in Appendix A. Let $\zeta(x, t)$ denote the elevation of the water surface (in reference to the still-water level) and $\mathbf{v}(x, t)$ the horizontal motion, which is assumed uniform over the depth.

The positive $x$-axis, originating at the closed end of the channel points seaward; $t$ denotes time. Given channel length and depth, amplitudes $\zeta$ and $\mathbf{v}$ depend upon the bottom friction, in the Lorentz method determined by the friction angle $\theta$.

In the following, dimensionless variables (cf."Method") will be indicated with a star.

---

3 This under the restriction of zero (or slightly seaward) tide-averaged drift at the site of the sill
fig.3. Amplitude vertical tide and horizontal tide along the channel; phase difference vertical tide and horizontal tide; comparison numerical and analytical computation.

a: Vertical tide; b: plan view channel; c: horizontal tide; d: Phase difference
As elucidated in appendix A, fig. 3a shows the dimensionless amplitude $\zeta^*$ of $\zeta$ as function of $x^*$. Curves are given for various values of $\theta$. In the same way, fig. 3b shows the velocity amplitude $\vartheta^*$. For zero friction, curves would have the shape of a $|\cos|$- and a $|\sin|$-function, respectively.

Important for the calculation of the tide-averaged resultant current is the phase difference of the first harmonic between $\zeta$ and $v$, called $\phi$. Fig. 3c depicts the phase difference $\phi$ between $\zeta$ and $v$. Phase difference is about $180^\circ - \theta$ near the seaward end and is $90^\circ$ at the landward end. This indicates, that the wave has the character of a propagating wave at the seaside (moving in negative $x$-direction) and of a standing wave at the closed side.

Checking the values with a non-linear computation is difficult, as - because of non-linear friction - a constant Chezy-friction value does not result in a constant $\theta$-value over the channel. Furthermore, for friction values which are physically real the reflected wave under normal conditions of real estuaries practically always will be attenuated after half a wave length or less: values of $\theta$ of $7.5^\circ$ or $15^\circ$ are not very likely in practice.

In order to check the mathematics, some tests with physically unrealistic values of the Chezy-value have been performed. Two cases have been checked, in which the channel length was $L_0$ and $L_0/4$ respectively. The channel length in either case was equal (86.4 km), but the depth $h$ was different: .408 m, resp. 16*.408=6.41 m. The tidal wave period $T$ was taken: 12 hours. Chezy-values $C_h$ were: 120, resp. 60 $\sqrt{m/s}$ and the amplitude $i_s$ at the seaward boundary was taken $h/10$.

When relating $C_h$ to $\theta$, the velocity amplitude $\vartheta$ enters the formula (see (A3)). In the case of a channel with a closed end, neglecting friction, one finds a channel-averaged value of $\vartheta$:

$$\vartheta = \frac{2}{\pi} \frac{\zeta_0}{h} \sqrt{gh}$$

(2)

Here $\zeta_0$ denotes the vertical wave amplitude in the antinodes.

Then from (A3) the following relation between relation between $C_h$ and $\theta$ can be derived:

$$\tan(2\theta) = \frac{8}{3\pi^3} \frac{C_h^2}{h^3} \frac{L_0 g}{h}$$

(3)

For the $L_0/4$-channel a value $\theta = 25.44^\circ$ is found. For the $L_0$-channel, the fact that friction is neglected in the derivation of (2) gives some ambiguity: in fact $\vartheta$ in the most landward node (at $x = L_0/4$) will be much less than the one in the most seaward node ($x \approx 3L_0/4$). If for $\zeta_0/h$ in (3) the seaward boundary value of .1 is taken,
the same value of θ results as for the $L_4/4$-channel as (3) shows. However, if one takes for $\xi_0/h$ the value at the landward side of the channel, which is $0.1377/0.408$, a value of $11.37^\circ$ is found. Thus, for the $L_0$-channel $\theta$ should be in the range $11.4^\circ < \theta < 25.4^\circ$.

Fig. 3abc shows the correspondence between the given ranges of $\theta$, for the amplitudes of the vertical and horizontal tide, as well as for the phase differences.

**Calculation accretion/erosion rate**

Let $S_1$ be (in magnitude) the transport (per unit of width), when the velocity is 1 m/s. Writing $S = S_1v^3$, the appropriate unit for $S_1$ is [sec$^2$/m], since the transport is expressed in m$^2$/sec. The calculated transport rate is expressed in terms of deposited sediment volume. In order to obtain the solid volume, one should multiply by 1- the pore content of the bed.

Denoting tide-averaged values by $<>$, the third-power sand transport formula yields for the tide-averaged local erosion rate, $< \partial h / \partial t >$:

$$< \frac{\partial h}{\partial t} > = \frac{3S_1v^3}{2h} (w + 2\delta \omega \xi \sin \phi)$$

(4)

This equation is derived in Appendix B. Here $\omega$ is the angular velocity of the dominant tidal constituent (mostly $M_2$) and $\delta$ and $w$ are defined by:

$$\delta = \frac{\langle v \rangle}{\bar{v}}$$

$$w = h \frac{\partial \langle v \rangle}{\partial x}$$

(5a, b)

$w$ being the rain in the drain. Starting from the definitions (5a, b) $w$ can be expressed as:

$$w = h \left( \frac{d\delta}{dx} + \delta \frac{d\bar{v}}{dx} \right)$$

(6)

The second term inside the brackets of (4) shows the effect on the erosion $< \partial h / \partial t >$ of the phase coupling between vertical tide $\xi$ and horizontal tide $v$: $\sin \phi = 1$ for a standing wave, where $\xi$ and $v$ are out of phase and $\sin \phi = 0$ when $\xi$ and $v$ are in phase).

For the derivation of (4), it has been assumed, that $\delta$ is much smaller than 1.

Remembering that $gS_1$ is dimensionless one may write (4) in a dimensionless form, yielding:

$$\frac{\partial h^*}{\partial (\omega t)} = \frac{gS_1}{(h^*)^2 (h^*-1)} f(x^*, \theta)$$

(7)

4 for the long channel $\xi_0/h$ remains the same; $L_0$ is divided by 4 and $h$ is divided by 16; $C_k$ is multiplied by 2.
Function $f(x^*, \theta)$ (of which the exact expression is derived in appendix C) follows from (4) to (7) and the harmonical tidal theory (LORENTZ et al. (1926); THIJS-SE (1965)). It is depicted in fig. 4.

\[
\frac{x}{T \sqrt{gh}}
\]

\[

\]

\[
\theta = 22.5^\circ
\]

\[
\theta = 15^\circ
\]

Fig. 4. Dimensionless accretion/erosion as function $f(x^*, \theta)$ of site and bottom friction

**Morphodynamic stability analysis**

With the aid of (7), the morphological instability of a channel can be traced. Here instability will be defined as an acceleration of erosion ($\frac{\partial^2 h}{\partial t^2} > 0$).

Mechanism will be: increased $h$ gives increased tidal wave length, whence the ratio "channel length/ wave length" becomes less. When originally the channel was somewhat larger than 1/4 of a wave length, a subsequent decrease of the relative channel length enhances the wave amplitude $Z_0$ at the closed end of the channel. This may enhance the erosion process in the channel, etc.

In the following some simplifying assumptions will be made: the effect of changes in friction (in angle $\theta$ and thus in $f(x^*, \theta)$) will be neglected. As $\theta$ tends to decrease during the erosion process described, the probability of instability will be underestimated.

Let $x^*$ be the dimensionless channel length and let $\bar{f}$ be the mean value of $f$ between 0 and $x^*_r$.

The tide-averaged equivalent of eqn. (7) shows, that if $x^*$ is such, that $\bar{f} > 0$ no instability has to be expected.

Investigate now the case: $\bar{f} < 0$. Considering eqn. (7) as a differential equation in a dimensionless depth and a dimensionless time, it seems logical to incorporate the dimensionless $gS_f$ in the reference time scale, call $t_0$:

\[
t_0 = -\frac{T}{(2\pi \bar{f} g S_f)}
\]

Thus switching from the hydraulic time scale to the morphological time scale,
Note that in the present case \((\tilde{f} < 0)\) \(t_0\) will be larger than zero.

For convenience, the dependent variable \(h^*\) in (7), equal to \(h/Z_0\), will be replaced by \(h' = h/Z^*_s\), in which \(Z^*_s\) is the amplitude at the seaward boundary. For \(h'\) only changes in time if \(h\) changes, where in \(h^*\) a change of \(h\) affects also the reference, i.e., the vertical tide \(Z_0\) at the closed end of the channel. Denoting \(t/t_0\) by \(t'\), and \(Z^*_s/Z_0\) by \(Z^*_s\), the non-dimensional depth-evolution equation becomes:

\[
\frac{\partial h'}{\partial t'} = [(h'Z^*_s)^2 (h'Z^*_s - 1)]^{-1}
\]

(9)

where \(h'Z^*_s\), equal to \(h/Z_0\) can be assumed much larger than 1. Instability occurs, if the righthand part of eqn.(9) increases with \(h'\). This implies, that \(h/Z_0\) should decrease as \(h'\) (or \(h\)) increases. In other words: instability occurs when \(\partial(h'Z^*_s)/\partial h'\) is negative. Thus the stability criterion is:

\[
\xi^*_s + \frac{h \partial \xi^*_s}{\partial h} > 0 \implies \text{stable} \quad (10a)
\]

\[
1 + h \frac{\partial (\ln \xi^*_s)}{\partial h} > 0 \implies \text{stable} \quad (10b)
\]

Here one finds \(\partial (\ln \xi^*_s)/\partial h\) as:

\[
\frac{\partial (\ln \xi^*_s)}{\partial h} = \frac{\partial (\ln \xi^*_s)}{\partial x^*} \cdot \frac{\partial x^*}{\partial h}
\]

(11)

Differentiation of \(x^* = x/T\sqrt{gh}\) to \(h\) gives \(-x^*/(2h)\) as result. Thus the stability criterion becomes:

\[
\frac{\partial (\ln \xi^*_s)}{\partial x^*} < \frac{2}{x^*} \implies \text{stable} \quad (12)
\]

Here \(x^*\) denotes the channel length, expressed in \(T\sqrt{gh}\). In fig. 2, both \(\partial (\ln \xi^*_s)/\partial x^*\) and \(2/x^*\) are plotted. All the points above the line \(2/x^*\) (which corresponds with a certain dimensionless channel length and a certain friction angle \(\Theta\) ) refer to potential unstable channels, provided that \(\tilde{f}\) (cf. fig 4) is negative.

When the channel length is less than about a quarter of a wave length, no instabilities are found. However, longer channels with a moderate bottom friction should theoretically become often unstable.

\[\text{6 This was, mentioned in "Results"}\]

The author gratefully acknowledges the work done by Mr.G.Bult, in checking the analytical results with DUFlow. The reviews of C.v.d.Kreeke, A.Langerak, K.Dyer, E.Bouwmeester and A.Baquerizo were stimulating. Special thanks to prof.dr.ir H.J. de Vriend for his comments and support.

Appendix A. The Lorentz theory

The Lorentz theory starts from the linearized equation of motion and the continuity equation, viz.:

\[
\frac{\partial v}{\partial t} + g \frac{\partial \xi}{\partial s} + (\omega \tan 2\theta)v = 0 \quad (A1)
\]

\[
\frac{\partial \xi}{\partial t} + h \frac{\partial v}{\partial t} = 0 \quad (A2)
\]

Here, \(\omega \tan 2\theta\) is a linearized friction coefficient, related to the Chezy coefficient \(C_h\) in the following way:

\[
\omega \tan (2\theta) = \frac{8g}{3\pi C_h^2} \frac{\bar{v}}{h} \quad (A3)
\]

For the case of a prismatical channel, closed on one side, the following solution is found, which can be presented in a dimensionless way.

Define the complex function \(Z(kx)\) in such a way, that

\[
\xi(x,t) = Z_0 \text{Re}\{Z(kx)e^{i\sigma t}\} \quad (A4)
\]

and the complex function \(V\) such, that

\[
v(x,t) = Tg/h \text{Re}\{V(kx)e^{i\omega t}\} \quad (A5)
\]

where the wave number \(k\) equals:

\[
k = \frac{\omega}{c} (1 - i \tan \theta) \quad (A6)
\]

and where the propagation velocity \(c\) of a wave component (incoming or reflected) equals:

\[
c = \sqrt{gh(1 - \tan^2 \theta)} \quad (A7)
\]

In the paper, the horizontal coordinate is dimensionless \((x')\), where in (A4) and (A5) still the original coordinate \(x\) is used; however, \(kx\) is dimensionless and can be written as \(k'x''\), where \(k'\) can be derived from (A6) and (A7).

For the given boundary conditions the solution of (A1) and (A2) is:

\[
Z = \cos kx \quad V = i \sqrt{\cos 2\theta \sin kx} \quad (A8)
\]

\(\bar{v}\) and \(\xi\) are found as the modulus of \(Z\) and \(V\) and are shown in fig.3\(a\) and 3\(c\). The difference in argument between \(Z\) and \(V\) is depicted in fig.3\(d\).
Appendix B. Derivation of equation (4)

The local erosion according equation (4) can be derived from the transport equation. Splitting into means and harmonics gives (indicating first harmonics by a tilde):

\[
\frac{\partial \mathcal{S}}{\partial x} = 3 S_1 (\bar{v} + <v>) \left( \frac{\partial \bar{v}}{\partial x} + \frac{\partial <v>}{\partial x} \right) \tag{B1}
\]

Neglecting the effect of bottom changes, the equation for momentaneous continuity of water gives:

\[
-h \frac{\partial \bar{v}}{\partial x} = \frac{\partial \zeta}{\partial t} \tag{B2}
\]

According to (B2) \( \partial \bar{v} / \partial x \) is proportional to \( \partial \zeta / \partial t \), of which the phase is 90° ahead with respect to \( \zeta \). Denoting the phase difference between \( \bar{v} \) and \( \zeta \) by \( \phi \), the phase difference between \( \bar{v} \) and \( \partial \bar{v} / \partial x \) will be 90° - \( \phi \).

Choose \( t = 0 \) in this way, that \( \bar{v} = \bar{v} \sin \omega t \). Use of (B2), (5a) and sand continuity transfers (B1) into:

\[
\frac{\partial h}{\partial t} = 3 \frac{S_1 \bar{v}^2}{h} \left( \sin \omega t + \delta \right)^2 \left( \omega \xi \sin \frac{\omega t + \pi}{2} - \phi \right) + \omega \right) \geq 0 \tag{B3}
\]

Neglect of \( \delta^2 \)-terms leads to (4), as all odd powers of \( \sin \omega t \) and combinations of \( \sin \omega t \) and \( \cos \omega t \) cancel during the time-averaging process.

Appendix C. THE FUNCTION \( f(x^*, \theta) \)

The function \( f(x^*, \theta) \) has been derived from (4). The equation has been made dimensionless by dividing by \( -\omega Z_0 \); thus emerges the lefthand side of (7).

Call \( \xi \) the dimensionless local amplitude of \( \zeta \).

For the flux above the LW-line (calculated as described in "Method") is found: \( (\bar{v} \cos \phi) / 2 \).

Because of continuity, this flux should pass (in opposite direction) as well between the LW-level and the bottom. It is assumed, that the latter flux is stationary and uniform over the depth. Approximating further this separation plane between seaward and landward flux as horizontal, i.e. everywhere equal to the LW-level at the closed end of the channel, one finds for \( \delta \):

\[
\delta = \frac{(\xi Z_0) \cos \phi}{2 \left( \frac{h}{h_0} - 1 \right)} \tag{C1}
\]

Here \( \xi \) indicates the local tidal amplitude and \( Z_0 \) the amplitude at the closed end of the channel.

Furthermore \( \delta \) will be replaced in this Appendix by a more concise variable \( \delta^* \):

\[
\delta^* = \frac{\xi}{2} \cos \phi \tag{C2}
\]

and thus, according to (C1), \( \delta = \delta^*(h^* - 1) \). Thus (6) reads, in a dimensionless way:

\[
\frac{w}{\omega Z_0} = \frac{1}{2 \pi (h^* - 1)} \left( \frac{\partial \delta^*}{\partial x^*} + \delta^* \frac{\partial \delta^*}{\partial x^*} \right) \tag{C3}
\]
Substitution of (C3) into (4) gives, in a dimensionless shape:
\[
\frac{\partial h^*}{\partial t} = \frac{gS_i}{h^* (h^* - 1)} \frac{3}{2} \frac{\partial^2}{\partial x^2} \left[ \frac{1}{2\pi} \left( \psi^* \frac{\partial \psi^*}{\partial x} + \phi^* \frac{\partial \phi^*}{\partial x} \right) - 2 \delta^* \frac{\partial \phi^*}{\partial x} \sin \phi \right]
\]
(C4)

Using (7) and (C4), and after substitution of (C2), one can express \( f(x^*, \theta) \) in values, to be derived from the Lorentz theory (1926; app.A):
\[
f(x^*, \theta) = \frac{3}{2} \frac{\partial}{\partial x} \left[ -\frac{1}{4\pi} \left( \psi^* \frac{\partial \psi^*}{\partial x} + \phi^* \cos \phi \frac{\partial \phi^*}{\partial x} + \phi^* \cos \phi \frac{\partial \phi^*}{\partial x} \right) + \phi^* \right]
\]
(C5)

This function \( f(x^*, \theta) \) has been depicted in fig.4. It is memorized, that in the Lorentz theory vertical and horizontal tide are found as the real part of the complex values \( z^* \) and \( \nu^* \) (made dimensionless according to (A1a,b) and to be multiplied with \( \exp(i\omega t) \)):
\[
\begin{align*}
Z &= \cos kx \\
V &= i\sqrt{\cos 2\theta \cdot \sin kx}
\end{align*}
\]
(C6)

with:
\[
\begin{align*}
k &= \frac{-1}{\tan \theta} \\
c &= \sqrt{gh (1 - \tan^2 \theta)}
\end{align*}
\]
(C7a,b)

The difference in argument between \( Z \) and \( V \) is depicted in fig.3d; \( \xi \) and \( \nu \) are found as the modules of \( Z \) and \( V \).

INLET CROSS-SECTIONAL AREA CALCULATED
BY PROCESS-BASED MODEL

Nicholas C. Kraus

ABSTRACT: This paper introduces a process-based model for calculating the equilibrium cross-sectional area of a tidal inlet and temporal behavior of small perturbations in channel area from equilibrium. The model accounts for the dynamic balance between inlet ebb-tidal transport and longshore sand transport at the inlet entrance. Expressed in terms of a water discharge through the inlet and the gross longshore sand transport rate, the formulation can account for tidal, river, and wind-driven flows. The resultant predictive equation recovers the form of the well-known empirical formula \( A_E = CP^n \), where \( A_E \) is the equilibrium (minimum) cross-sectional area, \( P \) is the tidal prism, and \( C \) and \( n \) are empirical coefficients. An explicit expression is obtained for \( C \) in terms of coastal sediment-transport processes, and the value of \( n \) derived is in the range found empirically. The process-based model qualitatively predicts the difference in trends in inlet cross-sectional area on wave-sheltered and fully-exposed coasts. In time-dependent mode, the model reproduces qualitative behavior of the departure of the cross-sectional area from equilibrium under perturbations in the driving forces of discharge and waves.

INTRODUCTION

A quantitative empirical relation between the equilibrium or minimum stable cross-sectional area \( A_E \) of an inlet and its tidal prism \( P \) has been known for almost a century (LeConte 1905). Based on data from a limited number of locations along the coast of California, LeConte arrived at the linear equation \( A_E = CP \). The value of the empirical coefficient \( C \) was about 34 % larger for inner harbor entrances (restricted longshore sediment transport) than for unprotected entrances (unrestricted longshore transport). LeConte’s observation indicates that the same tidal prism on a coast with restricted longshore transport can maintain a larger equilibrium channel area than on a coast with less restricted or greater longshore sediment transport.

The presently accepted empirical relation for the cross-sectional area of inlets on exposed coasts is still expressed in terms of the bulk properties of the hydrodynamics

3265
(tidal prism). Following the work of O'Brien (1931, 1969), Johnson (1972), and others, Jarrett (1976) analyzed 108 inlets (yielding 162 data points) along the Atlantic, Gulf, and Pacific Ocean coasts of the United States. His objectives were to determine if inlets on all three coasts of the United States follow the same inlet area – tidal prism relation, and if inlet stabilization altered that relation. With relatively high correlation coefficients, all predictive relations were found to fit the form

$$A_E = CP^n$$  \hspace{1cm} (1)$$

in which $C$ and $n$ are empirically determined. Jarrett found the exponent $n$ to vary between 0.86 and 1.10 for inlets with no jetty or with a single jetty and between 0.85 and 0.95 for inlets with two jetties. For coasts fully exposed to wave action, $n$ varied between 0.85 and 0.95.

Table 1 summarizes Jarrett's findings (converting his U.S. customary units to metric units). Among other observations, Jarrett (1976) noted that the smaller waves on the Gulf coast relative to those on the Pacific Coast and on (most of) the Atlantic Coast would produce smaller littoral drift.

The concept that the equilibrium area of an inlet (tidal entrance or river mouth) is determined by a balance between the transporting capacity of the inlet flow and the littoral or longshore transport has appeared throughout the literature (e.g., LeConte 1905, O'Brien 1931, 1969, Bruun and Gerritsen 1960, Bruun 1968, Byrne et al. 1980, Riedel and Gourlay 1980, Hume and Herdendorf 1990). In particular, Byrne et al., Riedel and Gourlay, and Hume and Herdendorf studied inlet channel stability on sheltered coasts and demonstrated that larger values of the empirical coefficient $C$ and smaller values of $n$ apply to coasts with limited littoral transport. Quoting Riedel and Gourlay, "In contrast (to exposed coasts), for sheltered inlets the littoral drift rate is small and, consequently, a much smaller volume of material needs to be moved out of the entrance in each tidal cycle." The aforementioned three studies also indicate that the mean-maximum velocity (mean over the cross section of the maximum at spring tide; see Bruun (1978), p. 321) required to maintain stability of the inlet channel is less (reaching approximately one-third less) than the typical 1 m/s (Bruun and Gerritsen 1960, O'Brien 1969) required to maintain a channel on an exposed coast.
Changes in inlet cross-sectional channel in response to changes in hydrodynamic forcing (waves, tidal or river current, tidal range, storms) have been documented by Mason and Sorensen (1972), Byrne et al. (1974), Behrens et al. (1977), FitzGerald and FitzGerald (1977), Nummedal and Humphries (1978), Van de Kreeke and Haring (1980), and others. FitzGerald and FitzGerald also discuss inlet channel response to changes in neighboring beach morphology.

In this paper, a mathematical model is introduced that describes, in a rational and quantitative way, the two main concepts described above. First, the model produces an equilibrium or stable channel cross section under the balance of tidal (and river) transporting capacity and the longshore sediment transport at the inlet. Second, the model can describe variations of the cross-section about its equilibrium in response to small changes in sediment-transport forces. The time scale governing the response of a channel to perturbations is also obtained.

**PROCESS-BASED APPROACH**

In the following, a tidal-inlet entrance or river mouth is considered on an alluvial shore with no geologic controls such as a rock or clay substratum.

Referring to Fig. 1, we assume that an ebb shoal or entrance bar forms and is maintained by a balance between the transport capacities of the ebb-tidal (or river) current and the longshore current. The gross longshore transport rate $Q_g$ is given by

$$Q_g = \varepsilon_L Q_L + \varepsilon_R Q_R$$

where $\varepsilon_L$ and $\varepsilon_R$ are efficiency factors associated with the longshore transport rates for sediment moving to the left (for an observer on land) at rate $Q_L$ and to the right at rate $Q_R$. The efficiency factors vary, in general, functions of time and vary between the limits $0 \leq \varepsilon \leq 1$ to account for blocking at jetties, bar bypassing, sediment availability, and similar processes. In this paper, $\varepsilon = 1$.

![Fig. 1. Definition sketch for process model, (A) plan view, and (B) cross-section view.](image)
The rate of sediment transport out of the inlet entrance is \( qW \). Here \( q \) is the rate per unit width (m\(^3\)/s per meter across the inlet channel) as transported by the current (whether tidal-ebb, river-, or wind-generated current, or a combination), and \( W \) is the width of the inlet. We are interested in the channel equilibrium area, related to the water volume above the sea bottom. The time rate of change in bulk volume of sediment transported to the channel \( V_s \) and that of the volume of water \( V \) above the bed are related as \( dV_s/dt = -dV/dt \), where \( t \) is time. Balance of the rates of sediment transported to the channel bar in Fig. 1 with the change in volume of water above the channel gives

\[
\frac{dV}{dt} = qW - Q_g \quad (3)
\]

If simple rectangular geometry for the entrance bar is assumed such that the \( V = BWh \), where \( B \) and \( h \) are, respectively, the cross-shore width of and depth over the bar, and further assuming \( B \) is constant, then the channel area \( A = WH \), and Eq. 3 becomes

\[
\frac{dA}{dt} = \frac{W}{B} \cdot \frac{1}{B} \cdot q - \frac{1}{B} Q_g \quad (4)
\]

The gross longshore sediment transport rate \( Q_g \) will be assumed to be known, as from the CERC formula or data. The transport rate \( q \) will be expressed as a Meyer-Peter and Muller (power law) in the form expressed by Watanabe et al. (1991) as

\[
q = a \left( \tau_m - \tau_c \right) v_m \rho g \quad (5)
\]

in which \( a \) is an empirical coefficient expected to be of order unity, \( \tau_m \) is the bottom shear stress associated with the mean maximum velocity, \( \tau_c \) is the critical shear stress for sediment transport, \( \rho \) is the fluid density, \( g \) is the acceleration of gravity, and \( v_m \) is the depth-averaged mean-maximum velocity along the channel. In the following, \( \tau_c \) will be neglected. The critical shear could play a role at inlets where the hydrodynamic forces are weak or at inlets with coarse sediments.

The bottom shear stress under the maximum current is parameterized as

\[
\tau_m = \rho c_f v_m^2 \quad (6)
\]

where \( c_f \) is a bottom friction coefficient taken to be \( c_f = g m^2/h^{1/3} \) where \( m^2 \) is the Mannings coefficient squared (units of \( s^2/m^{2/3} \)). Then Eq. 5 becomes,

\[
q = \frac{a m^2}{h^{1/3}} v_m^3 \quad (7)
\]

and Eq. 4 becomes

\[
\frac{dA}{dt} = \frac{\alpha m^2 W}{B h^{1/3}} \left( \frac{D_m}{A} \right)^3 - \frac{1}{P} Q_g \quad (8)
\]
in which the velocity was replaced by \( v_m = D_m/A \), where \( D_m \) is the maximum discharge, for example, the mean-maximum discharge at spring tide for the case of a tidal inlet without river flow or other non-tidal contribution to the discharge.

At equilibrium, \( dA/dt = 0 \), giving the equilibrium or minimum channel cross-sectional area \( A_E \) as

\[
A_E = \Lambda_h D_m
\]  

where

\[
\Lambda_h = \left( \frac{\alpha m^2 W_E}{h_E^{1/3} Q_g} \right)^{1/3}
\]  

in which \( h_E \) and \( W_E \) are the depth and width corresponding to the equilibrium area \( A_E \). It is noted that a linear form as Eq. 9 will result for any transport rate formula for \( q \) that is a simple algebraic function of \( v_m \) or \( D^m \).

Eq. 9 has the same form as the classical Eq. 1, but with the tidal prism \( P \) replaced by the discharge \( D \). At equilibrium we have \( h_E = A_E/W_E \), where \( W_E \) is the width of the channel at equilibrium. Replacing \( h_E \) in Eq. 10 by this relation results in

\[
A_E = \Lambda D_m^{0.9}
\]  

where

\[
\Lambda = \left( \frac{\alpha m^2 W_E^{4/3}}{Q_g} \right)^{0.3}
\]  

Eqs. 11 and 12 can be compared to Eq. 1 by assuming that the discharge is solely related to the tidal prism. Keulegan and Hall (1950) assumed a sinusoidal discharge so that the tidal prism \( P \) or volume of water ebbing in half a tidal period \( T \) is

\[
P = \int_0^{T/2} D_m \sin \left( \frac{2\pi t}{T} \right) dt
\]  

They introduced a coefficient \( C_K \) such that \( 0.81 \leq C_K \leq 1 \) to account for a more realistic non-sinusoidal tide, giving,

\[
D_m = \frac{\pi C_K}{T} P
\]  

Then, Eq. 11 expressed in terms of the tidal prism becomes,

\[
A_E = C_p P^{0.9}
\]  

in which the process-based coefficient \( C_p \) is given by

\[
C_p = \left( \frac{\alpha \pi^3 C_K^3 m^2 W_E^{4/3}}{Q_g T^3} \right)^{0.3}
\]
Eq. 15 is similar to the classical and well-verified Eq. 1 with the empirical coefficient $C$ in Eq. 1 replaced by $C_p$. Eq. 16 shows that $C_p$ depends on $Q_g$ inversely as the $3/10$ power, an inverse dependence in qualitative accord with observations for sheltered and unsheltered coasts. The inverse dependence on the tidal period as $T^{0.9}$ is testable if adequate data are available for coasts with a diurnal tide.

Bruun (1978), in his Table 5.35, lists data for 11 jettied and unjettied inlets that include the channel cross-section (assumed to be near equilibrium), maximum discharge, and the approximate total longshore sediment transport to the inlet. The data set contains estimates of annual $Q_g$ ranging from $7 \times 10^4$ m$^3$ (with $D_m$ of $0.87 \times 10^3$ m$^3$/s) for Mission Bay, California to $8 \times 10^5$ m$^3$ (with $D_m$ of $36.4 \times 10^3$ m$^3$/s) for Grays Harbor Washington. In this limited data set, Grays Harbor falls along trend lines to be discussed, but is omitted because the discharge is an order of magnitude larger than any other. The next largest inlet is Thyboron, Denmark, with annual $Q_g$ of $7 \times 10^5$ m$^3$ and $D_m$ of $5.6 \times 10^3$ m$^3$/s.

Figure 2 plots the channel cross-sectional area against the mean-maximum discharge, indicating a close relation, as noted earlier by Bruun and Gerritsen (1968). Figure 3 plots $A$ versus the functional relation $D_m^{0.9}/Q_g^{0.3}$. The scatter about the best-fit line is considerably greater than in Fig. 2 owing, in part, to the uncertainty in knowledge of $Q_g$. Although the data set is limited, the result is promising. The process-based approach appears capable of predicting the cross-sectional area without necessity of determining an empirical coefficient, while accounting for variations in sediment type (through $\alpha$ and $m^2$, longshore transport rate, and width of the inlet).

![Data from Bruun (1978)](image)

Fig. 2. Inlet cross-sectional area versus discharge.
To examine the validity of the above formulation, the magnitude of $C_p$ is estimated with representative values for the East Coast of the United States as follows: $\alpha = 1$; $C_K = 1$; $m^2 = (0.025)^2 \text{s}^2/\text{m}^{23}$; $W_E = 400 \text{m}$; $Q_g = 315,000 \text{m}^3/\text{year} = 1 \times 10^4 \text{m}^3/\text{s}$; and $T = 44,712 \text{s}$ for a semi-diurnal tide. With these values, one finds $C_p \approx 8.7 \times 10^4 \text{m}^{-7/10}$. Because of the assumption of constant width of the inlet channel, comparison with $C$-values for dual-jettied inlets is most appropriate. From Table 1, Jarrett (1976) found $C = 7.5 \times 10^3$ for all U.S. tidal inlets considered that had dual jetties, and with exponent $n = 0.86$. The close agreement of the estimated $C_p$ and $C$, as well as the $n$-values (0.9 derived versus 0.86 empirical) is considered fortuitous, but achieving the correct order of magnitude is encouraging. The exponent 0.3 in Eq. 16 makes the magnitude of $C_p$ relatively insensitive to reasonable changes in values comprising it. For example, changing the value of $\alpha$ from 1 to 0.1 reduces the value of $C_p$ by one-half.

CHANNEL RESPONSE TO TIME-DEPENDENT FORCING

This section explores time dependencies of the change in channel cross-sectional area in the process-based approach.

Characteristic relaxation time

Eq. 8 is the time-dependent governing equation for the channel cross-sectional area $A(t)$. Noting from Eqs. 9 and 10 that

![Fig. 3. Inlet cross-sectional area versus functional form of Eq. 11.](image-url)
then, assuming that \( \frac{W_E}{h_E^{1/3}} = \frac{W}{h^{1/3}} \), Eq. 8 can be rewritten as

\[
\frac{dA}{dt} = \frac{Q_g}{B} \left( \frac{A_E^3}{A^3} - 1 \right)
\]  

(18)

If, instead, the assumption \( W = W_E \) is made, the exponent 3 in Eq. 18 becomes 10/3.

Suppose that for some reason \( A \) is perturbed by a certain small amount \( a \) from equilibrium, that is, \( A(t) = A_E + a(t) \), where \( |a|/A_E \ll 1 \), with the driving forces remaining constant. Then, by applying the binomial expansion to lowest order, Eq. 18 becomes

\[
\frac{da}{dt} - \frac{1}{\tau_0} a = 0
\]  

(19)

where \( \tau_0 = B A_E / 3Q_g \) is a characteristic relaxation time scale for the channel cross section to return to equilibrium according to the solution of Eq. 19, \( a = a_0 \exp(-t/\tau_0) \), in which \( a_0 \) is the magnitude of the initial perturbation. Order-of-magnitude estimates show \( \tau_0 \) in the approximate range of 0.3 to 2 year.

**Time-Varying Forcing**

More generally, suppose that the discharge and gross longshore sediment transport rate are time varying, leading to a time variation in the channel cross-section. Let

\[
A = A_E + a(t) \\
D = D_E + d(t) \\
Q_g = Q_{gE} + Q(t)
\]  

(20)

where \( a, d, \) and \( Q \) are small departures from their respective equilibrium values such that \( |a|/A_E \ll 1, |d|/D_E \ll 1, \) and \( |Q|/Q_{gE} \ll 1 \). Then Eq. 8 becomes

\[
\frac{da(t)}{dt} + \frac{\beta}{A_E} a(t) = \frac{\beta}{D_E} d(t) + \frac{1}{B} Q(t)
\]  

(21)

where \( \beta = 3Q_{gE}/B \), and

\[
\frac{\beta}{A_E} = \frac{3Q_{gE}}{A_E} = \frac{1}{\tau_0} \equiv \sigma_0
\]  

(22)

This equation is general, subject to the small-perturbation assumption, and can be solved once the functional dependencies of \( d(t) \) and \( Q(t) \) are known.

As an illustrative analytical solution of Eq. 21, we consider simple sinusoidal forcing, namely,
\[ d(t) = d_0 \sin(\sigma_1 t) \]
\[ Q(t) = Q_0 \sin(\sigma_2 t - \phi) \]

where \( d_0 \) and \( Q_0 \) are the magnitudes of the perturbations, \( \sigma_1 \) and \( \sigma_2 \) are angular frequencies for the respective perturbations or forcings, and \( \phi \) expresses a possible phase shift between the forcings. For example, \( \sigma_1 \) might relate to a cycle of higher spring tides and corresponding change in the discharge, and \( \sigma_2 \) might relate to seasonal changes in waves. With the notation, \( A_1 = \beta d_0 / D_E \), and \( A_2 = Q_0 / B \), Eq. 21 becomes

\[
\frac{da}{dt} + \sigma_0 a = R(t)
\]

where \( R(t) \) is the known forcing,

\[
R(t) = A_1 \sin(\sigma_1 t) + A_2 \sin(\sigma_2 t - \phi)
\]

The solution of Eq. 24a for the initial condition \( a = 0 \) at \( t = 0 \) is

\[
a(t) = \frac{\sigma_1 A_1}{\sigma_0^2 + \sigma_1^2} \left( \frac{\sigma_0 \sin(\sigma_1 t) - \cos(\sigma_1 t)}{\sigma_1} \right) \\
+ \frac{\sigma_2 A_2}{\sigma_0^2 + \sigma_2^2} \left( \frac{\sigma_0 \sin(\sigma_2 t - \phi) - \cos(\sigma_2 t - \phi)}{\sigma_2} \right) \\
+ \left[ \frac{\sigma_1 A_1}{\sigma_0^2 + \sigma_1^2} + \frac{\sigma_2 A_2}{\sigma_0^2 + \sigma_2^2} \left( \frac{\sigma_0 \sin(\phi) - \cos(\phi)}{\sigma_2} \right) \right] \exp(-\sigma_0 t)
\]

Similarly, a numerical solution of Eq. 24a can be developed with the discretization scheme

\[
\frac{a' - a}{\Delta t} + \frac{\sigma_0}{2} (a' + a) = R(t)
\]

where the prime symbol denotes the next time step. Eq. 26 leads to the algorithm

\[
a' = \frac{1 - \delta}{1 + \delta} a + \frac{\Delta t}{1 + \delta} R(t)
\]

in which \( \delta = \sigma_0 \Delta t / 2 \). Solutions with Eq. 27 will be plotted for comparison with the analytic solution given by Eq. 25. Eq. 27, which is unconditionally stable, is a general numerical solution to Eq. 24 for any given forcing \( R(t) \) and associated initial condition.

Eqs. 25 and 27 were calculated with the values given in Table 2. The parameter values correspond to a moderately-sized inlet on the east coast of the United States with \( A_E \approx 10^3 \text{ m}^2 \), \( Q_{gE} \approx 3 \times 10^5 \text{ m}^3/\text{year} \), and \( B \approx 3 \times 10^2 \text{ m} \). The annual maximum of spring tides, hence greatest mean-maximum discharge, was assumed to have periodicity of a half-year, and the gross longshore sand transport rate was given an annual cycle to represent a characteristic winter-summer difference in wave conditions.

Calculations for an elapsed time of 3 years after initiation of the perturbative forcing are plotted in Figs. (4) and (5) for phase lags $\phi$ of 0 and $\pi$, respectively. Both the analytical and numerical solutions are shown in these figures. For the numerical solution, the forcing $R(t)$ was set to 0 after 1.5 years to show the decay of the perturbation (dashed line) according to the relaxation time $\tau_0$. The time step for the calculation was $\Delta t = 1$ day. Even for this relatively large time step, the analytical and numerical solutions are almost indistinguishable (prior to setting of the forcing to zero).

The transient portion of the solution for this example damps after about one-half year. After that, the perturbation $a$ varies periodically. Phasing between the two forcings of discharge and longshore transport rate can greatly alter the behavior of the solution at initiation of the forcing or for a change in forcing. In the present example, the two lags produced a difference in cross-sectional area of approximately 45 m² in the first half year (difference of $+23$ m² and $-22$ m²).

As a final example, a calculation was made with parameters held as in Table 2, except that $\sigma_1$ was changed to an approximate fortnightly variation. Also, $\Delta t$ was reduced to 0.5 day to allow the numerical solution to better capture the rapid variations in the inlet cross-sectional response, as shown in Fig. 6. The more rapid variation in the discharge, as compared to that shown in Figs. 4 and 5, produces considerably smaller changes in the cross-sectional area. The inertia of the inlet system does not allow rapid response of the cross-section, being scaled by the relaxation time $\tau_0$. In addition, because one of the two forcings does not have sufficient time to fully develop, the magnitude of the total response is less than shown in the previous example, where the periods of the forcings were longer and comparable.

In summary, on the assumption that a channel cross section tends to be stable, Eq. 21 is capable of describing small changes in area about equilibrium in response to changes in the two major forcings that move sediment along or toward the channel. Such changes have been documented by Byrne et al. (1974), Behrens et al. (1977), FitzGerald and FitzGerald (1977), Nummedal and Humphries (1978), Van de Kreeke and Haring (1980), and others.
Fig. 4. Change in inlet area around equilibrium for forcing by sinusoidal discharge and sinusoidal longshore sediment transport rate, no lag between the forcings.

Fig. 5. Change in inlet area around equilibrium for forcing by sinusoidal discharge and sinusoidal longshore sediment transport rate, lag of 180 deg between the forcings.
CONCLUDING DISCUSSION

An equation relating the equilibrium or minimum cross-sectional area of an inlet channel was derived by balancing the input of longshore sediment transport with the transporting capacity of the inlet's discharge or tidal prism. The equation has the same functional form as previous empirical equations, but with the empirical coefficient expressed as a function of quantities related to the acting coastal processes. By expressing the inlet discharge in terms of the tidal prism, the derived coefficient $C_p$ was found to have the same order of magnitude as accepted empirical values. The process-based expression qualitatively explains the long-recognized, greater inlet cross-sectional areas, for the same tidal prism, which are observed on more sheltered coasts where longshore sediment transport is less than on exposed coasts.

The time-dependent governing equation was perturbed from equilibrium to give a general linear differential equation describing variations in channel cross-section for small changes in the discharge and longshore sediment transport rate. The equation showed that longer-period perturbations (perturbations with periods comparable to or greater than the relaxation time of the inlet channel) tend to greatly alter the cross-sectional area of an inlet channel.

To arrive at the simple governing equation, three model-defining assumptions were made. First, the channel bar has idealized geometry, by which a simple form of the sediment continuity equation could be derived. Second, sediment exchange such as among the entrance bar, flood shoal, and beaches, is omitted. And third, it was assumed that the sediment-transport dynamics can be represented by relatively simple
expressions. In principle, these assumptions can be weakened or eliminated by extension of the process-based formulation that would be solved numerically. Because little is known about sediment pathways at inlets, a comprehensive process-based model would lend insight to the functioning of these pathways.

In summary, although the model introduced here has limitations, it represents rational incorporation of the main physical processes that have been identified by observations made at coastal tidal inlets by numerous authors. Extensions of the model can readily be accomplished, and the author expects to report some of these in future publications.

POSTSCRIPT

After presentation of this paper at the Twenty-Sixth International Coastal Engineering Conference, an attendee, Dr. Hitoshi Tanaka brought to my attention his work and that of his colleagues at Tohoku University, Japan. Their work concerns river mouth closure, and in it they have introduced a model similar to that of Eq. 4 concerning balance of river discharge and longshore sediment transport. Details can be found in Tanaka et al. (1996), which references an earlier work, Ogawa et al. (1984). Tanaka et al. examine the evolution of the width of an unstabilized river mouth, considering the time dependence of the variable $W$ in the present work.

ACKNOWLEDGEMENTS

I appreciate stimulating discussions with Mr. William Seabergh of the U.S. Army Engineer Waterways Experiment Station (WES), Coastal and Hydraulics Laboratory. Also, I would like to thank Dr. Hitoshi Tanaka for providing several articles on his studies related to modeling of river mouth closure that were not available to me. The work reported in this paper was conducted under the Inlet Channels and Adjacent Shorelines Work Unit of the Coastal Inlets Research Program conducted at WES. Permission was granted by Headquarters, U.S. Army Corps of Engineers, to publish this information.

STABILISATION OF THE TIDAL ENTRANCE AT HORNAFJORDUR, ICELAND

Gisli Viggosson¹, Sigurdur Sigurdarson¹ and Bjorn Kristjansson¹

Abstract

Hornafjordur is a tidal entrance on the south-east coast of Iceland, a shore with a heavy littoral drift. An extreme storm hit the coast in January 1990. It caused large shoaling to encroach upon the entrance channel from both sides, and a breakthrough occurred between the rock headland Hvanney and the South Barrier. The inlet was closed for several weeks.

A rubble mound shore protection was built on its west side in 1991 to restore the South Barrier. A curved breakwater of berm type was constructed during the summer 1995. Due to severe wave action and strong current a berm structure with toe protection was chosen.

The paper presents the experiences gained on the tidal inlet based on hydrodynamic and hydraulic models, both calibrated to the field data.

Introduction

The inlet is the entrance channel to the town of Hornafjordur, an active fishing harbour. The entrance has a rock headland on its west side and rock reefs which

![Figure 1. The location of Hornafjordur](image)

¹ Icelandic Maritime Administration, Vesturvor 2, 200 Kopavogur, Iceland
shelter the entrance from southerly waves are located about 2 km south of it. Although the entrance has been stable in its present location for about 100 years, heavy shoaling has occurred in the entrance at 10-15 year intervals. The configuration of the coastline around Hornafjordur is controlled by two headlands, Skinneyjarhofdi 15 km in the west and Stokknes 7 km in the east as shown in Figure 1. The sea off Hornafjordur is very rough. While the total amount of drift along the shore may be of the order of millions of cubic meters of material, the net drift appears to be relatively small due to the headland configuration of the shore which made an entrance possible (Viggosson et al, 1994).

Southeast storms move material into the entrance to the shoal at the tip of the East Barrier and at high tides some material is flushed over the East Barrier into the navigation channel. At an interval of 10 to 15 years, shoaling has occurred in the navigation channel at the tip of the East Barrier as the ebb current is not able to flush material out to the shoal. Southwest and southeast storms move material into the entrance to the shoal at the tip of East Barrier and at high tides during storms some of the material may be flushed over the barrier into the navigation channel. During the summer when the wave activity is low the ebb current flushes material from the tip of East Barrier out to the shoal, so the tip may recede up to 100 meters. Usually in late August the entrance is considerably wider than in January when the wave activity is normally the highest. The diversion of currents due to shoaling and material being carried over the East Barrier cause the shore on the inlet side of the South Barrier to recede and the southeasterly waves cause the shore on the ocean side to receded due to the westward littoral drift. This leads to weakening of the barrier.

Figure 2. About 700,000 m$^3$ of material flushed into the navigation channel and a breakthrough through the South Barrier
On January 9, 1990, a severe south-west storm struck, with offshore wave heights exceeding 16.7 m. The storm was followed by unusually high wave activity and a breakthrough through the South Barrier occurred in March as shown on Figure 2. It is estimated that over 200,000 m$^3$ of material was flushed over the East Barrier into the navigation channel during this period and about 500,000 m$^3$ were flushed over South Barrier. As a result, the inlet was closed for coasters for several weeks.

Environmental parameters
An extensive field measurement program commenced during the summer of 1990 and continued to 1994. Included were several bathymetric surveys, water level measurements, bottom sampling, seismic refraction surveys, hydraulic measurements in the inlet and the channels into the west and east bays, aerial photography, offshore wave measurements, collection of weather data, geological assessments and research for quarry selection for the construction of rubble mounds.

Wave Climate
A Waverider buoy has since 1988 been located offshore off the south coast of Iceland close to Surtsey at 130 m water depth. The results of a statistical analysis fitting the data with a three parameter Weibull distribution is shown in table 1.

Measurements of currents and estimation of discharge in the Inlet

At the time when the measurements were performed, the inlet was still recovering from the shoaling that occurred the preceding winter and there were still two channels in the entrance (Snorrason et al., 1994). Current velocity measurements were made in cross section at the tidal entrance during August, 1990, twice during ebb tide and once during flood tide. The maximum recorded current velocity was 2.7 m/s and the maximum discharge during ebb tide was 3,125 m$^3$/s and 4,239 m$^3$/s during flood tide. Flow measurements were made in cross section to the Hornafjördur bay (west bay), once during ebb tide and once during flood tide, Figure 3. The maximum recorded current velocity was 2.1 m/s, ebb tide discharge of 2,008 m$^3$/s and flood tide discharge of 1,920 m$^3$/s. The same measurements were repeated for cross section to Skardsfjördur bay (east bay), with the maximum recorded current velocity of 1.2 m/s, ebb tide discharge of 1,080 m$^3$/s and flood tide discharge of 1,130 m$^3$/s.

The fresh water influx to the inlet was estimated to be less than 5% of the tidal prism and is therefore of minor importance to the total water budget of the inlet.

For each set of measurements, the current velocity is measured in several locations distributed across the width of the cross section at different depths. The discharge is calculated from the current velocities and area of the cross section. The water level measurements at the three cross sections were made by pressure gauges from May, 1990 to January, 1991 with few brief interruptions.

The current measurements were made from July until September 1990 in cross sections to the west and east bay and outside the entrance to the harbour. Measured parameters were the current velocity, its direction, temperature of the water, the all-around pressure and the sea conductivity.

Seismic Refraction Measurements

In May 1993, a seismic profiling survey was carried out in the inlet area and the navigation channel up to the harbour. The survey indicated a basalt, generally occurring at a depth of 25 m or more, and is overlain by sediments of a variable provenance. In the channel outside the harbour entrance, for example, a thick sequence of cross-bedded sediments, dipping towards the north, may be precursors of the East Barrier.

Bottom Sampling

The material in the inlet is coarse. The main trends that can be noted are that it is primarily 3-5 mm material in the shoal off the East Barrier. The material in the channel is very coarse, $d_{50}$ of 3-20 mm. Outside of Hvanney and west of Einholtsklettar, the material is generally fine, 0.2 mm, except in an isolated spot between Einholtsklettar and Hvanney with $d_{50}$ of 10 mm. These samples were taken shortly after the closing of the gap between Hvanney and the South Barrier.

Hybrid Model

The goal of the study was to improve the stability and the navigational conditions in the tidal inlet of Hornafjördur. The plan for construction of shore protection and stabilisation of the inlet consists of three elements. Firstly, a rubble mound shore protection on top of the South Barrier was built to prevent overflowing of material. Secondly, a curved jetty was laid out from the tip of the East Barrier to stabilise the tip and the shoal in the entrance. The aim of the curved jetty was also to improve the current conditions, by deepening and channelling the entrance and thus
improving the navigational conditions. And thirdly, a groin has to be built at Thinganessker which is about 1.2 km east of the entrance to minimise sediment transport from the east.

For a very complex situation like the one at Hornafjordur only a hybrid model was possible. It composed of field data, properly interpreted, including sediment budget, numerical and hydraulic models, both calibrated to the field data. In 1994 and 1995 both numerical and physical models of the inlet hydraulics were run to obtain further data to improve the design of solutions for the navigation through the entrance and stabilisation of it.

Figure 3. Stabilisation of the Hornafjordur tidal inlet. Layout of the shore protection on the South Barrier, the curved jetty on the East Barrier and the groin 1.2 km east of the entrance which will be constructed in 1999

Numerical Modelling

The AQUASEA mathematical modelling system, developed by Vatnaskil Consulting Engineers, was used to set up a numerical model of the hydrodynamics of the tidal inlet of Hornafjordur (Tomasson et al, 1994). The goal of this model applications was:
- to describe currents and discharge and to establish the relationship between the different types of field measurements carried out at different times and locations
- to describe currents and discharge in the tidal inlet for winter and summer conditions.
- to describe currents around the tip of East Barrier for different proposals for stabilising the barrier.
- to evaluate the influence of dredging the navigation channel and adding a landfill south of the harbour.
- to evaluate the influence of a proposed harbour inside the entrance.
to evaluate the siltation of suspended load from the Hornafjordur rivers into the existing harbour and the proposed harbour.

The basis for calibration of the model was the field measurements conducted in August 1990 and a bathymetric survey from the same time. As the inlet was still recovering from the shoaling the preceding winter, bathymetric surveys performed in January 1991 and in June 1992 were chosen the basis in the model to describe typical winter and summer conditions respectively. The effects of drying of the two bays, Hornafjordur and Skardsfjordur are included in the model.

Evaluation of Data

Discharge and Tidal Prism

Table 3 summarises the discharges and tidal prism through the different cross sections at mean spring tide (Tomasson et al, 1994). The water levels are approximately the same at the start and the end of the tidal cycle.

The high water in the harbour is reached over 2 hours later than the maximum discharge and velocity in the entrance. At low water in the harbour, the velocity and discharge in the entrance are very nearly zero. The maximum velocity is 2.7 m/s on the ebb and 2.0 m/s on the flood tides. The change in velocity is very rapid. As an example, it increases from 0.7 to 1.3 m/s over a period of 10 minutes.

Figure 4. Maximum flood flow at spring tide at summer condition
It is interesting to note the eddy generated on the lee side of the East barrier as shown on Figure 4. A corresponding eddy, but much larger in extent forms on the other side of the east barrier at maximum flood tide.

**Hydraulic Model Studies**

In April 1994, a physical model study for Hornafjordur was prepared in the 20 x 40 m hydraulic model hall runned by the Icelandic Maritime Administration (Viggosson et al, 1994).

The goal of the model study was to provide design data and information for the improvements to navigation, maintenance and stability of the entrance.

The model was constructed to the scale 1:100, both in plan and vertically, covering the area from a water depth of 10 m up to the harbour area including the entrance and the inlets into the two bays, Hornafjordur and Skardsfjordur. Calibration of the model was done both by field measurements and by results from the numerical model. The model is constructed according to a 1992 bathymetric survey (summer conditions) which corresponds to the topographic information used in the numerical model. The model was built with a fixed bottom but the facility to reproduce a movable bottom in limited areas is featured. Random wave generators simulate south-west and south-east waves. Closed circuit water pump simulates the currents by creating a steady state flow conditions through the inlets.

**Stabilisation of the Entrance**

In order to stabilise the entrance it has to be protected against rapid inflow of sediments to the navigation channel. Although the net drift is eastward, stability considerations following Bruun (1978) procedures, reveal that the quantity of westward drift towards the entrance may be of the order of 200,000 to 300,000 m$^3$ per

---

Figure 5. Construction of the shore protection on the South Barrier. The alignment of the shore protection is set according to the maximum known scouring from the entrance.
year causing large deposits in the outer entrance area, in the ocean and on the either side of the lava reef, Thinganessker, located about 1.2 km east of the entrance.

**Improvements to the South Barrier**

After the gap between Hvanney and South Barrier was closed, a southerly swell started to build up the barrier. In 1991, a 665 m long rubble mound shore protection was built along South Barrier. The alignment of the shore protection are shown in Figure 5. To prevent overflowing of material over the South Barrier a decision was made to accelerate this phase as it did not affect the hydraulics in the entrance.

**Improvements to the East Barrier**

To stop the transfer of material into the navigation channel it was necessary to build a curved jetty at the tip of the East Barrier. It served the dual purpose of putting a strong brake on the drift towards the channel from east at the same time working as a training wall for currents in the entrance. An accumulation capacity exceeding to 80,000 m$^3$ was sought. It could come during a couple of storms but as the updrift shoreline curves out the accumulation close to the jetty slows down and more material is deposited updrift. We were, therefore, facing a double-sided problem; (1) we wanted less sand from the east towards the entrance, (2) at the same time we wanted material enough to keep a stable shore between the entrance jetty and the Thinganessker tombolo.

During the evaluation of the improvement of the tip of the East Barrier a range of scenarios were developed with respect to bathymetry in the inlet, summer and winter flow conditions and different forms of the proposed jetty and the accumulation of material on the updrift side of the jetty.

Three different forms of a proposed jetty at the tip of the East Barrier, varying in the size, shape and location, were investigated. Considerable differences were found in the current field in the entrance depending on the form of the jetty, especially at flood tide where one form of the jetty was found to channel the current quite efficiently through the entrance and around the tip, while an eddy of considerable size formed on the leeward side of the two other jetties.

Comparison of flow separation at the tip of the East Barrier in the numerical versus hydraulic models reveals high degree of separation in the hydraulic model, especially after the curved jetty has been added. Therefore, careful recalibration of the models were carried out.

For each scenario, the numerical and hydraulic models were calibrated and tested. But the flow conditions at ebb and flood tide were not acceptable regarding eddies with the bathymetry from 1990 and 1992.

The bottom conditions in the spring 1994 had almost stabilised. The depth at the shoal at the tip of the East Barrier was about 4 m along the proposed jetty. By testing various forms of the jetty with material accumulated on the lee side and the bottom topography of 1994, minimum flow separation and turbulence was achieved, both in the hydrodynamic and the physical models when the depth along the jetty was increased from −4 m by natural slope down to −8 m. Figure 6 shows the currents at spring tide for the final proposal of the layout of the East Jetty.

To fulfil the criteria of natural slope down to −8 m along the jetty some 60,000 m$^3$ of material had to be dredged. Based on these findings, dredging along the proposed jetty was planned a year or two after the construction of the east jetty. Due
to the curvature of the east jetty some maintenance dredging along the jetty can be expected in near future.

The methods of (van Rijn, 1993) for bed load transport were used to predict the bottom changes in various time steps from the building of the curved jetty, where both current and wave related transport was included. Coarse sand and gravel are transported primarily as bedload where larger gravel tend to armour the upper most layer.

![Figure 6. Currents at spring tide for the final proposal of the layout of the east jetty](image)

To investigate the influence of expected increased depth along the proposed jetty, shear stress calculation were carried out. The Chezy bottom friction coefficient in the calibration process of the numerical model was found in the inlet $C_h = 45 \text{ m}^{1/2}/\text{s}$. Comparisons were made between the shear stress at maximum flood and ebb tide with and without increased depth to $-8 \text{ m}$ along the proposed jetty. At flood tide the maximum shear stress were calculated at the bottom in 1994, to maximum $80 \text{ N/m}^2$ in the curved of the jetty compared to $30 \text{ N/m}^2$ with increased depth. Nearby the entrance the maximum shear stress were $45 \text{ N/m}^2$ compared to $30 \text{ N/m}^2$ with increased depth. At maximum ebb tide, peak shear stress occurs at the tip at the jetty and along the straight leg of the jetty. In both areas the maximum shear stress decreases from $50 \text{ N/m}^2$ to $40 \text{ N/m}^2$ with increased depth.

The results for flow and tidal prism of the final proposal of the layout of the east jetty are shown in table 4.

A total of 99,700 m$^3$ were excavated from the quarry, of which 27,400 m$^3$ were over 2 tonne. Total project cost was 1.53 million USD, in comparison to the original cost estimate of 1.50 million USD, a difference of only 2%. (All prices include 24.5% VAT).

In the tender documents the contractor was asked to build a construction road between station 262 and 462 during the neap tide from June 3 to 10, but this could be postponed in case of a bad weather. The purpose to minimise the risk of erosion in front of the construction road and at the toe of the breakwater during the construction period. The contractor constructed a 6 m wide low road of quarry run and managed to complete the structure to station 500 within this period, Figure 8. At the same time the road was secured with 0.2 - 2 tonne rocks at the inlet side. Due to the fast progress of the work the erosion in front of the tip was limited, a maximum of 30 cm was observed. The outcome from the quarry was carefully monitored and a 100% utilisation of the quarried material was achieved.
Construction of the Rubble Mounds

The shore protection on the South Barrier

During the summer of 1991, in the early phase of field measurement and modelling, a 665 m long conventional rubble mound shore protection was constructed at the South Barrier (Sigurdarson et al, 1994). The rock in the main quarry for the South Barrier is an 8 m thick basalt lava situated about 30 km from the construction site. A total of 60,000 m$^3$ of material was needed from the quarry. Total contractor cost was 1.80 million USD, in comparison to the original cost estimate of 1.64 million USD, a difference of only 10%. (All prices include 24.5% VAT).

The berm breakwater on the East Barrier

The jetty is 330 m long in addition to the 200 m long shore protection along the tip of the East Barrier was constructed during the summer 1995. The design condition of the wave height, current and erosion were evaluated by the numerical and the physical models (Sigurdarson et al, 1997).

Design conditions for the jetty were established as follows:
- The bottom material in the tidal entrance consists of coarse lava sand with particle size of 2-30 mm in diameter with some larger gravel.
- The barrier material is 1-5 mm with some gravel.
- The maximum current velocity was estimated 3.0 m/s at ebb tide and 3.5 m/s at flood tide.
- At spring tide the maximum discharge through the inlet during ebb tide was estimated 3,440 m$^3$/s and 4,420 m$^3$/s during flood tide.
- At spring tide the water level is about +2.1 m and the design water level is +3.5 m.
- The offshore significant wave height with 100 year return period is about 17 to 19 m with peak period 18 to 20 s.
- At 30 m water depth outside the entrance the 100 year significant wave height is about 12 m with peak period 18 to 20 s.
- During the design storm the significant wave height just outside the jetty is 3.8 m.

The design of the jetty had to take into account strong currents and moderate storms during the construction time. This led to a berm type breakwater of several stone classes with large toe protection as shown in Figure 7. Stone classes in the range of 2 tonne up to over 10 tonne were used. The berm consists of two classes of mean weight 6.7 and 3.0 tonne, the larger on top of the other, which corresponds to a stability numbers of 1.5 and 2.0. In front of the berm there is a toe protection of 0.2 - 2 tonne stones 20 m$^3$ per meter length of the structure. The predicted quarry yield over 2 tonne was 25 - 30 % which the design aimed to utilise completely to the advantage of the berm structure.
Monitoring of the tidal inlet and the breakwaters

Depth soundings in the entrance are performed regularly at an interval of 2 - 3 months and the breakwaters are visually inspected every two months. During the construction phase, bottom changes were in accordance with the predictions of the mathematical model (Viggosson et al, 1998). Figure 9 and 10 show an aerial photo of the tidal entrance at Hornafjordur on the completion of the stabilisation.

Large volumes of sand and gravel were transported as shown on differential plan in Figure 11 between May 1995 and June 1998 which have not caused any problems for ships navigating the inlet.

Local accretion of sand of up to 2 meters started already near the strait part of the jetty during its construction. According to Figure 11 this accretion has eroded and the distance has decreased between the two erosion areas at the end of the jetty and near the curved jetty. The volume needed to be dredged along the jetty to fulfil the criteria of natural slope down to -8 m are about 15,000 m$^3$ instead of 60,000 m$^3$ after the completion of the jetty.

Special attention is paid to the toe of the breakwater. The toe protection 0.2-2 tonne has been washed down and protects the eroded slope from further erosion. Figure 11 the differential plan between May 1995 to June 1998 shows an erosion up to -7 m near the tip and -11 m along the curved part of the jetty and accretion up to 5 m. The erosion along the curved jetty and at the tip started during the construction. The maximum erosion reaches temporary -10 m at both places compare with 7-8 m today.

The accumulation of material at the updrift side of the jetty developed fast during the first winter. An accumulation of some 80,000 m$^3$ was observed after the first winter but since then the accumulation has slowed down. At present some 100,000 m$^3$ of material has been accumulated and more material is deposited updrift. With 10 to 15 years interval, storms from east and southeast with duration of up to 10
days have cause heavy littoral drift to the entrance. It is, therefore, planned to build a 250 m long groin next year, connecting the Thinganessker reef to the shore, some 1.2 km east of the entrance. The groin is expected to prevent littoral drift to the west and thereby stabilise the entrance.

Figure 10. Arial photo of the tidal entrance at Hornafjordur

Figure 11. Differential plan between May 1995 to June 1998 showing erosion up to -7 m near the tip and -11 m along the curved part of the jetty and accretion up to 5 m. Dashed areas show accretion.
Conclusions

A natural inlet on a shore with heavy littoral drift, large wave forces, coarse material and strong current velocity. It was successfully stabilised with minimum impact on the surrounding environment and navigational conditions were improved.

In 1991, a 665 m long rubble mound shore protection was built along South Barrier. To prevent overflowing of material over the South Barrier a decision was made to accelerate this phase as it did not affect the hydraulics in the entrance.

Large volumes of sand and gravel have been transported through the tidal inlet since the construction of the east jetty in 1995 and until now it has not caused any problems for ships navigating the inlet or for the berm breakwater.

Instead of a dynamic approach to berm breakwaters, as was the initial philosophy, a more stable approach has been adopted. This has lead to the “Icelandic berm” which is more economical and a more stable design than the original dynamic design approach. The toe protection and the berm breakwater have functioned as expected and the navigation conditions in the entrance are according to expectations.

According to the sounding of June 1998 it is necessary to dredge some 15,000 m$^3$ to fulfil the criteria of natural slope down to - 8 m along the jetty. Dredging is planned in the autumn of 1998.

There are plans to build a 250 m long groin next year, connecting the Thinganessker reef to the shore, some 1.2 km east of the entrance. The groin is expected to prevent littoral drift to the west and thereby stabilise the entrance. Due to the curvature of the east jetty some maintenance dredging along the jetty can be expected in near future.

APPLICATION OF A LONG-TERM EVOLUTION MODEL OF TIDAL INLETS TO THE DESIGN OF A NAVIGATION CHANNEL, THE NAVIA INLET CASE.

R. Medina¹, M. A. Losada², Member, ASCE, P. Lomónaco¹ and A. Baquerizo³

Abstract

The navigation channel of Navia is designed applying a long-term evolution model of tidal inlets. Navia is a port located on the North coast of Spain, and accessed by a narrow inlet, influenced by strong tidal currents, waves and a variable morphology. To define the design depth, the most important oceanographic processes are included in a probabilistic approach. The model allows comparing different scenarios, according to jetties length and maintenance dredging. In this way, optimum design represents a balance between capital costs and maintenance requirements. The long-term evolution model turns out to be an efficient tool for navigation channel design, and a must for optimum design.

Introduction

Tidal inlets are among the most active sedimentary units. Waves, tidal currents, river discharge, density currents and wind driven currents influence them. Sediments are continuously in motion, due to the strong hydrodynamics and the sediment size ranges from fine silt to pebbles. On the other hand, estuaries are generally used for port activities, since they provide naturally sheltered areas and allow inland navigation. The access to these ports is done through the estuary inlet.

The tidal inlet natural cross section is the result of a balance between sediment input, onset of motion and transport, tidal current patterns and tidal prism, among other factors. The result is a dynamically stable section, which tends to an equilibrium condition. Hence, a tidal inlet may be in equilibrium even though its morphology changes.

continuously, since the latter is given by the current hydrodynamic conditions, but the mean condition is, in long-term, constant.

Therefore, two time scales are defined for the morphological variability of the inlet, the short-term variability (days, weeks), controlled by the time scale of waves, tides or river, and the long-term variability (months, years), controlled by the natural tendency towards equilibrium of the inlet. Several authors had proposed relationships between some estuary properties in equilibrium and the hydrodynamic conditions, e.g. tidal prism versus inlet cross section (O'Brien, 1930, Bruun, 1966), or tidal flats extension versus estuary area (Eysink, 1990). Any change in these properties will produce a different equilibrium condition, and the estuary morphology will tend towards a new stability state. Since the most active unit inside the estuary is the tidal inlet, one can find the strongest changes in it.

But the problem is that natural equilibrium conditions may not fulfil navigational requirements, at least during some time periods (at low tide or during storms). In most cases, it becomes very hard to achieve these requirements, particularly with respect to depths, and it is necessary to accept nature’s conditions, or to pay a very high price in maintenance dredging.

As mentioned before, after dredging, the inlet will evolve and, after some time, will attain its equilibrium condition. In order to preserve the required depth, maintenance dredging must be performed and the time evolution of the inlet has to be assessed. A long-term evolution model can predict the inlet behaviour.

In this paper, a long-term evolution model will be applied to the Navia inlet, in the northern coast of Spain. The model is based on the work published already by several authors and will be presented here in detail. First, the physical environment within Navia will be shown and the navigation channel design principles will be defined. Then the long-term evolution model concepts and theory will be elucidated in order to apply it in the design of Navia’s navigation channel and the maintenance works. With these results, an optimum balance between capital costs and maintenance dredging can be found for a particular channel geometry.

The Navia Inlet

The North coast of Spain consists of a series of pocket beaches and bays separated by pronounced rocky headlands. The coast in general faces North, towards the Cantabrian Sea, in the northern Atlantic Ocean. Depths here reach more than 4000 m far offshore and the continental shelf has an average width of 30 km. The mean tidal range is about 4 meters; spring tides reach ranges up to 5 meters and they are all semidiurnal.

Navia is a small inlet on this coast, in Figure 1 its location is indicated, and also can be seen the large fetch area to the Northwest, where strong extra-tropical cyclones generate wind and waves which make the Cantabrian Sea one of the roughest in the
world. Hence, waves arrive to Navia from the NNW and a typical winter storm has a significant wave height between 4-6 meters.

![Map of North Atlantic and the Cantabrian Sea. Navia inlet location.](image)

Figure 1. North Atlantic and the Cantabrian Sea. Navia inlet location.

Navia is an old port, meant for bulk cargo (iron ore) and fishing. In Figure 2 a 1786 chart is presented, where one can identify the original shape of the outer shoal, the river path and water depths. Comparing with recent charts, even though some differences are clear, it can be found that, in general, the shape and depth of the shoal are very similar. This means that the estuary is in equilibrium, and since the rocky headlands protrude quite offshore, the amount of sediment in the system is fixed and constant, no longshore transport occurs. Furthermore, several dams had been constructed along the river basin, stopping all sediment before it reaches the estuary and controlling the river discharge.

Nowadays, (Figure 3) Navia estuary presents a tidal prism of about $5 \times 10^6$ m$^3$ and an offshore shoal that almost emerge in low tide. Human intervention in Navia's estuary starts at the end of the last century, with dredging, reclamation of tidal flats, shore protection along the river margins and the construction of two small jetties. Land reclamation was not very extensive, and the jetties become a lateral support for a beach east from the tidal inlet.

Recently, a new expansion project has to be made for the port, considering the possibility of maintenance dredging versus jetties enlargement. The outcome was a new approach for optimum design applying a long-term evolution model.
Figure 2. Navia inlet. Chart from 1786.

Figure 3. Navia inlet. Present day chart.
Navigation Channel Design Principles

Water depth at the inlet is one of the factors controlling the access to a port. On one hand there is a minimum channel depth required for a given ship to enter safely, this depth is the result of considering ship's draft, the under keel clearance corresponding to cargo's characteristics and bottom material, and ship's dynamical response to waves and displacement, i.e. squat and heave. On the other hand, the real water depth at a certain moment is the result of minimum depth, astronomical tides and storm surge (see Figure 4). As one can see, some of these factors varies with time and, furthermore, a few are purely stochastic parameters. Thus, for a given vessel, there is a percentage of time where the channel can be accessed, in other words, to be operational. A combination of all these factors gives a curve for different dredged channel scenarios and a plot of percentage of time versus channel depth can be constructed for each vessel (Figure 5). In this curve, the minimum design water depth can be obtained given a desired functionality and vice versa.

![Figure 4. Real and required channel depth definition.](image)

The obtained design depth corresponds to vessel requirements and has nothing to do with nature's equilibrium depth. Typically, both depths are different and the problem arises when the equilibrium depth is smaller than the required depth, thus the access channel is dredged. According to the preceding paragraphs, the inlet will try to recover the equilibrium immediately after changing its original condition, but this will take some time, depending on the strength of the hydrodynamic and morphologic processes, and sediment availability. Consequently, in order to warrantee the desired functionality, over dredging is commonly performed, as a sedimentation bulk capacity, delaying maintenance dredging. Thus, maintenance ($m$) should be done as soon as the inlet has evolved to the minimum depth, at least to fulfill the minimum requirement for functionality. Hence, three depths has been defined: the initial depth (i.e. over-dredged depth, $h_0$), the minimum depth for required functionality (design depth, $h_L$) and the final depth or equilibrium depth ($h_f$).
Figure 5. Functionality versus channel depth for the design vessel.

As a result, it is required to know the depth evolution time history at the inlet. A long-term evolution model will provide this information. Figure 6 shows an example of channel depth time evolution, indicating the initial, design and final depths and defining the maintenance interval. Here two approaches can be followed: to dredge and maintain the inlet or to modify the evolution trend by constructing jetties, or changing any of the main parameters that control the time evolution. In any case, the long-term evolution must be determined. The theory behind, concepts and how it was applied to Navia will be presented in the following paragraphs.

Figure 6. Time evolution example of channel depth.
**Long-Term Evolution Model**

As mentioned before, a long-term evolution model is based on the assumption that the estuary, and its elements, will tend to a known natural equilibrium condition. The dynamical stability, with a mean morphology, is a feature of tidal inlets measurable all over the world. Several researchers had studied these mean morphologies, and found empirical relationships between the morphology and some parameters representative of the estuary.

Hence, if any estuary parameter is modified, there will be a change in the morphology accordingly, or if the inlet cross section is altered, it will recover its original shape (van Dongeren, 1992).

The main approaches for modelling long-term inlet morphology are:

1. To use small scale physics and to integrate the results over larger time scales. This is known as aggregated scales and can only be used when the process modelled is dominated by a linear behaviour.
2. To use empirical relationships, i.e. those mentioned before which relate an estuary parameter with hydrodynamics.
3. To use a hybrid model (van der Kreeke, 1996).

In the present paper, a hybrid model has been developed to evaluate the long-term evolution of Navia inlet. Following de Vriend, et al., 1994, the proposed model is based on the assumption that the system, which consists of four interacting elements (the tidal basin, the outer shoal, the offshore shelf and the adjacent coast, see Figure 7), will try to attain the equilibrium after a human work (dredging and/or jetties).

The model describes the transition of the outer shoal from the initial disturbed position to the equilibrium. It uses physics as well as empirical relationships. In particular, the along-shore and cross-shore transport are calculated using physics based models. Tidal basin sediment transport and outer shoal equilibrium is calculated by means of empirical relationships.

Basically, the evolution model performs a sedimentary balance at the inlet, from the input and the output volume of material. It is assumed that the output volume is inversely proportional to the degree of instability of the inlet, in other words, the closer is the inlet to equilibrium, the more sand is exported to the adjacent morphological units.

In a long-term time step (months/years), the inlet organises the input volume in the shoal, thus some part will be under the waves and currents influence and will be transported back to the beach or inner estuary. The volume of sediment, which actually remains is, therefore, a fraction of the originally deposited (Losada, et al., 1997):

\[
\Delta V_t = k_1 (Q_o+Q_R+Q_B) \Delta t
\]  

(1)
The volume of the outer shoal, which includes the inlet, and is proportional to the inlet depth (Eysink, 1990). \( k_i \) is a constant and represents the fraction of sand volume, which remains at the inlet. The value of \( k_i \) is obtained from the wave incidence pattern (Hicks and Hume, 1996) and is also calibrated from adjacent inlets. The rest of parameters are defined below.

\[
Q_0 = Q_{OB} \\
Q_B = Q_R \\
Q_{RB} = Q_{OB}
\]

Figure 7. Morphological units of a tidal inlet.

In Figure 7 also the sediment transport flux between each unit is shown. \( Q_0 \) is the cross-shore transport, mainly induced by waves. \( Q_R \) is the estuary sediment input and output due to tidal oscillatory currents and river discharge. \( Q_B \) is the longshore transport from the adjacent beach produced by oblique wave incidence, set-up and tidal currents, and \( Q_{OB} \) is the cross-shore transport from the outer shoal to the adjacent beach. Hence, two different processes have been defined, the process within units, based on empirical relationships and formulations, which is considered to be instantaneous, and the process among units, defined by the continuity of sediment flux between units.

Notice that in each time step, the value of the fluxes depends on the inlet condition, the farther the inlet is from its equilibrium condition, the larger is the sediment input. With this approach, each unit is modelled in a different way, according to its morphological response.

The estuary will contribute with sediment linearly according to the degree of instability of the inlet:

\[
Q_R = k_2 (V_I - V_e)
\]

Where: \( Q_R \) is the sediment flux from the estuary,

\( V_I \) is the volume of sediment in the inlet.
Ve is the tidal inlet equilibrium volume, and 
k_2 is a constant based on empirical models (Eysink, 1990) and 
calibrated from adjacent inlets.

The river input is independent to the inlet condition; therefore its flux is assumed 
to be constant. The ocean unit can endow or receive sediment from the inlet. The ocean-
inlet flux is an exponential function of inlet degree of instability:

\[ Q_o = Q_{OE} \exp(-k_2(h-h_f)) \]  (3)

Where: 
\( Q_{OB} \) is the ocean-beach sediment flux, 
\( Q_o \) is the ocean-inlet sediment flux, 
\( Q_{OE} \) is the ocean-inlet sediment flux for equilibrium conditions, 
\( h \) is the inlet water depth, 
\( h_f \) is the inlet equilibrium water depth, and 
k_2 is a constant based on empirical data and calibration.

Finally, the beach will supply sediment to the inlet according to the incident wave 
field. If there is no jetty, the wave will approach to the spit of the sand bar with an angle, 
which will create a longshore current and sand transport. If there is a jetty, the shoreline 
position, relative to the tip of the jetty, will indicate the percentage of sand flux from the 
beach to the inlet.

\[
QB = \begin{cases} 
Q_{B(MAX)} & \text{if } D_L = 0 \\
k_4 D_L & \text{if } 0 < D_L < D_L(MIN) \\
0 & \text{if } D_L > D_L(MIN) 
\end{cases}
\]  (4)

Where 
\( QB \) is the beach-inlet sediment flux, 
\( Q_{B(MAX)} \) is the long-shore sediment transport, computed with the overall 
incident wave climate, 
\( D_L \) is the distance from the shoreline to the tip of the groin, 
\( D_L(MIN) \) is the surf zone width, where long-shore transport mainly 
occurs, and 
k_4 is a constant based on equation (4) requisites.

The sand transport, \( Q_{B(MAX)} \), is computed using one of the several formulae 
available from the literature, and the actual flux is computed using a multi-line model of 
the beach profile, which in turn depends on the total volume of sand at the beach.

The beach behaves as a special sedimentary unit in this case, since the total 
amount of sand in it will define the shoreline position. The actual volume of sand is a 
balance from the output flux towards the inlet and the input flux from the ocean (or any 
other source, e.g. sand by-passing, wind transport, nourishment, etc). The model assumes 
that the ocean-beach flux \( (Q_{OB}) \) will be exactly all the sand volume exported by the inlet 
during its sedimentary balance, thus:
\[ Q_{OB} = (1 - k_1)(Q_o + Q_R + Q_b) \] (5)

The sand volume and distribution at the beach is based on accurate bathymetry and charts. The shoreline position and cross-shore profiles are based on empirical formulations and similar beaches formed on inlets along the North coast of Spain (e.g. Zumaya, Orio, Suances, among many others).

Each morphological process, for every sedimentary unit, has a stochastic character. Thus a probabilistic approach is used to include individual strong events, such as a storm or high runoff discharges. The first case, linked with high wave energy, will try to close the inlet, moving sediment from the outer shoal and the adjacent coast. The second case will wash off the sediment from the inlet, due to the related high velocities. Each situation will delay or shorten the evolution time.

Introducing for each process a mean value and its standard deviation, the procedure is repeated several times to assess the overall trend and confidence intervals (Montecarlo simulation). To attain the mean values and deviations, historical data is collected from Navia and adjacent inlets, similar in behaviour and configuration. Some of these inlets have been modified in the same way as planned for Navia, so detailed surveying of medium and long-term evolution has been undertaken to calibrate the model.

In this way, knowing the sediment flux for each unit, the sedimentary balance at the inlet is performed, as mentioned above. The relationship between the inlet sand volume and depth will provide its time evolution.

Next, the model will be applied to Navia's inlet and a relationship between percentage of operational levels, jetties length and mean maintenance requirements will be studied, leading to an optimum design procedure based on capital and maintenance costs.

Results

The long-term evolution model, combined with the percentage of operational time data, has been used to determine the maintenance requirements at Navia inlet for different scenarios of jetty construction. The optimum solution is somewhere in between two extremes:

1. No jetty construction and maintenance of functionality purely with dredging, and
2. Extremely long jetties, reaching a depth such as the inlet becomes independent of the adjacent sedimentary units. This includes an initial dredging of the whole inlet up to the closure depth.

In the first solution, continuous dredging has to be undertaken, and the solution is more sensitive to individual events like storms or high river discharges. The second solution is extremely expensive, and might have tremendous effects on the environment, not only the estuary under consideration, but also to the neighbouring coast.
Two different scenarios will be presented as possible solutions. One with two short parallel jetties (240 m) and an initial dredging depth $h_0 = -2$ m, the other with two long parallel jetties (600 m) and dredging up to $h_0 = -6.5$ m. All levels are referred to chart datum, which is at MLWS. The required data and computed parameters to apply the long-term model are given below.

Equilibrium depth at the inlet, $h_e$: 1.1 m  
Equilibrium volume of the inlet, $V_e$: 420,000 m$^3$  
Initial estuary and river sediment flux, $Q_R$: 5,000 m$^3$/yr  
Ocean sediment flux for equilibrium conditions, $Q_{OE}$: 10,000 m$^3$/yr  
Maximum long-shore transport, $Q_{B(MAX)}$: 15,000 m$^3$/yr  
Surf zone width, $D_{L(MIN)}$: 680 m  
Constant $k_1$: 0.5  
Constant $k_2$: $(h_0-h_j)/Q_R$  
Constant $k_3$: 0.35  
Constant $k_4$: $-Q_{B(MAX)}/D_{L(MIN)}$

The equilibrium depth is obtained from O'Brien, 1930 and Bruun, 1966 formulations. Also this depth is compared with present and old data from charts (Figures 2 and 3). The equilibrium volume is computed following Hicks and Hume, 1996 and the estuary and river sediment flux are based on comparisons with similar inlets in the neighbourhood. The ocean-inlet flux for equilibrium conditions is also based on adjacent inlets and the maximum long-shore transport is computed as in the Shore Protection Manual, 1984. The surf-zone width was assumed to be the same as the active profile at the beach, measured and observed in several beaches along the Cantabrian Sea coast. The constant $k_1$ was proposed by a simple geometrical consideration, from the wave incidence pattern and the inlet characteristics. The constant $k_3$ was defined arbitrarily; in order to have half of the volume flux when the actual depth is the equilibrium depth plus 2 metres.

In Figure 8 the time mean evolution of the inlet is shown for the long groin scenario, as can be seen the fastest changes occurs at the beginning and the equilibrium is attained in less than, say, 40 years. Also, in Figure 9 the sediment fluxes between units are presented. Notice that these curves are not given formulations, but the output of the model for each time step according to inlet demands and morphological evolution.

Figure 10 presents the time evolution of the inlet for the short groin scenario; also the evolution sensitivity is presented as a function to process variability. In this case the inlet will attain the equilibrium in 4 – 6 years, depending on the environmental conditions present. The sensitivity analysis was not presented for the long groin scenario, since it becomes almost negligible, due to the relatively long equilibrium period.

As shown before, each scenario will present a different evolution pattern. Hence, fixing the minimum depth for a given required functionality ($h_{Li}$), the maintenance interval ($m$) is obtained from the time evolution curves. Including all scenarios, a curve can be constructed with the groin length on one axis, and the maintenance interval, on the
other, for a given functionality, as presented in Figure 11. Here, the short groin scenario implies maintenance dredging every 6 months and the long groin scenario a maintenance dredging every 5 years. Both scenarios presented are meant to allow the entrance to the port 90% of the time for the design vessel. Nowadays, Navia’s inlet functionality is less than 30%.
Translating these results to economical meaning is straightforward, and depending on each case and budget availability, one solution might be better than the other might be. The financial and environmental best solution was beyond the scope of this paper, but it was clear that, to give the port authority a better forecast for the investment, based on technical foundation was, for the first time, an improved approach for optimum design.

Figure 11. Groins length versus maintenance interval for Navia inlet (Functionality: 90%)

Conclusions

In order to attain an improved methodology for optimum design of Navia’s navigation channel, a long-term evolution model of tidal inlets is applied. The special
features of Navia coast and oceanographic process are presented and the navigation channel design principles lead to require the knowledge of the long-term evolution in the inlet.

Thus, an aggregated scales model was implemented and used in Navia inlet, where the sedimentary units were modelled in a simplified way, employing historical data and surveying from adjacent inlets. The time evolution was found to be in the order of decades and the obtained information was not old enough to ensure the morphologic response. Therefore a sensitivity analysis was performed to study the variability of each process leading to a relatively more sensitive solution for shorter evolution periods.

The long-term evolution model was then applied for different scenarios and, by means of a minimum required functionality for the port, a maintenance period was obtained. As a result, a relationship between groin length and maintenance dredging was obtained. The economical impact is evident and a financial study for optimum groin length and periodic maintenance will provide, for the first time, a long-term evolution forecast and better budget planning.

The deepening of estuarine waterways enforces essential changes of mean tidal water level peaks and range. Legal requirements ask for their determination by preservation of evidence. A method has been established to evaluate these effects quantitatively by statistical tools for each measure, even in the case of subsequent deepenings.

Introduction

Deepening of estuarine waterways enforce there changes of tidal water levels. They start immediately after deepening but continue after execution of dredging for a certain period of time being necessary for the development of a new dynamical equilibrium between estuarine geometry and tides. The order of magnitude of changes of mean tidal water levels is particularly of importance for water management and ecological zonation but is also regarded as a primary indication for changes of tidal currents, salinity and storm surge levels. Therefore the quantitative determination of changes of mean tidal

Fig. 1: Elbe estuary, southern North Sea

peaks and tidal range due to waterway deepening is given high priority in order to qualify its impacts. This is not only necessary for planning purposes but also for the environmental assessment studies and for the later preservation of evidence procedure due to legal requirements in Germany. Preservation of evidence gets increasingly difficult if subsequent deepenings have been carried out and their impacts are still continuing at the beginning of the successive one. An impressing example is the continuous increase of tidal range at the tidal gauge of Hamburg-St. Pauli since the beginning of this century whereas during the same period neither the tidal range at the island of Heligoland and in Cuxhaven at the estuarine mouth nor the fresh water discharge have experienced comparable changes (fig. 2).

This paper deals with a method to quantify the changing of mean tidal water levels and range due to a waterway deepening in the Elbe estuary (fig. 1) for a navigational depth of 13.5 m below mean low spring tide water level (C.D.) during the years 1974 to 1976 being the fourth since 1949. The legal boundary conditions required a preservation of evidence procedure quantifying the singular effects occurring due to the specific deepening. The significant changes of mean tidal

**Fig. 2:** Tidal range at the gauges Heligoland, Cuxhaven, Hamburg-St. Pauli and fresh water discharges of the Elbe river since 1843

**Fig. 3:** Periods of successive waterway deepenings ↔ and time series of tidal range at estuarine tidal gauges Cuxhaven, Kollmar, Schulau and Zollenspieker (fig.1)
water levels for the last sixty years are documented here explanatory for the tidal range at four estuarine tidal gauges connected with the periods of the coincidently executed successive deepenings in the Elbe estuary. (fig. 3). The tidal range has increased relatively the more the further upstream the tidal gauge is located. Due to that effect the relations of local tidal range in the estuary have changed: E. g. at the gauge Schulau located immediately downstream of Hamburg it does therefore nowadays exceed that one at the gauges Kollmar and Cuxhaven. Before the intensive deepenings during the last decades tidal range decreased continuously from the estuarine mouth upstream (fig. 3); but meanwhile the maximum tidal range occurs in the central part of the estuary. The relatively largest increase has occured upstream of Hamburg where no dredging has been carried out. The development of tidal ranges during that period highlight two major effects: the changes are not only correlated to the period of dredging itself and the changes increase the more the gauge is further upstream located.

Basic effects of waterway deepening on mean tidal peaks

The deepening of an estuarine waterway leads to an extension of cross-sections allowing the propagation of a higher amount of tidal energy further upstream. The increase of the range of the tidal wave is symmetrically distributed to high and low water level peaks (fig. 4). The lowering of the bottom - generally increasing in upstream direction - creates additionally a lowering of the mean water level (fig. 5).

Fig. 4: Basic effect of cross-sectional extension on tidal range and peaks

The superimposition of both effects leads to a resulting relatively larger lowering of the tidal low peaks than heightening of the tidal high peaks (fig. 6). This phenomenon is well known from estuarine deepenings for the stretches of waterway deepening. Beyond there is only an increase of tidal range which is nearly evenly distributed to the high and low water level peaks.
Evaluation of suitable time series

In order to determine time series of mean tidal water levels which experienced only significant impacts due to the last deepening double-mass analysis [SEARCY & HARDYSON 1960] was applied to the time series as well of yearly mean high and mean low water levels as of mean tidal range in the downstream and central part of the estuary with respect to the same parameters at the offshore tidal gauge on the island of Heligoland (fig. 1) which was taken as base station representing the natural variation of tidal water levels in the southern North Sea. It is assumed that as far as offshore as the location of the island of Heligoland (fig. 1) no impacts of estuarine deepenings will occur. Further upstream the method has not been applied since ther the impacts of the fresh water discharge variations being not considered in the double-mass analysis would be to strong in order to allow a successful application of that method.

First a comparison was carried out for distinct tidal gauges at the German North Sea coast in order to check if there are general changes not related to impacts in the Elbe estuary itself in order to avoid any misinterpretation of effects being not specific for the Elbe estuary. The double-mass analysis of the tidal ranges at the gauges of Wilhelmshaven (Jade Bay), Bremerhaven (Weser estuary) and Cuxhaven (Elbe estuary) with respect to that one at the at the island of Heligoland makes evident that its variations differ locally at the German North Sea coast (fig. 7).
Exemplary for the analysis for the Elbe estuary here the results for the tidal range at the gauges Kollmar and Schulau are discussed. In order to avoid the typical difficulties occurring by application of double-mass analysis no interpretation by visual observation of the double-mass curve itself has been carried out. The gradient of the double-mass curve was continuously computed and any change of more than 0.75% is taken into consideration (fig. 7a + b). The results led to the conclusion to use the time series between 1970 and 1974 being representative for the situation before the deepening incorporating also the total effects of the previous deepening. The time series between 1977 and 1992 were used in order to determine the impacts of waterway deepening whereas 1975 and 1976 were regarded as a transition period between dredging and readaption.

Another check was carried out for the data of the tidal gauge Schulau (fig. 1): The gradient is changing for the whole period but with significant increase since about 1970 (fig. 8a). In order to gain results allowing a proper interpretation the tolerance for changes of the gradient of the double-mass curve was doubled to 1.5%. The results of that analysis fit well with that carried out for the data of the tidal gauge Kollmar: during the period between 1970 and 1974 there is no change in the behavior of the tidal range at the gauge Schulau.
with respect to that one at the gauge of Heligoland (fig. 8b). The higher tolerance for the data of the gauge Schulau is obviously necessary for getting proper results. The reason behind is that at this further upstream located gauge the impacts of freshwater discharge variations on tidal water levels are stronger than at Kollmar. The higher tolerance is explainable as a filtering technique for suppressing these effects.

Determination of deepening effects

Established method

The local estuarine mean low and high water levels at each estuarine gauge \( \text{LWL}_{\text{EGI}}, \text{HWL}_{\text{EGI}} \) were approximated by use of multiple regression as a function of the corresponding parameters \( \text{LWL}_{\text{Hel}}, \text{HWL}_{\text{Hel}} \) and the mean tidal range \( \text{TR}_{\text{Hel}} \) at the offshore gauge Heligoland (fig.1), the latter one as a measure for the offshore energy input, and additionally the inland fresh water discharge \( Q_f \). Effects of estuarine waterway deepening on tidal water levels at the island of Heligoland (fig. 1) do not occur; they could therefore be used as well as an independent boundary condition as the inland fresh water discharge. Empirical optimizations led to the following functional equations for estuarine mean low and mean high water levels:

\[
\text{LWL}_{\text{EGI}} = a_{1,i} \cdot \text{LWL}_{\text{Hel}} + a_{2,i} \cdot \text{TR}_{\text{Hel}} + a_{3,i} \cdot Q_f^{b_{1,i}} \tag{1}
\]

\[
\text{HWL}_{\text{EGI}} = a_{4,i} \cdot \text{HWL}_{\text{Hel}} + a_{5,i} \cdot \text{TR}_{\text{Hel}} + a_{6,i} \cdot Q_f^{b_{2,i}} \tag{2}
\]

Regression analysis was initially carried out for the period immediately before the waterway deepening on the basis of the time series of monthly means of the period from 1970 to 1974 in order to determine the coefficients. A comparison of computed and measured data made evident the reliability of the approximation (fig. 9 - 11). Afterwards these coefficients were used to determine the estuarine mean tidal peaks on the basis of the boundary conditions for the offshore tidal parameters and the freshwater discharge for the period after the waterway deepening. The differences between measured and computed data are regarded as the deepening effects \( D_L \) and \( D_H \) (fig. 9 - 11).

Changes of mean tidal peaks and range

The changes of mean tidal peaks and range are rather small at the estuarine mouth but increase upstream. Exemplary the changes of mean high and low tide at the gauges Cuxhaven, Kollmar, Schulau and Zollenspieker (fig. 1) are compared: There is no change for mean high tide at the gauge Cuxhaven and the change in mean low water is only 4,5 cm (fig. 12). Further upstream at the tidal gauge Kollmar the changes are more pronounced: 6,0 cm for mean high tide (fig. 9a) and 8,9 cm for mean low tide (fig. 9b). Again for this gauge also the scatter is much lesser for mean low tide than for mean high water levels. The effects of waterway deepening on mean tidal peaks at the gauge Schulau is higher than downstream: Mean high tide has risen for 12,8 cm (fig. 10a) and the mean low water level has been lowered for 25,1 cm (fig. 10b). The scatter of the monthly mean peaks is of an acceptable
Fig. 9: Determination of mean low water level changes $D_L$ (a) and mean high water level changes $D_H$ (b) due to waterway deepening to C.D.-13.5 m (tidal gauge Kollmar)

Fig. 10: Determination of mean low water level changes $D_L$ (a) and mean high water level changes $D_H$ (b) due to waterway deepening to C.D.-13.5 m (tidal gauge Schulau)

order of magnitude with respect to the objective of the analysis. The tidal gauge Zollen- speker is located upstream of the harbour of Hamburg; there has been no dredging in that part of the estuary. Nevertheless the deepening effects are also here significant: an increase of mean high tide of 17.3 cm (fig. 11a) and a lowering of the mean low water level of 18.3 cm (fig. 11b). Particularly for the mean low water levels the scattering of data is remarkably higher than for the time series of the gauges being located further downstream. This effect must be credited to the here stronger impact of the variations in freshwater discharges.
Fig. 11: Determination of mean low water level changes $D_L$ (a) and mean high water level changes $D_H$ (b) due to waterway deepening to C.D.-13.5 m (tidal gauge Zollenspieker)

The changes of the tidal peaks are mostly non-symmetrical with respect to that of the tidal range (fig. 12): In the estuarine stretch where the deepening has taken place the descent of the LWL is larger than the rise of the HWL. Contradictory in the upstream area where no dredging has been carried out the changes in tidal range are symmetrically distributed on mean high and low tide. The deepening causes two superimposing effects: a

Fig. 12: Changes of mean low an high water levels along the Elbe estuary due of waterway deepening to C.D.-13.5 m
lowering of mean sea level and an increase of tidal range resulting in a lower rise of high tide than fall of low tide. In the non-deepened stretches of the estuary the increase of tidal range due to the impact of higher tidal energy from the downstream deepened part of the estuary is dominant. Since there is no lowering of the mean water level the changes for high and low water peaks have a similar order of magnitude (fig. 12) which fits into the explanation of the deepening effects on tidal water levels given before (fig. 4 - 6).

Comparison with previous model tests

The effects of the Elbe waterway deepening have been investigated before execution by hydraulic model tests with both a movable and a non-movable bed [BAW 1974]. In comparison to the measured effects the forecasted changes are remarkably smaller (fig. 13). But the test results fit much better if compared with the changes occurring immediately after dredging in the transition period of the first two years (fig. 9 - 11) whereas the later changes of the mean peaks exceed the forecast significantly. This is due to a readaptation of estuarine morphology to the changed tidal hydrodynamics occurring after deepening. This cross-sectional enlargement allows again an increase in tidal energy enforcing afterwards once more morphological changes. Generally the slopes of the estuarine navigation channel are

![Fig. 13: Comparison of evaluated changes of mean tidal peaks and range with forecast by hydraulic model test](image-url)
after deepening steeper than fitting to natural conditions. Furthermore both capital and maintenance dredging leads to lowering of the bottom beyond the required navigational depth. Consequently these effects in acting together with the increased tidal energy create a process of cross-sectional readaptation continuing after capital dredging, until a new morphodynamical equilibrium is established (fig. 14). This effect of a morphological phase-lag after estuarine deepenings has to be considered for forecasts in order to get proper and reliable results for the effects of anticipated estuarine deepenings with respect to tidal water levels.

Conclusions

Deepenings of estuarine waterways effect an increase in tidal range and a lowering of the mean water level. The superimposition of both leads to relatively larger lowering of the tidal low water peaks than heightening of the high water levels. Upstream of the dredged parts of the estuary only an increase of tidal range occurs contributing evenly to the changes of the low and high water peaks.

It has been shown that even for successive deepenings of estuaries a separated quantification for singular measures is possible by combined application of double-mass and regression analysis. Double-mass analysis is a useful tool for the evaluation of coherent time series being suitable for event-related regression analysis. The implementation of physically sound boundary conditions and parameters allows a proper quantification of deepening effects on tidal range and peaks.

The morphological phase-lag after the dredging itself allows a further significant change of tidal water levels afterwards. Its time scale is about years. Hydrodynamical modeling of deepening effects must take these effect into consideration for getting reliable results.
Acknowledgements

The basic work for this paper was carried out in the framework of a joint working group of the Federal Waterway Administration and the Water Management authorities of the States of Lower Saxony and Schleswig-Holstein. The author is indebted to his colleagues in that team, particularly to its former chairman Dr. Heinz Wismer (Federal Directorate North for Waterway Engineering) who provided both support and advice. Valuable advice was also delivered by Ralph Annutsch (German Hydrographic Service) and Werner Dietze (Federal Directorate Northwest for Waterway Engineering). The author is also grateful for the support which he got from his colleagues Jochen Fleßner, Detlef Glaser, Thomas Hartkens and Ralf Kaiser from the Section of Coastal Hydrodynamics at the Coastal Research Station.

Inlet Dynamics from Semi-Annual Surveys

Owen W. Callard, William R. Dally, M. ASCE, and Kathy FitzPatrick

1. Introduction

Field surveys, carefully conducted with state-of-the-art equipment, remain the best source of information for studying tidal inlets. Data from an ambitious hydrographic surveying program that is ongoing at Sebastian Inlet, Florida (see Figure 1), are being analyzed to examine the morphologic dynamics of the inlet, to maintain a sediment budget, and to identify any ongoing impacts of the inlet to the adjacent beaches.

Historically, the presence of Sebastian Inlet caused the formation of both ebb and flood shoals, and accretion and erosion along the beaches to the north and south, respectively. However, because 1) the inlet is relatively small, 2) its jetties were originally constructed in 1923-24, and 3) a sediment trap in the inlet’s throat is periodically dredged and the material placed on the downdrift beaches, any persistent, long-term erosion/accretion trends have abated. Modern-day changes are limited to variation about a quasi-equilibrium state (Dally and FitzPatrick, 1997).

The predominant wave energy along the east central Florida coast during the winter months emanates from the north and northeast sectors due primarily to extratropical storms commonly referred to as ‘northeasters’. It is thus expected during the winter months sand will accrete at the north side of the inlet, and erode from the south. During the summer months, the direction of predominant wave energy switches to the southeast quadrant. Low-energy ‘recovery’ swell is caused by persistent winds from an entrenched system of high pressure (Bermuda High) which dominates the summer weather in the central North Atlantic. Higher energy swell from this sector also occurs as a result of occasional hurricanes. Consequently during the summer, erosion of the north fillet is expected, with accretion on the south. The purpose of the study described below is to identify and quantify this seasonal behavior, and any other patterns or trends present.

2. The Survey Data Set

The data set used in this study consists of 15 surveys of the Sebastian Inlet system, which cover the flood shoal, navigation channel, sediment trap, inlet throat, ebb shoal, and north and south beaches. Figure 2 presents a plan view of the data coverage from a recent survey. Although an initial survey was conducted in August, 1989, surveys have been performed on a semi-annual basis since July, 1990, usually in February and July.

Although the equipment and techniques used in the surveying program are continually improved, in general, standard land surveying methods are used to wading depth, with boat/fathometer methods used in deeper water. Transect spacing in the ebb shoal, sand trap, and navigation channel is 100 ft, whereas the spacing in the inlet throat and flood shoal is 200 ft. Beach profiles are measured at 500 ft or 1000 ft intervals, and are based upon the system of monuments ('R-monuments') maintained by the Florida Department of Environmental Protection. The spatial coverage, resolution, and semi-annual basis of the surveys makes this a distinctive data set, from which seasonal changes at Sebastian Inlet can be determined.

Figure 1 - Location of Sebastian Inlet, on Florida's central Atlantic coast.
Figure 2 - Plan view of data from July 1997 survey of Sebastian Inlet, showing area used in studying fillers and ebb shoal.
3. Analysis Methods

For the purposes of studying morphodynamics in the immediate vicinity of the mouth of the inlet, herein the study domain was limited to 6000 ft (1830 m) in the longshore direction, from R-217 in Brevard County to R-004 in Indian River County. In the seaward direction, the domain extended roughly 5000 ft (1524 m) offshore, as is shown in Figure 2.

The survey data were analyzed using commercially available Digital Terrain Modeling software, specifically, the Eagle Point Civil Engineering Series (v. 13.2) that runs using AutoCAD (v. 13) as an operating platform. The Eagle Point Surface Modeling module was first used to create a three-dimensional representation of each survey by generating a Triangular Irregular Network (TIN), from which maps of bathymetric contours were created. The TINs created for each data set were then used to develop difference-contours, i.e contours of the changes in bathymetry that occurred between sequential surveys. Using maps of these difference contours, seasonal behavior of the inlet could be examined synoptically. Finally, the Site Design module of Eagle Point was used to make volumetric computations, in order to quantify seasonal changes to the inlet system.

4. Results and Discussion

4.1 Difference Contours

Difference contours were developed between consecutive seasonal surveys, beginning with 7/90 and concluding with 7/97, and allow one to examine the Sebastian Inlet region in a synoptic fashion. Two-foot contour intervals were used in order to identify areas where change was significant, and Figure 3 presents an example of typical results for a winter-to-summer comparison (2/94-7/94). The elevation contours of the earlier survey are also shown for reference. The area of the north fillet closest to the north jetty experienced up to 8 ft (2.4 m) of erosion, with the amount of erosion decreasing northward. In contrast, the area of accretion in the south fillet extends over a larger area, between R-001 and R-003 (at which point the ebb shoal ties into the beach), but shows only up to 4 ft (1.2 m) of accretion. Although relatively inactive during this particular time period, the ebb shoal has a small spot of 2 ft (0.6 m) of accretion on its seaward flank, and a slightly larger spot of erosion on its landward side. An area of accretion is found directly off the end of the north jetty.

The 7/94-2/95 comparison shown in Figure 4 displays typical behavior for summer-to-winter changes. Extensive and significant accretion of up to 8 ft (2.4 m) is found on the north fillet whereas the south fillet experienced up to 6 ft (1.8 m) of erosion. As mentioned in the introduction, northeasters and other lesser storms cause sand to accrete as it becomes trapped against the north jetty, at the expense of the south fillet. In contrast to the previous season, the ebb shoal experienced significant (and reversed) change. A broad area of up to 6 ft (1.8 m) of accretion is seen on the landward side of the shoal, and erosion, but to a lesser degree is found on the seaward flank.
Figure 3 - Bathymetry and difference-contours for 2/94 - 7/94 surveys showing erosion of north fillet and accretion on south fillet, with only minor change to ebb shoal.
Figure 4 – Bathymetry and difference-contours for 7/94 - 2/95 surveys showing accretion on north fillet and erosion of south fillet, with moderate shift of material on ebb shoal.
The typical seasonal changes displayed by Sebastian Inlet in Figures 3 and 4 confirms expectations, given the usual seasonal shift in wave climate characteristic of the region. That is, high-energy, short-period, erosive waves from the northeast are typical during the late fall and winter, with low-energy, long-period, accretive swell from the south during the summer.

Although most seasonal changes experienced by Sebastian Inlet are qualitatively similar to those of Figures 3 and 4, the results from the 2/91-7/91 and 7/91-2/92 comparisons are significantly different. The difference-contours presented in Figure 5 show erosion as expected at the north fillet. Significant accretion is displayed by the south fillet region extending from the beachface to the -10 ft (-3 m) contour. The ebb shoal shows an area of mild accretion that is broader than would be considered normal, and little erosion is found on the leeward side of the shoal. It is noted that in 2/91, severe weather precluded boat/fathometer surveying of the north and south beaches, and reduced the coverage of the ebb shoal.

The 7/91-2/92 comparison of Figure 6 displays essentially a pattern reversed from the previous season but with even stronger change, especially on the ebb shoal. Uncharacteristically, erosion of the ebb shoal is widespread, typified by changes of 2 ft (0.6 m). Although these findings were originally viewed with skepticism, the field notes and reduced data were checked exhaustively, and the tide stage corrections for the boat survey verified. It is also noted that the large changes observed on the north and south fillets were documented using land surveying techniques, and were not subject to boat-survey errors. It is believed that the changes to the ebb shoal were real, and possibly caused by waves from the 'Halloween Storm' of late October, 1991. These waves were not only large ($H_m \approx 2.5$ m), but more importantly were atypically long for the region ($T_m \approx 20$ s), and so were capable of mobilizing sand at even the 20 ft (6m) depth contour.

### 4.2 Volume-Change Computations

Volume changes were computed for the three specific domains examined above, in order to quantify their seasonal behavior. Indicated in Figures 3-6, the north fillet domain extended from R-217 to R-219 o/s - a distance of 1800 ft (549 m), and extended seaward to roughly -10 ft (-3 m) NGVD, a distance of 1000 ft (305 m). The south fillet domain extended from R200-S to R-003, which is 2250 ft (686 m) in the longshore direction. The south fillet domain was extended offshore to only -5 ft (-1.5 m) NGVD in order to capture changes in the south fillet while excluding the ebb shoal. The ebb shoal domain extended seaward 3275 ft (998 m), and 3248 ft (990 m) in the longshore direction, and its border cut diagonally across the jetty mouth.

In order to calculate volumes within the selected domains, the Site Design module in Eagle Point was used to superimpose the TINs in pairs sequentially, to determine raw cut and fill volumes within the area of interest. The computed cut and fill volumes were then used to obtain a net volume change within a domain for each season.
Figure 5 - Bathymetry and difference-contours for 2/91 - 7/91 surveys showing erosion of north fillet and major accretion on south fillet, with significant deposition on ebb shoal.
Figure 6: Bathymetry and difference-contours for 7/91-2/92 surveys showing accretion on north filler, and significant erosion of south filler and ebb shoal attributed to long-period waves of the 'Halloween Storm'.
North Fillet

Results for the north fillet are presented in Table 1 and Figure 7. Of the fourteen seasonal comparisons made, eleven fit the expected pattern of accretion during the summer-to-winter transition and erosion in the winter-to-summer. Three comparisons displayed behavior not expected at the north fillet. The 7/90-2/91 comparison had a net

Table 1. Volume Change Calculations for North Fillet.
loss of 10,856 yd$^3$ (8,300 m$^3$) when a net accretion would have been expected. During the 2/92-7/92 season a net accretion of 22,225 yd$^3$ (16,992 m$^3$) was observed when erosion might be expected. Finally, there was a net accretion of 2,636 yd$^3$ (2015 m$^3$) for the 2/93-7/93 surveys, but this quantity is not significant. Noting the seasonal and annual variability, the net cumulative volume of 43,612 yd$^3$ (33,344 m$^3$) from 7/90 to 7/97 also is not wholly significant, and indicates that the north fillet was experiencing no net trend towards erosion or accretion during this time.

It is noted that the volume-change calculations were repeated for the north domain, but with the seaward boundary reduced to -5 ft (-1.5 m) NGVD to be consistent with the south fillet domain. The seasonal volume changes were identical in their pattern, but generally smaller in magnitude. A net cumulative volume of 13,306 yd$^3$ (10,173 m$^3$) was computed in this smaller domain.

South Fillet

In the south fillet domain, ten of the fourteen comparisons showed erosion in the summer-to-winter and accretion in winter-to-summer, as shown in Table 2 and Figure 8. Of the four comparisons that displayed reversed behavior for the south fillet, (i.e. 7/92-2/93, 2/94-7/94, 7/95-2/96, and 7/96-2/97), only 7/96-2/97 was significant (16,511 yd$^3$ accretion). The net cumulative volume of 50,039 yd$^3$ (38,258 m$^3$) found on the south fillet is significant in that it is accretion, and is larger than the net cumulative volume of 43,612 yd$^3$ (33,344 m$^3$) found on the north fillet for the same time period.

Ebb Shoal

It appears from the fourteen comparisons made for the ebb shoal domain, presented in Table 3 and Figure 9, that although half showed erosion and half accretion, no clear seasonal pattern exists. Overall, when accretion happens, it occurs at a fairly uniform rate, whereas erosion is much more variable. During the erosion episode in 7/91-2/92,

Table 3. Volume Change Calculations for Ebb Shoal.
more than 440,000 yd$^3$ (336,660 m$^3$) of sediment was lost from the shoal. The lack of seasonal pattern on the ebb shoal is attributed to the fact that, in addition to the wave climate, the hydrodynamics here are governed by the flood and ebb currents, which of course vary in the long-term according to general trends in ocean and lagoon water levels.

5. Conclusions

Clear patterns of seasonal behavior occur in the north and south fillet domains of Sebastian Inlet; however, the ebb shoal appears to experience gradual accretion and episodic erosion. All three domains show cumulative accretion for the seven-year time period, with that on the south fillet being the most significant as it is contrary to 'conventional wisdom' for the Atlantic coast of Florida. Further interpretation of these findings awaits detailed study of the long-term wave climate, meteorology, and water levels for the region.

Abstract

Two tidal inlets with strikingly different physical characteristics have been investigated through an analysis of multi-year beach survey results and field investigations of the nearshore wave and current structure adjacent to the inlets. The survey results indicate that the downdrift shoreline adjacent to both inlets is dominated by persistent inlet directed currents, which run counter to the net sediment transport direction. The two wave and current studies differed in both their spatial and temporal resolution, requiring the use of separate analysis techniques to determine the forcing mechanisms responsible for the observed inlet directed currents. The two analysis techniques produced similar results which indicate that tidal-induced circulation generates the persistent nearshore current structure. Episodic wind-generated currents and nonlinear wave and current interactions were found to reach the same order of magnitude as the tide-induced currents, and could either enhance or reverse the observed nearshore current structure.

Introduction

It has been observed that in the vicinity of coastal inlets, complex interactions between tidally-driven currents and shoreward propagating waves produce unique wave transformation patterns that in turn give rise to sediment transport characteristics that differ greatly from adjacent shoreline areas. Shorelines adjacent to tidal inlets are subjected to a number of spatially- and temporally-varying forces, such as tidal motions, wind stress, wind waves, swell, freshwater inflow, density driven circulation, and variations in atmospheric pressure. Although much has been learned about the nature of these interactions, and their impact on sediment transport, there are very few comprehensive

measurements in dynamically-active regions such as tidal inlets that would allow one to examine the response of the shoreline to the multitude of forcing mechanisms.

Two recent multi-year shoreline monitoring studies in New Jersey have focused on the impact of tidal inlets on shoreline evolution. Each study included an analysis of long-term beach profile surveys and short-term wave and near-bottom current measurements. The initial study was conducted at Townsends Inlet in Avalon, New Jersey (Figure 1). Townsends Inlet is a relatively unimproved inlet approximately 500 m wide, stabilized by a 180 m long stone jetty located on the south side of the channel. Analysis of 10 years of beach profile data at the site indicate that the sediment transport pattern adjacent to the inlet is opposite the net southerly transport direction along this reach of coast (Farrell et al., 1995). A second multi-year study was conducted 110 km north of Townsends Inlet at Manasquan Inlet, New Jersey (Figure 1). This improved inlet has a 122 m wide entrance channel protected by two 400 m long parallel stone jetties. Analysis of 3 years of beach profile data north of the inlet also indicates the presence of a localized reversal in the net northerly sediment transport direction.

![Figure 1. Location Map](image)

Field Measurements and Analysis

**Manasquan Inlet**

Repetitive, high-resolution cross-shore beach profile measurements, obtained over a period of 3 years along the shoreline north of the Manasquan Inlet, indicated the presence of an area of localized erosion between 250 m and 750 m from the inlet. This erosion hot spot is characterized by a 38 m recession in the position of the mean low water line relative to the shoreline position 100 m to the north and south.
In an effort to identify the possible causes for the area of accelerated erosion, a comprehensive field study was conducted in and around Manasquan Inlet on 17 April 1996. Wave and near-bottom current measurements (1 m above the seabed) were obtained during the one day study by 3 bottom mounted InterOcean Systems S4 electromagnetic current meters fitted with high resolution pressure, temperature and conductivity sensors. Two of the bottom mounted gauges were located seaward of the inlet; S1 approximately 700 m offshore in a water depth of 13 m mean sea level (MSL), and S2 approximately 360 m offshore at a depth of 11 m MSL (Figure 2). The third gauge was located 385 m offshore of the erosion hot spot, 550 m north of the inlet, in 9.5 m of water MSL. All of the gauges were configured to sample continuously at 2 Hz and internally record the measured parameters over the duration of the study. In addition to the near-bottom point measurements, the spatial distribution of both the horizontal and vertical current structure was obtained through the use of a towed Acoustic Doppler Current Profiler (ADCP) (Bruno, et. al., 1998). The ADCP provided measurements of the top to bottom current profile along a series of transects that spanned the inlet throat, the adjacent shorelines to the north and south, and across the ebb shoal out to a water depth of 13.5 m MSL. The position of the ADCP during each transect was determined continuously using a shore-based surveying total station equipped with an Electronic Distance Meter (EDM), which obtained angle and distance measurements to a reflective prism mounted on the boat. Meteorological conditions (wind speed and direction) during the study were obtained by an anemometer located at the eastern tip of the southern inlet jetty, 10 m above the water surface.

Figure 2. Location of bottom mounted S4 meters. Depth contours in feet, MSL
The high-resolution current study spanned both the ebb and flood portions of a spring tidal cycle with a predicted range of 1.5 m. The meteorological and oceanographic conditions over the duration of the study are presented in Table 1.

Throughout the study period the wind was directed offshore toward the southeast at 10 m/s, significant wave heights ranged from 0.74 to 1.00 m propagating from the northeast with an average peak period of 9.2 s.

The high-resolution current survey spanned both the flood and ebb portions of the tidal cycle. Each round of transects was completed in approximately 30 minutes in order to provide a nearly synoptic measurement of the current pattern at various phases of the tide. Figure 3a illustrates the near-surface current distribution at peak ebb tide (1500 GMT). The measurements indicate a strong flow exiting the inlet, with near-surface currents exceeding 1 m/s. The near-bottom current structure exiting the inlet at peak ebb (Figure 3b) indicates a reduction in the current velocity to between 0.33 and 0.55 m/s. In contrast to the strong jet-like outflow on the surface, the weaker near-bottom currents are directed inshore toward the inlet. Interestingly, in both the surface and bottom currents there is evidence of inlet-directed return flows along the transects north and south of the inlet. This return flow is reflected in the near-bottom current measurements obtained by the three S4 gauges. Figure 4 illustrates the time history of the north-south component of the 9 minute average near-bottom velocity at each gauge (north is positive). Note that although the two gauges located seaward of the inlet, S1 and S2, recorded a reversal in current direction as the tide turned from flooding to ebbing, the nearshore gauge, S3, recorded a nearly constant southward directed near-bottom motion.

In an effort to gain some insight into the forcing mechanism responsible for the observed persistent inlet directed near-bottom flow seaward of the erosion hot spot, an order of magnitude comparison of the measured forcing mechanisms can be conducted. The physical forcings of interest include, wave-induced longshore transport, wind-generated currents, and inlet-induced circulation.
Figure 3. Spatial Current Distribution at 1500 GMT: (a) Near-Surface; (b) Near-Bottom

Figure 4. Average (9 min.) Near-Bottom Current: (a) S1; (b) S2; (c) S3
Utilizing the breaking criteria, \( h_b = 1.28 H_b \), where \( H_b \) is the wave height at breaking and \( h_b \) is the water depth at breaking, the location of the average location of the surfzone on 17 April, 1996 was in 1.1 m of water MSL, placing meter S3 approximately 305 m seaward of the surfzone. Based on Longuet-Higgins' (1970) formulation, the wave-induced longshore current 300 m seaward of the surfzone is negligible.

The wind-generated current at the surface of the water column can be estimated as 3 \% of the wind speed 10 m above the water surface \((U_{10})\). In shallow water the wind-generated transport is essentially in the direction of the wind stress (Pond and Pickard, 1983). Assuming a logarithmic decay of the surface current with depth, the current generated by the wind stress 1 m above the bottom can be expressed as:

\[
V_0 - V_1 = \frac{u^* \ln \left( \frac{h}{z} \right)}{\kappa}
\]  

where \( V_0 \) is the surface current (\( = 0.03 U_{10} \)), \( V_1 \) is the current speed 1 m above the bottom, \( u^* \) is the current shear velocity, \( \kappa \) is von Karman's constant (\( \kappa = 0.4 \)), \( h \) is the water depth, and \( z \) is the distance of the current meter above the bed. The current shear velocity is calculated as:

\[
u^* = \left( \frac{\tau}{\rho} \right)^{1/2}
\]

where the bottom shear stress, \( \tau \), is given as:

\[
\tau = \frac{1}{2} \rho C_f V_0^2
\]

In equation 3, \( \rho \) is the water density and \( C_f \) is the current friction factor. Substituting equations (2) and (3) into (1) and rearranging:

\[
C_f = \left( \frac{2}{V_0} \right) \left[ \frac{\kappa (V_0 - V_1)}{\ln(h/z)} \right]^2
\]

Utilizing the ADCP current profile data, equation 4 can be used to directly solve for the current friction factor, \( C_f \). Table 2 lists the near-surface and near-bottom current velocities, and the calculated friction factor, \( C_f \), measured within 300 m of gauge S3 at peak ebb (1500 GMT) on 17 April 1996.
Table 2. Measured Current Shear within 300 m of gauge S3 at 1500 GMT

Substituting the data obtained at peak ebb, \( h = 9.64 \text{ m}, U_{10} = 10 \text{ m/s}, \ z = 1 \text{ m}, \rho = 1026.9 \text{ kg/m}^3 \), and the average \( C_f = 0.05 \), into equations (1) through (3) and solving for \( V_i \), yields a near-bottom wind-generated velocity of 3.1 cm/s directed 123° from North. Decomposing the current vector into north and east components gives an alongshore wind-generated current component of 1.7 cm/s to the south.

Joshi and Taylor (1983) analyzed the alongshore and cross-shore velocity components induced by the entrainment of water into nonbuoyant tidal jets issuing into water of constant depth with arbitrary bottom friction. The potential motion induced by an ebbing tidal jet is modeled as a series of sink singularities which constitute elementary solutions to Laplace’s equation:

\[
V^2 \psi = 0
\]

where \( \psi \) is the two dimensional stream function \( \psi(x,y) \). Analytic solutions for the jet-induced circulation are obtained by relating the sink strength to the inlet characteristics. These characteristics and the values for Manasquan Inlet include inlet half-width, \( b_0 = 61 \text{ m} \), mean channel depth, \( h_0 = 3.05 \text{ m} \), inlet throat cross-sectional area, \( A_c = 366 \text{ m}^2 \), average velocity over the throat area, \( u = 1.0 \text{ m/s} \), length of inlet channel or jetties, \( a = 400 \text{ m} \), the Darcy-Weisbach friction factor, \( f = 0.043 \) the Chezy coefficient, \( C = 42.82 \text{ m}^{1/2}/\text{s} \), and Manning’s \( n = 0.028 \).

A series of nondimensional solution curves are presented to determine \( V \), the ratio of alongshore velocity to inlet velocity, based on \( \zeta \), the ratio of distance alongshore from the inlet to inlet half width. Solution curves are given for various combinations of dimensionless jetty length, \( A = a/b_0 \), and dimensionless friction parameter, \( \mu = fb_0^2/h_0 \). For the Manasquan Inlet, \( A = 6.5 \) and \( \mu = 0.107 \). From the solution curves presented in Figure 12 (Joshi and Taylor, 1983), the predicted alongshore current 550 m north of the inlet, due to steady potential motion induced by the tidal jet alone, is 1.04 cm/s.

**Townsend’s Inlet**

A seven-day time series of wave and near-bottom current measurements were obtained 60 m inshore of the western edge of the main ebb channel of Townsend’s Inlet,
Avalon, New Jersey, in September, 1993 (Figure 5). The wave and current meter was mounted 1 m above the sea bed, 180 m south of the southern inlet jetty, in a mean water depth of 3.0 m MSL. In this configuration the meter was exposed to both nearshore wave and current action as well as strong tidal currents. The meter was initialized to provide measurements of the pressure and two orthogonal components of velocity at 2 Hz over 9 minute burst samples, at one hour intervals.

![Figure 5. Townsends Inlet. Location of channel and shoals indicated by dashed line.](image)

The measured time series is presented in Figure 6. The tidal elevation record is plotted in the upper panel, followed by the surface wind observations from Atlantic City, (located 45 km north of the inlet), the measured significant wave height ($H_s = 4(m_0)^{1/2}$), the peak wave direction, and the 8.5 minute average current measured 1 m above the bottom.

All of the recorded vectors were decomposed into shore-parallel and cross-shore components. Since the axis of the ebb channel of the inlet lies on a bearing of 0° Magnetic North (MN), all of the recorded directions are reported relative to Magnetic North. Thus, shore-parallel components are parallel to the axis of the inlet channel and cross-shore components are perpendicular to the inlet channel. Positive values of the shore-parallel and cross-shore components are directed to magnetic north and east, respectively. Directions are given as the direction of propagation (i.e. a shore-parallel wind of -5 m/s is a wind directed from the north). The x-axis is scaled in tenths of days Eastern Daylight Savings Time (EDT) so that 20.5 would represent the 20th day of the month at 1200 hours.
Figure 6. September, 1993 Observations at Townsend's Inlet
The energy density spectra for the tidal elevation and shore-parallel component (U-Comp) of velocity is presented in Figure 7. Energy density spectra were calculated for the zero mean records of tidal elevation and the shore-parallel current component for the 7 day data set. The time series were divided into five 64 hour data segments and ensemble averaged with 50% overlap, providing spectral estimates with 10 degrees of freedom and a 95% confidence interval of 25 to 150 percent of the estimates. Examining Figure 7, two peaks are evident in the tidal elevation energy density, one centered at the semidiurnal frequency (0.08 cph) and one centered at a frequency of 0.02 cph. Three peaks in kinetic energy are present in the shore-parallel velocity component. Peaks of equal magnitude \((0.175 \text{ (m/s)}^2\) are centered at 0.02 cph and the semidiurnal tidal frequency and a lesser peak of 0.13 \((\text{m/s)}^2\) is centered at a frequency of 0.16 cph.

![Energy Density Spectra Sept. 12 - 20, 1993](image)

**Figure 7. Elevation and Kinetic Energy Density**

In an effort to determine the forcing mechanisms responsible for the observed energy density distributions, a multivariable polynomial autoregressive analysis with exogenous variables (PARX) model was utilized to produce empirical fits to the measured nearshore current data. The analysis technique decomposes the measured time series data into a multivariate data set which is utilized to predict one measured variable based on a polynomial function of the remaining variables (see Herrington and Bruno, 1998). Utilizing the six parameters measured, water elevation, \(h\), wave amplitude, \(a\), shore-parallel wave number, \(k_x\), wave frequency, \(\omega\), shore-parallel wind speed, \(W\), and the time rate of change of shore-parallel wind speed, \(dW/dt\), a PARX model was developed to predict the measured shore-parallel current velocity. The empirical equation developed by the PARX model to predict the shore-parallel component of velocity, \(U_{sp}\), is

\[
U_{sp} = K_w + K_{dW} + K_{AH} + K_K
\]
where

\[
K_w = \left[ 0.015157 \left( \frac{\omega^2}{W_{t,1}} \right) - 0.0016022 h^2_{t,2} W_{t,1} \right] + \left[ 0.13338 a^2 + 0.011704 \omega_{t,1} + 0.00058704 \left( k W^2 \right) \right] W
\]

\[
K_{dW} = \left[ 0.0020512 \left( \frac{dW}{dt} \right) k - 0.0017450 \left( \frac{dW}{dt} \right) h_{t,1} - 0.0025645 k_{t,1} \left( \frac{dW}{dt} \right)_{t,2} \right]
\]

\[
K_{AH} = \left[ 0.010630 \left( \frac{h^2}{a_{t,2}} \right) - 0.010994 \left( \frac{h^2}{a_{t,1}} \right) \right] + \left[ 53.695 / h - 92.342 / h_{t,1} + 40.090 / h_{t,2} - 0.087996 h^2_{t,2} \right] a^2_{t,1} + 0.10636 a_{t,1} h_{t,2}
\]

\[
K_K = \left[ -0.00000040479 / \left( k_{t,1} k_{t,2} \right) \right]
\]

Figure 8 presents the measured (solid line), fit (dotted line) and predicted (dashed line) shore-parallel current component. The fitted nonlinear model, spanning the first 150 hours (day 12.75 to 19.0) of the time series, is able to resolve to a reasonable degree most of the peaks contained within the shore-parallel current record. The fit does quite well in resolving the strong southerly directed flow between day 16.5 and 17.5, only missing the magnitude of the initial strong spike in velocity. The predicted shore-parallel current over the final 36 hours (day 19.0 to 20.5) of the time series indicates that the model is able to predict the overall magnitude and direction of the current but loses some of the higher resolution peaks contained in the data.

A determination of the dominant terms in equation 6 can be obtained by comparing the contribution of each forcing term utilized to fit the shore-parallel current component. Figure 9 is a comparison plot of the contribution of each predictive term in equation 6 relative to one another. The four terms in the empirical equation are those terms which are a function of the wind velocity, \( K_w \), rate of change of the wind velocity, \( K_{dW} \), tidal elevation and wave amplitude, \( K_{AH} \), and the wave number, \( K_K \). Examining Figure 9a and 9c, it is apparent that the dominant tidal structure of the predicted current velocity during these periods is driven by \( K_{AH} \), the terms containing both the change in water surface elevation, \( h \), and the wave amplitude, \( a \). Additionally, it is evident that the frequency of the forcing produced by the tidal elevation and wave amplitude terms increases during the time period of strong southerly-directed currents (Figure 9b). As Figure 10 indicates, the frequency distribution of the kinetic energy density associated only with the terms containing the variation of water depth, \( h \), and the wave amplitude, \( a \), verifies that the nonlinear interaction between the two parameters is responsible for the measured current variability at 0.16 cph. The relative contributions of the remaining terms in equation 6 (Figure 9) indicate that the predicted current is strongly modified by the magnitude and direction of the shore-parallel wind velocity term, which can be of equal or greater magnitude than the water depth and wave amplitude terms. The shore-parallel wind velocity and the water depth - wave amplitude terms combine to produce the strong southerly-directed currents observed during the period of increased wave height (see Figures 6 and 9b). These two predictive terms are slightly modified by the rate of change of the wind velocity and the wave number terms during the wave event.

Figure 9. Relative Magnitude of Terms in Equation 6

Figure 10. Influence of Water Depth and Wave Amplitude on Energy Distribution
Conclusions

Two tidal inlets with strikingly different physical characteristics have been investigated through an analysis of multi-year beach survey results and field investigations of the nearshore wave and current structure adjacent to the inlets. The downdrift shoreline adjacent to both inlets is dominated by persistent inlet directed currents, which run counter to the net sediment transport direction. The nearshore wave and current data obtained over a 8 day period at Townsends Inlet revealed that the nearshore current structure is dominated by inlet directed currents over both the flood and ebb tide. The empirical analysis of the measured data determined that an interaction between the wave climate and tide generate the observed inlet directed currents. However, strong episodic wind and wave events can reverse the observed current structure. The one day, high-resolution, wave and current study conducted at Manasquan inlet indicated a strong tidally-generated jet-like current exiting the inlet during ebb and persistent inlet-directed nearshore currents 550 m north of the inlet. A simplistic order of magnitude analysis of the measured data indicated that the potential motion induced by an ebbing tidal jet, and/or the wind-generated current contribute significantly to the observed current structure.

Although the characteristics of the two inlets differ, the hydrodynamic forcings are quite similar. Entrainment into the ebbing tidal jet leads to prolonged inlet directed nearshore currents updrift and downdrift of the inlet. The prolonged flood currents result in the reversal of the net alongshore current direction downdrift of the inlet, resulting in the formation of hot spots of erosion at the nodal points. The incident wind and wave forcing can be of equal magnitude to the potential flow generated by the tide, leading to episodic enhancement or reversal to the predominant flow characteristics.

Abstract

St. Augustine Inlet, a trained, ebb-dominated inlet, acts as an efficient sediment trap by impounding sediments in ebb and, to a lesser extent, flood shoals. The ebb shoal, containing 23 million cy of sand by 1994, impounds 425,000 cy/yr of sand without signs of abatement. Inlet sand trapping causes chronic erosion of the south beach. The large inlet sand trapping capacity appears to be related to the large magnitudes of and the large mismatch between the ebb and flood discharge prisms. Spreading characteristics of the ebb jet are consistent with observed sedimentation patterns of the ebb shoal.

Introduction

St. Augustine Inlet, located in northeast Florida (a state in the SouthEastern United States), connects the Tolomato River, flowing from the north, and the Matanzas River, flowing from the south, to the Atlantic Ocean (Figure 1). Vilano Beach and Conch Island lie to the north and south of the inlet, respectively. Salt Run, a 2.1-mile long embayment extending south from the inlet, is a relic of the old, pre-stabilization inlet.

The natural orientation of the inlet was northwest to southeast until about 1940. The U.S. Army Corps of Engineers (COE) cut a new, east-west oriented channel approximately 1,200 ft north of the natural inlet and constructed a 1,580-ft north jetty between 1940—1941. A 3,695-ft south jetty was later constructed by the COE in 1957.

This paper quantifies the inlet sand trapping effects by examining bathymetric and beach profile data, historical mechanical bypassing rates, and littoral drift in the inlet vicinity. An inlet hydrodynamic model and an ebb jet model are employed to relate the inlet sand trapping effects to inlet hydraulics.

Bathymetric and Beach Profile Data

A COE 1937 survey of St. Augustine Inlet, supplemented by aerial photographs and an old quadrangle, was used to characterize the pre-inlet stabilization bathymetry.
Figure 1  Location Map of the St. Augustine Inlet Vicinity
A 1974 survey of the Atlantic Ocean waters in the St. Augustine Inlet vicinity conducted by the National Ocean Survey (NOS) served as the primary bathymetric survey for this year. Another 1974 survey, performed by the COE, provided bathymetric information for the inlet throat and adjacent Atlantic Ocean waters. These surveys were supplemented as follows. Depths of inlet interior waters for 1974 were obtained from a National Oceanic and Atmospheric Administration hydrographic chart. Depths along a small region were obtained from a 1975 Florida Coastal Engineers (1976) survey of the nearshore north and south beaches. Additional subaerial elevations along some locations were obtained by adjusting 1972 and 1984 Florida Department of Environmental Protection (FDEP) survey data to 1974 conditions.

In October 1994, Taylor Engineering surveyed the interior waters of St. Augustine Inlet. The untoward occurrence of winter storms precluded survey of the inlet exterior waters that year. Taylor Engineering subsequently surveyed the inlet throat and nearby offshore waters in July 1995. The FDEP surveyed the subaerial beach system along the north and south beaches in September 1995. The combination of these three surveys served to define the inlet vicinity for 1995.

Region of Inlet Influence

The region of inlet influence is about 19,000 ft to the north and about 30,000 ft to the south of the inlet based upon shoreline and subaerial beach volume change analyses.

Bathymetric and Subaerial Beach Analysis

All the surveys were reduced to a common digitized format by representing the bottom elevations with respect to mean low water (MLW) at known horizontal locations. These discrete, digitized data were input to digital terrain modeling software. Using triangulation techniques, the software created continuous, three-dimensional surfaces of the inlet bathymetry for 1937, 1974, and 1995. Overlaid, these surfaces lent themselves to accurate computations of bathymetric change.

The 1937—1974 bathymetric comparison was used to estimate the beach and inlet short-term response to inlet relocation and structural improvements (Srinivas et al., 1996). The 1937 surface was also used to generate the bathymetric grid for the pre-inlet stabilization hydrodynamic model, described later. The 1974—1995 bathymetric comparison was used to estimate the present, long-term inlet impacts on the inlet-beach system. For this purpose, erosion-deposition volumes were computed in different submerged regions of the inlet vicinity, as presented in Table 1.

Though the north beach was erosive along almost its entire longshore length, this erosion was generally confined to the nearshore region close to the shoreline. The average total vertical change at any eroding location was generally of the order of 3 ft or less. The inner and outer ebb shoal areas experienced significant changes. Intensive accumulation of sand occurred in the outer ebb shoal region as the ebb shoal expanded eastward. Another notable feature, consistent with measured south beach shoreline
advancement adjacent to the south jetty, was the accretion of the beaches immediately south of the inlet as the ebb shoal welded to the shore. The inlet throat experienced substantial changes as the natural channel migrated south. The north channel experienced net accretion whereas the south channel experienced net erosion. Salt Run was almost entirely accretionary. The south beach experienced considerable net erosion. Generally, most of the erosion occurred close to shore and the magnitude of erosion exhibited a slow decrease from north to south.

Also, between 1974—1995, the subaerial beach typically eroded modestly on the north beach while eroding chronically on the south beach; however, the subaerial beach accreted immediately north and south of the inlet due to ebb shoal sheltering effects.

**Ebb Shoal Evolution**

During the inlet stabilization period, the system of shoals close to the old inlet channel started to collapse, consolidate, and emerge. Finally, by 1957 and into the post-stabilization period, the shoals welded to the mainland to form a continuous beach south of the inlet.

The ebb shoal was defined according to the method outlined by Dean and Walton (1973). Calculated from this procedure, the ebb shoal volume was about 29 million cubic yards (cy) in 1937 (Table 2). After 1940, the ebb shoal migrated in both the northerly and westerly directions in response to inlet relocation. By 1974, the relocated ebb shoal had about 14 million cy of sand. With continued growth, the ebb shoal had accumulated about 23 million cy of sand by 1995.

These ebb shoal volumes contrast sharply with the values reported about two decades ago. Upon investigating 44 inlets including St. Augustine Inlet, Walton and Adams (1976) developed a useful relationship between inlet tidal prisms and equilibrium...
They estimated the 1957 ebb shoal volume for St. Augustine Inlet as 106 million cy. Given the northerly ebb shoal migration in response to inlet relocation in 1940 and the south jetty construction in 1957, together with the continuous accretion of the post-inlet stabilization ebb shoal, the 1957 ebb shoal volume is expected to be less than the 1974 ebb shoal volume. However, Walton and Adams' estimate for the 1957 ebb shoal volume is almost an order of magnitude greater than the 1974 ebb shoal volume estimate of the present study. Though the source of Walton and Adams' bathymetric data is not documented, NOS hydrographic and navigation charts (scales 1:10,000—1:40,000) were typically used in estimating ebb shoal volumes. The limited resolution of data obtained from such charts might contribute to some differences in estimates; however, the magnitude of the discrepancy is hard to explain. Walton and Adams also failed to document the planform area used in the volume computations. Given the relative higher resolution of the bathymetric data used in the present study, the current estimates are believed to be more reliable.

Finally, it is interesting to compare the present estimate of the St. Augustine Inlet ebb shoal volume with the equilibrium volume predicted by the functional relationship developed by Walton and Adams (1976) which relates equilibrium ebb shoal volumes, tidal prisms, and degree of beach exposure. In particular, they predict the relation

$$V_{shoal} = 10.5 \times 10^{-5} P^{1.23}$$

for the vicinity of St. Augustine where $V_{shoal}$ is the equilibrium ebb shoal volume in cubic yards while $P$ is the tidal prism in cubic feet. According to their estimates, the tidal prism was $13.1 \times 10^8 \text{ ft}^3$ in 1957; whence Equation 1 predicts an equilibrium ebb shoal volume of 17.2 million cy. Notably, this ebb shoal volume is of the same order of magnitude as the current estimate and substantially less than the Walton and Adams estimate. As computed later, the ebb tidal prism for current conditions is estimated to be about $13.6 \times 10^8 \text{ ft}^3$. Applying Equation (1) yields a predicted equilibrium ebb shoal volume of 18 million cy. In contrast, the current ebb shoal volume is about 23 million cy and growing steadily with no evidence of abatement. In conclusion, the exact applicability of the Equation (1) relationship between equilibrium ebb shoal volumes and the tidal prism for St. Augustine Inlet is questionable.

Littoral Drift

The revised Wave Information Study (WIS) hindcast (Hubertz et al., 1993), believed to be the most reliable long-term wave climate information available, was chosen for estimating littoral drift in the area of interest. Twenty years of hindcast hourly wave data and the orientation of the local shoreline in the region of inlet influence were utilized to evaluate characteristic annual variations in longshore transport with the CERC (COE, 1984) littoral drift formula. Table 3 presents the results of the analysis for the region just north of the region of inlet influence. The average net drift is about 212,000 cy/yr from the north to the south. The magnitudes of the standard deviations indicate a fairly uniform yearly gross longshore transport rate; however, the northward, southward, and especially the net transport rates vary considerably from year to year. The analysis

revealed that the net transport rate is negligibly small for some years, and is actually reversed (south to north), albeit of small magnitude, for some other years.

Mechanical Bypassing

Over the period of interest (1974—1995) for sediment budget computations, about 480,600 cy of sand (a rate of 21,800 cy/yr) were dredged from locations east of the inlet entrance and placed in nearshore waters off the south beach (St. Augustine Beach).

Sediment Budget

A sediment budget is a comprehensive delineation of sediment transport pathways and magnitudes (Figure 2). Such a delineation, possible from results of the preceding analyses, is necessary to establish the sources and magnitude of sand being trapped by the ebb shoal and the inlet interior and to quantify sand loss rates from the south beach area.

About 212,000 cy/yr (the littoral drift) of sand enter the north beach from the north due to wave-driven littoral drift. About 5,500 cy/yr erode from the subaerial regions and about 198,400 cy/yr erode from the subaqueous regions of the north beach. Thus, about 415,900 cy/yr of sand move into the ebb shoal area from the north.

The ebb shoal vicinity gains sand at a substantial rate—about 405,700 cy/yr (after mechanical bypassing). The subaerial beach fronting the ebb shoal immediately north of the inlet accretes at a rate of 3,785 cy/yr whereas the subaerial beach fronting the ebb shoal immediately south of the inlet accretes at a rate of 14,900 cy/yr. Further, the inlet throat and the south channel erode at rates of 26,700 and 14,500 cy/yr while Outer Salt Run, the inlet interior, and the north channel accrete at rates of about 42,600, 76,600, and 5,800 cy/yr, respectively. Thus, about 83,800 cy/yr of sand deposit inside the inlet as flood shoals. About 21,800 cy/yr of sand is mechanically bypassed from the ebb shoal vicinity to the south beach vicinity. Balancing the influx of sand into the ebb shoal area from the north, losses to the inlet, efflux due to dredging, and accumulation shows that about 114,100 cy/yr of sand move into the ebb shoal area from the south beach vicinity.

The subaerial regions of the south beach erode about 59,400 cy/yr while the subaqueous regions of the south beach erode about 340,000 cy/yr. Thus, about 307,100 cy/yr move south out of the southern limits of the area of inlet influence. This value is
Figure 2  Sediment Budget (1974-1995) for the St. Augustine Inlet Vicinity
within 7% of the 330,000 cy/yr potential longshore transport rate computed by the independent analysis of spatial distributions of littoral drift. The potential longshore transport rate estimates should be reasonably accurate away from the region of inlet influence due to the diminished impacts of inlet hydraulics. Thus, given the preceding sediment balance, the supply of sand for beaches about 30,000 ft south of the inlet is sufficient to balance the sand requirement demanded by the local nearshore wave climate; this facet is consistent with observed beach behavior.

In summary, the ebb shoal draws sand from both the north and south beaches. Acting as a sink, the ebb shoal area accumulates sand at the rate of 427,500 cy/yr (after discounting the mechanical bypassing volume). The flood shoals gain sand at the rate of about 83,800 cy/yr. Consequently, sand does not naturally bypass the ebb shoal. The 330,000 cy/yr sand requirement of the region south of the zone of inlet influence, as predicted by the potential longshore transport capacity of waves, is approximately satisfied by sand supplied through aggravated erosion of the south beach.

Effects of Inlet Hydrodynamics

The constant recurrence of inlet-related tidal currents plays a key role in transporting sediments in the inlet vicinity. Waves transport sand into the inlet vicinity, primarily through longshore transport mechanisms. These sediments get entrained in the tidal currents which flow into the inlet during flood tide and out of the inlet during ebb tide and eventually get deposited as flood and ebb shoals. Thus, an understanding of inlet hydraulics is indispensable to understand the cause-effect relationships governing sediment interactions and exchanges in the St. Augustine Inlet vicinity. This was accomplished by the setup and application of numerical models of the St. Augustine Inlet vicinity for the post-stabilization (1994) and pre-stabilization (1937) conditions. Pre-stabilization model results are only briefly described in this paper; complete results for all conditions are presented in Srinivas et al. (1996). The modeling was used to define spatial and temporal distributions of currents in the vicinity of St. Augustine Inlet to develop an understanding of the hydraulic characteristics for the two stages of the inlet’s existence. Further, using existing conditions as a baseline for comparison purposes, the inlet model is necessary to assess the unique impacts of proposed inlet modifications on these conditions to evaluate their relative merits (Srinivas et al., 1997).

The inlet model is the hydrodynamics portion of TRANQUAL, originally developed by Taylor and Dean (1972) and updated and refined by Taylor and Pagenkopf (1981). TRANQUAL, a vertically integrated, two-dimensional model, uses an implicit finite difference numerical scheme to solve the governing equations of fluid motion and conservation of mass. The formulation incorporates a full treatment of the nonlinear propagation of long waves in complex, shallow estuaries. The model domain extends 334,000 ft and 287,000 ft, centered about the inlet, in the approximate north-south and east-west directions, respectively. The grid scheme consists of 95,858 grid elements, each of dimensions 100 x 100 ft, arranged in a 287 x 334 matrix.
To provide model boundary conditions, Taylor Engineering collected synoptic tide data using bottom-mounted pressure sensing tide gages offshore and inshore the inlet. This data was used to provide the offshore tide forcing and for model calibration.

Figure 3 presents a snapshot of the ebb velocity vectors in the inlet vicinity at approximately the time of peak flow velocity through the inlet throat. The vectors are overlaid on an image of the inlet bathymetry. Most of the flow in the inlet interior occurs along the east banks of the Tolomato and Matanzas Rivers. The maximum velocities are generally about 1 ft/sec. The flow accelerates on approaching the inlet throat and velocities of about 2 ft/sec occur immediately west of the inlet throat. Flow velocities in Salt Run are minimal. The flows from the Tolomato River, the Matanzas River, and Salt Run converge just west of the inlet throat and accelerate to velocities of about 3.8 ft/s just north of the south jetty towards the western region of the throat. Thus, flow through the inlet concentrates towards the southern regions of the throat where greatest depths occur. Regions towards the north of the throat are almost stagnant with flow velocities less than 1 ft/sec. Though velocities of around 3 ft/sec occur in some regions of the throat further east, the bulk of the flow exits the inlet at about 2 ft/sec. The 2-ft/sec contour persists into the channel through the ebb shoal until about 3,000 ft east of the inlet entrance. Upon exiting the inlet, the flow immediately curves southeast. Velocities elsewhere in the ocean are of the order of 1 ft/sec or less. Interaction of the ebb flow with the north jetty is minimal. A north to south circulation exists further offshore. Thus, the majority of the conveyance through the inlet throat is through the deep water channel in the south.

Figure 4 presents a snapshot of the flood velocity vectors in the inlet vicinity at approximately the time of peak flow velocity through the inlet throat. The vectors are of the same scale as in Figure 3. The south to north circulation in the offshore is consistent with the higher water level to the south during flood flow. Velocities in the ocean are of the order of 1 ft/sec or less. Immediately east of the throat, flood flow patterns are more symmetrical compared to the ebb flow patterns in the same region. Upon entering the throat, the flow accelerates to about 3 ft/sec as it feels the effects of the north jetty. The shoal regions in the north of the throat, which were relatively stagnant during ebb, now experience velocities of the order of 1 to 2 ft/sec. Thus, the flow becomes relatively well distributed in the eastern regions of the throat. However, the flow skews towards the south (in the deep water channel) in the western regions of the throat. Velocities of the order of 2 to 3 ft/sec, with peaks of about 5 ft/sec, occur in these southern regions. The bulk of the flow decelerates and exits the throat at velocities of about 1 ft/sec; however, higher flow velocities, of the order of 2 to 3 ft/sec, occur immediately northwest of the throat. Upon exiting the throat, most flow is diverted into the Tolomato River with lesser flow entering the Matanzas River. Flow velocities are between 1 to 2 ft/sec in the Tolomato River while the velocities are generally 1 ft/sec or less in the Matanzas River. Flow velocities are less than 1 ft/sec in Salt Run. In summary, the flow is relatively better distributed in the inlet vicinity during flood as compared to the ebb conditions. Peak flood velocities are also higher than the peak ebb velocities.

Discharge time histories through various cross sections revealed that the peak ebb and flood discharges are very similar everywhere. However, the ebb phase lingers longer
**Figure 3** Ebb Velocity Vectors

**Figure 4** Flood Velocity Vectors
than the flood phase. Discharge magnitudes through the Matanzas and Tolomato Rivers are of comparable magnitudes; however, flow through Salt Run is very small.

Similar analyses were also conducted for the pre-inlet stabilization condition (Srinivas et al., 1996). Table 4 presents the comparison of the discharge prisms. For the 1994 conditions, as inferred earlier from the discharge time-histories, the ebb prism through the inlet entrance is substantially more than the flood prism. This mismatch was smaller in 1937. Though the ebb and flood prisms through the Tolomato River are better balanced for both the 1994 and the 1937 conditions, the ebb prism is slightly larger than the flood prism for both conditions. Further, the ebb and flood prisms for the 1994 conditions are slightly larger than the corresponding prisms for the 1937 conditions. The ebb and flood flow prisms in the Matanzas River are smaller than the corresponding prisms in the Tolomato River. The ebb prism is substantially larger than the flood prism for the 1994 conditions. For the 1937 conditions, the prism mismatch is smaller. Finally, the ebb and flood prisms through Salt Run are minimal for the 1994 inlet.

The final analysis considered the residual (velocity) circulation over a full tidal cycle for the present (1994) and pre-stabilization (1937) inlets. Ebb flow dominance was evident almost everywhere for the 1994 inlet except by the eastern side of the inlet throat and by the shoal to the west of the inlet throat. In fact, the circulation patterns show the convergence of residual ebb and flood flows towards the deep gorge in the inlet throat. Residual ebb flows through the Tolomato and Matanzas Rivers are fairly large. The bulk of the residual flow exits the inlet in a southeasterly direction through the channel across the ebb tidal shoal. Similarly, ebb flow dominance is evident almost everywhere for the 1937 inlet. Residual flows through the Tolomato and Matanzas Rivers are fairly weak. The bulk of the flow moves in a southeasterly direction through the deepwater channel in the inlet. On exiting the inlet, the flow splits and moves both northeast and southeast. In summary, the patterns of residual circulation reinforce the concept of an ebb-dominant inlet for both the present (1994) and the pre-stabilization (1937) configurations.

The flow patterns, discharge prisms, and residual circulation patterns verify an ebb-dominated inlet. Many earlier studies (e.g., Dean and Walton, 1975; Walton and Adams, 1976) indicate that the imbalance between the flood and ebb prisms generally
dictates the locations and volumes of the primary shoals. Large ebb shoals generally form when the ebb prism is large and when the imbalance between the ebb and flood prisms is also large. As shown above, such conditions currently exist at St. Augustine Inlet. The results also suggest that improvements to the inlet should focus on reducing the ebb prism magnitude, concomitant with a reduction of the existing ebb-flood prism imbalance and a more southerly ebb jet redirection. Such inlet hydraulic behavior has the potential to reduce ebb shoal sand trapping, reduce the offshore penetration of the ebb jet (discussed next), move the ebb shoal closer to shore, and improve natural sand bypassing.

**Effects of Inlet Ebb Jet**

Strong ebb flows through the inlet set up a relatively large-scale circulation in the ocean which can result in sediment transport towards the inlet. The ebb flow on the seaward side of tidal inlets often occurs as unsteady turbulent flow with many properties similar to jet flow. The jet entrains lateral waters as it spreads and results in the transport of sand towards the inlet. The entrained sediments, together with portions of the wave-driven longshore transport in the vicinity, are often jetted and deposited offshore.

A simple numerical model of the ebb jet, based on the work by Özsoy and Ünlüata (1982), was used to characterize existing jet effects on ebb shoal location and growth since bathymetric analyses for the St. Augustine Inlet vicinity indicated that the ebb shoal is currently growing seaward. For model application, the velocity at the inlet mouth was assumed 3 ft/sec based on characteristic maximum ebb velocities inferred from the inlet hydrodynamic model. The input cross shore bathymetry was the average of shore-parallel depths over a distance spanning 1,200 ft either side of the centerline.

Figure 5 presents the velocity contours in the inlet offshore vicinity superimposed on an image of the inlet bathymetry. An implicit assumption of the present model is that the centerline path is straight and perpendicular to the general shoreline orientation, that is, the southeasterly offshore curvature of the natural channel is not accounted for. Ebb flow decelerates with minimal lateral spreading on exit from the inlet. The jet is fairly compact till it decelerates to 1.5 ft/sec, lateral spreading is accentuated beyond this velocity contour. Velocities of 0.5 ft/sec extend till the outer limits of the model grid—about 10,000 ft from the inlet mouth. Given the general bathymetric and sediment size characteristics offshore the inlet, a critical depth-averaged velocity of 1 ft/sec is necessary to initiate sediment motion. Thus, ebb velocities are sufficiently high to keep sediment in motion to a point about 5,000 ft offshore the inlet. This implies that depositional characteristics should dominate further offshore. Given the limitations of the present analysis, this facet is remarkably consistent with the patterns of recent long-term bathymetric changes where the ebb shoal area was seen to be accreting prominently starting about 5,000 ft offshore from the inlet.

**Conclusions**

St. Augustine Inlet is a very efficient sand sink which stores sand stored in ebb and flood shoals. The ebb shoal, estimated to contain about 23 million cy of sand by
Figure 5  Ebb Jet Velocity Contours
1994, traps sand at the rate of about 425,000 cy/yr. Flood shoals trap sand at the rate of 84,000 cy/yr. This impoundment of sand deprives the south beaches of sand and causes chronic downdrift erosion. The sand trapping action of the inlet is attributable to the large magnitudes of and the large mismatch between the flood and ebb tidal prisms. The large offshore penetration of the ebb jet is responsible for the ongoing offshore growth of the ebb shoal. Substantial changes to the inlet jetties are possibly necessary to improve the natural bypassing characteristics of the inlet.

Long-term morphological development of the Accumer Ee tidal inlet and its impact on island beaches and engineering responses

U. Abels, H. Kunz, G. Ragutzki, H.-J. Stephan

Abstract

At the East-Frisian coast (Germany) morphological changes of tidal inlets - anthropogenically or naturally caused - can have substantial effects on the sediment supply of adjacent beaches. Erosion periods of beach and dune areas occur, which necessitate engineering countermeasures to preserve the present shoreline. The East-Frisian barrier islands are integrated into the coastal protection strategy for the mainland as they reduce the impact of sea-forces on the flood defences. On the other hand, shoreline and foredunes have to be maintained to protect the urban and tourism infrastructures on the island itself. The maintenance by solid engineering works, like seawalls and groynes, is not favourable because it has drawbacks on the natural morphodynamic processes. Therefore, the technique of beach- and foreshore nourishment is implemented as an instrument of 'active coastal protection' whenever possible. The paper deals with an actual erosion problem on the island of Langeoog caused by morphological changes of its tidal inlet Accumer Ee. It discusses the long-term morphological development of the tidal inlet with its ebb delta shoals and of the adjacent shoreline. A coastal engineering solution for the coastal defence problem has been achieved by means of an integrative approach regarding the natural morphological processes, the ecological objectives, and the safety of the island population.

Introduction

The island of Langeoog is one of the seven East-Frisian barrier islands which extend along the North Sea at the western part of Germany (Fig.1). The sandy barrier islands are formed by the interaction of tides, currents, surf and wind-born accretion. The islands are separated from each other by tidal inlets which are connected with tidal flats located towards the mainland. The tides are semi-diurnal and propagate from west to east. The predominant wind direction is north-west. Tides and winds

---

1 Coastal Research Station of the Lower Saxony State Agency for Ecology; An der Mühle 5, D-26548 Norderney/Germany
generate a net littoral drift which is directed to the east. The tidal inlets exhibit a very high natural dynamic, which is characterized by morphological changes, both long-termed (structural) and comparatively short-termed. Most of the East-Frisian islands experience erosion of the western spit (Luck 1977). The protection of the barrier islands is part of the German coastal defence system. Consequently, erosion is counteracted by groynes, seawalls and artificial sand supply (Kunz 1996, 1997). The island of Langeoog is one of the two exceptions. Its western part has been subject to accretion as well as to erosion. The natural sand supply is related to the ebb delta shoal system (reef bow). It is created by interactions of tides, waves and littoral drift. The volume of the shoals as well as the movement-direction of the reef bow (downdrift foreshore bars) are essential for the sediment supply of the adjacent island beaches. A migration of the tidal inlet affects the configuration of the ebb delta bar system and therefore can cause a decrease in the sediment supply. The bars of the reef bow are only temporary accumulation areas as the sediment is permanently moved, resulting in a net sediment transport along the reef bow. The sediment bars of the reef bow can reach heights above low water level (Fig.2).
The western part of Langeoog, especially the area of the Pirolatal (Fig.3), is endangered by erosion, which is caused by insufficient natural sand supply. The laserscan-survey of the year 1996 (Fig.4) clearly exhibits the weak condition of the foredunes. Especially the part between profile no.39 and no. 43 has the smallest dune widths and the lowest dune heights. The losses after a severe storm surge can be estimated as a retreat of 10 to 20 meters. Consequently, the endangered foredunes in the Pirolatal - with dune widths around 35 meters and very narrow beaches in front - are imminent to break through during a stormy winter season. The average height-level of the endangered dune valley Pirolatal amounts only to 3 meters, and a second closed dune ridge is not existing. A break through would endanger the village by flooding and would affect the drinking-water supply of the island (Fig.3) by intrusion of salt water into the fresh water lense. A further aspect is that the endemic vegetation is classified as a highly protected habitat according to the Lower Saxonian Nature Preservation Statute.
Time-distance diagrams provide information about the beach and dune development, exemplary demonstrated by profile no. 39 (Fig. 5). Regular surveys have been carried out since 1935. The development can be divided into three periods. First: between 1935 and 1960 a positive trend prevailed, and several "peaks" refer to natural sediment supplies by downdrift foreshore bars until 1950. Second: between 1960 and 1970 a drastic beach and dune decline occurred, retarded in the beginning as long as the beach was large enough to provide substantial aeolian sand transport. During this period the foredunes lost on an average 70 meters in width, considerably intensified by the hurricane storm surge from February 1962. Third: because of the large and lasting dune losses several beach nourishment projects have been carried out since 1972 (their implementation will be described later) partly compensating the beach decline. Furthermore, a renewed natural sand supply can be observed since the end of the seventies but the amount of it seems to be reduced.

Fig. 6 demonstrates the extent of the dune losses: profile no. 39 shows a decline of 91m between the maximum in 1961 and the minimum in 1994 (reference level is NN +3m). In comparison with the erosion period (1960 to 1970) no considerable regeneration has occurred; decline and regeneration alternate with each other depending on whether natural or artificial supply take place or a shortage of sediment occurs. In general, no specific trend can be observed (see Fig. 5: 1970 to 1996).

**Long-term development of the tidal inlet and its ebb delta bar system**

The discussed beach and dune development is determined by the processes within the tidal inlet. Temporal alterations of the tidal inlet configuration - with respect to the ebb delta bar system (reef bow) - can be linked to the processes within the downdrift area of the reef bow itself and thereby to the development of adjacent beach and dune areas.
The morphological development of the Accumer Ee tidal inlet and its ebb delta shoals is well documented over a period of more than 100 years (Homeier 1956; Homeier & Luck 1971). The large-scale and long-term morphological development was investigated by the evaluation of topographical maps (1866 to 1995). The maps of the last century are mere sea maps with only few information about depths (just enough for navigational purposes). Due to this restriction, only a few horizontal reference levels (SKN, SKN -1m and SKN -2m, where SKN is the low water level at spring tide) were chosen to investigate the sediment distribution within the reef bow (Fig.7). On a visual basis the ebb delta bar system shows over a long period a more or less compact shape; the single bars, as well as groups of shoals, are only separated by small channels. At the end of the investigation period, however, (around 1985) the channels started to expand and the map of 1995 already exhibits a large gap at the vertex area of the reef bow (see Fig.7, marked by an arrow in the map 1995). The solely visual interpretation already indicates that the sediment accumulation within the ebb delta bar system is decreasing.

To get a quantitative overview the morphological changes of the ebb delta bar system were estimated by the determination of the area covered by the bars referring to three distinguished horizontal reference levels (Fig.8). The calculated total area for the three reference levels are named as ‘equipotential bar areas’. The development of the equipotential bar area values can be approximately transferred by constant factors to the corresponding changes of the sediment volume providing information on the predominant trends. Due to the limited number of available reference levels the calculation of volumes is not more effective than the applied method. The used German sea map reference level SKN is - in contrary to the fixed German datumn NN - a variable value. However, within the scope of the applied investigation methods these variations (up to 11cm for the entire investigation period) are irrelevant regarding the range of error connected with the small-scale of the maps and the limited accuracy of the survey, which exceeds this source of error to a great extent.

Results are shown in Fig.8. With reference to the entire investigation period, the equipotential bar areas of the reference level SKN -2m and SKN -1m have
Fig. 8: Development of equipotential bar-areas for three different reference levels

Fig. 7: Development of the ebb delta bar system of the Accumer Ee (AE) - tidal inlet between 1891 and 1995
decreased by about 30%; the area of the reference level SKN lost just around 15% of its former size. The decrease did not occur continuously. The ebb delta bar system shows its highest accumulation degree during the last quarter of the 19th century. At the end of the last century the equipotential areas of all reference levels gradually diminished. Between 1930 and 1980 their extent was more or less stable; afterwards the area for the reference levels SKN -2m and SKN -1m lost considerable size. Because of the more or less steady extent of the SKN reference level it is unlikely that the sediment has been transported and deposited in greater depths. Furthermore, the decrease took place rather quickly.

To allow a more detailed analysis the sediment distribution within different sub-areas of the ebb delta bar system - regarding the reference level SKN -1m - was examined. The distinguished 'sub areas' are: the east end of Baltrum, the bars of the reef bow, and the western part of Langeoog (Fig.9). Non available intermediate values have been calculated by linear interpolation (3-year intervals). The diagram does not show the shifting of single bars or groups of shoals but the shift of maximum sediment accumulations. Marked by A, B, C, the following becomes evident: in the beginning the sediment accumulated at the east-end of Baltrum leading to a rise with a maximum in this area between 1866 and 1908 (A); then the maximum moved into the reef bow area (B), where it reached a maximum between 1935 and 1960 (there is no distinct "peak" to be seen because no data were available for the period between 1931 and 1956; the values are exclusively based on calculation). At last, the maximum reached the western shore-line of Langeoog around 1975 (C). This shift of sediment covered a prolonged period. The extent of the subsequent sediment accumulation at the east of Baltrum is by around 40% to 60% smaller than the previous maximum. It accumulated around 1970, passed into the reef bow very quickly, and reached Langeoog around 1985. A further sediment supply is at the moment out of
sight. Although the sediment accumulation at the east part of Baltrum is recently slightly growing the reef bow exhibits a so far unprecedented minimum. The actual reduced sediment transport indicates that fundamental morphological changes - probably concerning the littoral drift in general - are in progress.

The investigation so far does not explain why there is actually a sediment deficit, which leads to a beach and dune decline in front of the Pirolatal. According to Fig.8, sufficient sediment quantities have reached Langeoog since the seventies. This can be explained by the fact that the sediment supply not only depends on the quantity of sediment (equipotential bar area) but is also dependent on the position at which the downdrift foreshore bars merge with the island beaches. Therefore, the development of the main tidal channel of the tidal inlet Accumer Ee and its impact on the position of the ebb delta bar system were examined.

The morphological changes within an ebb delta bar system are - besides littoral drift and wave climate - mainly determined by the position of the main tidal channel and its residual ebb tide current. The main tidal channel of the Accumer Ee - in this investigation defined by the SKN -5m and SKN -10m contour line - is situated at the western part of the tidal inlet directly at the east-end of Baltrum. Therefore, the morphodynamic situation of Langeoog is favourable with respect to the conditions for a natural sediment supply of the beaches because the downdrift foreshore bars can reach Langeoog at its western part.

The development of the main tidal channel Accumer Ee is represented by a cross-section of the tidal inlet at the seaward boundary of the drainage basin (Fig.10). Over a long time of the entire investigation period (1841 to 1955) the main tidal channel exhibits a more or less steady position and constant depths, whereas the cross-section of the tidal inlet enlarged continuously. However, it has to be taken into account that the diagram for the first period (1841-1955) is based on survey-intervals.
that amount to 20-30 years, i.e. intermediate short-term developments are not visible. Afterwards (1955 to 1978) the depth of the main channel decreased, whereas the location within the tidal inlet remained unchanged. After 1978, during the last period (1978 to 1996), shifting tendencies of a larger extent occurred and the position of the main tidal channel became unsteady: at first it moved in a westward direction, finally the shifting process is directed eastwards, so that in the end the resultant new main tidal channel is located more eastward than it had been before. In the course of the last years a newly deepening of the channel can be observed.

The shifting tendencies of the former more or less steady main tidal channel indicate that the drainage basin might be subject to major morphological changes as the cross-section of a tidal inlet is closely connected with the volume of the tidal basin. Current investigations have shown that the volume of the tidal basin is actually increasing, possibly caused by structural erosion processes in the tidal flats (Schroeder et al. 1994).

In the eastern part of the ebb delta bar system there are three different approach directions to be distinguished by 'downdrift foreshore bar'-systems. Fig. 11 shows the average position of a median reef bow representing the ebb delta bars, which are characterized by a split of their alignment: the medium-grey coloured part is lined up eastwards; the dark-grey coloured part is directed southwards. The split is presumably determined by the predominant weather conditions (weather-influenced hydrodynamic factors like wave and current direction, surf etc.). Depending on the direction from which the main amount of sediment reaches Langeoog certain sectors of the beach obtain a sufficient sediment supply, whereas others suffer from a deficit. Fig. 12 shows the size of the three downdrift foreshore bar-systems for the period from 1866 to 1995. The varying positions of the downdrift foreshore bars and their extent are obvious; the alternate maxima of the different directions are clearly visible.

The development of the beaches and dunes in front of the Pirolatal is dependent on the eastward directed sediment transport. The periods of supply and deficiency correspond with the development of the beaches and dunes (see Fig. 5). During the distinct erosion period between 1960 and 1970 there was no major eastward directed sediment supply to this area, whereas since 1970 larger amounts of sediment have reached the Pirolatal-area again provided by the eastward directed approach of the shoals. The recent development of the downdrift area is characterized by an intermediate position of the downdrift foreshore bars located between the southern and eastern direction (light-grey colour). This development is caused by the north-west extension of the main tidal channel which leads to a more westward situated splitting point of the downdrift bars. A distinct shift of the reef bow in a solely northern direction - which would result in an eastward shift of the downdrift area - has not taken place so far. Consequently, the sediment supply is not affected adversely, and the downdrift foreshore bars reach Langeoog still in front of the western part of the island.

Coastline and dune management by artificial sand supply

The discussed results demonstrate that the beach and dune decline in the Pirolatal-area can be attributed to a temporal restricted lack of natural sediment supply. This deficit is caused by varying positions of the downdrift foreshore bars which lead to temporary periods of erosion. It was possible to compensate shortages of sand supply
Fig. 11: Shifting of the main tidal channel Acumener Ee and its related ebb delta bar-system with three distinguished downdrift foreshore bar-systems (E), (I), (S)

Fig. 12: Equipotential bar-area (reference level SKN) for merging downdrift foreshore bars with respect to different directions (see Fig. 11)
by ‘soft’ engineering means up to now because only limited periods of erosion have to be covered. Since the drastic beach and dune declines (Pirolatal from 1960 to 1970) several beach nourishment projects - functioning as sacrificial structures - have been implemented; Fig.13 shows the nourishment projects carried out on Langeoog up to now. As a further countermeasure against erosion an artificial reinforcement consisting of sandfilled plastic tubes was installed into the beach in 1972 to hold back and secure the artificially replenished sand. During distinct erosion periods the tubes become partly visible again, whereas during periods with sufficient sand supply they are covered. As an additional measure artificial sand dams were constructed in 1982 and 1984, which interrupted the current in a swash channel and thereby turned the merging downdrift bars onto the beach. Furthermore, a very endangered dune area (profile 37, see Fig.3) was reinforced by a dune-backfill in 1982 (Lüders et al. 1972, Erchinger 1986, Kunz 1987).

Barrier dunes are only expected to maintain themselves naturally in strong conditions, if the dry beach in front of them is wide enough to guarantee an aeolian sand transport for regenerational purposes. Concerning coastal defence, the fordunes must be maintained strong enough to withstand the impact of severe storm surges. Based on experience, Erchinger (1986) proposes that the distance between the NN 0m line and the mean high water line (MHWL) should be more than 90m or, alternatively, the distance from the NN 0m-line to the NN +3m-line should be more than 150m. Fig.14 applies these criteria to the time-distance-diagram of profile 39 (focusing on the period after 1960): during the erosion period between 1960 and 1970 the beach was smaller than the minimum according to the criteria. The implementation of the sand filled tubes and the beach restoration could stop the further decline of the fordunes. The several beach nourishments during periods of sediment deficiencies as well as the natural sediment supplies led to a more or less beach and dune stabilisation. Nonetheless, the periods in which the beach had a sufficient width were too short and the amount of natural sediment supply too small to initiate ‘natural’ dune and beach regeneration processes of a greater extent.
"critical" beach width according to Erchinger (1986): \[\text{NN-MHWL} < 90 \text{m} \quad \text{NN-NN+3m} < 150 \text{m}\]

Fig. 14: Development of beach profile no.39 with nourishments and natural sand supply since the beginning of the dune erosion-period in 1960 (see also Fig.5)

Conclusions

The investigation has shown that the observed beach and dune decline in the Pirolatal-area on Langeoog island is not been caused by structural and therefore non-reversible morphological processes. The discussed development can be attributed to a temporal restricted lack of natural sediment supply caused by varying positions of the downdrift foreshore bars. However, a substantial and presumably structural morphological change revealed itself recently in the detected decrease of sediment accumulations within the ebb delta bar system. Further investigations are in progress to confirm, if there are structural changes developing within the littoral drift. If this assumption proved to be true, it is to be expected that extended beach areas of Langeoog are going to obtain comparatively smaller amounts of sand supply in the near future. Therefore, more beach nourishments will be inevitable, possibly accompanied by foreshore nourishments. A managed retreat of foredunes would provoke the opposition of the island population regarding losses of land. Furthermore, in some areas it would interfere with the existing drinking water supply out of the fresh water lense. As a preliminary answer to the problem, the most endangered parts of the foredunes were artificially reinforced at the landward side of the foredunes in 1997. By this means the capability of resistance at least for the next storm surges is guaranteed. A further beach nourishment is going to follow in 1998. The time gained by the two combined means (dune fill, beach restoration) allows further investigations of the tendencies of the natural developments and the elaboration of new concepts for engineering responses, which will include cost-benefit considerations. Up until now
the strategy for the classified protective foildunes on the German barrier islands is mainly based on the principle of 'hold the line'. Artificial beach nourishment is an effective technique but it has to be applied frequently. Also it has been proven as an effective tool to avoid conflicts with the island population concerned. In a long term perspective the possibilities of an accelerated rise of the relative sea level as well as a steepening of foreshore areas has to be taken into consideration. Concepts have to be proven and there is a need to discuss how we can proceed to more flexible responses creating a resilient shoreline by the process of an improved approach towards integrated coastal protection management.

Acknowledgement

The investigation was promoted by the regional government authority (Bezirksregierung Weser-Ems, Oldenburg) and has been carried out in close cooperation with the Lower Saxonian Local Board for Island and Coastal Protection (Staetliches Amt für Insel- und Küstenschutz, Norden) and the administration of the Authority for the National Park Wadden Sea of Lower Saxony, Wilhelmshaven.

Abstract

Bali Turtle Island Development is a major tourism-related coastal development project situated in the SE corner of Bali, Indonesia. The project includes large-scale dredge-and-fill reclamation for the purpose of enlarging the existing natural island of Serangan by 3.7 km². The completed reclamation will include three artificial lagoons, four artificial pocket beaches, six artificial headlands and a causeway/bridge connection to the Balinese mainland.

This paper provides an overview of the development project as a whole, as well as describing the numerous coastal engineering and environmental investigations that have been applied in the optimization of the design. Due to the complex bathymetry and interrelated wave, flow, sedimentological and water quality mechanisms, an integrated approach for design optimization was required. The steps taken for the management of dredging operations in the vicinity of sensitive habitats are also discussed.

Site Description

The study area lies near the shallow Lombok Sill separating the Indian and Pacific Oceans (Fig. 1). Regional tidal forcing is strong and complex, with spring tidal flows in Lombok Strait exceeding 2m/s. Furthermore, net seasonal currents of ±1m/s may be present over the Lombok Sill (Murray and Arief, 1988).

The project site is the existing natural cay of Serangan (post-construction: Turtle Island). Intertidal reef flats extend seaward from Serangan, as well as from the developed beaches

of Sanur and Tg. Benoa, to the surrounding reef fringe. The reef flats feature a patchy coverage of vegetation, sand and hard material. The existing beach faces are steep (~1:10) and consist of medium to coarse coral sand. The project area has a spring tidal range of almost 3m, and is subjected to some degree of swell wave attack year-round. Coral reefs, seagrass beds and mangroves surround the project site and must not be seriously impacted by the development.

Fig. 1  Geographical references for the study. Top left: The Indonesian Archipelago. Bottom: Bali, Lombok and the Lombok Strait. Top right: The pre-construction study area, the coverage shown is that of the local 40m model domain.
The importance of these ecosystems is not purely aesthetic. The existing beach material consists entirely of eroded coral, and the degradation of the living corals due to increased pollution loading has resulted in a reduction in the natural production of beach material for the area. This fact, in combination with the mining of the reef crest for construction materials (thereby increasing wave exposure) has resulted in erosion problems for the beaches of the area (JICA, 1989). Furthermore, the living reef provides quality sport diving and is considered an essential recreational resource.

Project Description

With the exception of a village lying at the northern tip of the island, Serangan was undeveloped prior to 1996. The Bali Turtle Island Development project aims to establish an up-scale tourist enclave to complement those already existing at Nusa Dua and Sanur Beach. The completed project will include three artificial lagoons, four artificial pocket beaches, six artificial headlands and a causeway/bridge connection to the Balinese mainland (Fig. 2).

Both the dredging and reclamation areas lie within the intertidal zone. Dredging/reclamation activities were initiated in July 1996 and will continue into 1999. A large capacity (~20,000 m$^3$/day) cutter-suction dredger is being used for the work. The total reclamation area is 370ha, and the corresponding dredging volume is 20 million m$^3$. No significant levels of contamination have been found in the borrow material, which typically consists of 20% fine material below 63μm. All dredged material will be utilized for infilling.

The study described in this paper was divided into two phases. The first phase involved the evaluation of 8 proposed design layouts, and the making of recommendations toward the optimization of said layouts with respect to:

- Design conditions (wave, water level & current)
- Impact upon navigation
- Spreading of dredged material
- Water quality / eutrophication
- Revetment stability
- Flushing
- Sediment morphology
- Beach stability

The second phase of the study involved the management of dredging operations, such that the proposed construction activities could be performed without significantly impacting the surrounding ecosystems.

Field Campaign

An intensive survey campaign, including point measurements of water level, current, salinity, suspended and bottom sediments, and numerous water quality parameters was performed. The spatial variation of the wave- and tidally-generated flows was repeatedly
Fig. 2  Detail of the area around Serangan / Turtle Island showing pre-construction (left) and post-construction (right) bathymetry. Reclamation areas are shaded; dredging areas outlined. Depth contours in meters to Port Datum (PD ~ LAT).

measured in transects with a vessel-mounted ADCP. Fig. 3 shows the coverage of the ADCP transects, as well as the locations of CTD and suspended sediment profiling. The measurement locations for fresh water inflow / nutrient loadings are also shown.

Numerical Wave Modelling

Waves generated locally due to winds over Lombok Straits were determined using the simple hindcasting model PWave (after Hawkes, 1988). The offshore swell wave climate was determined from acquired global spectral ocean wave modelling data (Clancy et al., 1986), verified against satellite measurements, and then transformed to five locations just outside the reef using the parameterized wave action model MIKE21 NSW (after Holthuijsen et al., 1989). Detailed local wave simulations were performed using the same model. The wave transformations occurring on the reef slope and reef flats were tuned in the numerical model to be consistent with the physical modelling results discussed below, as well as with nearby field measurements (Sulaiman et al., 1994, see Fig. 3).

Physical Wave Modelling

An undistorted 1:40 scale 3D physical model was created for the purposes of (a) providing calibration data for numerical modelling of wave transformations across the reef slope, crest
and flats, (b) providing design wave data for the development frontage, and (c) optimizing revetment design with respect to overtopping and stability. This portion of the study is described in an accompanying ICCE '98 paper (Jensen et al., 1998).  

Hydrodynamic Modelling  

Regional and local high-resolution hydrodynamic modelling was performed in 2DH using the model system MIKE21 HD (Abbott et al., 1981; Warren and Bach, 1992). A regional tidal model, driven by tidal constituents and supported by predictions from a global tidal model (Eanes and Bettadpur, 1995), was established. The regional model, in which net seasonal flows were also present, included a dynamic nesting of two Cartesian model domains of 600m and 200m resolution (Fig. 1). An M₂ constituent co-amplitude plot from a tide-only regional model simulation is shown in Fig. 5. It is seen that there is a strong attenuation of the semidiurnal signal from south to north in the Lombok Straits.  

The results of the regional tidal model were then used to provide boundary conditions to drive a local hydrodynamic model, which consists of a second pair of dynamically nested Cartesian grids with resolutions of 120m and 40m (Fig. 1). An excellent calibration was achieved through comparison with the ADCP transects and stationary profiles (Fig. 6).
The water level gradients and strong tidal flow velocities in the Lombok Strait are seen to have a significant influence on the project area, even inshore of the reef crest. As a result of the strong attenuation of the tidal signal from south to north, at times which would normally be considered "high water slack" there exists a significant offshore forcing which drives a northward flow both on the reef flats and in the channel between Turtle Island and the Balinese mainland. A complimentary offshore gradient exists toward south during "low water slack". However, this southward forcing is inconsequential in the pre-construction layout as the area is largely dry at low water. The result is a tidally-forced net northward drift which, although small, has a large influence on the flushing response of the design layouts. This net drift is eliminated in the channel west of Turtle Island in the design layouts, as a deep channel will be present there even at LAT. However, net northward flows will still be present on the seaward side of the island and can be used to enhance the flushing response of the design. It can thus be concluded that a comprehensive regional modelling approach is essential for resolving the local flow conditions in this complex area.

Additional sensitivity tests performed with the local hydrodynamic model showed that wave-induced circulation was also significant on the reef flats. Waves effect the nearshore hydrodynamics by continuously pumping water shoreward over the reef crest due to the breaking and corresponding setup which occurs on the reef slope. The result is a net flow of water onto the reef flats from offshore, which in turn drives a return flow seaward through the North and South Channels. As this circulation is forced primarily by the cross-shore gradient in momentum transfer due to wave breaking, it is present even for waves of normal incidence. This mechanism, also observed during the field campaign, is clearly of great significance in the spreading of dredging spill during the construction phase.

Fig. 6 (right) Comparison of current speed from local hydrodynamic model vs. depth-average of measured current profiles in South Channel during spring tide.
Flushing Modelling

The water quality in any semi-enclosed area is a function of the pollutant load and the time required for the resident water to be exchanged with unpolluted water from outside. For unchanged pollution loadings, the flushing response of a given layout relative to pre-construction provides a reliable indication of whether water quality problems are to be expected for the design. Two-dimensional advection-dispersion modelling was performed in the local nested 120m/40m model areas to evaluate the impact of various designs on the flushing regime. The model applied was MIKE21 AD (Ekebjoerg and Justesen, 1991), which is coupled with the local hydrodynamic model discussed above. The dispersion coefficients applied in the model were verified by accurately reproducing the dynamic salinity distribution in Benoa Bay and the waters surrounding Serangan, balancing the measured fresh water inflow with the mixing processes occurring throughout the area.

The flushing simulations were performed by initializing the calibrated advection-dispersion model with a conservative “tracer” concentration of unity in all areas inshore of the reef fringe. The remaining offshore areas, as well as the offshore boundary conditions, were set to a concentration of zero. The time required for the tracer concentration to be reduced in a given area then gives an indication of the water residence time for a given layout. Fig. 7 shows the tracer concentration remaining after 3 days for

Fig. 7 (left) Sample flushing results: map of tracer concentration at mean high water after 3 simulation days from advection-dispersion model. Darker areas imply longer retention times. Shaded edges of Benoa Bay denote dried water points.

Fig. 8 (right) Extracted time series of tracer concentrations from the same location (marked in Fig. 7) in the primary borrow area for 3 design layouts as well as pre-construction.
the final layout. Fig. 8 shows extracted time series of tracer concentrations at a point in the primary borrow area, clearly indicating that at this location Layout #7 provides the best flushing, responding comparably to pre-construction.

Eutrophication Modelling

In addition to the flushing evaluation, a full 2D eutrophication model was established to gauge the effect of both the proposed development and increased loadings due to future population growth on the water quality around Turtle Island. The model applied was MIKE21 EU (Bach et al., 1990), which is also coupled with the previously established hydrodynamic model.

The eutrophication model describes the condition in the model area by using a number of state variables including carbon, nitrogen and phosphorus in phytoplankton, zooplankton, detritus and benthic vegetation and, with regard to nitrogen and phosphorus, also the dissolved form in the water. The model describes the seasonal and spatial variations of the interrelated state variables. The effect of dredging plumes was included by inputting construction-induced suspended sediment plumes calculated via the mud transport modelling described below.

Modelling of Littoral Processes

The longshore sediment budget for the study area was calculated using the process-based 1D model LITDRIFT (Deigaard et al., 1988), valid for arbitrary profile shapes. Wave transformations over the reef were calibrated versus the physical modelling results and field measurements (Sulaiman et al., 1994). Sediment recharge requirements were calculated for the pocket beaches fronting the development using the combined results of LITDRIFT, the 2D sediment transport model MIKE21 ST (Deigaard et al., 1986) and the 1D profile development model LITPROF (Hedegaard et al., 1991).

Not surprisingly, waves and water levels were found to be equally dominant factors in the longshore transport climate. Transport was found to be negligible for water levels below MSL (+1.3m PD). An excerpt of the four years' hindcast longshore transport rates is shown in Fig. 9, plotted along with the mean water level variation for the same period. The longshore transport as plotted is for the swell component of the wave climate only, which induces a drift which is almost exclusively northward. A separate transport calculation was made for the waves generated locally by winds over Lombok Strait, which contribute a smaller but significant net southerly drift.

The seaward reclamation limit of the completed project lies within 200m of the fringe of the surrounding reef, whereas the pre-construction beachface on Serangan was approximately 2km from the reef fringe. The reef flats act to dissipate wave energy through bed friction, enhanced by the locally irregular and vegetated bed. The post-construction beach face thus
Fig. 9  One-month excerpt from the 4 years' calculated longshore transport climate on the seaward face of Serangan (pre-construction, negative northward), along with the simultaneous mean water level.

feels a significantly stronger local wave climate than was present on Serangan prior to construction. This is illustrated in Fig. 10, which compares the profiles, wave attenuation and net sediment transport calculated via LITDRIFT for pre- and post-construction profiles extracted across the seaward face of Serangan. This increase in net annual longshore drift demands both a rotation of the post-construction beaches and an increase in compartmentalization through the introduction of protective headlands in order to keep fill losses and seasonal beach rotations within acceptable limits.

Feedback Monitoring of Construction Activities

The scale of the dredging operations required for Turtle Island, in combination with the high content of fines in the borrow material and close proximity of sensitive habitats, dictates that the construction activities must be carefully managed to avoid serious environmental impact. Tools normally used for such a situation include (a) spill fate modelling performed prior to construction, or (b) biological monitoring of the status of the habitats during the construction process. The novel approach of feedback monitoring (Grey and Jensen, 1993; Bach et al., 1997) has been applied in the present study. On the simplest level, feedback monitoring can be described as an orchestrated joint application of spill fate modelling and biological monitoring. The strategy embraces four components:
Comparison of pre-and post-construction profiles, wave attenuation and net longshore drift. Wave height and water level shown are instantaneous values (offshore: $H_{rms} = 1.5\text{m}$, $T_z = 6\text{s}$, $\text{dir} = 145^\circ$, $\text{WL} = +2.5\text{m PD}$), whereas the net longshore drift shown is the annual rate. While the greatest transport potential is seen to lie just offshore of the reef crest, this portion of the profile has been rendered inactive in the model due to the lack of mobile sediment in these areas.

1) Careful planning using numerical models to avoid unnecessary environmental damage by forecasting the effects of possible sediment spills. This is performed at the planning stage of the project.

2) Medium-term spill forecast modelling throughout the construction process, such that the potential environmental impact can be assessed on the basis of detailed dredging schedules for the forecast period. This allows the formulation and testing of mitigating actions if the predicted impact exceeds certain pre-defined limits.

3) On-site monitoring of selected key species and variables -- in the case of Turtle Island seagrasses, corals and mangroves -- to provide a direct indication of the impact upon the habitats and to provide feedback based on the impact criterion used in processing the results of the spill forecast modelling.
4) Updating the net environmental impact assessment by performing numerical model hindcasts on the basis of the actual achieved dredging schedule (as opposed to the predicted schedule assumed in 2 above) and the results of the biological monitoring of the selected species.

Feedback monitoring is in many ways a union stronger than the sum of its parts. Initial spill forecasting can be used to more efficiently design the scope of the biological monitoring so that energy can be focused on the areas of most likely impact. Furthermore, as numerical spill fate modelling greatly increases the understanding of the local sedimentation processes, the results of the spill hindcasting allow for a much more definitive interpretation of the results of the biological monitoring.

The application of feedback monitoring to Turtle Island is described in detail elsewhere (Driscoll et al., 1997), but is summarized here. A two-mouth repeat cycle was prescribed for the Turtle Island feedback monitoring. Thus, every two months the contractor provided a detailed plan of upcoming dredging operations (dredger locations and schedules, as well as outlet pipe locations and settling pond configurations). This information was combined with tidal predictions and typical seasonal values of wind, offshore net flows, and waves to produce a 2-month forecast of dredging spill to evaluate the impact of upcoming construction tasks. Parallel data was provided by the contractor documenting the actual realized dredging operations achieved in the prior two months. This historical information was merged with the available hydrographic data to construct a detailed 2 month hindcast of the most recent dredging operations. Two-monthly biological monitoring campaigns were then performed, with the hindcast results being utilized for the purpose of verifying causality in any observed impact to the habitats.

Spill fate modelling was performed using the Eulerian 2D model MIKE21 MT (Johnsen and Warren, 1993, with subsequent improvements) which describes cohesive sediment transport processes under combined current and waves. The spill model was coupled with the previously established local hydrodynamic and wave models, so that the effects of wave-generated currents and setup were included both with regard to physical forcing and sedimentation. The model was calibrated based upon daily measurements of suspended sediment concentrations at fixed stations throughout the area. Output consisted of time-varying maps of suspended concentration and net deposition/erosion. These outputs were then processed to provide maps of parameters useful for quantifying biological impacts, such as light attenuation at the seabed due to plume shading, daily exceedances of threshold deposition rates, etc. This approach allows for the proper consideration of environmentally positive steps such as timing high-spill activities during hours of darkness, when plume shading has no effect on light-sensitive organisms. A comparison of % light reduction at the bed is given in Fig. 11 for two spill hindcast periods, showing the improved environmental loading in the latter period.
The complimentary biological monitoring took the form of two-monthly surveys covering 5 to 6 stations each for coral, seagrass and mangroves. For each habitat, the focus was placed on the detailed monitoring of quantifiable variables rather than qualitative observations. For corals, variables included % coral coverage along fixed transects, recolonization rates, and measured growth rates of resident and transplanted specimens for the dominant species *Acropora sp*. Table 1 below shows the change in observed coral growth rates between two survey campaigns. These time periods may be compared directly to the spill hindcast periods shown in Fig. 11. A strong correlation is seen between modelled loading and observed impact. It should be noted that, while temporary reductions in growth rates were observed in the corals, the loadings were found to be sub-lethal.

![Fig. 11](image)

**Table 1** Measured coral growth rates, based upon the results of the Oct. 1996, Dec. 1996 and Feb. 1997 biological monitoring surveys. (Station C2 omitted due to insufficient data coverage).
Summary of Conclusions

The integrated hydraulic and environmental design evaluation for the Bali Turtle Island Development project resulted in (a) a detailed description of the complex physical and biological environment surrounding the site, (b) an accurate description of how the development will impact that environment, and (c) recommended modifications to improve the design in light of these findings. A summary of the conclusions is presented in the following:

The preliminary revetment design was found to be inadequate with respect to both the overtopping and stability criteria. Larger stone sizes and increases in revetment crest height and width were recommended.

The optimized development was shown to have a beneficial effect on navigation, slightly reducing the peak tidal current velocities in the South Channel. No areas of notable current intensification due to the development were found, with the exception of the channel beneath the causeway bridge which will see typical spring flows of 0.9 m/s. Net tidal circulations were found to exist around Turtle Island. This tidal forcing has been utilized to optimize the flushing response of the design.

The flushing response around Turtle Island was optimized such that the final design shows either no change or a modest improvement in residence time for much of the area relative to pre-construction.

Due to the presence of the shallow reef flats between the reclamation and the reef crest, the wave climate and resulting littoral transport at the beach face was shown to be dominated by the water level. Waves attacking during water level below MSL produced negligible transport due to nearly complete attenuation over the reef crest and reef flat. Beach material losses for the optimized layout were within acceptable limits.

Feedback monitoring of the dredging operations was initiated to safeguard the habitats during the construction phase.

The results of the performed study have proven the benefits of integrating state of the art numerical modelling tools, supported by physical modelling and biological monitoring, for both the hydraulic / environmental optimization of the design and for feedback monitoring of the actual construction sequence.

The influence of Marina Construction in Beach Stability: El Milagro Case Study

J. Galofré, F. J. Montoya and R. Medina

Abstract

The analysis of the behaviour of a beach, after the construction of a marina at one of its side, is made in this paper. El Milagro Beach, Tarragona, (Spain) is a 1.5 km long sandy beach. Two nourishment works were carried out along the beach, the first in 1986 and the second in 1993. Eleven surveys have been carried out since 1986. A marina was constructed in 1995. From the monitoring program, the shoreline evolution and profile changes have been determined before and after marina construction. It is concluded that the construction of the marina changed the beach stability.

Introduction

El Milagro Beach is located close to Tarragona, a city 100 km south of Barcelona, on the Catalonian coast, Spain. It is a 1.5 km long beach located between El Milagro Cape, on the east, and Tarragona Harbour breakwater, on the west. Figure 1 shows a location map. This paper analyses the nourishment projects carried out at the beach since 1986 by means of the morphologic data taken in two monitoring programs. The effect of a marina construction on the beach stability is also studied. Finally a set of conclusions will be made in order to understand beach behaviour and evolution.

2Coastal Civil Engineer. Head of Tarragona Coastal Service. Environment Ministry. Pl. Imperial Tarraco 4-4°. 43005 Tarragona, Spain.
Description

Morphology:

This is a half opened beach located between El Milagro cape, on the east, and Tarragona harbour breakwater, on the west, whose end reach more than 20 m depth. The native sand had a mean diameter $D_{50} = 0.25$ mm and the borrowed sand had $D_{50} = 0.6$ mm. The submerged bottom slope, from the shoreline to bathymetric -5.0 m, changes from 1.5% on the east, near the El Milagro cape, to 3.0% on the west, near the Harbour breakwater. The last feature has an important relevance on beach behaviour and affects beach stability. The value of bathymetric -5.0 is considered the profile closure depth.

![Site location map.](image)

Figure 1.- Site location map.

Historical review

This beach has been noticed from Roman Times more than twenty centuries ago. This beach was graphed in several maps on the nineteen century. That means that the beach has been stable for a long time. The most recently changes are due to the human actuation from 1986 to now. On table 1 a resume of historical evolution and beach characteristics changes along the time is made

Beach nourishment projects

In 1986 a beach nourishment project was carried out with a 140,000 m$^3$ of borrowed sand. In 1993 a new nourishment work was carried out with a 165,000 m$^3$ of borrowed sand. The mean diameter of the sand was 0.6 mm. The
nourishment works were carried out because of the beach area reduction. This reduction is mainly due to the decrease of the sediment supply brought by the stream located in the middle of the beach. This has been theorised as a major factor in the erosion that has been witnessed in El Milagro beach.

Marina construction

In 1995 a marina was built in the West Side, near the harbour breakwater. Its breakwater reaches the bathymetric -10 m and it is a total barrier to the longshore transport. This marina changed the beach behaviour as it can be seen in
the next paragraphs. Figures 2 and 3 show the bathymetric maps before and after marina construction.

**Monitoring program**

Two monitoring programs were carried out, one from the first nourishment project to 1993, six bathymetric surveys were made: jun-86, mar-87, sep-87, oct-88, jan-88, nov-93. The other one from the second nourishment work to 1997, seven bathymetric surveys were made: aug-94, jun-95, feb-96, apr-96, oct-96, mar-97, nov-97. The data from the monitoring program can be used in order to evaluated the changes produced by the marina construction in 1995.

**Wave climate**

There are two predominant directions of wave approach: SW and E. More than three-quarter of deep-water waves approach El Milagro beach from those sectors. The annual average significant wave height is about 0.5 m with typical winter storm waves of $H_s$ of about 3.0 m. Tides at El Milagro are negligible. In figure 4 a visual wave distribution is made and the affected area is show, wave limits are defined before and after marina construction. The north limit is the same in both cases but the south limit changes with the marina construction, and the energy resultant is different.

![Wave Height Distribution](image)

**Figure 4.- Wave climatic**
In order to understand beach behaviour qualitative and quantitative models have been run. Longshore currents have been obtained with different wave hypothesis, in order to analyse the influence of the marina in coastal dynamics, that are responsible of beach stability. Qualitative results have been obtained studying beach wave climatic and comparing with aerial pictures and topobathymetrics. Wave propagation and wave driven current models have been used considering pre and post marina construction behaviour. Different wave heights, periods and directions were used applying the REFDIF and COPLA programs computed by the parabolic wave propagation model that combines refraction and diffraction phenomena. Figures 5, 6, 7 and 8 shows the wave induced currents determined from the wave field, before and after marina construction considering different wave hypothesis, from the east and from the south-west approach deep water angles. The wave height considered was 1.0 m and the angle approach was +/-45°. The object of these numerical models is to help to understand the beach behaviour from different hypothesis of wave climatic. It is not a real situation but it can be inferred from them the answer of the beach in these cases.

Figure 5.- Wave induced currents before marina construction, H =1.0 m, α = -45°, T = 10 s.
Figure 6.- Wave induced currents after marina construction, $H = 1.0 \text{ m}$, $\alpha = -45^\circ$, $T = 10 \text{ s}$.

Figure 7.- Wave induced currents before marina construction, $H = 1.0 \text{ m}$, $\alpha = +45^\circ$, $T = 10 \text{ s}$.

Figure 8.- Wave induced currents after marina construction, $H = 1.0 \text{ m}$, $\alpha = +45^\circ$, $T = 10 \text{ s}$.
It can be seen that the breaking wave induced currents direction decrease in the boundary of marina. It means that the sand in the west part of the marina is retained and accumulates in this area. The storms from the Southeast transport the sand to this area and the storms from the Southwest part can not return the sand to the beach, the dynamics in the area change the behaviour of the beach. Figures 9 and 10 shows the qualitative behaviour of the beach before and after the marina construction deduced from the wave climate models.

Figure 9.- Beach analysis before marina construction.

Figure 10.- Beach analysis after marina construction.
The recuperated sand, from the Southwest storms is minor after the marina construction than before, this sand is accumulated on the shadow area of the marina.

**Morphodynamics**

Topobathymetric data are a good information in order to analyse morphodynamic characteristics, to understand beach behaviour and to predict beach evolution. Shoreline evolution, planform analysis, longshore transport and profile analysis must be studied in this section.

Table 1. Historical beach evolution

On Table 1 a summary of events that have incidence on beach performance is shown. The most representative dates of beach incidences can be found in it. That includes: beach characteristics (including beach monitoring surveys and beach nourishment works and marina construction); beach area evolution measuring beach surface from the shoreline to landward limits; sand volume lost/won (lost between monitoring surveys comparing the areas in each
monitoring with the first one after nourishment works and win from filling projects; longshore transport ratio deduced from the data obtained before and the grain size characteristic.

Figure 11 shows shoreline evolution taken from the most representative topobathymetric surveys, it is shown five shoreline position (jun-86, jan-88, nov-93, aug-94, mar-97) from the twelve it were taken. They represent the most significant date on beach behaviour the first one in before the first nourishment work, the second is after this works, the third is before the second nourishment works, the forth is after this works and before the marina construction and the fifth is after marina construction.

In Figure 12 the analysis of beach area evolution is made. It is compared the relation between the relation $A_i / A_1$, where $A_i$ is the area corresponding to the $i$ topobathymetric survey and $A_1$ is the corresponding to the post nourishment work, to the time. The figure shows the evolution before and after marina
construction, $A_1$ in the first case correspond to march-87 and in the second case august-94. It can be inferred from this that comparing the graphic the medium slope is bigger after than before marina construction. It means that the erosion ratio, in El Milagro Beach, has been increasing since marina construction. A new beach appeared on the protected marina area, it is difficult to infer from the actual data about its stability, some consideration to profile slope must be considered in this analysis. The longshore transport calculated according with the field data surveys of the monitoring programs changes from 13,000 m$^3$ before marina construction to 24,000 m$^3$ after marina construction.

![Figure 12.- Beach area evolution.](image)

The analysis of beach profile can be made by comparing different profiles in the beach and each one in different topobathymetric surveys. The most interesting aspect in this case is how the natural bottom submerged slope change from the east to the west part. In the morphological description it can be seen how this slope change from the 2 % on the east to 4 % on the west. In Figure 13,14 15, 16 and 17 an overview of this changes is shown, four profiles have been selected for this analysis. Figure 13 give a location map of the situation of this profiles, the profiles are numerated from the west to the east the analysis will be made in the opposite order from profile P-15 to P-3, intermiddle profiles will be studied too. Profiles P-15 and P-12, Figure 14 and 15 have similar behaviour, profile changes has a range of variability from beach landward to bathymetric -5.0 m. The natural slope is around 2 % and beach nourishment works affect the slope of beach face and affect until bathymetric -2.5. Nourishment works were made from profile P-16 to P-7, it means that these profiles have the direct influence of the borrowed sand filling. The analysis of the three last bathymetries gives some information, after nourishment works a topobathymetric survey were made, august-94, in these
profiles the shoreline has an accretion compared with prenourishment shoreline, November-93, but the survey that was made in March-97 an erosion phenomena occurs in both in P-15 shoreline rise more than the situation in November-93 and in profile P-12 was in front of it. It means that the shoreline position is changing decreasing at the east part and accreting at the west.

The analysis of P-7 and P-3, Figure 16 and 17, show the sand accumulation that occurs in this area this phenomena is especially important on P-3. In this point sand accumulation is really significant, but the profile form with borrowed sand is not compatible with the natural bottom. It appears two peaks in the profile that broke the equilibrium profile, and the sand is lost on the foot of the profile.

Figure 13.- Beach profile location map.
Figure 14.- Profile 15 evolution.

Figure 15.- Profile 12 evolution.

Figure 16.- Profile 7 evolution
Diagnosis

Marina construction has changed beach behaviour because fewer waves from the West Side arrive and some sand are retained in the protected area of the marina. Shoreline orientation changed due to the influence of marina on wave climatic.

The erosion ratio after marina construction is greater than before, 24,000 m$^3$/year and 13,000 m$^3$/year are the respectively values calculated with the field surveys data from the monitoring programs.

On the west part of the beach, close to the new marina, beach profile is milder than natural profile. In these area beach profile is not stable because of different bottom slope of natural beach and the profile formed by the borrowed sand. On the west part beach wide is decreasing.

Conclusion

- The analyses of the field surveys data from the monitoring program have been useful in order to understand beach evolution.

- From these data a beach behaviour have been obtained:

  . The difference on beach slope, from 2% on the east side to 4% on the west side, has a lot of incidence on beach stability.

  . The erosion ratio is greater after than before marina construction.

  . The beach is not stable on the west side. Several alternatives must be studied in order to guarantee beach stability.
MAN MADE BEACHES BALANCING NATURE AND RECREATION

Ulf Anderskouv\textsuperscript{1}
Hanne Bach\textsuperscript{2}
Dan B. Haslov\textsuperscript{3}
Karsten Mangor\textsuperscript{4}

ABSTRACT

Intensive mixed development of township, industry and tourism takes place in the coastal zone worldwide. This is often giving reason for conflicts between the commercial and industrial development, the need for recreational facilities and the interest for protection of the natural quality of the coastal zone and the environment.

Artificial beaches has been developed in Denmark at a high quality level with a successful balancing of the priorities of interest for the urban area population and for the natural and environmental content.

The paper describes with examples how the development of artificial beaches in great scale close to the City can be an efficient tool for the balanced development which combines solutions to known areas of conflict.

1. INTRODUCTION

Public beaches are often scarce in the close vicinity of densely built areas.

Artificial beaches will therefore strengthen the recreational value of the area when the beach is developed in balance with the interests of the commercial and industrial development.

\textsuperscript{4}DHI, Agern Allé 5, DK-2970 Hørsholm, Denmark

3401
The environmental concerns for an artificial beach park are on the one hand the water quality at the new advanced sea beach and on the other hand the water quality in a created lagoon system. The water quality is usually related to hygienic water quality (bacterial and viral pollution) and eutrophication. The latter may be excessive growth of algae leading to accumulation of dead seaweed at the beaches or very turbid waters in the lagoon and potential problems with depression of the oxygen concentration in the water.

Many of these problems can be avoided when the proper methods for design are used including determination of the requirements for reduction of pollution load to the area, which may be conditional for turning the project into a success story.

The examples used in this presentation are from the two projects Køge Bugt Beach Park and Amager Beach Park, both located close to the center of Copenhagen and next to industrial areas and the densely populated township.

![Figure 1, Location of Beach Parks near Copenhagen](image)

2. BACKGROUND

The authors of this paper have through almost 25 years individually and in cooperation worked on a great number of projects in the coastal zone, in Denmark as well as internationally. They combine the wide experience from specialized scientists and practical planning, architecture and engineering and they have jointly been responsible for the technical preparation of conceptual design and model analysis of two alternatives for the new Amager Beach Park project. The design has been prepared for the Planning Section of the Danish Ministry of Traffic during 1995-1996.
Further the authors have, since their participation in the planning and construction in the seventies of the Køge Bugt Beach Park, followed and been involved in the monitoring and maintenance works for the beaches, dunes and dikes forming the waterfront of this beach park as well as in the functioning of the recreational facilities and the natural appearance developed by the artificially reclaimed areas.

3. AREAS OF CONFLICT

The Problem areas or Areas of Conflict which will be addressed through the examples in the paper are:

- **Recreational Values versus Densely built-up City Areas**
  Development of a sustainable connection between the high recreational value of the coastal zone and the densely built-up areas of the City with access for the public.

- **Recreational Coast versus Commercial Port**
  Combination of the recreational coastal zone and the continued development of the commercial port of Copenhagen as an important economic factor for the City.

- **Recreational Coast versus Industrial Development**
  Maintenance and renewal of the City’s industrial areas and employment in balance with the recreational value of the coastal zone.

- **Public versus Private Financing and Maintenance**
  Balancing public and private interests in financing and maintenance of the project.

- **Stability against Wave Exposure**
  Coastal morphology and exposure to wave action balanced to a stable beach configuration.

- **Bathing Water Quality versus Waste Water Discharge**
  Attractive bathing water quality in the City’s waste water environment.

- **Recreational activities creates increased pollution problems**

4. PREVIOUS PROJECTS

It has often been a tradition to develop densely built waterfronts with promenades and beaches based on the existing beaches with a well functioning coastal morphology.

The Køge Bugt Beach Park located south of Copenhagen, constructed in the late seventies, has previously been described at conferences as a new concept based on a qualitative development of the existing coastal zone with new beaches as a recre-
national support to the developed township in the hinterland. The new beaches was developed on a system of shallow sand barrier islands located 500 to 1500 metres from the coastline. The shallow lagoon behind the barrier was developed as a combination of reclaimed land, dredged lagoons and for the marinas.

![Figure 2, Køge Bugt Beach Park - Beaches and reclamation with lakes and marinas](image)

The tools available at the time when the beach park in Køge Bugt was designed was very simple compared with today's numerical models. The alignment of the beaches and their stability was designed on basis of numerical refraction calculations and morphological indications provided by the existing barrier island formations.

The result was successful as the artificial beach line has practically stable during the following 20 years and there has not been any need for replacement of sand lost from the beaches.

The existence of algae and drifting seaweed has always been a problem in the bay and the project has not eliminated this problem. Algae and seaweed is still appearing along the shoreline during the bathing season as it is the case along most natural beaches in Denmark.

However, the quality of the bathing water at Køge Bugt Beach Park is so good - despite the existence of a next door large sewage treatment plant - that the beach park has been able continuously to flag the attractive blue flag permitted only for recreational areas with a proven high quality of the bathing water. The project has thus proved that it is possible to retain a high recreational quality with a limited amount of maintenance resources in a highly developed area, however the precondition is that the society maintains a high standard with respect to the treatment of sewage.
5. NEW STEPS IN THE DEVELOPMENT

The New Amager Beach Park is an example of a new generation of artificial beaches. The location of the beach park, which is very close to the centre of Copenhagen and densely populated areas, has for generations been used for industrial development. The industry in the area is however undergoing a winding up process and a rehabilitation of the area to an attractive residential township is now being planned. The Port of Copenhagen is at the same time planning to merge all their bulk activities in the area in immediate vicinity of the beach park.

The area was previously burdened with some of the larger discharges of sewage from the city.

The coastal zone today is a narrow park with a beach of poor quality. The water quality is good following the implementation of one of Copenhagen’s largest treatment plants some years ago, but still a number of storm water run-offs are existing.

The planned project will result in the development of a new advanced beach coast and lagoons.
The new urban beach park will be a more intensive developed activity region for the city population, not only with beaches, but also with sports facilities and specialized centres of activity. The project is at the planning phase in which the government and the City of Copenhagen has cooperated in the preparation of a conceptual plan, for the development of the area. The possibilities for project financing is being analysed and negotiated at present.

Figure 4, Amager Beach Park

The presentation will also describe how this type of project can be politically and economically integrated in the township development of the hinterland. The project is thus not based on a substantial reclamation to be sold in order to provide the economic background for the construction and maintenance of the public area as often practised in similar situations worldwide. It will be described how the concept used for the Amager Beach Park can be developed so that it is meeting the demand for actual town development as well.
6. COASTAL MORPHOLOGY AND HYDRODYNAMICS

The present Amager beach is located along the Sound approximately 5 km S of Copenhagen, as shown on Figure 1 and 3. Due to its location, the present Amager Beach Resort is not fully exposed to wave action. The island of Saltholm provides partly shelter for waves coming from Eastern directions. Consequently, waves from the direction intervals N-ENE and ESE-SSE are dominating along the frontage of the Amager Beach, refer Figure 5.

Figure 5, Wave roses for three locations along the Amager Beach according to numerical modelling by MIKE 21'NSW
Furthermore, the slope of the shoreface in front of Amager Beach is very mild. A large part of the wave energy is lost due to bottom friction.

In the layout of the new Amager Beach Resort, the quality of the beaches is improved considerably by increasing the exposure of the beaches to wave action by seaward shifting of the beach, thus eliminating the shallow shoreface.

The littoral transport distribution rose, Figure 6, right, for the area shows clearly the shadow effect from Saltholm Island and from the Port of Copenhagen.

![Diagram showing sheltering angle and beach orientation](image)

**Figure 6.** Definition of sheltering angle in relation the the artificial headlands (left) and the corresponding adjustment of the littoral transport distribution

Stable beach configurations were obtained by intersecting the beaches by artificial headlands. These stable beach planshapes have been computed by taking into account the sheltering effect of the headlands, as shown in Figure 6 (left and right), so that the orientation of all sections of the beaches corresponds to the equilibrium orientation. The design of the stable beach configurations were supported by detailed 2D modelling of waves, hydrodynamics and sediment transport.

The diagrammes in Figure 7 shows the longshore sediment transport profiles for the existing and the future beach configurations, respectively. It is noted that the present very wide distribution of the littoral transport is transferred to a narrow distribution concentrated on the foreshore of the future beach. This will provide a better beach quality.
Figure 7. Distribution of the littoral transport in the coastal profile for the present and future coastal profiles as computed by LITPACK

7. WATER QUALITY

The firming water quality problem foreseen at Amager Beach park is the hygienic pollution due to the discharge of treated waste water from the two treatment plants for Copenhagen located not far away and storm water run-offs located along the existing beach as shown on Figure 8. The secondary problem is the potential excessive growth of algae in the lagoon and the accumulation of seaweed at the beaches in the lagoon area and at the seaside. Models describing the spreading and decay of bacteria and the eutrophication were established using MIKE21. Because of the large number of studies of water quality in the adjacent areas model calibration could be extracted very easily from previous works. Situations describing the year 2000 assuming the planned discharge and treatment of waste water and also some extra actions concerning diversion of storm water were investigated for two different beach layouts.
The design and the natural conditions revealed a relatively high water exchange in the lagoon, which means that the fear of excessive algae blooming could be excluded. The primary production in the lagoon was predicted to be of the same order as in the adjacent areas, which means that some accumulation of seaweeds must be foreseen, similar to what can be observed at the beaches today. Due to the water depths in the lagoon, growth of eelgrass can not be expected. The bathing water criteria were achieved in the lagoon. The criteria were observed even under
At the seaside beach the water quality is expected to be better than at the present beach. The amount of accumulated seaweed is not expected to be larger than at similar beaches in the region. The bathing water quality (i.e. the hygienic water quality) is predicted to be even better than at the present beach due to avoidance of storm water run-offs at the new seaward shifted beach.

8. CONCLUSION

The development of artificial beaches which can support the demand for recreational outdoor life for the population in the urban areas and create the background for tourism development has proved to be an attractive concept for development. It is possible to create projects with a high quality level in which the prioritization of the urban against the natural content can be made according to the local interests and demand for development. The studies will underline that a presumption for these projects is that they are viewed in their entirety and with a substantial and careful planning in order to ensure their environmental functionalism and viability.

9. REFERENCES

Environmentally Friendly Coastal Protection
The ECOPRO Project

Brendan Dollard¹

Abstract

In the battle to preserve land against the ravages of the sea man has created many inappropriate protection structures on the coast. Often the coastline which is being protected is, inherently, in dis-equilibrium with nature. When combined with the increased recreational usage of the coastal zone, the rise in sea level and the increased incidence of storms, accelerated erosion rates are often the result. The Environmentally Friendly Coastal Protection project, or ECOPRO for short, developed a coastal erosion assessment method for the non-specialist. It devised a system for optimising erosion monitoring and developed a guide to select an appropriate coastal protection response. The project results are contained in the ECOPRO Code of Practice. This 320-page guide explains the steps involved in assessing and monitoring coastal erosion problems, planning protective actions and evaluating their environmental impact. Prepared by the Offshore & Coastal Engineering Unit of Enterprise Ireland, it is the result of four years of work which was supported under the EU LIFE Programme and drew on expertise from Ireland, Northern Ireland and Denmark. This paper presents details of the project and the development of the Code.

1. Introduction

In recent years it has become accepted that the coastline is a valuable natural resource which needs careful and sensitive management. This is especially so in the case of small island countries where the coastal zone has a direct and major influence on the economic welfare of the country. Coastal erosion has always been seen as one of the main threats to this resource and for centuries man has been fighting what was perceived as the ravages of the sea.

¹ Senior Engineer, Offshore & Coastal Engineering Unit, Enterprise Ireland, Dublin 9, Ireland.
In the Republic of Ireland, following destructive storms in the late 1980's which caused severe damage and accelerated erosion rates, there was a perceived need to seriously address the question of coastal erosion. A National Coastal Erosion Committee, formed under the auspices of the County and City Engineers Association, produced a report in 1992 which concluded that a Coastal Management policy rather than a purely Coastal Erosion policy was needed. This report also recommended that 'A code of practice for coastal protection should be drawn up to ensure the uniformity and appropriateness of all works'.

Following an initiative by Enterprise Ireland, the late Professor Bill Carter of the University of Ulster and The Department of the Marine, a proposal was developed for a coastal protection and management demonstration project and was successful in obtaining funding under the E.U. Life Programme. Managed by Enterprise Ireland, the project team consisted of the Department of the Marine and a number of local authorities in the Republic of Ireland, the Department of the Environment and the National Trust in Northern Ireland, Coastwatch Europe, and the Danish Coastal Authority (Kystinspektoratet). Inputs were also be sought from Universities in the Republic and Northern Ireland and from private firms with particular expertise in this field.

The project aims were to develop a method for the assessment of coastal erosion, to devise a system for monitoring erosion and to optimise the selection of an appropriate response. The project was titled Environmentally Friendly Coastal Protection and as this suggests the emphasis was on using environmentally friendly coastal protection techniques (i.e. soft engineering) wherever possible so as to mitigate the impact of coastal protection measures on the environment. These techniques, such as marram grass planting, dune ridge re-contouring, sand trap fencing, beach nourishment, etc., attempt to emulate the natural coastal processes rather than directly oppose them.

The final product of ECOPRO is the Code of Practice on environmentally friendly coastal protection. The principle behind the Code is the need to maintain as far as possible the protection afforded by the natural features of the coast. A beach is nature's response to erosion and is extremely effective in dissipating the energy of the sea. Therefore the objective should be to keep beaches in place. The sand dunes backing beaches are an integral part of the system and must be allowed to fulfil their natural function of acting as a buffer zone between land and sea.

This Code of Practice should be of considerable use as a guide to current best practice on coastal protection and management. It is hoped that it will avoid the instant palliative response to storm damage and also ensure that those involved in coastal protection first look at the soft engineering techniques. It was not intended that the code would attempt to supplant the technical manuals on the subject of coastal protection as it is not aimed at the coastal engineer. It is instead, to be used by the non-expert and, it is hoped, will help them to avoid making mistakes in their response to coastal erosion. The code also attempts to make the non-expert more aware of the fragility of the coastal environment and how complex and interrelated is the problem of coastal erosion.
2. Project Objectives

The specific objectives of 'ECOPRO' were:

1. To develop coastline monitoring methods which will be adaptable to various types of coastline.

2. To develop a Sensitivity Index by which a coastline's susceptibility to erosion is graded.

3. To present an assessment of performance of shoreline protection/management methods.

4. To present a report on the design, construction and success of two types of protection methods at selected sites.

5. To present all of the above as a 'Code of Practice'.

These five objectives form the five main tasks of the project. Each is dealt with in the Code of Practice with the exception of the Sensitivity Index. While a lot of work was carried out on this, particularly by the University of Ulster, the Danish Coastal Authority and a private company Natural Environment Consultants Ltd., the conclusion was that at the present time it was not possible to develop a practical index which would be usable by non-experts. The work carried out in this area has been reported on separately (Dollard, B., et al, 1996).

The overall aim of the project was to promote the use of soft engineering coastal protection techniques by firstly promoting a methodology which will allow the non-expert to assess the erosion problem and identify the likely causes. Secondly, it aimed to provide information on suitable coastal protection and management solutions with particular emphasis on environmental impact. Finally, the project intended to supply reference information on coastal processes and identify useful environmental and historical data sources.

3. Project Management

The project organisational structure is shown in Fig. 1. Enterprise Ireland was the overall Project Manager and was responsible for the day to day running of the project. The project was directed by the Steering Committee which was chaired by the Department of the Marine. The Technical Group provides the Committee with technical analysis of its proposals and drew up specifications for project work. It also drafted the progress and interim reports of work in hand.

The collaboration between the Universities, Government and local authority personnel and public volunteers was excellent and the multi-disciplined mixture of scientists, engineers and environmentalists ensured that most viewpoints were aired. The international dimension between the North and South of Ireland and Denmark helped to broaden our perspective. A successful visit to Denmark by the ECOPRO members, where a number of soft engineering coastal protection methods were viewed, was also very beneficial.
4. Project Tasks Undertaken

4.1 Coastline monitoring

*Project objective:*

The objective of this work was to devise and test various coastline monitoring methods in order to optimise the time and money spent in obtaining data on coastline and beach level fluctuations. The resultant techniques were to be detailed in the ECOPRO Code of Practice.

Seven sites were chosen for detailed study and are shown in Fig. 2. Each has a distinct soft coast and suffer from differing types of erosion. The extent of erosion also varies from place to place.

Coastline monitoring is a very important tool in assessing the sensitivity of the coast to erosion. There are two stages to monitoring the coast. Firstly, it was necessary to fix the present position of the coastline so that historical changes could be compared. This we termed the baseline survey. Secondly, regular monitoring of beach levels when compared with accurate environmental data gave an insight into the overall response of the beach to external forces. The results of these exercises were used in the assessment of the nature and cause(s) of the erosion problem.
Baseline survey

This involved the association and comparing of the present day topography for the chosen embayment with the historical data. Under ECOPRO a number of methods were examined to try to fix the present position of the coastline at our seven sites as economically as possible. These were:

- Aerial video
- Aerial photography
- Satellite imagery
- Aerial digital CIR photography

ECOPRO commissioned an aerial video recording, of the entire coastline of the four ECOPRO counties in the Republic of Ireland and this was very useful as a source of information on land use and vegetation classification. Satellite imagery of the sites was also examined but the resolution from satellite imagery was not suitable for accurate erosion measurement.

Aerial photography was the most successful, although expensive. The colour, stereoscopic images, allowed the vegetation line to be easily identified and a height contour map, (0.5m contour interval) was prepared for one of the sites.

ECOPRO fixed the vegetation line for three of the ECOPRO study sites from commissioned aerial photographs. These were then compared with the position of the dune
A historical data search was conducted for four study sites and a list of sources along with practical information on the techniques are covered in the Code of Practice.

Aerial digital photography using an infrared filter was found to be the most economic technique for mapping large coastal areas. The imagery was easily stored on, and retrievable from, digital tapes or CD's and the infrared filters highlight the vegetation line and indicate the condition of the vegetation.

The methodologies involved in all of these methods are included in the Code of Practice.

**Beach level monitoring**

Beach level monitoring is the measurement of vertical and horizontal erosion/accretion of beaches and nearshore bathymetry and the analysis of sediment. As with the baseline study, a number of different methods were employed to monitor the changes in beach levels. These were:

- Standard surveying techniques
- Cut-down monitors
- Measurements from fixed points (erosion questionnaire)
- Hydrographic surveys
- Sediment sampling

All seven study sites were monitored using either standard levelling or total station techniques and details are given in the Code of Practice. In order to facilitate the identification of which storm or event caused specific beach changes, ECOPRO initiated a programme of regular beach cut-down measurements. Measurements were taken every two weeks at each of the 16 monitor posts. This gave both the lowest beach level achieved and the amount of sand subsequently deposited on the beach. The Code of Practice includes details of this method and comments on its suitability.

Measurements from fixed points e.g. rocks, piers, etc. were also carried out at a number of sites as part of the Coastwatch Europe erosion questionnaire.

**Hydrographic surveys**

Hydrographic surveys were made at four sites. The bathymetry at a fifth site was measured on a regular basis to aid with the Sensitivity Index computer studies. Sediment sampling was carried out at the four Republic of Ireland sites. One of the Northern Ireland sites was regularly sampled, again as part of the Sensitivity Index work.

**Data storage**

ECOPRO opted for a custom built coastal data storage and display system SANDS (Shoreline and Nearshore Data System). Three packages were initially installed in the Department of the Marine, Enterprise Ireland and the Department of the Environment, Northern Ireland and later one copy was transferred to a Local authority, in order to determine its suitability for local data storage and analysis.
Wind and wave data

Offshore wind and wave data for 4 representative points around the island of Ireland was purchased from the UK Meteorological Office Wave Hindcast Model. This data covered a two year period. Storm data was obtained from the Irish weather service Met Éireann.

4.2 The Sensitivity Index

Project objective:

Gather together as much information on the factors that influence coastal erosion and 'weight' them accordingly. Based on these 'values' deduce the overall sensitivity of the coastline to erosion.

The background to this work was a paper written by V. Gornitz (Gornitz, V, 1990) who developed a simple scoring system which could be used to determine the vulnerability of coast to erosion. It was intended to be used on a large scale for isolated areas where it was not feasible or economical to collect accurate data. However, the ECOPRO group decided that for this method to be useful as an assessment tool and for its results to be used in the selection of protection methods it must be user friendly, accurate and on a scale that is practical. In addition the index should identify the causative factors of erosion as this will allow suitable protection to be prescribed. Fig. 3 lists the variables typically involved in coastal erosion.

![Diagram of forces and coastal type](image)

**Fig. 3 Variables involved in coastal erosion**

The ECOPRO group entrusted the Danish Coastal Authority (D.C.A.) (Kystinspektoratet) with the task of further developing Sensitivity Index method. The Environmental Studies Department of the University of Ulster was commissioned to examine the level of accuracy required of nearshore wave data for analysis of wave/sediment interaction. A private company, 'Natural Environment Consultants Ltd', who are specialists in coastal environment habitats, was also employed to carry out work on the dune vegetation condition aspect of the index. These three form a sub-group which reported on progress to the ECOPRO Technical group.
The ECOPRO group decided to tackle this work in two complementary stages. Firstly a method to calculate a general indicator of sensitivity needed to be devised. This was essentially an extension of the V. Gornitz work and would be useful as a first step assessment method by, for example, a local authority on the entire coast under its jurisdiction. The second stage was a refinement of the method based on the most accurate information available and on computed wave/sediment interaction data. This involved computer models, beach monitoring, vegetation classification, beach sediment analysis, wave and current measurement (or hindcasting). This method was used on short lengths of coast (typically 100m).

The prediction of sensitivity was correlated against historical and short term erosion trends and, thus, the index was fine tuned. Erosion rates usually vary across a coastal cell mainly due to the different levels of exposure of parts of the coastline to wave action. Modelling these processes using computers gives an indication of the sensitivity of the coast to erosion and when combined with other factors such as wind, geology and topography of the coastline, strength and regenerative ability of dune vegetation, beach sediment size, etc., an overall sensitivity grade was assigned. This was checked against historical records such as maps and aerial photographs and more recent beach level measurements.

Although the work on the index did not reach a stage where it was appropriate for inclusion in the Code of Practice, the exercise did provide some interesting results which could provide the basis for more extensive studies.

In order to satisfy the objective of this part of the project and to provide the users of the Code of Practice with an erosion assessment method it was decided to develop a technique using Field and Historical Survey decision support flowcharts. The result was a user friendly and practical approach to a complex problem and trials conducted by non-experts using the flowcharts have helped the ECOPRO team to refine the technique. Initial results are very encouraging but it is only when the method is more widely used will its full potential be realised.

4.3 Evaluation of coastal protection/management options

Project objective:
To examine current coastal protection measures being used and to evaluate their success. Each technique is to be summarised and included in the Code of Practice.

Once the nature of the erosion problem has been assessed, the method of protecting the coast needs to be decided. ECOPRO advocates the use of soft engineering options wherever possible. These attempts to work with the natural processes rather than oppose them. This approach often means that the shore zone is used as a buffer and must be wider than would be envisaged under conventional hard engineering schemes. An environmentally friendly scheme must often consider a certain amount of erosion as being beneficial, providing sediment interchange along the coast.

The ECOPRO Code of Practice identifies which type of erosion problems can be tackled with soft engineering and what particular method should be employed. 27 different coastal protection and management techniques are detailed in the Appendix of the Code.
In practice, the most commonly used protection methods are located in the lower and upper shore regions where most of the wave energy is absorbed. Lower shore techniques attempt to dissipate the incoming wave energy whereas upper shore techniques try to strengthen the existing natural structure. The supra shore or backshore and hinterland techniques assign land to act as a buffer against the sea. The most common form of these techniques is the use of set-back lines and this usually forms part of an overall Coastal Zone Management policy adopted by the relevant local authority. This involves the drawing of lines on maps by the local planning authority, seaward of which no new developments will be allowed and, more controversially, no attempt will be made to protect the existing land or buildings. This has two obvious advantages. Firstly, it almost eliminates the cost of coastal protection and secondly, it will reduce the demands for protection in the future. It does, however, raise the question of compensation to and also the longer term question of what to do when the buffer zone has been exhausted.

Many of these soft engineering techniques are not suited to exposed 'high energy' coastal areas where large waves impinge on the coast. Here, if protection is absolutely required, hard structures are necessary. General information on these and their likely impact on the environment is given in the Code of Practice.

The suitability of each technique is based on published literature and the results of a questionnaire survey of the Irish and Danish local authorities. Details of each technique are included in the Code of Practice and the experiences of the local authorities with the various methods is outlined.

4.4 Case histories of protection techniques

Project objective:

To give practical information on the design, implementation and monitoring of two different types of environmentally friendly coastal protection techniques.

One of the projects covered was a beach nourishment scheme in Rosslare Co. Wexford. Here 160,000m$^3$ of sand, dredged from offshore bars, was placed on the beach. This is the largest beach nourishment scheme carried out in Ireland to date.

The second was a small scale scheme involving the re-contouring of a sand dune ridge, marram grass planting and dune toe protection in Courtown Co. Wexford.

These two techniques are possibly the most popular soft engineering methods employed in Europe today. Practical information on both is included in the Code of Practice.

4.5 The ECOPRO Code of Practice

Project Objective:

To provide the non-expert with practical advice on how to identify the possible causes of marine erosion, select an appropriate response and how to evaluate its likely impact on the environment. Advice should also be given on coastal processes, data sources, monitoring techniques, legal implications and funding opportunities.

The layout of the code structure is shown in Fig. 4.
The Code of Practice deals firstly with the assessment of an erosion problem using field and historical erosion surveys. The aim is to try to determine the nature of the problem, whether it is continuous erosion or erosion caused by a single storm event or a sequence of storms. It also aims to identify the causes, whether natural or man induced. This section is structured around the use of decision support flowcharts which guide the user through a series of yes/no questions.

The next section of the Code uses these assessment results to identify suitable solutions. It gives information on the technical suitability of various coastal protection and management options. It also gives advice on assessing their legal and environmental impacts, and provides information on carrying out a cost/benefit analysis.

The following section is devoted to the two case studies. Practical information on their installation is supplied.

Appendix 1 of the Code gives general information on the coastal environment, its structure, the forces acting on it and its response. Appendix 2 contains sources of historical
and environmental data. Appendix 3 details coastline monitoring methods and Appendix 4 gives details of 27 different coastal protection and management options.

5. Project Results

Code of Practice

The Code of Practice is the final product of ECOPRO and whether it achieves its aims of increasing the awareness of the fragility of the coastal environment and preventing mistakes being made with coastal protection measures, will be the true result of the project. Initial indications in this respect are good. A workshop held in September in Cork was attended by engineers from most of the maritime counties in the Republic of Ireland and each were presented with copies of the Code of Practice. By general consent it was agreed that the code answered most of their queries on coastal erosion. Encouragingly the section on monitoring the coast was considered very useful. This bodes well for the future as once coastal monitoring begins, an awareness of the dynamic nature of the coastal zone is sure to follow.

The Code of Practice is essentially generic and can be used in all situations. The techniques are clearly and fully described using user friendly flowcharts wherever possible. The sections of the Code covering legislation and data sources are, through necessity, specific to the island of Ireland, but their format is such that they could be easily rewritten to suit other countries.

The Code of Practice follows a logical step-by-step path guiding the user through the assessment and solution of an erosion problem. General information on the coastal environment, contained in the appendix, is applicable, not only to North Atlantic coasts, but to most European Community waters. This section is also written in a clear style aimed at the non-expert. Formulae are only included where necessary and are usually backed up with graphic illustration.

The Sensitivity Index

The overall conclusion on the Sensitivity Index was that the use of such an index requires the availability of specialist knowledge and computer modelling capability. As such, it would not be of practical use to the target audience of the Code of Practice. Although an interesting formula to predict erosion rates from beach slope and wave statistics emerged from one study, it was considered that its application was only valid for micro-tidal, open coastlines. It was decided not to include it in the Code as it might be used inappropriately.

Coastline Monitoring

The data obtained from monitoring the seven pilot sites and the two case study locations have demonstrated the usefulness of the various techniques. The data collected covers:

- 8 sets of 70 beach profiles cross sections taken approximately every two months from October 1993 to March 1996
- 30 sets of 20 beach monitor post data taken approximately every month
• Wave hindcast data for 4 points offshore Ireland covering a two year period (3 hourly readings of wave height, period and direction for wind waves, swell waves and resultant waves)
• Four volumes of historical erosion data covering four of the study sites. Each contains all available maps and aerial photography along with reports from national and local sources
• Bathymetric survey data for four study sites
• Detailed digital ground survey data from commissioned aerial photography for one site
• Digital imagery (full spectrum and infrared) from aerial and video photography for 60 km of soft coast.

The survey methods advocated in the Code of Practice are devised with the premise that the user will have a limited amount of data available. In most European coastal areas there is a lack of coastal environmental data, especially nearshore wave data and water level measurements. Where economically justified, this difficulty can be overcome by specialist using computer models. However, these models are usually not available to the target users of the Code, the non specialist. The survey techniques should, therefore, be re-usable throughout the Community and the Code of Practice itself could provide the format for national guides to environmentally friendly coastal protection throughout Europe.

The analysis of the data collected has provided ECOPRO with the practical knowledge necessary to be able to optimise the choice of monitoring technique for a particular erosion problem. These recommendations are included in the Code of Practice and details of the techniques are given in the Code Appendix. The data was also used by the Sensitivity Group in their work on the Sensitivity Index.

The ECOPRO database has been used in a number of academic studies (to date four final year projects and two post graduate degree thesis). It has also been used to fine tune and validate two sediment transport computer modelling investigations carried out by coastal engineering specialist on behalf of a local authority and the owners of a golf course.

6. Dissemination of Project Results

Since the results of the project are contained in the ECOPRO Code of Practice, dissemination will be primarily through the distribution of the Code. The Code is available from;

Government Publications Sales Office, Molesworth Street, Dublin 2, Ireland.
Tel; +353 1 6613111 Fax; +353 1 4752760

The ECOPRO project promoted the cause of environmentally friendly coastal protection through public exhibitions. In 1994, as part of a exhibition on coastal environment matters in the ENFO centre, Dublin, ECOPRO provided a display stand promoting the project and its aims. The exhibition ran for two weeks and was attended by over 5,000 people. Under ECOPRO, Coastwatch Europe organised two national and a number of local workshops on dune dynamics, monitoring and coastal protection measures.
7. Recommendations on Future Work

One of the main findings of ECOPRO's work on the Sensitivity Index was the importance of accurate wave and water level data. This data is not available for the vast majority of European coastal sites. Obtaining this data for a particular site is very expensive and can only be justified where costly coastal protection schemes are being adopted to protect valuable property. In less developed areas this type of data collection is not viable. The alternative is to make decisions based on less accurate but more readily available information. ECOPRO attempts to help the user make these decisions based on best current practice. As technology advances and our knowledge of coastal processes improves, this best current practice will evolve and it is important that ECOPRO evolves alongside. The ECOPRO team have committed themselves to continuously update the Code of Practice and to conduct questionnaire surveys of selected users to ensure that it is achieving its aims.

The structure of the decision support flowcharts and the Code in general, is such that it would lend itself readily to being encoded as a computer program. This is currently being investigated by the ECOPRO team. If possible this would make the Code much more widely available especially if placed on the Internet.

The work on the Sensitivity Index could be progressed so that ultimately a more accurate technique on erosion sensitivity would be available. For this to be usable by non-experts much of the data required, i.e. nearshore wave statistics, water levels, etc., would need to be pre-processed and presented in atlas format for ease of use. Eventually it is envisaged that each local authority or coastal community could, without specialist knowledge, have a technique which would allow them to accurately assess each area's susceptibility to erosion and to identify the cause by using readily available information.

Acknowledgements
The author would like to express his gratitude to the European Commission, DGXI, for the financial assistance and encouragement given. My appreciation is also extended to the ECOPRO project team who worked tirelessly to make the project a success.

COASTAL RESTORATION CONSIDERATIONS

Karsten Mangor

Abstract

The paper discusses the problems associated with the loss of coastal resources, which is often the result of applying traditional coast protection measures in densely developed areas. It is recommended to distinguish clearly between coast protection, as measures mainly securing the coastline, and shore protection, as measures protecting also the shore and the natural coastal resources. The planning concepts Shoreline Management Planning and Management Unit Master Planning have been discussed, in which connection the importance of obtaining broad consensus for a management strategy and for cost sharing has been highlighted. The importance of preserving the coastal resources by working with the nature has been illustrated and innovative shoreline protection principles have been proposed for different types of coastal classifications. New types of environmentally optimised coastal structures have been proposed and an overall comparison of various protection measures has been made.

Introduction

The paper discusses the important physical and management issues in the delicate balance between (a) the requirements of primary protection against coastal erosion and (b) protection of the coastal resource, which in this context is constituted mainly by the dynamic coastal landscape. Historically, protection measures have been reactive in nature and have concentrated on preventing loss of existing facilities and coast due to coastal erosion. This type of protection has at many locations resulted in loss of the shore (or beach) and it has seriously degraded the fascinating scenery of the dynamic coastal landscape. Such protection measures can consequently not be called "shore protection" as they result in loss of the shore, but should rather be called "coast protection", where the term coast is defined as the strip of land that extends inland from the coastline. For clarification, the definition of the generally used terms for the form elements in the coastal area is presented in Figure 1.

1 Chief Engineer, Coastal Engineering and Environment, Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark, E-mail: km@dhi.dk.
Figure 1. Definition of Coastal Terms, mainly from (Shore Protection Manual, 1984).

The most important terms are the following:

- **COASTAL AREA**: The land and sea areas bordering the shoreline.
- **COAST**: The strip of land that extends from the coastline inland to the first major change in terrain features.
- **COASTLINE**: Technically the line that forms the boundary between the COAST and the SHORE, i.e. the foot of the cliff. Commonly, the line that forms the boundary between the land and the water.
- **SHORE or BEACH**: The zone of unconsolidated material that extends from the low water line to the line of permanent vegetation (the effective limit of storm waves).
- **SHORELINE**: The intersection between the mean high water line and the shore.
- **SHOREFACE**: The active littoral zone off the low water line.
- **CLOSURE DEPTH**: The depth beyond which no significant longshore and cross-shore transports take place, and where no significant bed movements due to littoral transport processes take place. The closure depth can thus be defined as the depth at the seaward boundary of the littoral zone. (Hallemeyer, 1981)
- **OFFSHORE ZONE**: The offshore zone is not well defined. In relation to beach terminology, it is thus not clear if it starts from the littoral zone, from the breaking or from the nearshore zone or even from the shoal zone. In the present context, the offshore zone is defined as the zone off the nearshore zone.

There is, however, some confusion between the terms "shore" and "coast", as these terms in common perception are synonymous. Consequently the terms "shore protection" and "coast protection" are also synonymous in common perception and signal that the shore (or beach) is protected when such measures are introduced, which is not the case with traditional hard protection measures. Actually, traditional hard coast protection maintains the location of the coastline and protects the coast, according to above definition, but at the expense of the shore (or the beach); consequently it is proposed in the future to distinguish clearly between the two terms:
- COAST PROTECTION, as measures aiming at protecting against coastline retreat, thus protecting housing and infrastructure, the coast and the hinterland from erosion, however often at the expense of losing the beach and the dynamic coastal landscape;
- SHORE PROTECTION, as measures aiming at protecting, preserving or restoring the shore and the dynamic coastal landscape as well as protecting against coastline retreat to the extent possible.

Causes of Coastal Erosion
Most coastal erosion problems have their origin in deficit in the littoral budget for a specific area, such deficits can have many causes of which the most common are the following:
- Blocking, or reduction, of the littoral transport by some kind of protruding coastal structure, such as port structures, inlet regulation works, or coastal protection works.
- Reduction of the supply of littoral material to a section by river regulation works, sand mining or by protection of neighbouring coastlines.
- Loss of littoral material into tidal inlets.
- Loss of littoral material by dumping of maintenance dredging material offshore.
- Loss of sand inland by dune destruction.
- Blocking of part of the buffer zone on the shore by structures on the shore.

All these causes are well known, and in many cases their damaging effects have been eliminated, at least partly, by regulatory measures. However, many developed areas are characterised by a highly degraded coastal environment, brought on by a historic combination of the above mentioned causes and where sufficient mitigation of these is not realistic.

Problem Scoping and Overall Planning Concept
In modern legislation there are often requirements for sustainable development and preservation of natural resources, which has resulted in seeing shore protection in a new long-term perspective, which has led to the discipline of Integrated Coastal Zone Management (ICZM). The concept of ICZM may be defined as a structured co-ordination of the various activities and resource demands that occur in the coastal zone in order to achieve economically, environmentally and socially sustainable development in compliance with adopted relevant local, regional or international goals. ICZM is often expressed in the form of a Coastal Zone Management Plan (CZMP), which provides input to national or regional development plans. A CZMP thus provides an overall framework for a balanced development of the following main issues, which are normally exposing the coastal zone to competing pressures: (a) Coast protection and shore protection; (b) agriculture and fisheries; (c) habitation, infrastructure, industrial development, public utilities and navigation; (d) recreation, landscape and environmental preservation; and (e) raw material utilisation.

The ICZM concept is best suited for planning in areas where there are still some options for the planning of the coastal hinterland. In areas prone to long term erosion and where the coastal development is already so advanced that comprehensive hard shore protection measures have been constructed years ago, the consequence is very often that
the shore has been heavily degraded or completely lost. Such highly developed areas, where the coastal resource has been degraded over many years, are numerous in most coastal countries. Typically, the population pressure on the sparse remaining coastal resources is very high, and the value of the development is correspondingly high. The present paper concentrates on management and technical methods for restoring such highly developed coastal areas.

**Detailed Planning Concept**

The modern management of shore protection and/or coastal restoration projects have their origin in the world-wide legal requirements for preservation and restoration of the natural resources through a sustainable holistic management. The challenge in this context is to combine the public shore protection/restoration interests with the private interests for coast protection. There are often inherent conflicting interests in such projects, both with respect to the objectives of the protection and with respect to cost sharing. Resolving these planning matters often proves to be equally challenging than to finding a suitable technical solution. Resolving planning matters is normally not the strong side of the coastal engineer, but it is important for the success of the entire planning and design process that the coastal engineer is aware of these conditions.

The level where coastal engineers are involved in the planning is normally not in the ICZM process, but at the more specific and project orientated level, where the planning concepts are Shoreline Management Planning and Management Unit Master Planning. A Shoreline Management Plan (SMP) is a strategic plan for shore protection or shore development covering a sediment cell or a sub sediment cell. An SMP normally contains the following items:

- Basic data collection for the following types of data: Meteomarine conditions, coastal processes, coastline development and coastal structures, present and planned land use and environmental conditions.
- Programme for additional data collection.
- Overall description of coastal morphology and sediment budget.
- Identification of Management Units.
- Consultation with all interested parties with the purpose of obtaining consensus on the goal for a management strategy.
- Definition of the Management Strategy.

In Denmark the SMPs are prepared by the Counties. In other countries this may be the responsibility of other similar bodies. The SMP sets the strategy for shore protection projects in the various Management Units (MU). A Management Unit is a length of shoreline with basically similar characteristics in terms both of natural processes and land use. Different shore or coast protection measures may very well be used for neighbouring MUs, as the preferred measures are dependent on the land use and the ownership of the coastal land. However, the SMP has set out the general guidelines for applicable protection measures assuring that there will be no negative impact from one MU to the neighbouring units. The development of the protection options is often performed in the form of a Management Unit Master Plan (MUMP) or a Shoreline
Master Plan. In Denmark it is normally the landowners who take the initiative to request the County to prepare a MUMP. However, the County can also take the initiative by itself. The County is also responsible for the allocation of costs among the landowners and others, as found relevant in the specific cases. The general rule in Denmark is that the landowner must pay for the protection. The County will normally not prepare the MUMP itself, but it will establish a project organisation, which typically has the following composition:

**Consulting team:** This should as a minimum include the following professionals: Coastal Morphologist, Coastal Design Engineer, Landscape Architect/Planner and Environmentalist.

**Steering Committee:** County, Municipality, Coastal Authority and representatives from land owners and other involved groups (NGO’s).

The preparation of a MUMP will normally involve the following activities:
- Establishment of consensus on local goals, especially with respect to the weighting between shore and coast protection objectives and on cost sharing.
- Performance of detailed data collection, field surveys and analysis.
- Detailed analysis of coastal morphology.
- Detailed analysis of land use and public access corridors.
- Preparation of conceptual design of alternative shore protection projects, including coastal and environmental impact assessment (by numerical modelling) and aesthetic optimisation.
- Preparation of costing for alternative projects and preparation of financing plan.
- Maintenance of contact to authorities responsible for approving alternative projects.
- Selection of preferred project.
- Preparation of plan for monitoring of project performance.
- Preparation of plan for maintenance organisation and follow-up.

The main output of a MUMP is thus a well documented conceptual design of a combined shore and coast protection scheme, which has been documented and balanced with respect to coastal impact, environmental impact and aesthetic considerations. Furthermore the cost sharing and the financing plan have been agreed and the project has been approved.

Based on this MUMP, the responsible body can now call for tenders for detailed design, including preparation of tender documents for construction.

**Main Physical Principles in Shoreline Restoration**

A precondition for establishing a successful shoreline restoration project is that all the involved parties have a minimum understanding of the coastal morphological processes, so that they can understand why the present situation has developed and why certain solutions are applicable and others are not.
The following perspectives should be considered in connection with shoreline restoration projects:

- Work with nature, for instance by re-establishing the coastal profile by nourishment and by utilising site specific features, for instance by strengthening of semi hard promontories.
- Manipulate littoral drift rate and gradient by use of a minimum of structures.
- Preserve sections of untouched dynamic landscape. Allow only protection measures if valuable buildings/infrastructure are threatened.
- Secure passage to and along the beach.
- Enhance aesthetic appearance, such as by minimising the use of structures thereby providing long uninterrupted sections of beach.
- Minimise maintenance requirements to a level, which is possible to manage by the concerned owner(s) of the scheme. A clean nourishment solution at an unstable section of coastline, which for many reasons may be the preferred one, will normally not be practical to handle by a group of land owners, as recharge will be required at short intervals.
- Secure good local water quality and minimise risk of trapping debris and seaweed.
- Secure safety for swimmers by avoiding structures generating dangerous rip currents.
- Be realistic and pragmatic, keeping in mind that the natural untouched coastline is an utopia in highly developed areas. Create small attractive locations at otherwise strongly protected stretches if this is the only realistic possibility.

Coastal classification

The general principles, which should be followed to develop a successful shoreline restoration project, were discussed above. However, in order to be able to arrive at the optimal shoreline restoration measure in an actual case, it is also important to take into account the actual coastal morphodynamic conditions of the site. A coastal classification has been established in the following in order to provide some guidelines as regards which measures are best suited for different types of coasts.

Only littoral coasts, which are characterised by the presence of non-cohesive sediments on the shoreface and on the beach, will be included in the following classification.

The littoral transport for a given coastal environment is mainly dependent on the wave climate in terms of wave height-direction distribution. A simplified classification of coastal areas based on wave exposure and the angle of incidence of the prevailing waves is presented in Figure 2.

The coastal classification is closely related to the variation in transport capacity as function of the angle of incidence and the magnitude of the waves, which has been expressed in form of exposed, moderately exposed and protected coastal areas. The possibility of artificially establishing a practically stable sandy shore is very much dependent on the angle of wave incidence of the prevailing waves and the magnitude of the transport deficit, which is closely related to the transport capacity.
It should be noted, that a prerequisite for obtaining an attractive sandy shore is that the location is exposed or moderately exposed, as it is the constant movement of the beach sand under these circumstances which generated the attractive clean sandy beach.

The coasts have been divided into four main types in relation to the angle of incidence of the prevailing waves and in subtypes in relation to the exposure. The resulting coastal characteristics are presented in Table 1.

It should be noted, that the above given classification is very simplified, and is in practice also dependent of many other parameters, such as the type of coast and sediment supply from the neighbouring areas, as well as seasonality in wave climate, tides and storm surges etc. Figure 2 also shows a schematised coastline, where different typical coastal types have been shown.

Figure 2 Coastline classification
Table 1 Coastal classification as function of angle of incidence and wave exposure for littoral coasts.

Discussion of Innovative Coastal Restoration Schemes

The discussion of the different types of suitable restoration schemes will be divided into the four main types of coastal areas, which reflects the angle of incidence of the prevailing waves, as the different types require different restoration measures.

Type IP to 4P, Protected, all directions

These physical conditions result in a marshy coastline, where there will normally not be any problems related to coastal erosion, but where there may be some problems in relation to flooding. Furthermore, there may be a requirement for upgrading to a sandy shore. However, this is only possible if the reason for the protected status of the coastline is related to a very shallow shoreface. If this is the case, an attractive and more exposed coast can be constructed by moving the shoreline seawards by nourishment. The plan stability of the beach shall also be considered. This principle is shown in figure 3, left.

Type 1M and IE, Perpendicular wave approach, moderate to exposed

These conditions will often result in a sandy beach. The perpendicular wave approach is characteristic for accumulative sand formations in bays, where the net littoral drift is close to zero. If the original bathymetry in such a bay is shallow, there will be a tendency towards formation of sand spits and barrier islands, which are separated from land by a shallow lagoon, refer Figure 2 and Figure 3, right. As these morphological features are characterised by accumulative processes, they will normally not be associated with erosion problems. However, there might be a requirement for upgrading of the entire coastal area towards a more attractive beach environment from a recreational point of view. This can be obtained in two principally different ways:

1. By filling the lagoon and moving the beach seawards, whereby a more exposed and attractive sandy beach is obtained with easy access, as the difficult access caused by the lagoon is eliminated.
2. By dredging the lagoon, whereby it can be upgraded to a recreational protected water area, in combination with seaward movement of the coastline.
Figure 3 Upgrading of: (a) Protected coastal areas with all directions of wave approach, coastal types 1P – 4P and (b) Moderate/exposed beaches with perpendicular wave approach, coastal types 1M and 1E.

These two beach park rehabilitation solutions are shown in Figure 3, lower part. The Køge Bugt Beach Park, near Copenhagen, has been constructed according to this principle and the New Amager Beach is presently being planned also following these principles, Anderskov et al. (1998).

*Type 2M and 2E, Moderate/exposed beach with small angle of incidence*

These types of wave conditions will often result in a narrow to wide sandy beach, however, also depending on tidal and storm surge conditions. These beaches are close to their equilibrium direction and normally subject to a moderate littoral drift; they are often seen in the form of crescentic beaches suspended between headlands or in connection with deltas or tidal inlets, see Figure 2. Their stability is dependent on a continuous supply of littoral material. If such supply does not occur or is interrupted they will tend to rotate towards the direction of the new equilibrium. This will normally lead to shoreline setback.

Coastal protection of such beaches has traditionally been performed by revetments, groyne fields and coastal breakwaters. These traditional measures normally provide good protection of the coastline and, in the case of groynes and breakwaters, some short sections of beaches. However, they have also a series of negative effects on the beach quality as shown in Figure 4. These can be summarised as follows: (a) Revetments: Loss of the beach, erosion of down-drift beach, difficult passage and aesthetically undesirable, (b) Groyne field: Trapping of sand and debris, lee-side erosion, rip currents and offshore loss of sand, rips dangerous for bathers, difficult passage on beach and aesthetically undesirable, (c) Segmented breakwaters: Trapping of
sand and debris, poor water quality in narrow bays, lee-side erosion, rip currents and offshore loss of sand, rips dangerous for bathers, and obscured view to the sea.

An ideal rehabilitation of a coastal section, which has been protected by a combination of traditional coastal protection measures and thereby been degraded, will, from a physical point of view, be a beach nourishment programme. However, this has the disadvantage that is has to be maintained at regular intervals. This is not very attractive for most landowners. Normally, landowners have as one of the main objectives to a shoreline restoration project that the maintenance requirements shall be small. Therefore the coastal engineer has to find restoration solutions, which fulfil this objective. Such a rehabilitation solution is shown in the lower part of Figure 4. The philosophy behind this rehabilitation is to tidy up the old unplanned mixture of small structures, and to re-establish a wide stable sandy beach by the combined use of a few large structures and considerable initial nourishment, plus limited regular recharge.

![Figure 4](image)

Figure 4 Performance of traditional coast protection measures and proposed upgrading to shore protection scheme for moderate/exposed coasts with small angle of incidence.
This concept is only applicable on coasts where the incidence angle of the prevailing waves is small, which means that a fairly long section of beach can be supported by each structure. The equilibrium angle of the new beach section is mainly dependent on the wave conditions and the supply of littoral material to the section from the updrift coastal section. The new beach concept can be characterised by the following qualities: (a) Long sections of natural looking sandy beaches, (b) Small maintenance, (c) Small downstream effects, (d) The protection against coast erosion is provided partly by the wide beach and partly by the structures. Identical safety towards coast erosion along the entire section may require the introduction of buried emergency revetments or the use of beach drains along the narrowest sections of the new beaches, and (e) The new large structures can be used as active elements in the landscaping, for instance to underline natural strong points in the original coastline.

The supporting structure has in Figure 4 been shown as a slightly curved coastal breakwater. However the layout of this structure can be optimised according to the principles shown in Figure 5.

Figure 5 Optimisation of coastal breakwater to artificial headland, applicable for moderate/exposed coasts for small angles of incidence.
The philosophy in the optimisation of the breakwater in terms of a curved breakwater, a shore connected smooth breakwater or ultimately an artificial headland is (a) Improve the bypass, minimise the offshore loss and minimise the lee-side erosion, (b) To eliminate dangerous rip currents and to eliminate lee areas, thereby minimising the risk of trapping of debris, (c) To enhance the aesthetic appearance of the coastal structure and to gain some useful land.

Type 3M and 3E, Moderate/exposed beach with large angle of incidence

This type of coast has a large littoral transport potential, it is often eroding and will therefore in many cases already have been protected. Whereas a suitable, coast protection measure for this type of coast is revetments, it is difficult to propose an optimal shore protection system. The protection principles counting on long sections of accumulated material upstream of protruding coastal structures cannot be used in this situation due to the very oblique wave attack. This type of coast is normally neither suitable for artificial nourishment as a stand alone measure, as this will result in large maintenance requirements, nor nourishment in connection with structures, as the structures can only hold a short beach section due to the oblique wave exposure.

A possible solution for an innovative upgrading of a small coastal section from being protected by a revetment into an attractive recreational environment is the construction of a small cove, as shown in Figure 6. The shape of the small cove will be fairly independent of the oblique wave attack due to its relatively narrow opening.

![Figure 6 Innovative shore protection measure for a moderate/exposed coast with oblique wave attack.](image)

Type 4M and 4E, moderate/exposed beach with nearly parallel wave attack

This type of coast is the downdrift section of a coastline of one of the other types; the littoral drift capacity is small due to the very large angle of wave incidence. This type of coastline is often accreting as the supply of littoral material is typically greater than the transport capacity. However, due to the very oblique wave attack, the coastline development is often unstable and shows a tendency to form coast-parallel land
forms some distance from the coastline, see Figure 7. A characteristic of this separated spit formation is that the coastline downstream of the spit has no supply of sediments, and consequently will be exposed to erosion.

![Diagram](image)

**Figure 7** Special shoreline erosion problem at coastline with very oblique wave attack.

It is important to note that protruding coastal structures in such an environment can initiate the above-mentioned separation, for which reason such structures shall be avoided under these circumstances. The recommended shore protection measures at such a location are withdrawn emergency revetments in combination with artificial nourishment. The source for the nourishment could be the accumulated material in the spit, which is causing the local downstream erosion.

**Final evaluation of coast protection and shore protection measures**

Evaluations of the different kinds of coast protection and shore protection measures, which have been discussed in the paper, have been given in table 2. The protection and restoration measures have been divided in four categories:

- Structures
- Combined, which is combinations of nourishment and structures (beach parks)
- Soft, which is nourishment and beach drain
- Natural, which is management solutions without any structures or other physical measures

The evaluation of the different measures have been divided into four main categories:

- Protection, capability of protecting the coast and influence on adjacent stretches
- Recreation, divided into: capability of protecting the shore, safety for bathers and water quality
- Sustainability, divided into: aesthetics and preservation of coastal resource
- Management requirements, which is the associated efforts for obtaining consensus between stakeholders (not to be underestimated) and to the performance of shoreline management planning.

Please note that the cost of the different measures has not been taken into account in the evaluation scheme.

Table 2 Evaluation of function and impact of coastal protection, shore protection and shoreline restoration measures.

It is of course difficult to make the scoring and some of the given scores can be discussed, however, the tendency is quite clear:

- Structures can provide coast protection, but most often at the expense of the coastal resources
- Combined solutions can be very attractive providing both protection and restoration
- Soft solutions can be attractive providing both protection and restoration
- Natural. Setback restrictions can normally not be used in already highly developed areas and do-nothing can only be used if continued coastal erosion can be accepted

Integrated approach on the safety of dikes along the Great Dutch Lakes

Jentsje W. van der Meer, M ASCE
Harry de Looff
Peter C.G. Glas

Abstract

Two great lakes of approximately 1000 km² exist in the Netherlands surrounded by low lying land. Under extreme events storm surges of 2-3 m can be expected with significant wave heights up to 3 m. The question to answer was to what extent, under extreme conditions, the situations around the two lakes are comparable with situations along the sea coast. And whether or not the dikes along these lakes should give similar safety against flooding. An integrated approach was followed based on risk analysis. The study contained the following parts: hydraulic boundary conditions, probabilistic calculations on required dike heights, cost estimates on possible dike improvements, damage due to flooding and risk analysis on inundation. The main conclusion is that the two lakes have a similar behaviour with respect to risk of flooding which is also comparable with estuaries and other areas along the sea coast.

Introduction

Dikes protect the hinterland from flooding by storm surges from the sea or by high river discharges. Both situations are well known in low-lying countries and safety in the Netherlands relies heavily on reliable, strong dikes. On the basis of risk analysis, including both the probability of failure and the effects of flooding, it has been decided that such dikes in The Netherlands must be strong enough to withstand very extreme events with return periods up to 1/10,000 years. Compared to breakwaters, for example, this is two orders of magnitude higher and such events are difficult to imagine.

A sea such as the North Sea, can create high storm surges and high waves against coastal defences. But large lakes can also generate storm surges and waves, particularly in the case of the extreme events already mentioned.

Two great lakes exist in The Netherlands which both were part of the North Sea system before 1932. They were created at that time by closing the estuary with a dike (the Afsluit dike). Both lakes are only separated by a dam in between. The IJsselmeer ("meer" means lake) has a surface of about 1200 km\(^2\) and the Markermeer about 750 km\(^2\), see Figure 1.

Under extreme events, storm surges of 2-3 m can be expected with significant wave heights up to 3 m. Although not as severe as situations along the North Sea coast, it is comparable. Furthermore, some areas behind the dikes lie more than 4 m below the mean lake level. The differences between the two lakes are that a river flows into the IJsselmeer and that this lake can directly sluice water into the North Sea, which is not the case for the Markermeer.

The question has arisen, both in Dutch Parliament and elsewhere, as to what extent the situations around the two great lakes under very extreme conditions are comparable with situations along the sea coast under similar conditions. And whether the dikes along these lakes should provide similar safety against flooding. An extensive study was performed by Delft Hydraulics, as an independent consultant, to give insight into the problem. An integrated approach was followed based on the concept of risk analysis. A full account of the study results is given in 15 reports by Delft Hydraulics, see the reference list. The study contained the following parts:

- hydraulic boundary conditions
- cost estimates on possible dike improvements
- damage due to flooding
- risk analysis on inundation
- integration of technical and legal aspects
Only the hydraulic boundary conditions with effects on safety and dike heights, the damage due to flooding and the risk analysis are treated in this paper. The problem in more detail can be defined as follows:

- are IJsselmeer and Markermeer comparable with respect to safety?
- what will be the influence of a better control on the lake level of the Markermeer (the river IJssel flows into the IJsselmeer which gives less control)
- what will be the difference in flood damage if the same areas are flooded by IJsselmeer or Markermeer
- what will be the difference in risk of flooding
- is risk of flooding from the lakes comparable to sea coast areas?

Hydraulic boundary conditions: lake levels

A run-off model was first made of the entire lake system, calibrated using 20 years of measurements. The free parameters in the calibration were the control parameters of the sluices. Therefore, the calibration was carried out on management of the two lakes, because this determines the lake levels. A longer period of measurements for calibration than 20 years was not possible as the dike that separates the Markermeer and IJsselmeer was constructed in 1976. Data before 1976 was available, but then for one large and not separated IJsselmeer. Actually, data from the closure of the northern Afsluit dike in 1932 and onwards was available, resulting in more than 60 years of measurements.

![Figure 2. Example of calibration of the run-off model for the Markermeer for the winter of 1993-1994](image)

A result of the calibration for the Markermeer is given in Figure 2 for the winter of 1993-1994. In that winter high lake levels occurred in December and January. The peak is fairly well predicted. In summer the lake level will be maintained at -0.2 m NAP and in winter the lake level is lowered to -0.4 m NAP. Here, NAP is a national level. It is, however, more difficult to control the level in
winter than in summer, which can also be concluded from Figure 2. This is caused by heavier rainfall, storms and higher discharges of the river IJssel in winter than in summer. The peak in December 1993 was the highest in the 20 years of measurements.

After calibration, data before 1976 was used to run the model and to predict lake levels for the two lakes. The maxima were then used to determine a statistical distribution based on 60 years. These distributions were then extrapolated to give predictions for events with return periods up to 1 in 10,000 years, by statistical methods which are also used to predict extreme river run-off.

Similar calculations were made for various scenarios like sea level rise or climate change, increase of pump or sluice capacity into the North Sea, partly reclaiming the Markermeer and a modified control of the sluices between IJsselmeer and Markermeer. Finally, all calculations resulted in three possible lake level statistics for each of the two lakes. These statistics are shown in Figures 3 and 4. The middle curves give the present situation and the highest curves include climate change. The lowest curves give the effect of double pump or sluice capacity into the North Sea.

![Figure 3. Three possible (extrapolated) lake level distributions for the Markermeer](image)

A modified control of the sluices between IJsselmeer and Markermeer gives also the lowest line in Figure 3. This modified control means that, if due to the river IJssel the lake level in the IJsselmeer increases, the sluices to the Markermeer will be closed and that, therefore, the Markermeer will not be influenced by a high level in the IJsselmeer (which may increase the lake level in the IJsselmeer, however). The highest lines in Figures 3 and 4 are comparable. The lowest line in Figure 3 is much lower than the one in Figure 4.
Figure 4. Three possible (extrapolated) lake level distributions for the IJsselmeer

Based on Figures 3 and 4 the following conclusions about extreme lake levels were derived:

- the river IJssel determines mainly the lake level of the IJsselmeer
- the sluice control between the IJsselmeer and Markermeer during high lake levels in the IJsselmeer determines the lake level in the Markermeer:
  - if the sluices stay open, the Markermeer level will follow the IJsselmeer level
  - if the sluices are closed, the Markermeer level will stay low
- in principle the Markermeer level is better manageable than that of the IJsselmeer. But what will be the effect on safety of the dikes?

Hydraulic boundary conditions: extreme storms

Storms generate surges and waves and the dikes should withstand these conditions. Flow and wave height calculations were performed with DELFT-3D (in the 2DH mode), the integrated modelling system developed by Delft Hydraulics. These calculations result in storm surge levels and wave heights, periods and directions at more than 1000 locations along the lakes' dikes.

In total 216 calculations were performed covering the following conditions:

- lake levels of -0.4 m, +0.3 m and +1.3 m NAP
- 12 wind directions, each covering a sector of 30°
- 6 wind velocities, from 15 m/s up to 42 m/s

All data of the calculations and for the more than 1000 locations along the lakes' dikes was stored in a data management system and used for further analysis. Figure 5 gives an example of a calculation with DELFT-3D for the Markermeer. The condition given is a very extreme one: a lake level of +1.3 m NAP, combined with a wind velocity of 42 m/s from 330°. Figure 5 shows the storm surge levels. The highest levels occur in the south-east part where the levels may exceed +4 m NAP. The joint probability of this lake level and wind velocity is so small, however, that it
is not a realistic situation for the Markermeer. These conditions were the upper boundary of the set of conditions given above.

![Figure 5. Calculation of storm surge levels in the Markermeer for a lake level +1.3 m NAP and a wind velocity of 42 m/s from 330°](image)

**Probabilistic calculations on required dike heights**

The long-term statistics of the water levels (Figures 3 and 4) and the data management system on storm surge levels and waves were input for full probabilistic calculations of expected wave run-up or wave overtopping. The model includes also the long-term wind statistics (and through the data management system its effects in surges and waves).

The locations with the hydraulic boundary conditions from the data management system, however, were chosen about 400 m from the dike. Very often the foreshore leads to shallower water at the toe of the dike. And the wave conditions at this toe are required to make the right calculations on required dike height. If the water depth at the toe was different from the location from the data management system, calculations were performed to establish the required conditions.
With these boundary conditions, calculations on wave run-up or wave overtopping were performed according to Van der Meer and Janssen (1995). All these calculations were integrated in the full probabilistic model. With the long-term lake level and wind statistics, the conditions from the data management system, the geometry of the foreshore and the dike itself, a Riemann integration was performed to give the required dike height for a given safety level of say 1 in 10,000 years.

Comparison of the two lakes

Calculations with the full probabilistic model were performed to compare required and existing dike heights and to establish necessary improvements. Other calculations were made in order to compare the IJsselmeer with the Markermeer and to investigate possible essential differences. Figure 6 shows in each of the lakes 15 locations. Locations with the same numbers (for example M01 in the Markermeer and IJ01 in the IJsselmeer) have more or less a similar location in the lake and have also the same orientation of the dike.

![Figure 6. IJsselmeer and Markermeer with similar locations for comparison](image)

Calculations were made for a “standard” dike with a smooth slope of 1:4 and without a foreshore. The required dike heights at all locations were determined for the 2%-wave run-up level as governing condition and for a safety level of 1 in 10,000 years. These calculations were performed for all three lake level statistics given in
Figures 3 and 4. The results are shown in Figures 7 and 8 for Markermeer and IJsselmeer, respectively. The low, middle and high points of the legend correspond with the curves in Figures 3 and 4.

The conclusion on the influence of the long-term lake level statistics on required dike heights becomes very clear from Figures 7 and 8. There is hardly any influence as most of the three lake level statistics give the same required dike height, except for a few, more sheltered, locations.

Figure 7. Required dike heights for locations in the Markermeer given in Figure 6 and for 3 long-term lake level statistics given in Figure 3

Figure 8. Required dike heights for locations in the IJsselmeer given in Figure 6 and for 3 long-term lake level statistics given in Figure 4
The reason why the long-term lake level statistics have hardly influence on required dikes heights, is that extreme lake levels and extreme storms are independent events. A (very) strong wind with a level close to the winter level of $-0.4$ m NAP has a larger probability of occurrence, than a less strong wind with a much higher lake level to give the same required dike height. In fact very strong wind governs the required dike height and not the long-term lake level statistics. This means also that the lake level control of the Markermeer has no or only marginal influence on dike safety. From that point of view the Markermeer and IJsselmeer are comparable.

Possible damage due to flooding

There are two areas that can be flooded by both the IJsselmeer and the Markermeer, see Figure 9. One area is just north of the separating dike and the other just south. An in-depth study was made of the expected damage in the two areas. The main goal was to investigate the influence that the difference in lake size has on damage. The areas were divided in smaller areas with similar bottom levels. With a simple inundation model the maximum water depth after flooding was calculated for each of these areas.

![Figure 9. Two areas that can be flooded by both lakes](image)

A large number of damage categories were used to calculate the total damage. Each category had a given relationship between inundation depth and damage. A few of the damage categories were: agriculture, cattle breeding, horticulture, urban area, recreation, roads, houses, transport, etc. Also a category victims due to drowning was used. The expected damage and the expected number of victims for the southern area (Flevoland) is given in Table 1. Flevoland is one of the polders reclaimed from the lake and the depth is more or less equal to the old bottom of the IJsselmeer which is about $-4$ m NAP.
COASTAL ENGINEERING 1998

</tr>
</tbody>
</table>

The damage by flooding from the IJsselmeer is a little larger than from the Markermeer. The reason is that the Markermeer in size is about 2/3 of the IJsselmeer, giving inundation depths that are approximately 0.5 m smaller. Inundation depths in average will be about 2.2 m to 3.3 m. Although the figures for the Markemeer are a little lower, the order of magnitude is the same. A similar conclusion was drawn for the northern area in Figure 9. This means that also from the point of view of damage due to flooding, both lakes are comparable.

Risk analysis on inundation

Dikes in the Netherlands are currently designed and examined on a prescribed load, given as an event with a certain return period (between 1/1,000 and 1/10,000 years). A dike must be capable of withstanding such an event. In future, rather than considering each dike section individually, a total area surrounded by dikes or other forms of protection must have a certain safety level. This should make it possible to describe the circumstances under which dikes really do breach and how a breach develops.

A further step will be to describe safety in terms of risk. Risk is then described as the combination of probability on flooding and the consequences in terms of loss of material (economic damage) and human lives (risk = probability * effect). It is currently not possible to perform a quantitative risk analysis in full detail as described above, but a first attempt was made in this study, using recent studies of the TAW (Technical Advisory Committee on Water Defences in the Netherlands).

In these studies existing dike ring areas were taken and all data on dikes and hydraulic boundary conditions were gathered. A probabilistic computer model was made that includes all possible failure mechanisms of a dike and that is able to calculate the probability of flooding by breaching of one of the dike sections. The description to the actual failure mechanism is still preliminary and needs more research in future (what overtopping discharge can a dike really withstand?).

Each dike section was designed for a prescribed load with a certain return period. The outcome of the probabilistic calculation was the probability of flooding of the whole dike ring area. In total six different dike ring areas were treated by the TAW. The main results are given in Figure 10.

A preliminary conclusion is that the probability of flooding of a dike ring area is similar to the probability of the prescribed load under which conditions the dike should be capable of withstanding this event. This conclusion needs further research for confirmation, but for the present study it was used for a complete risk analysis.
The probabilities of occurrence of the prescribed loads of each of the dike sections around IJsselmeer and Markermeer have been given by law. These probabilities vary from 1/1,250 to 1/10,000 years. With above conclusion, the probability of flooding of each dike ring area was given the same value. The economic damage of two areas had already been calculated, see Figure 9 and Table 1. In a similar, but slightly simplified way, damage caused by flooding was calculated for all dike ring areas around the both lakes. Together with the probability of flooding it was then possible to calculate the risk of flooding for each dike ring area, by multiplying the probability of flooding with the economic damage.

The main question to consider, however, was the comparison of both lakes with each other and with areas situated along the sea coast. A lake or a sea is not a dike ring area, but a threat to the dikes. Therefore, the definition of risk is not applicable to the hydraulic system and a modified definition had to be established. The term risk profile was invented for these threats or hydraulic systems:  

\[\text{risk of flooding} = \text{probability of flooding of a dike ring area} \times \text{damage due to flooding}\]

\[\text{risk profile} = \text{the cumulative flooding risks of all dike ring areas along the threat}\]

In this way the risk profile of each hydraulic system like a lake, sea or estuary can be calculated and compared. Both risk and risk profiles are given in value per year, say in million Dutch guilders per year (one US dollar is about two guilder). Figure 11 gives the risk profiles of 5 hydraulic systems in the Netherlands. Two of them are of course the IJsselmeer and Markermeer. They have similar risk profiles of 4.5 and 4.2 million guilders per year.

Although the Markermeer gives lower inundation levels, and therefore lower damage compared to the IJsselmeer, the risk profile is the similar. The main reason for this is that more people live in the dike ring areas around the Markermeer than around the IJsselmeer (Amsterdam is situated on the Markermeer).
Figure 11. Risk profiles of various hydraulic systems in the Netherlands

The above system analysis leads to the first overall conclusion of the study:

• with respect to safety the two lakes do not show significant differences and should be treated in the same way.

Three other hydraulic systems are given in Figure 11. The Grevelingen is also a lake and after the Markermeer the largest in size in the country. There is more than an order of magnitude difference with the Markermeer and this lake should not be considered like the IJsselmeer or Markermeer or like estuaries or seas.

The last two hydraulic systems are the Eastern Scheldt and the North Sea which directly attacks the rest of the Netherlands. The Eastern Scheldt is an estuary which is closed by the well-known Eastern Scheldt barrier if the storm surge reaches a level of +3 m NAP. From that moment on the estuary becomes a closed lake. The risk profile for this estuary is smaller than for the IJsselmeer and Markermeer, but still comparable. The North Sea threatens a large part of the Netherlands and gives of course the largest risk profile. There is, however, less than an order of magnitude difference with the two lakes. Comparing the two lakes with the two salt water systems gives the final conclusion:

• large lakes like the IJsselmeer and Markermeer give similar risk profiles as for areas along the sea coast and should, with respect to safety, be treated in the same way.

Conclusions

A system analysis of the threat that hydraulic systems, such as large lakes, estuaries and seas, can form for the safety of dike ring areas around these systems, gives a good insight into the physical aspects. Together with a risk analysis, finally leading to the description of the risk profiles of hydraulic systems, it makes it possible to compare the various hydraulic systems from the point of view of safety. To that
aspect the IJsselmeer and Markermeer should be treated in a similar way as estuaries and the North Sea.

Lake level control has hardly any influence on required dike heights, or safety, as the dike heights in most situations are determined by very strong wind, high storm surges and high waves. Flood damages from IJsselmeer and Markermeer are comparable, although the damage due to the Markermeer will be a little smaller as the lake is also smaller (the inundation depths, therefore, are a little smaller).

Acknowledgement

The authors wish to thank all those who have actively participated in the extensive technical, legal and managerial discussions, which have formed the basis for this study. During the 1½ year study representatives from the Netherlands’ Ministry of Transport, Public Works and Watermanagement, several Provinces and Waterboards worked together with the research staff of Delft Hydraulics, the Technical University of Delft and the University of Utrecht. The outcome of this work underlines that a technical study, set in the context of a political and managerial debate, can indeed lead to consensus on the management steps to be taken and the legal changes that are necessary to make this happen.

Abstract

Walvis Bay, the major port of Namibia, is earmarked for extensions. The extension of the entrance channel and the port can increase the maintenance dredging cost considerably, and if not correctly planned could impact negatively on the nearby Walvis Lagoon. An improved layout for the extended port is recommended, taking into account the sediment transport regime. The future maintenance dredging rate for the extended port is determined to be 720 000 m³/year compared with the 200 000 m³/year for the existing commercial and fishing harbours. The future general cargo quays could be located so as to minimise the influx of sediment into the Walvis Lagoon. It is shown that the water exchange to the lagoon will not be significantly affected.

1. Introduction

The Port of Walvis Bay is situated in a natural harbour along the central Namibian coastline (Figures 1 and 2). This harbour is formed by the Walvis Peninsula with Pelican Point located at its tip (Figure 1; see Schoonees et al., 1998 for more details). The land surrounding Walvis Bay is low-lying and consists of desert sand. Traditionally the port has been operated as two entities, namely, the commercial and fishing harbours; however, at present the Namibian Ports Authority has jurisdiction of the full water area. The ecologically sensitive Walvis Lagoon (Figure 1) is located south of the town of Walvis Bay. This lagoon used to be the mouth of the Kuiseb River, which is a river that rarely reaches the sea except during large episodic floods.

As the only major deep-water port of Namibia and because of the short distance to the central heartland of Namibia (Windhoek) and the existing

2 Research Engineer, CSIR, P O Box 320, 7599 Stellenbosch, South Africa
infrastructure, it can be expected that Walvis Bay will be the focal point of future commercial port development in Namibia and the adjacent landlocked regional countries. An extension and deepening of the entrance channel and the port is planned (Figure 3), which could increase the maintenance dredging cost considerably, as well as impacting negatively on the Walvis Lagoon.

A feasibility study (CSIR, 1994) was carried out to assess the viability of the proposed future extensions to the Port of Walvis Bay as shown in Figure 3. The aim of the feasibility study was to use existing information and to evaluate the environmental conditions (waves, current, winds and tides), assess the effect of the proposed port development (Figure 3) on the movement of sediment in the bay, comment on the present port capacity and the navigational aspects of the proposed berth and channel layout and carry out a preliminary ecological investigation into the effect of the development on the lagoon. This paper deals only with the sediment transport and dredging aspects such as the present sediment transport regime, the increased maintenance dredging requirements of the extended port and the effect of sediment transport on the Walvis Lagoon. The paper includes the prediction of mud infill rates and the minimisation of dredging costs without endangering the lagoon.

2. Environmental data

Seven sets of vertical aerial photographs are available from 1943 to 1980. These photographs show amongst other things, the development of the port and town, changes to the Walvis Lagoon and the growth of the Walvis Peninsula. The bathymetry of the whole Walvis Bay area is shown in Figure 2. From this figure it can be seen that the average water depth in the bay is about -10 m to chart datum (CD = 0.90 m below mean sea level). The main entrance channel to the port is dredged to -10 m to CD.

The tide is semi-diurnal with a spring tidal range of 1.44 m. From Waverider measurements obtained in 50 m depth of water outside the bay, it was found that the median significant wave height (H_s) is 1.1 m and the median peak wave period is 11.6 s. The 1-in-1 year deep-sea H_s is 3.6 m for Walvis Bay. Wave directions were obtained from voluntary observing ships. The dominant deep-sea wave directions are southerly to south-westerly (89% of the time). This means that Walvis Bay harbour is protected from the dominant waves. The port is, however, exposed to waves from the sectors between west and north which occur only 2% of the time.

Moored current buoys and drogues were mainly used in field studies to determine the current regime in Walvis Bay. A clockwise surface current circulation to an anticlockwise circulation occurs in the bay in the ratio 3:1. The velocities of these currents are low, generally of the order of a few cm/s. A diurnal reversal of current directions occurs as well, with clockwise (south-going along the eastern shore) currents in the morning followed by anticlockwise currents in the afternoon. This reversal is brought about by an associated change in wind direction. In the surf zone along the bay, especially along the eastern shore, wave-driven currents are
normally dominant. At both Dolfynstrand (Figure 1) and Langstrand (Figure 1), the surf-zone currents are usually northbound, while at the breakwater immediately to the north of the port (Figure 1), the current is southbound. This reversal in the surf-zone current direction is primarily due to diffraction effects. At the mouth of the Walvis Lagoon strong currents in and out of the mouth are found.

Generally speaking, the material found on the sea bottom in Walvis Bay consists of fine to medium shelly sand overlain by a soft marine mud layer. Mostly mud is dredged from the port in order to maintain the required depths. Sand is, however, found on the surface of the sea bottom along the shoreline. The present influence of the nearby Kuiseb River on the harbour is considered to be small and intermittent because a retaining wall diverts the infrequent major floods away from the bay and port.

3. Sediment transport regime

3.1 Growth of the Walvis Peninsula

The Walvis Peninsula is growing northwards at a rate of 22.6 m/year (Schoonees et al., 1998) because of the northbound longshore transport along its western shoreline. The effect of this growth is primarily to decrease wave action at the harbour even further, since the dominant deep-sea waves are from the southerly to south-westerly sector. The secondary effect of this growth is that the sediment transport rates in the bay will also decrease in time as will be discussed below. However, because the circulation in the bay is wind-driven (and possibly tide-driven as well) this will most probably not reduce the sedimentation of the port significantly.

3.2 Longshore transport

In Schoonees et al. (1998) it was determined that the net longshore transport is about 860 000 m³/year along the western shoreline of the Walvis Peninsula. Along the eastern shore of the peninsula a very low net longshore transport can be expected.

Inside the bay, at both Dolfynstrand and Langstrand, the net longshore transport is northbound. The respective potential net transport rates at these sites are about 150 000 m³/year and 510 000 m³/year (CSIR, 1985). Immediately to the north of the breakwater north of the port, accretion has taken place. The direction of the net longshore transport is therefore southbound at that location. This is due to a southerly current generated by a gradient in breaker wave height. This gradient is caused by wave diffraction around Pelican Point. Because of this reversal in the net longshore transport direction, an area subject to erosion has to exist between the breakwater and Langstrand. This is indeed the case: a rocky stretch of coastline is found around Dolfynstrand.

At the mouth of the lagoon there is a low net westbound longshore transport as evidenced by a spit on the eastern side of the mouth, which grows westwards, as can be seen on aerial photographs.

For the stretch of coastline between Dolfynstrand and Langstrand, 50 years
of growth of the peninsula results in a considerable reduction in the (still) northbound net longshore transport (CSIR, 1985).

3.3 Aeolian sand transport

Wind data collected from 1987 to 1993 south of the town of Walvis Bay have been used to compute seasonal and annual wind-blown sand transport rates. A median sand grain size of 0.29 mm was used.

The results show that, on an annual basis, the dominant aeolian transport is bound between the north-east and the north-west. Considering the position of the town of Walvis Bay and the lagoon (Figure 1), it is clear that the port and its proposed extensions are shielded from the dominant aeolian sand transport. It is only north of the breakwater at the shore connection of the future bulk cargo handling platform (Figure 3) where problems may occur. The influx of wind-blown sand there is estimated to be 15 m\(^3\)/year per m of westbound transport.

3.4 Cross-shore transport

Cross-shore transport is not a very important process causing sedimentation in the harbour, because the harbour is situated in a calm area and due to the extensive quays built all along the shoreline inside the port.

4. Dredging

4.1 Analysis of dredger records

Figure 2 shows the commercial and fishing parts of the port. The commercial harbour consists of the main entrance channel and the south-western side of the port while the fishing harbour is situated on the north-eastern side, including the secondary channel.

Dredging has been carried out fairly regularly in the commercial harbour. From 1965 to 1993, major maintenance dredging was performed about every five years. Dredging has also been done by means of a small grab-and-barge dredger on a continuous basis. Figure 4 shows the annual dredge volumes from minor and major maintenance dredging. The volumes given are not in situ volumes but hopper volumes; the bulking factor has been estimated to be 1.1. Also shown in Figure 4 is the running annual average rate (that is, the first point is the mean rate over one year, the second point is the mean rate of the first two years, etc.). The running average is about 130 000 m\(^3\)/year for the commercial harbour.

It is suggested that annual surveys be performed throughout the whole harbour. These surveys should be conducted before and after major maintenance dredging in order to determine the in situ quantities dredged (the so-called in-and-out surveys). At the same time, dredge data should be collected from the dredgers and volumes dredged should be determined as accurately as possible with a number of methods. It is further recommended that the harbour be divided into practical areas where maintenance dredging is to take place (Figure 11 shows these areas for the new proposed harbour layout) and to keep records of the quantities dredged in these areas.
4.2 Prediction of maintenance dredging requirements

Method

A number of techniques have been developed to predict dredging rates in harbours (O'Connor, 1985; Vicente and Uva, 1984; Schoonees, 1994). Most of these techniques are based on survey data being collected over a number of years (often from test pits). Plotting these data shows that in all cases there is an exponential or power law decrease in the depth (due to sedimentation) over time. This principle is used to predict the future dredging rates at the Port of Walvis Bay. The depth of the new channels and new basins is, however, far greater than the existing channels and basins. In theory each channel or basin with a certain relative depth (Ho; Figure 5) and its banks at a certain depth (do) have their own characteristic sedimentation curve in a certain environment. By using curves from similar areas with different depths, curves can be extrapolated to determine the sedimentation in deeper or shallower channels. The existing harbour (including the fishing harbour) has been subdivided into eight areas for this reason.

Surveys were conducted for the different areas on a number of occasions, but only subsequent surveys could be used when no major maintenance dredging had taken place in between. Data from two of the eight areas could not be used. This is because either the data covered only a short period of time and/or the sedimentation (decrease in water depth) was minimal during the particular period and thus within the accuracy of the survey method.

The sedimentation (Ho) and the sedimentation ratio (Ht/Ho; Figure 5) were plotted against time. Power law curves were fitted through the data points (exponential curves did not fit the data as well). The curves for the different areas were compared in order to evaluate the compatibility and to classify them according to the relative channel depth (Ho) and surrounding depth (do). Only the curves for the commercial harbour could be used for calibration purposes (as will be explained below) and eventually the calibrated curves could be extrapolated to obtain representative sedimentation curves for the new proposed layout.

Results

Figure 6 shows the sedimentation and the sedimentation ratio as a function of time for the south-turning circle area from November 1976 to February 1981. The goodness of fit is given by the coefficient of determination (R²), which is 0.96 for the example in Figure 6.

In order to see if there are trends in the curves with regard to the relative depth (Ho) of the channels, the sedimentation ratio curves were plotted to indicate the relative channel depths (Figure 7). It is shown that the curves for the southern quays, south of the turning basin, the south channel (fishing harbour) and the northern quays all show similar curves while the inner channel of the commercial harbour and the tanker basin are the two extremes. No clear trends can be seen when comparing the relative channel depths. Comparing the depth of the surrounding areas in a similar way also showed that there is not a clear trend, although deepest depths show the highest sedimentation ratios.
Because no clear trends were detected when comparing the sedimentation ratios of the various areas, it was decided to use the average sedimentation ratio of the commercial and fishing harbours (Figure 8). The minimum and maximum curves were used to determine the extreme values (Figure 8).

**Calibration**

A twofold calibration of the method was carried out: (1) by fitting the power curves to the measured sedimentation of mud (Figure 6 shows an example); and (2), by comparing the computed sedimentation rates with the net average dredging rate in the commercial harbour. In the latter case, the computed sedimentation rate was determined for a specific area by multiplying the predicted vertical sedimentation of mud with the surface area of the specific area. By summing all these computed sedimentation rates for the different areas, the total predicted sedimentation rate was obtained for the particular period under consideration.

The calibration factor was defined as the computed sedimentation rate divided by the measured average dredging rate. Because of this calibration, the required maintenance dredging rates are given in terms of hopper (dredged) volumes. Figure 9 shows the calibration factor as a function of time. The apex of the curve is caused by the fact that the annual dredging rates, which are a linear function of time, are compared with the predicted dredging rates which change according to a power law over time. The average calibration factor is used for the whole harbour. The calibrated sedimentation curve is as follows:

$$\frac{H_t}{H_0} = 0.59 \left(10^{0.0118t + 0.976}\right)$$

where \( t = \) time (months)

**Future dredging rates**

The best estimate of the sedimentation volume for the total existing harbour is about 200 000 m\(^3\)/year (dredged volume), while for the new proposed layout (Figure 10) this value will be about 720 000 m\(^3\)/year with minimum and maximum values of about 165 000 m\(^3\)/year and 1 661 000 m\(^3\)/year respectively (also dredged volumes). The annual dredging rate will increase dramatically for the new proposed layout. This is mainly due to the increased surface area of the basins and channel, but also because of the increased channel depths. Adequate sediment (mostly mud) is available to cause the sedimentation.

4.3 Proposed port layout and influence of harbour extensions on the lagoon

With regard to sediment transport and the associated dredging considerations, it is logical to try and make entrance channels as short and berthing areas as small as possible. (Of course, navigational and other aspects also play a vital role in designing the size of berthing areas.) Applying this principle of minimising areas, the orientation of the main entrance channel should be north-west instead of north (Figure 2). This means that the channel will be about 500 m shorter.
resulting in approximately 900 000 m$^3$ less to be dredged if the whole channel is to be dredged from scratch. Naturally an unnecessary cost would result if a completely new channel is dredged; it is much more feasible to use the existing channel and change its orientation when extending the channel. It is recommended that the new seaward portion of the channel should start at the extremity of the existing channel and head north-westwards (Figure 10 shows the new proposed port layout). In this way the channel will not only be 100 m shorter (and thus save on capital dredging), but it will be in a calmer (more protected) area and facing right into the waves requiring less maintenance dredging. In addition, the access to shipping will be easier because of reduced ship motions. For bigger ships the channel will lead straight to the future bulk cargo handling platform.

By further applying the principle to minimise channels and berthing areas, it is suggested that the turning circle in front of, and the access channel to the bulk cargo handling platform (Figure 3) be amalgamated with the main entrance channel as shown in Figure 10. This will not be a hindrance to shipping because at present fewer than one ship visits the port per day. Considering this access channel, only a short length of about 1.5 km of channel will be required. This will be about 2 million m$^3$ less to be dredged initially. Another saving is to discontinue using and maintaining the two entrance channels. This originally probably stemmed from the fact that the commercial and fishing ports were run by two different controlling bodies. It is recommended that the smaller entrance channel (to the fishing harbour) be left to fill up over time and that only the main channel be maintained. This also applies even if the port is not extended in the near future.

The harbour extensions will have the following effect on the Walvis Lagoon:

- Wave action and therefore wave-driven longshore sediment transport (which is southbound in this vicinity) will be drastically reduced.
- The quays will trap this longshore transport and will severely limit the influx of the finer sediment carried by the clockwise circulation to the mouth of the lagoon. In fact, the circulation pattern will be altered.

Less sediment will thus be available at the lagoon mouth to be transported into the lagoon. Historically the lagoon experienced siltation problems. Therefore the harbour extensions will in fact benefit the lagoon. Because the currents in and out through the mouth are tidally driven, the proposed port extensions will probably not affect the water exchange to the lagoon (which is an important ecological consideration) significantly.

5. Conclusions and recommendations

Presently about 200 000 m$^3$ of sediment (mainly mud; dredged volumes) is dredged annually from the navigable harbour areas.

Existing survey data have been used to verify that the depths of channels and basins decreased as a power function over time. The method was first
calibrated against the sedimentation rates, then calibrated against the required annual dredging rate for the commercial part of the port, and finally used to predict the future dredging rate for the enlarged harbour. A maintenance dredging rate of about 720 000 m³/year was computed for the total future extended port as shown in Figure 10. All these volumes are dredged volumes, divide by the bulking factor of about 1.1 to obtain an estimate of in situ volumes. Adequate sediment (mostly mud) is available to cause this sedimentation.

The construction of the future general cargo quays on the south-western extremity of the port will most probably limit the influx of sediment into the Walvis Lagoon, thereby benefiting the lagoon. Because the currents in and out through the mouth are tidally driven, it is unlikely that the port extensions will significantly affect the water exchange of the lagoon.

Applying the principle of minimising channel lengths and berthing areas, the originally anticipated extensions (Figure 3) have been adapted to the layout shown in Figure 10. Considerable savings in both capital and maintenance dredging are the result.

Hydrographic surveys should be conducted before and after major maintenance dredging in order to determine the in situ quantities dredged as accurately as possible. At the same time, dredge data should be collected from the dredgers in order to determine the volumes dredged as accurately as possible. It is further recommended that the harbour be divided into practical areas where maintenance dredging is to take place and to keep records of the quantities dredged in these areas.

Accuracy in Spill Monitoring
Turbidity Distribution and Conversion Factors

Klavs Høgh\textsuperscript{1} (M.Sc.), Iris Buxbom\textsuperscript{2} (M.Sc.) and Trine Borum Bojsen\textsuperscript{2} (M.Sc.)

The present paper is based upon work carried out at the Spill Monitoring Department within Øresund Marine Joint Venture (ØMJV)\textsuperscript{3}.

Abstract

In connection with the dredging and reclamation works at the Øresund Link Project between Denmark and Sweden carried out by the Contractor, Øresund Marine Joint Venture (ØMJV), an intensive spill monitoring campaign has been performed in order to fulfil the environmental requirements set by the Danish and Swedish Authorities.

Spill in this context is defined as the overall amount of suspended sediment originating from dredging and reclamation activities leaving the working zone.

The maximum spill limit is set to 5\% of the dredged material, which has to be monitored, analysed and calculated within 25\% accuracy.

Velocity data are measured by means of a broad band ADCP and turbidity data by four OBS probes (output in FTU). The FTU's are converted into sediment content in mg/l by water samples.

The analyses carried out, results in high acceptance levels for the conversion to be implemented as a linear relation which can be forced through the origin.

Furthermore analyses verifies that the applied setup with a 4-point turbidity profile is a reasonable approximation to the true turbidity profile. Finally the maximum turbidity is on average located at a distance 30-40\% from the seabed.

Introduction

In connection with the construction works at the Öresund Fixed Link Project connecting Denmark and Sweden, the potential environmental effects of the associated construction works were of great political interest.

For the dredging and reclamation works this meant strict environmental requirements regarding the allowable amount of spill caused by these activities. A large scale Spill Monitoring Programme as prescribed by the owner was put in action by the Contractor. The Spill Monitoring System was ship and land based, and monitoring of the spill causing activities was performed on a 24 hour basis as dredging was not permitted after 6 hours lack of spill monitoring.

In general the overall spill limit is set at 5% by weight of the design quantity to be dredged (some 7 million m$^3$) and has to be determined with a 25% accuracy with a 75% probability. Also seasonal variations in daily and weekly spill limits are to be followed in order to protect the biological life on a short term basis.

As spill monitoring in this intensive way with such strict specific requirements has never been carried out before, the system was (and still is) under continuous discussion and verification. The intention of this paper is to clarify some of the more serious discussions related to accuracy in spill monitoring that have been raised, based on the very large amount of data which are available after almost 3 years of spill monitoring.

### Spill in this context is defined in the contract as the portion of dredged or excavated material brought into suspension during dredging, transport or filling and leaves the work zone or land reclamation areas as follows:

1. Suspended and resuspended materials originating from the dredging activities leaving the work zone.
2. Suspended materials leaving the reclamation or backfilling areas.
3. Materials lost during transport from dredging to reclamation areas or from reclamation areas to backfilling areas.

Spill at any time is the sum of 1. to 3. and is measured by dry weight of suspended material.

The work zone is defined as the area to be dredged plus a surrounding 200 metre zone.

Basic theory

The governing equations for the spill calculations are derived by considering a balance (continuity equation) of suspended material through an enclosed box as shown in Fig. 1.
The flux intensity of suspended material at a given coordinate in time is given by

\[ I(x,y,z,t) = C(x,y,z,t) \cdot \dot{V}(x,y,z,t) \]  

(1)

and the net flux through the box at time (t) is calculated by integration along the vertical surface (\(\Gamma\)) of the box

\[ F(t) = \int_{\Gamma} I(x,y,z,t) d\Gamma \]  

(2)

This way the spill (S) related to the production (P) during a dredging period of duration (T) will equal

\[ S = \int F(t) dt \]  

(3)

which is the basic formula used for calculation of spill from dredges.

The most common situation is a one-directional current with a clear and well defined plume and in this case the spill calculation can be expressed as the difference between downstream and upstream values

\[ S = \int (F_d(t) - F_u(t)) dt \]  

(4)

Data Collection

Considering eq. (1)-(4) the necessary data needed for the spill calculations are current velocity and concentration of suspended material.

Current data are gathered by a broad band Acoustic Doppler Current Profiler (ADCP) mounted at the hull of the vessel. Data are hereby obtained from 0.7 m below the ves-
Concentration data are gathered by four Optical Back Scatter (OBS) sensors with one mounted on a pole at a fixed depth and the remaining three mounted at 2 m intervals on a winch controlled streamer. Output from these sensors is Formazin Turbidity Unit [FTU] which is converted into sediment content by means of water samples.

Since the turbidity sensors work by light reflection, the magnitude of the output depends upon several material parameters such as colour, shape and grain size distribution. This means that water samples have to be gathered at regular intervals in order to reflect the geological changes in the dredged material. How the conversion process should be implemented will be discussed further in this paper.

Considering the gathered current and turbidity data approximated velocity and turbidity profiles are produced as described in the following. The velocity profile is constructed by vertical extrapolation of the top measurement to the water surface, straight line interpolation in between all points and a power fit from the lowest point towards sea bed. The turbidity profile is made by linear interpolation in between points and vertical extrapolation of top and bottom sensor registration. Examples of both profiles are shown in Fig. 2, and it is clear that the velocity profile is relatively well described due to the more measuring points. However the turbidity profile may stand as a weak part with its 4-point approximation when compared with the velocity profile. Furthermore the lowest measurement will always be located around 1-2 m away from the sea bed due to equipment safety.

The turbidity intensity profile is obtained by multiplication of the two approximated profiles, and can be seen in Fig. 2. Current and turbidity data are logged continuously (10 per second) and average values are stored at regular intervals (e.g. every 6 s which corresponds to a registration at distances of average 10 m).

When enclosing a spill source with the survey vessel a discrete 3D picture of the intensity is derived and the net flux of suspended material through the box can be calcu-
lated numerically based upon eq. (2). Numerically integration in time is then obtained by sailing enclosed boxes continuously around the spill source and use of eq. (3).

Problems

The summary of the problems introduced in the previous section is:

I) What is the relation between turbidity and sediment content?

II) The 4-point approximated turbidity profile is coarse compared to the velocity profile. Does this lead to large deviations from the true turbidity profile?

III) Where is the maximum turbidity located? Does the lack of turbidity information close to the sea bed lead to any systematic error in the 4-point profile?

Conversion Factors - ad I)

An example of a water sample session can be seen in Fig. 3. It is important to cover as wide a turbidity range as possible during the water sampling process to obtain a satisfactory picture of the conversion relation. In Fig. 3 the best line fit is included and it seems evident that a linear relation exists.

\[
\text{Sediment (mg/l)} = 1.91[\text{FTU}] - 3.53
\]

Figure 3. Ideal Water Sample Session Result.

When performing a water sample session it can be difficult to obtain a wide range of turbidity registrations due to the nature of the sediment plumes, which can lead to results as seen in Fig. 4. This water sample session does not indicate any linear relation. However a linear relation through the origin has proven to give reasonable values for the conversion factor when comparing with results obtained from more ideal water sample sessions.
In order to verify an existing linear relation a large amount of water samples have been analysed.

As mentioned previously the conversion factors are strongly dependent upon the type of suspended material. Therefore the dredging areas have been divided into subareas within each a high degree of geological homogeneity can be assumed. For each of these subareas all water samples have been plotted in one graph as shown in Fig. 5 and the linear relation becomes obvious.

In Fig. 5 all water samples for an area 900 metres long and 400 metres wide (FL A) are plotted in one graph. The dredged material is here a mix of approximately 50% Clay Till (or Moraine) and 50% Limestone.
Implementing the linear conversion

\[ C(\tau) = a_1 \tau + b_1, \quad \text{with} \quad \tau = \tau(x,y,z,t) \]  

(5)

in the spill equations (1)-(2) yields

\[ F(t) = a_1 \int \tau(x,y,z,t) \tilde{V}(x,y,z,t) d\Gamma + b_1 Q_{net}(t) \]  

(6)

and in the ideal case, that is if the time used to box in the source is small compared to the current velocity, the net discharge through the box will equal zero which reduces eq. (6) to

\[ F(t) = a_1 \int \tau(x,y,z,t) \tilde{V}(x,y,z,t) d\Gamma \]  

(7)

So in the case of a one directional current spill can be calculated as

\[ S = a_1 \int_0^T (\tau_a V_a - \tau_a V_a) d\tilde{A} dt \]  

(8)

Eq. (8) shows that the spill calculation is independent upon the conversion offset \( b_1 \) and depends upon the conversion factor \( a_1 \) only.

With the result from Fig. 4 in mind and the fact that the origin is the natural zero (since clear water has zero turbidity) the conversion results are tested (T-test) for the hypothesis \( H_0: \text{Offset} = 0 \) against \( H_1: \text{Offset} \neq 0 \) on a 95% significance level.

In the analysis related to Fig. 5 the best line fit has been determined with one (zero intercept) and two (free fit) degrees of freedom respectively by use of least squares method. With two degrees of freedom the conversion factor yields \( a_1 = 1.71 \) [g/m\(^3\)/FTU] with an offset \( b_1 = 0.51 \) [g/m\(^3\)]. The conversion factor with zero intercept becomes \( a_0 = 1.74 \) [g/m\(^3\)/FTU] corresponding to an increase \( \Delta a = 2\% \) compared to the free fit. Finally the outcome of the T-test shows a minimum of 82% probability of rejecting a true hypothesis, if \( H_0 \) is rejected.

A summary of the results from all investigated sub areas can be seen in Table 1, where CS indicates a Cutter Suction dredge and M indicates a Mechanical dredge. The material is described by the relative amount of Clay Till (CT) and Lime Stone (LS).

In Table 1 the uppermost results originate from dredging activities whereas the last three results represent samples taken inside the pipelines used for pumping out of excess surface water from the reclamation basins. The suspended material inside these basins is very homogeneous and varies slowly with time. Only areas where more than hundred accepted samples were available have been included in the analyses.
The areas named WP and EP consist of several small pits dredged over a long distance with an uncertain degree of homogeneity. This may explain the large offset and low acceptance level for EP.

From all these results it can be concluded that a linear relation exists between turbidity and sediment concentration. Furthermore the generally high acceptance levels imply that the conversion line can be forced through zero, indicating that $a_0$ can be assumed equal to $a_1$ (the difference $\Delta a$ between $a_0$ and $a_1$ is within ±5%).

**Turbidity Profiles - ad II-III**

Regarding the uncertainty that may be related to the turbidity profile a large series of spot checks have been carried out. A spot check was performed by logging the turbidity approximately each 4 cm from sea bed to water level. Hereby a very accurate turbidity profile was obtained, hereafter denoted "the true profile". In each of these spot checks the "would have been" survey positions of the four sensors are marked. The corresponding approximated 4-point turbidity profile can then be compared with the true profile, see Fig. 6 and Fig. 7.

As it can be expected that different dredging methods create different turbidity patterns, the analysis is divided into profiles originating from cutter suction, Fig. 6, and mechanical dredge, Fig. 7. Furthermore the cutter suction analysis has been subdivided based upon topography, as flat cut (data from two different areas available) or trench.

Table 1. Water Sample Results for Subareas.
In order to compare the 4-point profile with the true profile, the depth averaged turbidity is calculated by

\[ \mu(SC) = \frac{1}{2D} \sum_{i=1}^{s} (d_i - d_{i-1})(\tau_i - \tau_{i-1}) \] (10)

\[ \mu(WS) = \frac{1}{n} \sum_{j=1}^{n} \tau_j \] (11)

SC indicating the 4-point approximation and WS indicating the true profile.

The depth averaged deviation from the true profile can then be directly calculated as

\[ \Delta = \mu(SC) - \mu(WS) \] (12)
Fig. 8 shows a frequency plot of Δ for 133 spot checks for a cutter suction dredge working on a flat topography.

![Figure 8. Frequency Plot of Δ.](image)

The symmetrical shape of the frequency plot together with an average difference close to zero (which means that the error introduced because of the difference is nonbiased) is also recognised for the other analysed areas, see Table 2.

For all four areas an average value of Δ between ± 0.2 FTU has been found, thus indicating that the 4-point approximated profile on average describes the true profile satisfactory. The standard deviation on Δ seems to decrease with increasing number of spot checks.

Another important result from the spot checks is the distance, \(d(\tau_{\text{max}})\), from the seabed to the location of the maximum turbidity. This distance is normalised by the water depth.

\[
\partial = \frac{d(\tau_{\text{max}})}{D}
\]  

(13)

Examples of frequency plots for \(\partial\) are shown in Fig. 9 for a cutter suction dredge working respectively on a flat bed and in a trench, and for a mechanical dredge working on a flat bed.

Fig. 9 shows that the maximum turbidity most often occurs in the middle third of the water column for a cutter suction dredge working on a flat bed. This may be due to the rotation of the cutter head which whirls the sediment upwards. When the cutter suction is dredging in a trench the maximum turbidity most often is located in the lowest third of the water column, because the sediment has to be dragged over the edge of the trench. For the mechanical dredge on a flat cut the maximum turbidity occurs most often in the lowest third. Considering only the lowest 10% of the water column it
seems that the maximum turbidity occurs at a rate of respectively 15%, 30% and 30% in the three different situations.

Table 2. Results From Turbidity profile Spot Checks.

On average it has been found that the maximum turbidity is located 30% - 40% away from the sea bed for all areas. Based on this information it must be important to cover this depth region in order to avoid any systematic error in the turbidity measurements.

Furthermore the results indicate that the minimum turbidity amounts to some 30%-35% of the maximum turbidity and the mean turbidity is between 40%-60% of the maximum turbidity. This implies that the typical turbidity profile only varies over a limited turbidity range.
Conclusion

Based on the results from the analyses carried out on a large amount of data, the following can be concluded:

I) It has been validated that the conversion from turbidity into sediment concentration can be expressed by a linear relation. Furthermore the statistical T-test resulted in high acceptance levels for the offset = 0, implying that the conversion line can be forced through the origin.

II) The analysis of the applied 4-point approximation of the turbidity profile leads to results which on average comply with the true profile.

III) It is verified that the location of the maximum turbidity on average is located 30% - 40% away from the sea bed. Hence it can be concluded that the lack of turbidity information close to the sea bed does not lead to any systematic error in the 4-point profile.

DEFINING AN UNUSUAL LITTORAL REGIME TO OPTIMIZE DREDGING AT EAST LONDON

A K Theron and J S Schoonees

Abstract

Maintenance dredging at the Port of East London is a major annual expense. The aims of this investigation were to obtain relevant information on the sedimentary processes and to apply this information to reduce or optimize various facets of the required maintenance dredging. Information gleaned on various components of the sediment transport regime led to a holistic understanding of the sediment budget for the littoral sub cell at the port. The sedimentary regime is very interesting with a complex pattern of sediment movement around the harbour. In turn, this information could be applied practically in terms of: more efficient sandtraps, a new dump-site closer to the port, a spur which successfully protected the dolos armour units, and proposed extensions to the breakwater which potentially could significantly reduce maintenance dredging. Most of these applications have already led to significant savings on maintenance dredging costs for the port.

1. Introduction

Background

The Port of East London is situated on the south-eastern coast of South Africa on the Indian Ocean seaboard (Figure 1). It is one of the six largest ports in South Africa and maintenance dredging (ca. 600 000 m³/annum) at this port also represents a major annual expense (ca. U$ 850 000). East London is exposed to fairly severe wave conditions (Figure 2) and is also renowned as the origin of the world renowned dolos breakwater armour unit. The port layout and local references are depicted in Figure 3.

Sedimentary regime

The sedimentary regime at East London is very interesting and quite unlike that of the other ports in South Africa. A major ocean current (the Agulhas) flows exceptionally close to the coastline in this area, thus significantly affecting nearshore sediment

1Research Engineers, CSIR, P O Box 320, Stellenbosch, 7599, South Africa
(fax: +27 21 888 2693, e-mail: atheron@csir.co.za)

3479
movements. Of particular interest in this case, is that this strong deeper water current predominantly flows in the opposite direction of the longshore current in the surf zone (Figure 4). Furthermore, the Port of East London is the only riverine (the Buffalo River) harbour in South Africa; which all leads to a complex pattern of sediment movement around the harbour.

Aims

The aims of this investigation were to obtain relevant information on the sedimentary processes at East London and to apply this information to reduce or optimize various facets of the required maintenance dredging.

2. Environmental Data and Coastal Processes

General

The natural processes of sediment transport and deposition are the cause of sedimentation in ports, which necessitates routine maintenance dredging to maintain prescribed water depths. In order to reduce or optimize the required maintenance dredging at a specific port, it is therefore necessary to have a complete (as possible) understanding of the sedimentary processes at that port. To define the littoral regime at a specific site, certain environmental data and an understanding of the relevant coastal processes, are required (CSIR, 1994a, 1995, 1996).

Continental shelf sediment dynamics

The continental margin of the east coast of South Africa is characterised by an extremely narrow shelf. At East London the shelf is about 25 km wide and the shelf break is located at about the 100 m isobath. The south-westwardly (downcoast) flowing Agulhas Current reaches a peak surface velocity of over 2.5 m/s just beyond the shelf break off East London. The total downcoast sediment transport on the shelf along the East London coastline is estimated at about $24 \times 10^6$ m$^3$/annum.

In general it is possible to distinguish three more or less shore parallel physiographic seabed regimes, each reflecting specific wave and current characteristics (Martin and Flemming, 1986). The narrow nearshore zone is subjected to a high energy swell regime, and is covered by a thin wedge of sandy sediment. This wedge appears to have achieved dynamic equilibrium with the prevailing energy regime, and additional (terrigeneous) sediment is rapidly dispersed and fed into a sand stream, situated slightly further offshore on the broad continental shelf, where the Agulhas Current dominates sediment transport. Thus, the nearshore sediment wedge progrades seawards until it meets sufficient current strength for sand to be entrained. The sand is entrained and carried on the central shelf by the so-called "conveyor-belt process", driven by the Agulhas Current. This current-controlled part of the shelf can be further subdivided into two parallel zones: a broad central-shelf sand stream and a narrow outer-shelf gravel pavement. The current-scoured gravel pavement stretches along the outer margin of the shelf and probably extends onto the upper continental shelf slope. This lateral sequence clearly indicates a progressive increase in current velocity in the offshore direction - a phenomenon which is consistent with available current data.
The above description clearly indicates that vast amounts of sediment are transported along the shelf by the Agulhas Current. Furthermore, it appears that any excess sediment transported onto the current dominated zone of the shelf or deposited on the nearshore sediment wedge near the margin of the current dominated zone, would eventually be carried away by the south-westwardly flowing Agulhas current.

**Tides**

The mean spring tidal range at East London is 1.59 m, while the mean neap tidal range is 0.47 m.

**Wind**

The south-westerly wind is the dominant wind throughout the year, while strong north-easterlies may occur in all seasons. These directions are approximately parallel to the coast. The average recorded wind speed is about 4.5 m/s.

**Waves**

In this study, the incident wave climate was determined from deepsea VOS (Voluntary Observing Ships) data and nearshore Waverider recordings. The median significant wave height is 1.6 m and the 1% exceedance wave height is 3.4 m. The median peak wave period is 11.2 s. The most common deepsea wave direction is south to south-west. To obtain more information on the nearshore wave climate, wave refraction modelling was also carried out. An example is shown in Figure 5, for a deep-water wave height of 3 m and a peak wave period of 13.5 s with a southerly deepsea wave direction. The weighted mean surf zone width along the seaward half of the main breakwater is about 150 m.

**Currents**

Currents were measured by means of Endeco and Aanderaa current profilers, drogue tracking, drifter buoys and dye tracking. Figure 6 shows information on some of the deeper water current measurements as well as the current patterns derived from this information. Thus, it was found (for example) that the offshore currents flow in a south-westerly direction for about two-thirds of the time and in the opposite (north-easterly) direction for about one quarter of the time.

Currents were also simulated by means of the Delft 3D mathematical model (WL/Delft Hydraulics, 1996). Figure 7 shows an example for the most common situation which is a south-westerly current of 0.3 m/s.

Surf zone (wave induced) currents were measured along the beach to the south-west of the port. These measurements were conducted by means of dye tracking tests (in conjunction with drogue measurements). The associated wave conditions were derived from Waverider recordings, while the waves directions were hindcasted.

**Sediment**

Sediment samples were collected over a wide area around the port. The sediment
characteristics were determined by analysing samples in a settling tube. The average median grain size is about 0.2 mm.

Aerial photographs
Analysis of aerial photographs provided additional information on nearshore wave directions, current patterns and shoreline changes. South of the harbour, the direction of the incident waves is such that in virtually all instances a current generally flowing towards the harbour would be generated near the shore. The wave attack on the seaward side of the main breakwater would mostly not generate very significant currents parallel to the breakwater. At the beach directly north of the port, no significant wave generated longshore currents are indicated. Past port developments initially caused the shorelines on both sides of the port to prograde significantly. More recently, the shoreline appears to have stabilised with smaller variations occurring.

Bathymetric surveys and dredging data
Analysis of subsequent bathymetric surveys proved to be a valuable tool in studying the changes in bottom topography, erosion and deposition areas and determining volume changes. Bottom topography changes, together with the dredging data, in terms of sediment volumes dredged over time in specific areas, provided an important part of the overall picture. Information on the dredging records for the main sandtrap is shown in Figure 8, while the annual dredging volumes for the other port areas are shown in Figure 9. The total volume of sediment dredged annually at the port, is about 600 000 m$^3$ to 650 000 m$^3$ on average.

3. Sediment transport regime/budget
3.1 Transport through/around main breakwater
A separate study was conducted to determine specifically the rate of sand deposition on the inside of the main breakwater and from where this sand originates. This basically entailed determining the volume of sand moved through the breakwater and the volume moved to the inside of the breakwater from around its head. A wide variety of different means were employed to determine this: long-term dredging records, repeated surveys of a specially dredged "test-pit", suspended sediment samples, a newly developed suction sampler, an electronic current profiler, drogue and dye tracking, drifter buoys and a theoretical determination of the suspended versus bedload ratio. Interesting comparisons of the results could thus be made. The results of a side-scan sonar survey of the area was also interpreted with regard to the study, as this information provided interesting circumstantial "evidence" completing a part of the sediment transport "puzzle". Thus, it was concluded that 60 000 - 80 000 m$^3$/annum of sediment moved through the breakwater, while 20 000 - 50 000 m$^3$/annum moved around the head of the main breakwater (The breakwater has since been made more impermeable and as such, the rate of sediment movement through the breakwater has been reduced.).

3.2 Longshore Transport
The longshore transport along the beach to the south-west of the main breakwater (300 000 - 500 000 m$^3$/annum ) was estimated by means of the modified Kamphuis
method (Schoonees and Theron, 1996). The directional distribution of the longshore sediment transport was determined from the nearshore wave climate.

3.3 Transport in deeper water

The sediment transport in deeper water due to the combined effects of currents and waves was also estimated (by means of the Van Rijn (1989) method). Thus, the sediment carrying capacity of the currents was assessed, leading to estimates of the sediment transports at the dump-site and in the “bar” area (Figure 9). The strong deepwater current (the Agulhas) predominantly flows in the opposite direction of the longshore current in the surf zone.

3.4 Fluvial transport

Riverine sediment inputs were calculated from sediment production charts and the sediment trapping efficiency of dams in the river. The mean annual runoff of the Buffalo River is estimated to be about $41.10^6$ m$^3$, with a sediment load of about 80 000 m$^3$/annum. However, the dams trap more than 90% of the sediment; thus, the sand transported into the port is estimated to be less than 10 000 m$^3$/annum.

3.5 Sediment balance/budget

Analysis and interpretation of all of the above lead to a relatively complicated sediment balance for the littoral sub cell at the Port of East London, as depicted in Figure 10 (CSIR, 1994a, 1995, 1996).

4. Applications

Having obtained a holistic understanding of sediment transport patterns, this enabled the use of this information to optimize maintenance dredging activities in the area (CSIR, 1994a, 1994b, 1995, 1996).

4.1 Sandtraps

The location and layout of a number of new sandtraps were determined so as to intercept the main sources of sediment deposition in the harbour and entrance channel. The old, newly dredged and proposed sandtraps are depicted in Figure 11. The optimum dimensions of these sandtraps were also determined in terms of theoretical sand trapping efficiency and practical aspects of the dredging.

4.2 Dump site

Based mainly on the current patterns and the carrying capacity of the offshore currents, the location of a new (closer) dredge-material dump site was determined, as depicted in the Figure 12. The risk of sediment moving back to the port is acceptably low and the much shorter dumping cycle represents a significant cost saving.

4.3 Spur

The location and layout of a spur on the main breakwater was determined conceptually. The main purpose of this spur is to traps stones, rocks and debris which damage the armour units and secondarily, to reduce sediment transport towards the
harbour. This spur was built (Figure 13) and functioned well in trapping rocks, etc, (but, as expected, was too small to significantly affect sediment transport).

4.4 Current deflecting structure

The practical and economical feasibility of reducing the amount of sediment transported towards the port by means of a "current deflecting" structure attached to the main breakwater was investigated conceptually. This investigation included limited hydrodynamic modelling of various alternative extensions to the main breakwater (eg. Figure 14). Such a structure could possibly significantly reduce the annual amount of maintenance dredging required with potential substantial direct cost savings. As an example, the estimated cost/benefit ratio of a 200 m extension to the main breakwater is shown in Figure 15. An additional major benefit of such as structure could be significant savings in maintenance costs of the present main breakwater. (More detailed investigations are being proposed at present.)

5. Final Conclusion

Information gleaned on various components of the sediment transport regime led to a holistic understanding of the sediment balance/budget. In turn, this information could be applied practically in terms of: more efficient sandtraps, and new dump-site closer to the port, a spur which successfully protected the dolos armour units, and proposed extensions to the breakwater which potentially could significantly reduce maintenance dredging. Most of these applications have already led to significant savings on maintenance dredging costs for the port.

The development of sand waves and the maintenance of navigation channels in the Bisanseto Sea

Kazumasa KATOH\textsuperscript{1)}, Hidetoshi KUME\textsuperscript{2)}, Keiji KUROKI\textsuperscript{3)} and Junzo HASEGAWA\textsuperscript{3)}

Abstract

An Inosakinotsugai is a shoal located in the Bisanseto navigation channel, on which are formed sand waves of 100m wavelength. The heights of sand waves develop to be about 5 meters, which makes the water depth shallower than that required for navigation. Authors have analyzed the process of sand wave development by utilizing the sounding data obtained during a period from 1984 to 1996. As a result, it is shown that 1) the sand waves developed faster in the area where the speed of sand accumulation is faster, 2) the sand waves migrated from the both sides of the shoal toward the shoal ridge, and 3) the speed of migration is proportional to the horizontal distance from the ridge. In the maintenance dredging, the developing speed of sand waves must be taken into consideration.

1. Introduction

The Bisanseto navigation channel is the only trunk channel connecting the eastern and the western parts of the Seto Inland Sea and branches off to the southern and the northern channels in the offshore area of Kagawa Prefecture. The connection channel joins the southern and the northern channels near the juncture (Figure 1). As shown in Figure 2, a shoal (called Inosakinotsugai) extends from Mitsugo Island to the northwesterly direction at the depth of less than 20 m, and caldrons greater than the maximum depth of 85m are on the eastern and the western sides. In other words, the seabottom topography from the connecting channel to

E-mail:jhasegawa@ecoh.co.jp
the north channel resembles horseback. At the saddle are formed sand waves of about 5 m wave height and 100 m wavelength (Ozasa, 1975). There are several areas in Bisanseto where sand waves are formed at the saddle of the shoal. The problem here is that they are located inside the channel and the sand wave crests develop to the height which decreases the water depth below the required depth for a navigation channel (the northern channel; 19 m, the connection channel; 13 m).
During the period between 1981 to 83, about 2.2 million m$^3$ dredging was performed to remove sand waves. Dredging to 22 m water depth in the north channel and 15 m in the connection channel was conducted by removing the convex portions of the sand waves. During 10 years following this period, sand waves were again formed and have developed to reduce the depth to less than the water depth that should be maintained.

Ozasa (1975) studied in detail the shapes and the mechanism of formation of sand waves at Inosakinotsugai. So, this paper discusses the maintenance of the navigation channels (water depth) in Inosakinotsugai area (Figure 2) and the future needs of maintenance dredging. We utilized the data obtained from the sounding surveys conducted once a year between 1984 (immediately following the dredging) and 1996, and conducted the analysis by converting the data to digital values in 10 m grids.

2. Outline of Sand Waves

Figure 3 shows deviations in the geological features of the seabottom observed in November, 1996 using the average profile of the entire study period as the standard, and shows the sand wave crests with deviations of +1 m and more than +2m. According to the figure, the crests occur successively in the direction from NNW to SSE. The reference lines of A to H are set in the direction perpendicular to the crests. The sand wave cross profiles along these lines are analyzed in Chapter 4.

Figure 3. Sand Wave Formation
Ozasa (1975) conducted the sediment surveys, tidal current observations, and diving surveys in the area surrounding Inosakinotsugai. According to his surveys, the median grain size of sediments forming Inosakinotsugai falls within the range of 0.5 to 2.0 mm and tends to become smaller toward the tip (NNE direction) of Inosakinotsugai. The sorting coefficient was more than 2 at the base of Inosakinotsugai and becomes smaller toward the tip (or sorting becomes efficient). These results suggest that the net sand transportation occurs at "Mitsugo Island (the base of the shoal), passes over the shoal, and heads towards the tip of the shoal (see Figure 2)."

The currents are basically in the east-west directions. However, the velocity is different at the time of flood tide and the ebb tide; the flood current (the westerly current) predominates to the north of the shoal, and the ebb current (the easterly current) predominates to the south. Therefore, the crest line of sand waves is essentially normal to the direction of the predominant current.

According to the diver's visual observation, there are many ripples of a scale not sufficiently measurable by the sounding survey (the wavelength 50 to 100 cm, the wave height several cm).

3. Changes in the Depth of Navigation Channels

3.1 Definition of the Minimum Water Depth

Inosakinotsugai area was divided into eight segments as shown in Figure 4. The segments ① through ⑥ in the north channel are set by crossing the crest line of the sand waves at right angle. The areas of the

![Figure 4. Segments for Water Depth Calculation](image-url)
segments 1 through 6 are substantially the same, but those of the segments 7 and 8 in the connecting channel are about 66% of the former.

The average depth in the segments is calculated for each sounding survey. The water depth above the sand wave crests (the minimum water depth) is important for maintaining the channel depth.

The segment 7 became shallower than the maintenance depth earlier than any other segments. The Maritime Safety Agency imposed navigation control in this area in December, 1992. Therefore the minimum water depth was defined based on the conditions of the segment 7 prevailing at the time the control was initiated. Figure 5 shows the grid scores for each year of the water depth data in the segment 7 where the water depth is shallower than the maintenance depth of 13 meters. Increases in the grid scores can be approximated by parabolas shown by the dotted line in the figure, which is determined by the method of least squares of the data after 1988. Based on the approximated curve, the grid score of 8.89 for the month immediately preceding the month when the navigation control was imposed, November 1992, was obtained. Thus, the mean of the water depths for the top 9 grids from the shallower depth in the segment was defined as the minimum water depth. Since the area of segments 1 through 6 is larger than that of 7, the number of grids to calculate the minimum water depth must be increased accordingly. However, the number of grids was set at 9 for all the segment in this paper.

![Figure 5. Grid Scores in the Water Shallower than 13 m](image)
3.2 Chronological Changes in Mean and Minimum Water Depths

Figures 6-(1) and 6-(2) show chronological changes in the mean water depth, open circles, and the minimum water depth, solid circles, in the segment 4 on the side of the north channel and the segment 7 on the connecting channel side, respectively.

As the mean water depth becomes shallower at a substantially constant rate, the equation (1) is approximated;

\[ h = a + bt \]  

\[ h_c = 21.75 - 2.11(1.0 - \exp(-0.5155t)) - 0.07t \]

\[ h_m = 22.85 - 0.07t \]

Figure 6(1). Chronological Changes in Mean and Minimum Water Depths (Segment 4)

\[ h_c = 15.06 - 1.98(1.0 - \exp(-0.2539t)) - 0.08t \]

\[ h_m = 15.86 - 0.08t \]

Figure 6(2). Chronological Changes in Mean and Minimum Water Depths (Segment 7)
where $h$ is the mean water depth, $t$ is the years after dredging, and $a$ and $b$ coefficients.

On the other hand, variations for the minimum water depth were large in the initial period and the amount of variation tended to decrease with time. This change can be interpreted that the sand waves were formed again after the artificial impact of dredging and developed toward equilibrium. This change can be approximated by exponential function. Provided, however, the change in the minimum water depth included that of the mean water depth, inflow of sand into the segment, the equation (2) is approximated:

$$hc = \alpha \left[ 1 - \exp(\beta t) \right] + \gamma + bt$$

where $hc$ is the minimum water depth, $t$ is the elapsed years after dredging, $\alpha$, $\beta$, $\gamma$ are constants, $\alpha$ is corresponding to the half wave height of the sand wave which has reached the equilibrium, $\beta$ is the speed with which the equilibrium is reached, and $\gamma$ is the initial value of the minimum water depth.

Coefficients for the equations (1) and (2) are obtained by the method of least square. That is to say, the coefficient $b$ in the equation (1) is obtained first, and the value $b$ is substituted in the equation (2) to obtain remaining coefficients. Figure 6 shows the approximate straight line and curve using thus determined coefficients.

Figure 7. Changes in Mean Water Depth in Segments
Figure 7 shows the speed, the coefficient $b$ in the equation (1), of changes in the mean water depth of the segments $\overline{1}$ thorough $\overline{7}$. The rate of the mean water depth becoming shallower is faster in the segment $\overline{7}$ and becomes gradually slower towards the segment $\overline{1}$. In other words, the rate of accumulation heading from Mitsugo Island toward the tip of Inosakinotsugai decreases and the water depth toward the same direction tends to become larger, indicating that sands are being transported and accumulating in the same direction. This result coincides with the direction of sand transportation inferred by Ozasa (1975) from the plane distribution of the mean grain size and sorting coefficient of sediments. From the rate of accumulation (3 cm/year) in the segment $\overline{8}$ (not shown), it is presumed that the sand is being transported from the segment $\overline{7}$ toward the segment $\overline{8}$ even the quantity is small. Ozasa (1975) assumed similarly in respect of this branch.

A relation between the rate of accumulation in each segment and the years of sand wave development is plotted in Figure 8. The years of development as used herein is the number of years required to reach 90% of the equilibrium value and is calculated using the coefficient $\beta$ in the equation $\overline{2}$. The figure shows that the greater the amount of sand flowing into the segment is, the faster the sand waves develop.

\[
\tau = -x + 15
\]

Figure 8. Relation between Accumulation Speed and Sand Wave Development Speed
4. Sand Wave Migration

Figures 9(1) and 9(2) show the transverse profiles of the reference lines A and F in the order of the years measured from the top to the bottom. Provided, however, the profiles are shown as deviations from the average profile during the period shown at the top.

Features of Figure 9 are also observed in respect of other reference lines not shown. The sand wave of 2 to 6 meters wave height and 80 to 180 meters wavelength exist, and when their crest positions, solid circles in the figure, are traced time-wise, they shift toward the top of the shoal as compared with the average profile at the top. The crest migration is approximated as in the solid lines and the rate of migration is calculated.

The migration rates for all the reference lines are plotted in Figure 10, where the horizontal axis is the crest position of sand waves in the median period during analysis as represented by distance from the shoal ridge with the positive direction toward east (to the right in Figure 9). According to this figure, the speed with which the sand wave approaches the shoal ridge is proportional to the horizontal distance, and holds the relation

\[ S \sim n \cdot \frac{E}{25.0} \leq 28.0 \]

Figure 9(1). Changes in Average Profile and Sand Wave Forms
(Measurement Line A)
of \( v = -0.04 \cdot x \) (m/year) up to 500 m on the horizontal axis. Here, \( x \) is in the relative position to the ridge. The data shown by solid circles where the horizontal distance is more than 500 meters are all inside the connection channel and are at the constant speed of 15 m/year.

There are many reports about sand waves migration (such as Harris, 1989). Mogi (1971) reported that the sand waves shift in the direction same as permanent current in long term. As, the westerly current prevails in the north side of Inosakinotsugai and the easterly current prevails in the south side, (Ozasa, 1975) suggests that Mogi is correct also in respect of this point. The forms of sand wave observed by Harris (1989) are asymmetrical and sharp in gradient on its migrating side. Based on the above going, Figure 9 is re-examined and the forms of sand wave are recognized to have sloped sharply toward the direction of it’s migration.

It is more reasonable to consider that the sand wave migration is not a mere phase shift but accompanies the sand transport in the same direction. The segment analyzed is therefore divided in the cross sectional direction to
extend the vertical direction of Inosakinotsugai (as shown in Figure 11). The volumes of sand accumulation during the analysis period in each
segment are shown in Figure 12. Figure 12 also shows the average profile in the south-north directions at the center of the segment, similarly to the average profile shown in the top of Figure 9. It is apparent that accumulations are greater toward the shoal ridge and decrease toward both sides. The result does not contradict the inference that sands are transported in the process of sand wave migration toward the shoal ridge.

5. Discussion of Maintenance Dredging

It is observed that two different factors are overlapped, which basically make the navigation channel shallow. They are the decrease in the mean water depth caused by accumulation of sands which are transported from the direction of Mitsugo Island and development of sand waves. These two factors act in combination to decrease the minimum water depth. The next dredging project must take them into consideration.

Dredging performed during the period from 1981 to 1983 anticipated that the sand waves would reach equilibrium after dredging and removed the convex portions (Onodera, 1981), thereby addressing one of the two factors. In order to deal with another factor of the decrease in the mean water depth, overall dredging of the further depth or pocket dredging on the upstream side where the sands flow into the channel may be conducted to capture the sands. The former is considered to accompany great difficulties since the last dredging was performed up to 22 m, a substantially critical depth for dredging. The latter method entails hardly any problems in dredging as it is performed at a shallower depth.

Pocket dredging is expected not only to control the inflow of sands
into the channel but also to achieve secondly effects. As shown in Figure 8, the years required for sand wave development is shorter if the accumulation speed is faster. By referring to Figure 8, it is assumed that the time required for the sand waves to reach 90% equilibrium increases from 9 to 15 years if the rate of accumulation becomes 0 cm/year from 6 cm/year, thus delaying the decrease in the minimum water depth.

6. Conclusions

Following conclusions are obtained.

(1) Basically, two factors are overlapped for decrease of the navigation channel depth in Inosakinotsugai area; they are the decrease of the mean water depth due to accumulation of sand inflowing from the direction of Mitsugoi Island, and development of sand waves.

(2) Sand waves develop faster in the segments where the rate of sand accumulation is faster.

(3) Sand waves formed after dredging migrated from both sides of the shoal toward the shoal ridge. The speed of migration is proportional to the horizontal distance from the ridge, and is 4 m/year if the distance is 100 meters. The direction of migration is the same as that of the permanent current.

(4) Maintenance dredging should be performed by considering development of sand waves and changes in the mean water depth. The former can be addressed by dredging in anticipation of sand waves developing to equilibrium as in the previous dredging project. The latter can be dealt with pocket dredging in the upstream side of the sand migration to decrease the sand inflow into the channel. This method may be effective to delay the sand wave development.

Coastal Disaster Prevention Works in Japan

MOTONO Ichio and NARUSE Susumu

Abstract

In this paper, we will present the Japanese coastal disaster prevention policy for the 21st century. First of all, we will show the characteristics of Japan's geographic conditions and coastal disasters. The next, we will review the evolution of coastal disaster prevention policy in our country in the last 5 decades. The third, we will discuss some aspects that affect coastal disaster prevention policy in 1990's and explore a new policy in order to meet the new waves: such as an coastal engineering development, an emergence of environmental awareness, and needs for recreational use of shorelines.

Introduction

The total length of Japan's shoreline is approximately 36,000 kilometers including various peninsulas, bays and small islands, half of the country's economic and social activities is done in the coastal area. Where people and industries are concentrated along the coast, they have been suffered severe damages from coastal disasters. An appropriate coastal protection works that protect people and infrastructure from coastal disasters is urgently needed in those days. Japan organized a coastal protection by enacting Coastal Protection Act and allocating a central and local governments' roles. It also introduced long range fiscal plans to implement coastal protection works efficiently in 1970. These efforts made our land safety to some extent last fifty years. However people gradually valued a coastline as an environmental protection, recreational use as well as the economic activity. The purpose of the coastal protection is diversified by these new demands. We introduce environmentally and user-oriented coastal protection

\(^1\) Ports and Harbors Bureau, Ministry of Transport, 2-1-3 Kasumigaseki, Chiyoda, Tokyo 100-8989, Japan
works as well as technically sound creditable coastal protection works to meet these new waves.

Natural and Geographic Condition of a Japan's Coastline

Japan is prone to several types of coastal disasters such as typhoons in the summer, wind waves in the winter and Tsunamis caused by earthquakes (Takayama, 1997). Figure 1 shows the major coastal disasters which run across our nation. High tides generated by the low pressure of a typhoon have caused floods in under sea level areas such as Tokyo Bay, Osaka Bay and Ise Bay. Table 1 shows major high tide disasters and Photograph 1 shows a high tide disaster at Yokosuka, Tokyo Bay 1996. The severe erosion caused by the wind waves is a significant problem in the coastal area that faces the Japan Sea. The disasters erode our national land by about 160 hectares each year.

Figure 2 indicates that the length of shoreline per land area of island nations such as Japan and the United Kingdom is relatively longer than that of peninsula nations (Korea and Italy) and continental nations (USA, France, Canada and the former USSR).

Figure 2 Comparison of coastal length per land area by nation
Figure 3 shows that population and industries are highly concentrated in the coastal municipalities. Nearly a half of nation's population and industries is found in coastal municipalities which occupy one third of the national land.

![Figure 3 Comparison of coastal municipalities and inland municipalities by area, population and industrial products](image)

The Coastal Protection Act

The protection of national land from the coastal disasters is defined to be a central government role under the Coastal Protection Act. The Act was established in 1956 to prevent coastal disasters which were very common after the W.W.II. Several coastal disasters such as those in the former chapter deteriorated our national land in those days. A coastal protection manager is responsible for coastal protection. Coastal protection is administrated by three competent Ministers depending on land use; Minister of Transport (MOT), Minister of Agriculture, Forestry and Fishery (MAFF), and Minister of Construction (MOC). MOT is in charge of sea ports and harbor areas. MAFF is in charge of agricultural areas and a fishery port areas. MOC is in charge of the rest of the coast. Under the Act, a governor can designate the coastal protection sea and land areas within 50 meters from seashore line by the due process of the law. In addition, a prefecture governor, a head of port authority or a fishery port manager manages a coast as a coastal protection manager. The manager's main task is to create a Coast Protection Facilities Plan and submit it to the Minister. He also has to register the coastal protection area and the coastal protection facilities and release this information to the public. Dredging, development or occupation of the area requires his permission. He collects a fee for all permitted activities. Those who violate the coastal protection ordinance will be fined by him. The central government supports the manager financially; up to half of investment when the manager constructs or renovates a coastal protection facility such as a dike, a jetty, a revetment or a sluice gate in the coast defense area. Each
Minister can construct or renovate the facility by himself when the coastal protection work is especially important for the national land protection when the work costs a lot, requires high technology and machinery power, or expands plural prefectures. The minister also has to show the design code of the coastal protection facility to the coastal protection managers in term of national land safety (Commission of Coastal Protection Facility Design Code, 1987). Figure 4 shows a flow of construction or renovation of a coastal protection facility.

Figure 4 A flow of construction of a coastal protection facility

Evolution of Coastal Protection Work

The Ministers and coastal protection managers were previously not able to perform coastal protection work sufficiently due poor economic conditions. The construction of coastal protection facilities was urgently required in the 50's and the beginning of the 60's. For example, 4,700 people and 150,000 houses were lost by the Ise Bay Typhoon in 1959. The Congress requested the central government to allocate sufficient funds for coastal protection. Hence, the government introduced a long range fiscal plan to implement the annual investment efficiently and effectively in 1970. The aim of the plan is considered to be an administrative purpose to implement the investment efficiently and effectively, rather than legislative obligation of investment. Table 3 shows a summery of the coastal protection work investment from 1970 to 2002.

(billions yen)

The Ministers and the managers quickly introduced low cost protection facilities and directed half of the budget to the densely populated and under water areas such as Tokyo bay, Osaka bay and Ise bay. Figure 5 shows the coastal protection works at under sea level area in Osaka Bay.

**Figure 5** Coastal protection work under sea level area (Osaka Bay)
The damages inflicted by the coastal disasters might be mitigated to some extent with these rapid investments. However these facilities need high cost maintenance or even replacement since they deteriorated easily by tidal fluctuations and wave forces. The high crowns of the embankment and revetment have also prevented people from seeing water and accessing the beach, and the numbers of concrete blocks has messed up the seashore landscape. Furthermore, in the 70's environment protection movement became very popular. In the 80's people gradually conceived an especial value of the coastal zone such as recreational activities, richness of wildlife, amelioration of polluted water, and so on. The growing awareness of the importance of environment has influenced coastal protection policy (Coastal Protection Study Group, 1995).

The 6th Seven-year Fiscal Plan For the 21st Century

The Cabinet established the 6th five-year fiscal plan with 1300 billion Yen (U.S. $10.8 billion when U.S. $1.00=120 Yen) in 1996. The coastal protection managers designated the 16,000 kilometer coastal protection area within the total 35,000 kilometer Japan's shoreline. According to a current study, 11 million people are living along the coastal protection area or behind it. However only 41% of the 16,000 kilometer coastal protection area is protected by the coastal protection facilities. More than 3.5 million people still live in fear of floods. Table 4 shows that the range of protected area rate would be expected to increase to 48% in the 2000 years under the new fiscal plan.

</tbody>
</table>
The plan also has two goals; first, the ministries will speed up their coastal protection works and construct technically sound creditable coastal protection facilities. Next, the ministries will not only maintain the environmental standards but also promote the coastal wildlife preservation and user-oriented coast.

Technically Sound Creditable Coastal Protection Facilities

In order to produce a safe coast, the ministries are preparing three methods of defending the coast. The first method is to introduce an integrated coastal protection configuration consisting of offshore banks, beach fills, and gentle slope revetments. Figure 6 shows that the configuration can weaken even the extraordinary strong wave forces with these serial facilities while an ordinary revetment is prone to suffer critical functional damage (Katoh, 1994). Furthermore the configuration can expect town’s local high amenity and the beach access.

Figure 6 An integrated coastal protection configuration
The second method is to appropriate countermeasure against an earthquake. MOT checked all the facilities after Hanshin-Awaji earthquake which took place in January 1995. It found that some facilities constructed in the 60's had not been applied the seismic code properly. The code established in the 60's also needed to be revised. According to Ministers' investigation, at least 400 kilometer-length facility requires seismic reinforcement. Tsunamis also generated by earthquakes and caused severe damage on a densely populated fjord area. Photograph 2 shows a breakwater would keep a harbor calm and break tsunami energy out. A coastal protection manager cooperates with a port authority to construct a breakwater in the fjord area.

**Photograph 2** A breakwater which has both function of defending a tsunami and of keeping the harbor calm (Kamaishi Port, Sannriku Region)
Finally, an automatic gate draw system and integrated disaster information system are introduced. There are many water/land gate in a coastal protection area. It requires a huge labor and time to open/shut the gate. *Photographs 3* shows that the system network between an inland control room and gates. The control room monitors the area for earthquakes, tsunamis and high tide information 24 hours in a day and operates the gates by a remote control. The system enables a quick response to the unpredictable tsunamis and free from manual labor on operating a gate.

A manual work on opening a gate (Port of Nagoya)

Environmentally Oriented and User Oriented Coastal Protection Works

The coastal protection manager is obliged to keeps his balance between coastal protection and coastal environment preservation owing to increase of environmental awareness. He is going to manage it by managing these conflicts rather than choosing either of them. A coast has rich but vulnerable wildlife resources. Environmentally oriented facilities such as an artificial reef, a tide pool, plantation and a beach should be considered when a coastal protection facility is designed and constructed on a coast. The facility has less impact to the coastal ecology than that we used to or ameliorate coastal environment. The artificial reef can cultivate sea weed and fish habitation. The tide pool also can keep water clean or bring rich oxygen into the water. The plantation can produce woods and supply a good atmosphere in the coast. The wild-life oriented beach can also become a sanctuary for endangered species such as red-turtles and
horseshoe crabs. **Photograph 4** shows that an artificial beach is also one of the best amenities to attract people to a coast. The purpose of beach replenishment is to defend a coast from disasters as well as to produce a recreational area where people can enjoy marine activities, bathing and sightseeing. The construction of pedestrian parkways, benches, trees as well as barrier-free facilities would enable elderly and handicapped persons to approach the coast easily.

**Photograph 4** An artificial beach and bathing (Port of Utsumi, Ise Bay)

**CONCLUSION**

All the public work including coastal protection work is strictly required its efficiency and productivity in our country owing to the nation's fiscal deficit right now. We reviewed our coastal protection's institution and showed our policy for the next decade. We always question to ourselves; what the people expect on coastal protection work? is it worth to invest on an artificial beach instead of an reinforced concrete revetment under the tight budget condition? whether a central government or local government should have a responsibility on coastal protection? and who should fund coastal protection work? . It will be great pleasure for us to exchange information on this matter over the world.

BREACH EROSION IN SAND-DIKES

by

Paul J. Visser

ABSTRACT

The process of breach erosion in sand-dikes is described. This process consists of five stages. For the final two stages three breach types are distinguished, depending on the erodibility of the base of the dike, the presence (or absence) of a solid toe construction on the outer slope and the presence and erodibility of a high foreland. A brief outline of a mathematical model based on the five-step breach growth process is presented. The validation of the model against the data of a field experiment shows good agreement.

1. INTRODUCTION

The Technical Advisory Committee on Water Defences (TAW) in the Netherlands has decided to substitute an inundation risk approach for the present design method for dikes based on an exceedance frequency of the water level. In this new method safety levels will be expressed in terms of risks. A risk-norm means that the inundation chance is combined with the consequences of flooding (deaths, loss of property and revenues, etc.), see Kraak et al. (1995). In order to determine the consequences of inundation, it is necessary to predict both the rate and speed of polder flooding. These are especially governed by the flow rate through the breach in the dike, which in its turn largely depends on the process of breach growth.

The aim of the investigation is a mathematical model that predicts the breach growth and the discharge through the breach in case of a dike-burst as function of relevant parameters as the cross-section of the dike (height, width, slope angles), the structure of the dike (dike material, revetments, foundation), polder area and the hydraulic conditions (water level against the dike, wave load). It is assumed that the dike was constructed with sand and that, after the formation of an initial breach at
the top of the dike, the clay-layers on the slopes do not decelerate the erosion process.

The first versions of the model (see Visser, 1995a) have been focused on the first three stages of the breach erosion process. The present model version includes also the final two stages of the dike breaching process. Also some improvements related to the physics of the erosion process have been implemented into the model.
2. BREACH EROSION PROCESS

It is assumed that the breach erosion starts (at \( t = t_0 \)) with the flow of water through a small initial breach at the top of the sand-dike with a trapezoidal cross-section. Generally five stages can be distinguished in the process of breach erosion (see Figure 1). These five stages are:

- **Stage I**: steepening of the slope angle \( \beta \) of the channel in the inner dike slope from an initial value \( \beta_0 \) at \( t = t_0 \) up to a critical value \( \beta_1 \) at \( t = t_1 \).
- **Stage II**: retrograde erosion of the inner dike slope at constant angle \( \beta_1 \) for \( t_1 < t \leq t_2 \), yielding a decrease of the width of the crest of the dike in the breach; this stage ends at \( t_2 \) when the crest vanishes and the breach inflow starts to increase.
- **Stage III**: lowering of the top of the dike in the breach, with constant angle of the breach side-slopes and equal to the critical value \( \gamma_1 \), resulting in an increase of the width of the breach for \( t_2 < t \leq t_3 \). At \( t = t_3 \) the dike in the breach is completely washed out down to the base of the dike at polder level.
- **Stage IV**: critical flow stage, in which the breach flow is virtually critical throughout the breach for \( t_3 < t \leq t_4 \), and the breach continues to grow mainly laterally. The side-slope angles remain at the critical value \( \gamma_1 \). The breach growth in vertical direction depends in this stage on the erodibility of the base the dike. At \( t_4 \) the flow through the breach changes from critical (\( Fr = 1 \) in Stage IV to subcritical \( Fr < 1 \) for \( t > t_4 \)).
- **Stage V**: subcritical flow stage, in which the breach continues to grow, mainly laterally due to the subcritical flow in the breach for \( t_4 < t \leq t_5 \). The side-slope angles remain at the critical value \( \gamma_1 \). At \( t_5 \) the flow velocities in the breach become so small (incipient motion) that the breach erosion stops. The flow through the breach continues and stops when at \( t_6 \) the water level in the polder has equalled the outside water level.

In Stages I, II and III the initial breach cuts itself into the dike. Most of the discharge through the breach takes place in the Stages IV and V. At the end of Stage IV backwater starts to effect the flow through the breach. In case of a relatively tiny polder with a very small storage capacity, the downstream submergence may start earlier. In theory this may occur in each of the Stages I, II and III. In practice, however, it will take place in Stage III, since the total flow through the breach is too small in Stages I and II to allow downstream submergence. Hence, in case of a relatively tiny polder, Stage IV may be passed over.

3. DEVELOPMENT OF BREACH IN STAGES I, II AND III

Figure 2 shows the flow through the initial breach at \( t = t_0^+ \) shortly after the start of the breaching process at \( t = t_0 \). From a hydraulic point of view the slopes of dikes are very steep, i.e. \( \sin \beta > C_f \) (the slope angle \( \beta \) is defined here as the inclination of the inner slope of the dike in the breach in the flow direction with respect to a horizontal line, \( C_f \) is the bottom friction coefficient). This means that the water depth at the top of the inner slope at \( x = 0 \) (\( x \) is the coordinate along the inner slope) is equal to the critical depth \( d_c \). The flow on the inner slope accelerates between \( x = 0 \) and \( x = l_n \), and is virtually uniform for \( x \geq l_n \). Consequently the capacity to transport sand also increases between \( x = 0 \) and \( x = l_n \) and is nearly constant for \( x \geq l_n \). This means that the rate of erosion increases along the stretch \( 0 < x < l_n \) and is nearly constant for \( l_n \leq x \leq l_a \) (where \( l_a \) is the adaptation length of the suspended
Figure 2  Flow over dike in the breach at $t = t_0^+$ shortly after the start of the breaching process (solid line) and development of inner slope of dike in the breach in Stages I, II and III (dashed lines).

sediment transport, similarly to $l_n$ being the adaptation length of the flow). As a result of this the inner slope becomes steeper and steeper along the slope and in time along the stretch $0 < x < l_n$, and for $l_n < x \leq l_a$ the inclination of the inner slope remains constant. The slope angle along $0 < x < l_n$ will, however, not exceed a limit $\beta_1$ (say $\beta_1 \approx \phi$, where $\phi$ is the angle of internal friction). If this limit has been reached along the entire stretch $0 < x < l_n$ (at $t = t_1$), the rate of erosion becomes constant for $0 \leq x < l_n$ as indicated by the lines for $t \geq t_1$ in Figure 2, and Stage II starts.

In Stage II retrograde of the inner slope of the dike in the breach occurs at constant angle $\beta_1$, resulting in a decrease of the width of the dike-crest in the breach. Stage II ends when the width of the dike-crest has become zero (at $t = t_2$).

It can be concluded that for $t_0 < t \leq t_2$ the rate of erosion of the inner slope in the breach is controlled by the erosion at $x = l_n$ (or also the erosion along the stretch $l_n \leq x \leq l_d$). This means that only the rate of erosion at $x = l_n$ has to be known.

In Stage I the width of the channel (initial breach) in the crown of the dike remains at its initial value. The increase of the depth of the channel in the inner slope causes also an increase of the width of this channel in the slope (see Figure 1). At $t = t_1$ the width of the breach starts to grow at the downstream side of the dike-crown.

As long as the flow accelerates, its capacity to transport sediment increases. This means that the adaptation length for the sediment transport is always larger than the adaptation length for the flow, i.e. $l_a > l_n$. Visser (1998) has derived the following practical approximation for $l_n$:

$$\frac{l_n}{L} \approx 10 \frac{h}{H_D}$$

where $h$ is the depth of the breach in the crest of the dike, $H_D$ is the height of the dike above the polder level and $L$ is the length of the inner slope.
A relatively high dike in The Netherlands has a height $H_D \approx 10$ m. If it is assumed that $h \approx 1$ m (i.e. the 1 m thick clay-layer at the crest of the dike has been washed out by the high water), then the ratio $l_n/L \approx 1$. Hence, the development of the inner slope in Stages I and II of the breach erosion process of such a typical dike will be as shown in Figure 2 for $x < l_n$.

Figure 2 shows also the triangular cross-section of the dike through the axis of the breach at $t = t_2$. Due to the proceeding erosion process, the top of the dike in the breach starts to drop. As a result, both the discharge per unit width $q_{br}$ and the breach width increase in Stage III. It is assumed that also in this stage the angle of the inner slope remains at the critical value $\beta_1$. So again the rate of erosion is constant along the entire stretch $0 \leq x \leq l_n$, and also in the interval $t_2 < t < t_3$ it is entirely determined by the erosion at the toe of the slope.

At $t = t_2$ the width of the breach at the upstream side of the crown also starts to grow (see Figure 1). The rate of erosion at the breach bottom ($E_{bo}$) is larger than the erosion rate at the side-slopes ($E_{sl}$) due to the larger flow velocities (as a result of the larger water depths). For the same reason the erosion rate at the toe of the side-slopes is larger than higher on the slopes. This means that in Stage III the side-slope erosion is entirely controlled by the erosion at the bottom (i.e. the increase of the breach depth). Hence, the rate of increase of breach width is controlled by the rate of erosion at the breach bottom (see Figure 3):

$$\frac{dB_t}{dt} = \frac{2}{\tan \gamma_1} E_{bo} \tag{2}$$

In Stage III the breach growth accelerates drastically when deepening of the breach opening magnifies the inflow rate and the latter accelerates the erosion process. Consequently the flow and the sand transport through the breach change drastically in this stage: from a supercritical flow with a Froude number $Fr$ much larger than 1 at $t = t_2$ to a supercritical flow with $Fr$ slightly above 1 at $t = t_3$, from sheet flow transport with a Shields' mobility parameter $\theta$ of orders 10 and 100 at $t = t_2$ to sediment transport with $\theta$ of order 1 at $t = t_3$ (see Visser, 1998).

It is clear that the duration of the breach erosion process in Stages I, II and III depends largely on the dimensions of the initial breach. The larger these are, the shorter the total duration of these stages is, and consequently an accurate description of the breach erosion process in Stages I, II and III is then less important for the evaluation of the rate of flooding of the protected low-lying land.
4. BREACH DEVELOPMENT IN STAGES IV AND V

The continuation of the breach erosion process after the complete wash-out of the dike in the breach at \( t_3 \) depends on the following geometrical and material conditions of the dike:

- the resistance against further erosion of the base of the dike;
- the presence or absence of a berm and a toe construction on the outer slope and its ability to protect the outer slope against further erosion;
- the presence or absence of a relatively high foreland and its resistance against erosion.

Three types of breaches can be distinguished, dependent of these conditions. In a Type A breach the vertical erosion at the breach inflow is prevented by a solid clay foundation of the dike, or by a solid berm and a solid toe construction on the outer slope or by a solid, relatively high foreland (solid means here: with relatively high resistance against erosion). Dikes breach as Types B or C in the absence of a solid clay foundation, or a solid berm and a solid toe construction or a solid high foreland. If a relatively high (erodible) foreland is present then the dike breaches as Type B, otherwise as Type C. The Types A, B and C breaches are described further in next.

Type A breach

If the base of the dike consists of a solid clay-layer, then this layer will considerably slow down or prevent further vertical erosion, see Figure 4. This means that the breach continues to grow laterally in Stages IV and V, as shown in Figure 5. Since the erosion at the toe of the side-slopes is larger than higher on the slopes, the angle \( \gamma \) remains at its critical value \( \gamma_1 \). Hence, the erosion at the toe of each of the side-slopes \( E_{st} \) in Figure 5) determines the erosion of the overall side-slope, and consequently also the growth of the breach width. The discharge through the breach can be described simply by the formula for the flow over a broad-crested weir.

The lower parts of the outer slopes of sea dikes and river dikes in The Netherlands are protected against waves and currents by a (low water) berm and a toe construction. Less is known about the behaviour of these constructions in breaching dikes. It is, however, likely that these constructions may hinder or slow down further growth of the scour hole in upstream direction in cases where the foundation of the dike does not consist of solid clay. Downstream of the low water berm the breach continues to grow in vertical direction resulting in the formation of a scour hole, see Figure 9. The berm acts as a spillway (broad-crested or sharp-crested, which has only a secondary influence on the discharge coefficient of the spillway) controlling the breach inflow rate. Then the growth of the breach width is also determined at this upstream control section, resulting in an increase of the breach width as in the above situation of a solid base of the dike.

In cases where the dike has a relatively high foreland with a relatively large resistance against erosion, the development of the breach inflow and the breach growth is similar to that of a dike with a solid low water berm on the outer slope.

Types B and C breaches

If the base of the dike does not have much resistant against erosion and the dike does not have a solid berm and a solid toe construction on the outer slope, the breach continues to grow vertically (scour hole grows both with and against the flow, see Figures 9 and 11) and laterally (widening of the breach, see Figures 10 and 12).
Figure 4  Cross-section and top view of flow in Stage IV through a breach in a dike constructed on a solid clay-layer (Type A breach).

Figure 5  Cross-section C₁ (see Figure 4) of breach showing increase of breach width $B_t$ in a Type A breach in Stages IV and V.

Upstream of the breach a spillway is formed which controls the breach inflow. The alignment of this spillway depends on the height of the foreland in front of the dike. The alignment of the overfall will be curved (elliptic or circular) in a Type B breach.
Figure 6  Flow in Stage IV through a breach when a toe construction protects the lower part of the outer slope against further erosion.

As described in Chapter 3, the growth of the breach width in Stage III is controlled by the rate of erosion at the breach bottom ($E_{bo}$), and not by the erosion at the side-slopes ($E_{sl}$). In Stages IV and V, however, it is the erosion rate at the side-slopes ($E_{sl}$) that determines the increase of the breach width (see Figures 5, 8 and 10):

$$\frac{dB_t}{dt} = \frac{2}{\tan \gamma_1} E_{sl}$$  \hspace{1cm} (3.3)

The argument behind this conclusion is simple. The order of magnitude of the widths of final-breaches is 100 m (see Visser, 1998), while the order of magnitude of their depths is 10 m. Hence, the widths of final breaches have always been much larger than their depths, so that:

$$E_{bo} < \frac{2}{\tan \gamma_1} E_{sl}$$  \hspace{1cm} (3.4)

Visser (1998) argues that the side-slope erosion in Stages IV and V is governed by the flow at the upstream spillway, which simplifies the modelling of the breach growth process significantly.

In Stage V ($t_4 < t \leq t_5$) the breach continues to grow laterally. The continuous flow through the breach causes the water level in the polder to increase and the flow velocity in the breach to decrease, resulting in a deceleration of the breach growth.

At $t_5$ the flow velocities in the breach become so small (incipient motion) that the breach erosion stops. As far as the rate of flooding of the polder is concerned, Stages IV and V are the most important stages, since in these stages most of the water is discharged through the breach and the ultimate dimensions of the breach are determined.

5. MATHEMATICAL MODEL

Based on the five-step breach erosion process described above, a mathematical model for the growth of a breach in a sand-dike and the inflow rate through the breach has been developed. It is assumed that the dike was constructed with sand and that the clay-layers on the slopes do not decelerate the erosion process.

An essential part of a breach erosion model is the description of the entrainment of the sediment and its transport through the breach. In the mathematical model a simplified version of Galappatti's (1983) description for the entrainment of sediment is applied. This approach requires, however, a formulation for the equilibrium value of the sediment transport. None of the existing sediment transport formulae has been derived and tested for the relatively steep slopes in the initial stages and the large flow velocities throughout most of the breach erosion process. For application into the model, a number of existing sediment transport formulae has been tested to breach erosion tests (see Visser, 1995b), leaving only a few formulae with a reasonable performance. These transport formulae have been implemented into the model for the confrontation with experimental results and prototype data.

The numerical version of the model (BRES) has been written in C++ for use on a personal computer.

![Figure 11 Cross-section of sand-dam in Zwin'94 experiment (NAP is reference level in The Netherlands at about mean sea level).](image)

6. ZWIN'94 FIELD EXPERIMENT

The Zwin'94 experiment was performed in the Zwin Channel, a tidal inlet at the Dutch-Belgian border connecting the nature-reserve The Zwin with the North Sea (see Visser et al., 1996). The Zwin area measures about 1.5 km²; the mean tidal prism is about 350000 m³. The experiment was done in quiet autumn weather, with negligible wave heights against the sand-dam.

A sand-dam closing of the Zwin Channel (see Figure 11) was built with a height $H_D = 2.6$ m above the channel bottom, a width at the crest of 8 m and a length of about 200 m. The inclination of the outer slope was $1:1.6$, that of the inner slope $1:3$. A small trapezoidal pilot channel, 0.8 m deep and with a width of about 1 m at the breach bottom and about 3.6 m at the dike crest was made in the upper part of the dam to ensure breaching near the middle of the Zwin Channel.

The experiment started at $t = t_0 = 0$, about 20 minutes before high water, with the flow of water through the pilot channel. At 3 locations upstream and 3 locations
Figure 12: Comparison of model prediction (solid line) for width of the breach at the dike top ($B_t$) and observed $B_t$ in Zwin'94 experiment (dotted line).

downstream from the breach, current velocity meters (Ott propeller type) and pressure probes measured continuously horizontal flow velocities and water elevations, respectively. The breach erosion process was both video-taped and photographed (marks put in the dike-top allowed the observation of the dimensions of the breach at different times from the video-images, slides and photos). A total number of 40 vibration probes, buried in the sandy bottom of the Zwin Channel, detected the development of the breach under water in Stages IV and V. Each probe acted as a burglar-alarm: by measuring its own rate of vibration it could detect when the erosion process had exposed it to the flowing water. The vibration probe system was tested and calibrated in a laboratory flume. The signals of all vibration probes were recorded on the hard disks of several personal computers. At $t = t_5 \approx 60$ min the flow velocities in the breach had become so small that the erosion process stopped. The Zwin'94 field experiment has clearly confirmed the five-step breach erosion mechanism as described above and shown in Figure 1. Figure 12 shows the result of the observations of the growth of the breach width $B_t$ in time (observed at the top of the dike): $B_t$ increased from $B \approx 3.6$ m at $t = t_0 = 0$ up to $B_t \approx 41$ m at $t = t_5 \approx 60$ min.

The data set of the Zwin'94 experiment is very useful for the validation of mathematical breach erosion models. Reference is made to Visser et al. (1996) and Visser (1998) for details about the data set resulting from this experiment.
7. COMPARISON OF MODEL PREDICTION WITH FIELD DATA

Figure 12 shows the comparison of the model prediction with the data of the Zwin'94 experiment. It can be concluded that the agreement of the model prediction with the experimental data is good. This result has been obtained applying the Bagnold-Visser formula (see Visser, 1989) in Stages I, II and III and Van Rijn's (1984a,b) sand transport formulation in Stages IV and V.

Visser (1998) has applied the model also to a laboratory experiment and to a prototype dike failure of the 1953 flood in The Netherlands. For descriptions of both cases and details of these validations of the model reference is made to Visser (1998).

Bayesian Estimation of Quantiles for the Purpose of Flood Prevention

J.M. van Noortwijk¹ and P.H.A.J.M. van Gelder²

Abstract

In this paper, the problem of Bayesian estimation of flood quantiles is studied. Bayes estimators of the optimal dyke height under symmetric and asymmetric loss are investigated when the annual maximum sea water levels are exponentially distributed with unknown value of the mean. Three types of loss functions are considered: (i) linear loss, (ii) squared-error loss, and (iii) linex loss. In order to properly account for the statistical uncertainty in the mean, a modified linex loss function is to be preferred. This new modified linex loss function is derived from the economic dyke heigthening problem of Van Dantzig. Since the loss function is based on a benefit-cost analysis, its parameters have a clear economic significance.

Introduction

In statistical analysis of civil engineering data such as water levels, wave heights, soil parameters, etc., many attempts have been made to establish what kind of fitting method is preferable for the parameter estimation of a probability distribution in order to estimate the q-quantile, i.e. the value with a probability of exceedance equal to q (where q is usually very small, in the order of $10^{-3}$ to $10^{-5}$). Recent research on this subject can be found in, for example, Yamaguchi (1997), Fortin et al. (1997), Burcharth and Liu (1994), and Van Gelder (1996). The main idea in their work is to generate random samples from a chosen probability distribution using Monte Carlo simulation, and to investigate the advantage of a certain parameter estimation method over the other method which is based on the viewpoint of bias and variance of the q-quantile. The estimation method with the

3529
smallest bias and/or variance of the $q$-quantile is then considered to be the best parameter estimation method for that particular probability distribution. In this paper, a new concept is presented in which the parameter estimation method is defined as such that the bias of the estimated $q$-quantile is minimised within a Bayesian framework of asymmetric loss functions. The use of asymmetric loss functions gives us the possibility to differentiate between underestimation and overestimation of the $q$-quantile. In civil engineering applications, an underestimation error of the $q$-quantile generally leads to much higher losses than an overestimation error.

Although Fortin, Bobée and Bernier (1997) also use asymmetric loss functions for comparing statistical distributions and estimation methods, they do not apply these loss functions in a full Bayesian framework. The parameters of the probability distributions have been estimated by using three well-known methods from classical statistics: the method of maximum likelihood, the method of moments, and the method of probability-weighted moments. The Bayesian point of view only comes in when Fortin et al. (1997) use a nonparametric Bayesian simulation methodology, called Polya resampling, instead of the classical bootstrap to draw observations with replacement from a reference sample.

Three loss functions have been studied: (i) the asymmetric linear loss function, (ii) the asymmetric squared-error loss function, and (iii) the linex loss function. For an overview of asymmetric loss functions, see Zellner (1986) and Thompson and Basu (1996). The linex loss function has been used in real estate assessment by Varian (1974). Basu and Ebrahimi (1991) determine an expression for the linex estimator of the survival function of a system having a Type II censored exponential lifetime. Using simulated data, Basu and Thompson (1992) and Thompson and Basu (1993) obtain linex estimates of the reliability of simple stress-strength systems. Pandey et al. (1994) study the problem of estimating the shape parameter of a Pareto distribution using a linex loss function.

The Bayes estimator of the $q$-quantile under asymmetric loss minimises the expected loss with respect to the probability distribution of an unknown parameter. In order to find the loss function that can best be applied to decision problems in civil engineering, we have studied the economic dyke-height optimisation problem of Van Dantzig (1956). He assumed the annual maximum sea water levels to be exponentially distributed. It appears that Van Dantzig's economic loss function differs slightly from the linex loss function. This modified linex loss function seems to be a promising candidate for solving quantile estimation problems in other civil engineering benefit-cost analyses.

The outline of the paper is as follows. First, an overview is given of the Bayesian estimation of quantiles by using the three above-mentioned loss functions. The economic optimisation of dyke heights is subsequently addressed. Next, we derive the relation between the economic optimisation and the loss function approach. This relation results in a modified linex loss function. The different methods are compared in a Dutch polder case study. Finally, conclusions are drawn.
Bayesian Estimation of Quantiles Using Loss Functions

Define the random quantity $X_i$ to be the maximal sea water level in year $i$, $i = 1, \ldots, n$. We assume the random quantities $X_1, \ldots, X_n$ to be mutually independent, identically distributed, random quantities with a cumulative distribution function $\Pr\{X_i \leq x\} = F(x | \lambda)$ with parameter $\lambda$, $i = 1, \ldots, n$. As a function of $\lambda$, the $q$-quantile of the probability distribution of $X$ is defined to be

$$y_q = g(\lambda) = F^{-1}(1-q | \lambda),$$

where $g'(\lambda) > 0$. Suppose the parameter $\lambda$ is unknown with a prior probability density function $\pi(\lambda)$. After observing the data $x = (x_1, \ldots, x_n)$, this prior density can be updated to the posterior density using Bayes' theorem:

$$p(\lambda) = \pi(\lambda | x) \propto l(x | \lambda) \pi(\lambda) = \prod_{i=1}^{n} f(x_i | \lambda) \pi(\lambda),$$

where $l(x | \lambda)$ is the likelihood function of the observations $x$ when the value of $\lambda$ is given.

For the purpose of flood prevention, we are interested in estimating the $q$-quantile of the probability distribution of the maximal sea water level $X$ per year, denoted by $g(X)$. In a Bayesian framework, this can be achieved by minimising the loss due to the simple estimation error $\Delta = g(X') - g(\lambda)$. Since the loss due to flooding increases with overestimation error (i.e. the real $q$-quantile is less than its estimated value: $g(\lambda) < g(X')$ or $\Delta > 0$) and, at a much faster rate, with underestimation error (i.e. the real $q$-quantile is greater than its estimated value: $g(\lambda) > g(X')$ or $\Delta < 0$), we focus on asymmetric loss functions (see Thompson and Basu, 1996). Beside loss functions of the simple estimation error, loss functions of the relative estimation error can also be considered.

The three most well-known asymmetric loss functions are: (i) the asymmetric linear loss function, (ii) the asymmetric squared-error loss function, and (iii) the linex loss function.

Asymmetric Linear Loss

The asymmetric linear loss function is defined by

$$L(\Delta) = \begin{cases} a\Delta & \text{if } \Delta \geq 0 \text{ or } \lambda \leq \lambda^*, \\ -b\Delta & \text{if } \Delta < 0 \text{ or } \lambda > \lambda^*, \end{cases}$$

where $a, b > 0$. This loss function is asymmetric for $a \neq b$. We can best choose the estimate $\lambda^*$ for which the expected loss is minimal with respect to the probability
distribution of $\lambda$:

$$E(L(\Delta)) =$$

$$= \int_{-\infty}^{\infty} a[(g(\lambda') - g(\lambda))p(\lambda) d\lambda + \int_{\lambda'}^{\infty} b[g(\lambda) - g(\lambda')]p(\lambda) d\lambda =$$

$$= ag(\lambda')P(\lambda') - a \int_{-\infty}^{\lambda'} g(\lambda) p(\lambda) d\lambda - bg(\lambda')[1 - P(\lambda')] + b \int_{\lambda'}^{\infty} g(\lambda) p(\lambda) d\lambda,$$

where $P(\lambda)$ is the cumulative distribution function of $\lambda$. The Bayes estimator under asymmetric linear loss is the solution of the equation

$$\frac{dE(L(\Delta))}{d\lambda'} = g'(\lambda')(a + b)P(\lambda') - b = 0,$$

which results in $\lambda^* = P^{-1}(b/[a + b])$. Hence, the Bayes estimator $\lambda^*$ equals the $b/[a + b]$-quantile of the posterior distribution of $\lambda$. When $a = b$, the linear loss function is symmetric and its Bayes estimator reduces to the posterior median $P^{-1}(0.5)$.

**Asymmetric Squared-Error Loss**

The asymmetric squared-error loss function is defined by

$$L(\Delta) = \begin{cases} 
  a\Delta^2 & \text{if } \Delta \geq 0 \text{ or } \lambda \leq \lambda', \\
  b\Delta^2 & \text{if } \Delta < 0 \text{ or } \lambda > \lambda', 
\end{cases}$$

where $a, b > 0$. This loss function is asymmetric for $a \neq b$ with expected value

$$E(L(\Delta)) = \int_{-\infty}^{\infty} a[(g(\lambda') - g(\lambda))^2 p(\lambda) d\lambda + \int_{\lambda'}^{\infty} b[g(\lambda) - g(\lambda')]^2 p(\lambda) d\lambda.$$

The Bayes estimator under asymmetric squared-error loss is the solution of the equation

$$\frac{dE(L(\Delta))}{d\lambda'} = 2g(\lambda')g'(\lambda')[(a - b)P(\lambda') + b] - 2g'(\lambda')[(a - b)\int_{-\infty}^{\lambda'} g(\lambda) p(\lambda) d\lambda + b \int_{\lambda'}^{\infty} g(\lambda) p(\lambda) d\lambda = 0,$$

which must be solved for $\lambda^*$ numerically. When $a = b$, the squared-error loss function is symmetric and the Bayes estimator $g(\lambda')$ reduces to the posterior mean of $g(\lambda)$.

**Asymmetric Linex Loss**

The asymmetric linex loss function is defined by
\[ L(\Delta) = b[a\Delta + \exp(-a\Delta) - 1], \]  
where \( a, b > 0 \). The expected loss can be written as

\[ E(L(\Delta)) = b\int_{-\infty}^{\infty} a[g(\lambda') - g(\lambda)]p(\lambda) d\lambda + \int_{-\infty}^{\infty} \exp(-a[g(\lambda') - g(\lambda)])p(\lambda) d\lambda - 1. \]

The Bayes estimator under asymmetric line loss, \( \lambda^* \), is the solution of the equation

\[ \frac{dE(L(\lambda))}{d\lambda^*} = ab \frac{g'(\lambda^*)[1 - \int_{-\infty}^{\infty} \exp(-a[g(\lambda') - g(\lambda)])p(\lambda) d\lambda]}{a} = 0, \]

which results in

\[ \lambda^* = g^{-1}\left(\frac{\ln(\int_{-\infty}^{\infty} \exp(\lambda p(\lambda) d\lambda))}{a}\right). \]

**Examples of Loss Functions**

Examples of the three loss functions are displayed in Figure 1: (i) the asymmetric linear loss function with \( a = 5.37 \times 10^7 \) and \( b = 1.94 \times 10^7 \), (ii) the asymmetric squared-error loss function with \( a = 1.07 \times 10^8 \) and \( b = 3.88 \times 10^7 \), and (iii) the asymmetric line loss function with \( a = 3.03 \) and \( b = 1.32 \times 10^7 \). The parameters \( a \) and \( b \) have been chosen as such that the three loss functions are equal for \( \Delta = \pm 0.5 \).

Note that both linear loss and squared-error loss are special cases of what Thompson and Basu (1996) called monomial-splined loss, defined, for fixed \( m = 1, 2, 3, \ldots \), by

\[ L(\Delta) = \begin{cases} 
|\Delta|^m & \text{if } \Delta \geq 0, \\
|\Delta|^m & \text{if } \Delta < 0,
\end{cases} \]

where \( a, b > 0 \). Fortin, Bobée and Bernier (1997) applied monomial-splined loss for \( m = 1, 2, 3 \) within a framework of classical statistics.
Figure 1. The linear, squared-error and linex loss function according to Eqs. (1-3).

Estimation of Optimal Dyke Height

Let us consider the benefit-cost analysis that is adapted from Van Dantzig (1956). Suppose we have to decide how high the dykes should be to prevent a polder from flooding. Let the height of the dyke \( h \) be the decision variable, and let \( h_0 = 3.25 \) metres be the initial height of the dyke at the moment the decision has to be taken. The only failure mechanism that we regard is overtopping, i.e. inundation of the polder will occur as soon as the sea water level exceeds the height of the dyke. To account for the stochastic nature of the sea water level, we assume the maximal sea levels per year \( X_i, \ i = 1, \ldots, n \), to be conditionally independent, exponentially distributed, random quantities with a known location parameter \( x_0 = 1.96 \) metres and an unknown scale parameter \( \lambda \) with expected value 0.33 metres. Hence, the likelihood function is

\[
l(x \mid \lambda) = \prod_{i=1}^{n} f(x_i \mid \lambda) = \prod_{i=1}^{n} \frac{1}{\lambda} \exp \left\{ -\frac{x_i - x_0}{\lambda} \right\}.
\]

Accordingly, the \( q \)-quantile of the probability distribution of \( X \) is
\[ y_q = g(\lambda) = x_0 - \lambda \ln(q). \]

The costs of heightening the dykes with \( h - h_0 \) metres depend on the fixed cost \( c_f = 1.1 \times 10^5 \) and the variable cost \( c_v = 4.0 \times 10^7 \): i.e. \( c_f + c_v [h - h_0] \). If the polder is inundated, an economic value of \( c = 2.4 \times 10^{10} \) Dutch guilders is lost. The discount factor is \( \alpha = \lceil 1 + 0.015 \rceil^{-1} \), compounded annually, where \( 0 < \alpha < 1 \). Since the probability of inundation of the polder is \( \exp\{- (h - x_0)/\lambda \} \), the expected discounted costs due to inundation of the polder over an unbounded time-horizon can be written as

\[ c(\lambda, h) = c_f + c_v [h - h_0] + \frac{\alpha}{1 - \alpha} c \exp\left\{ - \frac{h - x_0}{\lambda} \right\} \quad (4) \]

if the decision-maker chooses dyke height \( h \) and when the value of \( \lambda \) is given.

The decision with minimal expected costs, i.e. the dyke height for which the expected discounted costs due to inundation are minimal, is

\[ h^* = x_0 - \lambda \ln\left( \frac{c_v}{c} \frac{1 - \alpha}{\alpha} \right) \quad (5) \]

when the value of \( \lambda \) is given. Accordingly, the inundation probability that balances the cost of investment optimally against the cost of inundation is

\[ q = \exp\left\{ - \frac{h^* - x_0}{\lambda} \right\} = \lambda \cdot \frac{c_v}{c} \frac{1 - \alpha}{\alpha}. \quad (6) \]

When the value of \( \lambda \) is given to be 0.33 metres, the optimal inundation probability is \( q = 8.25 \times 10^{-6} \).

To account for the statistical uncertainty in the mean of the maximal sea water level per year, the prior density of \( \lambda \) is assumed to be an inverted gamma distribution with scale parameter \( \mu > 0 \) and shape parameter \( \nu > 0 \):

\[ \text{Ig}(\lambda | \nu, \mu) = [\mu^\nu / \Gamma(\nu)] \lambda^{-\nu-1} \exp\{- \mu/\lambda \} \]

for \( \lambda > 0 \). The prior mean and variance are \( E(\lambda) = \mu / (\nu - 1) \) and \( \text{Var}(\lambda) = E(\lambda^2) / (\nu - 2) \), respectively. Hence, the larger \( \nu \), the less uncertain \( \lambda \). On the basis of this prior density, the expected discounted costs over an unbounded horizon transform into
\[ \int_0^\lambda c(\lambda, h)p(\lambda) d\lambda = c_f + c_v(h - h_0) + \frac{\alpha}{1-\alpha} c \left[ \frac{\mu}{\mu + h - x_0} \right]^\nu. \]  

(7)

The dyke height with minimal expected costs, while taking the uncertainty in \( \lambda \) into account, is

\[ h^* = x_0 - \mu + \left[ \frac{\nu c \cdot \alpha}{\mu} \right]^\frac{1}{\nu+1}. \]  

(8)

The inundation probability that balances the cost of investment optimally against the cost of inundation, while taking the uncertainty in \( \lambda \) into account, is

\[ q^* = \left[ \frac{\mu}{\mu + h^* - x_0} \right]^{\nu} = \left[ \frac{\mu \cdot \alpha}{\nu \cdot c} \right]^{\frac{\nu}{\nu+1}}. \]

When the expected value of \( \lambda \) is 0.33 metres, the optimal inundation probability under statistical uncertainty is \( q^* = 1.02 \times 10^{-5} \) for \( \nu = 50 \), \( q^* = 9.17 \times 10^{-6} \) for \( \nu = 100 \), and \( q^* \to 8.25 \times 10^{-6} \) as \( \nu \to \infty \).

An advantage of the inverted gamma distribution as a prior density is that the posterior distribution of \( \lambda \), when the observations \( x_1, \ldots, x_n \) are given, is also an inverted gamma distribution with scale parameter \( \mu + \sum_{i=1}^n (x_i - x_0) \) and shape parameter \( \nu + n \). The inverted gamma distribution is said to be a conjugate family of distributions for observations from an exponential distribution with unknown mean (scale parameter). From now on, when we use the probability density function \( p(\lambda) \), we refer to the posterior density. Note that (inverted) gamma priors have also been applied by Basu and Ebrahimi (1991), Basu and Thompson (1992), Thompson and Basu (1993), and Pandey et al. (1994).

Relation Between Economic Loss and Linex Loss

The question arises whether Van Dantzig's economic cost function and the Bayesian loss function are interrelated to each other. In this respect, we reformulate Van Dantzig's cost function in terms of Bayesian loss, i.e. we rewrite the loss function as

\[ L(\Delta) = L(g(\lambda^*) - g(\lambda)) = c(\lambda^*, h^* + \Delta) - c(\lambda, h^*) = c_f + \frac{\alpha}{1-\alpha} c \exp \left[ \frac{h^* - x_0}{\lambda} \right] \exp \left[ \frac{\Delta}{\lambda} \right] - 1. \]

There are now two possibilities for rewriting the probability of exceedence
\[ \exp\left\{ \frac{-(h^* - x_0)}{\lambda} \right\} : \] (i) as a constant and (ii) as a function of the unknown scale parameter \( \lambda \).

First, we investigate the probability of exceedence \( \exp\left\{ \frac{-(h^* - x_0)}{\lambda} \right\} \) to be a constant, i.e. to be \( q = 8.25 \times 10^{-6} \):

\[
L(\Delta) = c_\nu \Delta + \frac{\alpha}{1 - \alpha} c q \left[ \exp\left\{ \frac{-\Delta}{\lambda} \right\} - 1 \right],
\]

(9)

where \( \Delta = g(\lambda') - g(\lambda) \) and \( g(\lambda) = x_0 - \lambda \ln(q) \). The Bayes estimator under asymmetric loss in terms of Eq. (9), \( \lambda' \), is the solution of the equation

\[
\frac{dE(L(\Delta))}{d\lambda'} = g'(\lambda') \left[ c_\nu - \frac{\alpha}{1 - \alpha} c q \int_0^\lambda 1 \exp\left\{ \frac{g(\lambda') - g(\lambda)}{\lambda} \right\} p(\lambda) \, d\lambda \right] = 0,
\]

which results in

\[
g(\lambda') = x_0 - \lambda' \ln(q) = x_0 - \mu + \left[ \nu \mu^\nu \cdot \frac{1}{c_\nu} \cdot \frac{\alpha}{1 - \alpha} \right]^{1/\nu} = h^*.
\]

Second, we consider the probability of exceedence \( \exp\left\{ \frac{-(h^* - x_0)}{\lambda} \right\} \) to be a function of the unknown scale parameter \( \lambda \), by substituting the optimal dyke height \( h^* \) according to Eq. (5):

\[
L(\Delta) = c_\nu \left( \Delta + \lambda \left[ \exp\left\{ \frac{-\Delta}{\lambda} \right\} - 1 \right] \right),
\]

(10)

where \( \Delta = g(\lambda') - g(\lambda) \) and

\[
g(\lambda) = x_0 - \lambda \ln\left( \frac{1 \cdot \alpha}{c_\nu} \right).
\]

The Bayes estimator under asymmetric loss in terms of Eq. (10), \( \lambda' \), is the solution of the equation

\[
\frac{dE(L(\Delta))}{d\lambda'} = c_\nu g'(\lambda') \left[ 1 - \int_0^\lambda \exp\left\{ \frac{g(\lambda') - g(\lambda)}{\lambda} \right\} p(\lambda) \, d\lambda \right] = 0,
\]

which results in
\[ g(\lambda^*) = x_0 - \lambda^* \ln \left( \frac{\lambda^*}{c_v} \cdot \frac{1 - \alpha}{\alpha} \right) = x_0 - \mu + \left[ \nu \mu^* \cdot \frac{c}{c_v} \cdot \frac{\alpha}{1 - \alpha} \right]^{\frac{1}{\nu+1}} = h^*. \]

**Modified Linex Loss**

We ought to notice that the two economic loss functions (9-10) differ slightly from the linex loss function (3). A difference is that both economic loss functions are not only a function of the simple estimation error \( \Delta \), but also of the relative estimation error \( \Delta/\lambda \). In terms of \( \lambda' \) and \( \lambda \), the loss function (9) can be written as

\[ L(\Delta) = -c \ln(q) \cdot (\lambda' - \lambda) + \frac{\alpha}{1 - \alpha} cq \left[ \exp \left( \frac{\lambda' - \lambda}{\lambda} \right) - 1 \right] = L(\Delta_1, \Delta_2), \]

where \( \Delta_1 = \lambda' - \lambda \) is the simple estimation error of \( \lambda' \) and \( \Delta_2 = (\lambda' - \lambda)/\lambda \) is the relative estimation error of \( \lambda' \). The general formulation of the modified linex loss function (11) is:

\[ L(\Delta_1, \Delta_2) = b(a\Delta_1 + d[\exp(-a\Delta_2) - 1]), \]

where

\[ a = -\ln(q), \quad b = c_v, \quad d = \frac{\alpha}{1 - \alpha} \cdot \frac{c}{c_v} \cdot q. \]

Since the main aim of this paper is estimating the \( q \)-quantile of a probability distribution, the most appropriate loss functions seem to be the economic loss functions (9 and 11) (in terms of \( g(\lambda) \) and \( \lambda \), respectively). These economic loss functions are modified linex loss functions, for which the parameters have a clear economic significance. The parameters represent the cost of investment (dyke heightening) on the one hand, and the cost of flooding on the other hand. Since the modified linex loss functions are derived from estimating the mean of an exponential distribution, more research has to be undertaken to find out whether they can also be applied to estimate the statistical parameters of other probability distributions.

**Comparative Results**

On the basis of the dyke heightening problem, we have compared the linear, squared-error and linex loss function with the economic loss functions. The results are summarised in Tables 1-2. The coefficients \( a \) and \( b \) of the linear, squared-error and linex loss function have been assessed in the following way. As suggested by the economic loss functions (9-10), the coefficients of the linex loss function are assumed to be \( a = [E(\lambda)]^{-1} \) and \( b = c_v E(\lambda) \). Furthermore, asymmetric linear and squared-error loss
functions have been fitted to this linex loss function by, somewhat arbitrary, assuming the linear, squared-error and linex loss to be equal to each other for $\Delta = \pm 0.5$ (see Figure 1). Results are also presented for the symmetric linear and squared-error loss function.

</table>

From Tables 1-2, we can conclude the following. The cost-optimal dyke height without taking the statistical uncertainties involved into account is, due to Eq. (5), equal to 5.82 m. When asymmetric loss functions are applied, the optimal dyke height is higher while taking the statistical uncertainty in $\lambda$ into account. The larger the uncertainty in the scale parameter $\lambda$, i.e. the smaller the number of observations $v$, the higher the cost-optimal dyke height. On the other hand, a symmetric squared-error loss function results in the same height without uncertainty (5.82 m) and a symmetric linear loss function can result in even lower heights (5.77 m and 5.80 m, respectively). As expected, the optimal dyke height under uncertainty according to Eq. (8) equals the dyke height that follow from both economic loss functions (9-10). Recall that the main difference between Eq. (9) and Eq. (10) is that the former is regarded as a function of the optimal $q$-quantile, whereas the latter contains the substitution for $q$ in terms of Eq. (6). Since the linex loss
function results in a dyke height much greater than the height in case of the economic loss functions, we recommend using the economic loss functions (modified linex loss functions) instead.

Conclusions

A Bayesian approach towards the estimation of flood quantiles has been suggested. Bayes estimators of the optimal dyke height under symmetric and asymmetric loss have been investigated when the annual maximum sea water levels are exponentially distributed with unknown mean. Three types of loss functions have been considered: (i) linear loss, (ii) squared-error loss, and (iii) linex loss. In order to properly account for the statistical uncertainty in the mean, a modified linex loss function can best be applied. This new modified linex loss function is derived from the economic dyke heighthening problem of Van Dantzig. The Bayes estimate of the dyke height under modified linex loss is equivalent to the optimal dyke height for which the economic loss is minimal. The modified linex loss function seems to be a promising candidate to solve quantile estimation problems in other civil engineering benefit-cost analyses. Moreover, unlike in most Bayesian literature, the parameters of the modified linex loss function have a clear economic significance. They represent the cost of investment (dyke heightening) on the one hand, and the cost of flooding on the other hand. The advantage of using a Bayesian loss function approach over a Van Dantzig approach is that the former approach is more closely related to the current design practice of hydraulic structures with fixed quantiles. The difference between under- and overdesign is more visible in the Bayesian loss function approach than in the Van Dantzig approach. The next step would be to repeat the type of work done in this paper on a larger scale in order to estimate the statistical parameters of other probability distributions.

Flood Protection in the Danish Wadden Sea Area
Jens Otto Andersen

Abstract
In the Danish Wadden Sea area the main coastal problem is the risk of flooding while coast erosion only takes place in a few small localities and in larger measure at the peninsula of Skallingen. In the Danish Wadden Sea area some 100 km of dike protects the lowlying areas, the marsh areas, against flooding. Through the years the dike protection has been extended and reinforced.
Since the 1970s, the frequency of storm surges has been much higher than earlier in this century. These surges have worn the dikes and many reinforcements have been carried out, and two new dikes have been built protecting the towns Ribe and Højer.
The Danish dikes have always been green dikes, i.e. they are grass covered. They are rather easy to reinforce if necessary to withstand also a relative sea level rise caused by the greenhouse effect, the continuing land subsidence in this area or possible more frequent and higher storm surges in the future.

Introduction
The Wadden Sea extends 500 km of the North Sea coast from den Helder in the Netherlands to the peninsula Skallingen in Denmark, the Danish part of the Wadden Sea being app. 70 km from the Danish-German border to Skallingen, fig. 1.

Figure 1. The Wadden Sea and the Danish part of the Wadden Sea.

Senior Coastal Engineer
Danish Coastal Authority, Box 100, DK7620 Lemvig, Denmark, E-mail: ki@kyst.dk
The Wadden Sea is dominated by the daily tide ranging from −0.7 m to + 0.7 m DNN (DNN is app. the same as the mean sea level, MSL) and by the strong in- and outgoing currents. At tidal low water app. 70% of the bottom of the Wadden Sea is dry.

Storm surges and floodings have influenced the landscape, the settlings as well as agriculture. In the Danish Wadden Sea, water levels above 3.5 m DNN are characterised as storm surges. In the last hundred years, the highest measured water levels during storm surges have been about 5 m DNN.

Figure 2. Upgrading of the dike system along the Danish Wadden Sea.

Large parts of the nearshore landscape are low lying and in risk of flooding if the dikes should breach, fig. 2. These low-lying areas are mainly 1 to 5 m above DNN, i.e. there are no areas below MSL. The areas are mainly used for agriculture but large parts of the two major towns Ribe and Tønder and also some villages are low-lying.
Severe Surges and Floodings

In 1362, the storm surge named “Grote Mandranke”, i.e. “Great man-drowning” flooded the whole Wadden Sea area. Some sources mention up to 200,000 dead people, but this number has later been evaluated to be much too high. Still the flooding was indeed a disaster.

In 1634 another severe flooding caused 10,000 – 15,000 victims.

In Denmark, the last flooding where people drowned took place in 1923, where a storm surge unusually occurred in August. At this time, one of the dikes was being built and many of the workers were caught by the storm surge at the building site and drowned.

A severe flooding took place in 1953, app. 1,800 were killed in the Netherlands and 300 in England. In 1962 a storm flood killed 350 people in Germany. These two floodings did no harm in the Danish Wadden Sea area.

In 1976 and 1981, the two highest surges in this century occurred in Denmark, both with water level app. 5 m above DNN. These two surges are described below.

The 1964 Storm Flood Committee

After the disaster in the Netherlands and Germany in 1953 and 1962, a storm flood committee was appointed in 1964 in Denmark to evaluate the existing safety against flooding. As part of the work an extensive study concerning frequency and height of storm surges, hydraulic conditions, and safety problems was carried out. The first result of the work was the establishment of a warning and alert system. The work ended in 1975 resulting in an act of reinforcement of Ribe Dike to a safety level of 200 years and building of maintenance roads along most of the dikes. There was a difference of opinion whether Tønder Dike should be reinforced or a new forward dike should be built to achieve a safety level of 200 years against flooding of Tønder.

Ribe Dike and the Forward Dike at Tønder

A severe storm surge in 1976 ended the discussion. Denmark and Germany made an agreement on the building of a new dike in front of Tønder Dike continuing on the German side of the border also as a forward dike. The reinforcement of Ribe Dike was finished in 1980 and the new forward dike was finished in October 1981. Already in November 1981, a more severe storm surge than the one in 1976 struck the Wadden Sea. This only caused small local damages to these new dikes while large damages took place on the older dikes, one dike breached totally (fig. 9c). The profile of the two new dikes is shown in fig. 3.

Figure 3. New dike design.
All the Danish dikes have always been green dikes i.e. covered by grass at the whole profile and no protection with stones, concrete, asphalt, etc.

The Dike Protection

Today, the dike length is app. 100 km.

The first dikes built some 500 years ago were only slight dikes functioning as so-called summer dikes, i.e. they protected the agricultural areas in the summer until the harvest was done. They would not protect against the more severe storms in the late autumn and winter. Most of the villages and sparse habitation were built either on natural higher areas or on artificially built rises.

![Diagram](image)

Figure 4. Evolution of dike profile

Fig. 4 shows the evolution in the dike profile since the first summer dikes, fig. 4a, to the newest dikes built some 15–20 years ago and shows the newer reinforcement of dikes.

The period 1910 – 1930 was very windy and some severe storm surges occurred. Because of this and the development in agriculture and habitation in the low-lying areas many new dikes were built, fig. 2 showing year of building and reinforcement, and fig. 4b showing the typical profile. The profile had a concave front slope with an average slope of 1:5 and a rather steep back slope 1:1.5 or 1:2. The strength against breaching has later been calculated to a safety level of 30–50 years.
The period from 1930 to the middle of the 1970s was rather calm. Since the middle of the 1970s there has been a "bad weather" period, fig. 5. Several storm surges have worn the dikes. It has been necessary to reinforce several of the dikes. These reinforcements have been made in different ways depending on the problem of the individual dike. Fig. 4c shows the reinforcement of the front slope with a clay cover to prevent erosion caused by wave attack. Fig. 4d shows a similar protection of the back slope but also a flattening of the back slope to prevent sliding and erosion caused by wave run over. Fig. 4e shows a reinforced dike profile with new flatter front and back slopes and reinforcements of the slopes with clay to protect against erosion from wave attack. Fig. 4f shows the profile of the new dikes in front of Ribe and Tønder.

Designing the Dikes

The principle of designing the height of the dikes is shown in fig. 6.

$$Z_{00} = C_H f(H) \left[ V \sqrt{gH_s \tan \alpha} \right]$$

Figure 5. Number of high water levels in 20 years periods.

Figure 6. Design of dike height.
The design water level varies from a 50 year storm surge level to a 200 year level, depending on the areas protected.

Fig. 7 shows the frequency of extreme water levels at Højør in the southern part of the Wadden Sea in front of Tønder.

![Graph showing the frequency of extreme water levels at Højør, 1920-1996.](Figure 7. Frequency of extreme water levels at Højør, 1920–1996.)

The wave run up is added to the design water level. The run up depends on the gradient of the front slope, see fig. 6. The run up is app. proportional to \( \tan \alpha \) so the flatter front slope, the smaller wave run up. When reinforcing the dikes, the front slopes are built with a gradient of 1:7 to 1:10 to reduce wave run up but also because the erosion of the front slope by wave attack will be much reduced when the slope is flatter that 1:6.

By the reinforcements, the back slope is also flattened typically from 1:2 to 1:3, while this prevents sliding if wave run over should occur.

In this part of Denmark, the relative land depression is taken into account when designing the dike height. Fig. 8 shows why this has to be taken into account. During the Ice Age the ice covered the eastern and northern part of Denmark. In fact the whole Scandinavia except the south-western part of Denmark was ice-covered. The ice depressed the earth beneath. Since the melting of the ice Denmark has tilted, where the north-eastern part rises and the south-western part subsides. When designing the new dikes to a safety level of 200 years the dike height is added 20 – 30 cm to take this subsidence into account.
The new dikes were designed in the late 1970s. Therefore the relative sea level rise caused by the greenhouse effect has not been taken into account, but it will be rather easy to do this at coming reinforcements of the dikes when the relative sea level rise in the future may be well calculated. In fact the dikes just have to be heightened in the same way as when taking the land subsidence into account.

Fig. 9 shows photos of damages of dikes after a storm surge. Fig. 9a shows damages of the front slope, fig. 9b shows damages and sliding of the back slope, fig. 9c shows dike breach, and fig. 9d shows the situation of wave run over during a storm surge.

The damages and floodings caused by a storm surge depend not only on the surge level but also on the duration of the surge.

The two surges in 1976 and 1981 nearly reached the same maximum water level, app. 5 m above DNN, fig. 10. The rise in the water level happened very quickly (1 m/hour) in 1976 but the duration of water level above 3.5 m was only 4.5 hours while the surge in 1981 rised more slowly with 0.4 m/hours and had a duration of app. 7 hours with water level above 3.5 m DNN. These courses meant that in 1976 there was only short time to evacuate people, there were many damages on both dike front slopes and back slopes but because of the short dura-
tion no dike breach took place. In 1981 the storm surge was predicted very good and the evacuation of people happened without problems but because of the long duration of the surge many and severe damages happened to the dikes and one of the dikes breached totally.

At the storm surge in 1976, the water level in the northern part of the Wadden Sea at Esbjerg was much lower than only 50 km more south at Højer, fig. 10. This example shows the great differences in the maximum storm surge level there can he in different localities in the Wadden Sea under the same storm. These differences depend on how the passage of the centre of the low air pressure takes place and the magnitude of the air pressure.

**Flood Warning and Alert**

As one of the results of the storm flood committee, a flood warning and alert system was established in 1975. The warning is based upon numerical models for the water levels. The water levels are monitored at five localities in the Wadden Sea and registered at once at the Danish Coastal Authority (DCA) and the Danish Meteorological Institute (DMI).

The models are run by routine several times a day and if the predicted water levels exceed certain levels the relevant authorities and the press are informed. Depending on the predictions different levels of warning are introduced where the alarm situation is the most severe and implies evacuation of people from the flood threatened areas.

The overall system is managed by DCA, DMI, and the police in the county.
Figure 10. The courses of 1976 and 1981 storm surges.
Administration of the Dikes

Most of the dikes are funded by the State, others also with contribution from the local authorities. The maintenance is managed by local dike committees and one of the new dikes by the Regional Authority. Twice a year the dike committees and the Danish Coastal Authority inspect the dikes to point out possible damages or other aspects that can influence the safety of the dikes. Each dike committee then takes care of the repair.

Preservation of the Wadden Sea

Today, the Wadden Sea and the Wadden Sea coast are preserved and classified as a RAMSAR area. The preservation assumes that new dikes will not be built and reinforcements of the forelands in front of the dikes are not allowed, even though this would improve for the dike safety. In some localities where a narrow foreland is eroded this means that it can be necessary to protect against further erosion with solid constructions as stone revetments. Through the years sedimentation fields have created new foreland.

Figure 11. Future challenges.
The Future

The development in the Wadden Sea is observed carefully. Water levels are measured continuously at five localities and wave registration takes place at four localities. The Wadden Sea was surveyed in the 1960s. A similar surveying is carried out these years for calculation of changes in the bottom level of the Wadden Sea. The southern part of this surveying is carried out in co-operation with the German authorities. The dikes are surveyed every five years. A working group with participation of the Danish coastal Authority and the two counties in the Wadden Sea area evaluates the safety level of the dikes on the basis of settlement of the dikes/land, recalculation of the wave climate, update of storm surge statistics and co-ordination of results from a new national precision levelling.

By means of these continuing studies it will be possible to follow a possible sea level rise because of the green house effect and also if the Wadden Sea bottom should rise within the same or less time.

At this moment (1998) it seems that the bad weather period which began in the middle of the 1970s might have ended now, however, it is too early to state this on the basis of the last few calm years, so in fact we do not know the future challenges. They may be as sketched in fig. 11 where the future impact (number of surges) can be everything from the average impact of this century to a continuing of the bad weather period with addition of a general rise in the sea level because of the green house effect and of course the problem with the continuous land subsidence of this area.

Conclusions

The safety level against flooding of the lowlying areas varies from app. 40 years to 200 years based upon the statistics of storm surge levels since 1920. During the last 20 years there have been more frequent and higher storm surges than before, there may occur a general rise in the sea level caused by the green house effect and the relative land subsidence of the area will continue.

These parameters are studied carefully so it is possible to reinforce the dike protection as soon as it is necessary for maintaining the safety level against flooding.

Dispersion of Wave Action

James M. Buick and Tariq S. Durrani

Abstract

The dispersion of particles beneath a random sea, produced by the associated random variations in the Stokes drift is considered. In particular, a sea state described by a Pierson-Moskowitz spectrum is considered and the diffusion rate on and below the surface is examined. For such a random sea the diffusion rate at the surface can be related to the wind speed. This expression is extended to consider dispersion rates below the surface and to relates these to the wind speed. The theory is then applied to study the dispersion of particles denser than water as they fall through a random sea.

Introduction

An accurate prediction of the dispersion of pollutants in the sea is essential in the planning of contingency exercises and also in risk analysis. Computer models have been developed to simulate the spread of pollutants in the sea but these generally ignore the effects of wave action in dispersing the material which, on a scale of up to a few kilometers, can have a large role to play (Schott et al. 1978, Herterich and Hasselmann 1982). Recent oil spill disasters such as the sinking of the Braer off the Shetland Islands have highlighted the fact that the dispersion of pollutants is highly dependent on the prevailing wave climate. Discharges
from chemical and sewage works can also cause pollution. In such cases an understanding of the dispersion of the pollutants, on and below the sea surface, is clearly desirable. In this paper we consider the dispersion of such pollutants due to random wave motion described by a Pierson-Moskowitz (Pierson and Moskowitz 1964) surface spectrum. The Pierson-Moskowitz spectrum is a JONSWAP spectrum (Hasselmann et al. 1973) describing a fully developed sea and is given by

\[ f(\omega) = \alpha g^{2} \omega^{-5} \exp \left[ -\frac{5}{4} \left( \frac{\omega_{m}}{\omega} \right)^{4} \right], \]  

where \( \omega_{m} \) is the peak frequency, \( g \) is the acceleration due to gravity, \( \omega \) is the frequency and \( \alpha = 0.0081 \). Other processes related to dispersion include turbulence and ocean currents. These act on a larger scale than the wave dispersion considered here and are discussed elsewhere (Craig and Banner 1994, Sanderson and Pal 1990).

**Diffusion at the Surface of a Random Sea**

The diffusion of tracers at the sea surface due to wave action has been investigated by Herterich and Hasselmann (1982) who consider the random fluctuations in the Stokes drift velocity,

\[ \langle u_{z} \rangle = 2 \int F_{\eta}(k) \omega k e^{2kz} d^{2}k \]

where angle brackets denote ensemble averaging, \( \omega \) is the frequency, \( z \) is the vertical distance, \( k \) is the wavenumber and the two-dimensional wave spectrum \( F_{\eta}(k) \) is normalized to the mean-square surface displacement of the wave. Herterich and Hasselmann (1982) show that, provided the surface spectrum can by expressed as \( F_{\eta}(\theta, \omega) = f_{\eta}(\omega)S(\theta) \) where \( S(\theta) \) is a directional spreading function, the dispersion of particles is governed by a mean advection velocity and a diffusion tensor \( D_{ij} \) which is associated with the random wave-surface. The mean advection velocity is simply the means Stokes-drift velocity. For a single particle the diffusion tensor is given by

\[ \begin{pmatrix} D_{xx} & D_{xy} \\ D_{yx} & D_{yy} \end{pmatrix} = \frac{\pi}{4g^{2}} \int_{0}^{\infty} \omega^{6} f_{\eta}^{2}(\omega) \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} S(\theta_{1})S(\theta_{2}) [1 + \cos(\theta_{1} - \theta_{2})]^{2} M_{ij} \theta_{1} \theta_{2} d\omega 

\]

where, provided \( S(\theta) \) is symmetric about \( \theta = 0 \), we have \( M_{xx} = (\cos \theta_{1} + \cos \theta_{2})^{2} \), \( M_{yy} = (\sin \theta_{1} + \sin \theta_{2})^{2} \), \( D_{xy} = 0 \) and \( D_{yx} = 0 \).
Diffusion Below the Surface of a Random Sea

The derivation of equation (3) is not reliant on the particle being on the surface and can equally be applied at any depth provided the horizontal displacement spectrum is known. To find this spectrum we model the surface, \( \eta \), of a random sea by

\[
\eta(x, y, t) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} d\Phi(k_x, k_y, \omega) e^{i(k_x x + k_y y - \omega t)}
\]

where \( k_x \) and \( k_y \) are the \( x \)- and \( y \)-components of the two-dimensional wave number and \( \{d\Phi\} \) is a stochastic, typically complex, function representing an innovation process which incorporates all the random features of the sea surface. Assuming that the fluid is irrotational and so can be described in terms of a potential, \( \phi \), which is separable: \( \phi(x, y, x, t) = \alpha(x) \beta(x, y, t) \), then we can solve the Laplace equation for the surface, equation (4), to find the displacements \( \xi_j(x, y, z, t) \). This is done in a manner analogous to the standard solution for a monotonic surface wave (\( \eta = Ae^{i(kx - \omega t)} \)) (Lighthill 1978) subject to the standard boundary conditions: no vertical motion at the bed; the vertical velocity at the surface is given by \( \partial\eta/\partial t \); and the Bernoulli equation is satisfied at the surface. With these boundary conditions the displacements are found as

\[
\xi_j(x, y, z, t) = \int_{0}^{\infty} \int_{0}^{2\pi} \int_{-\infty}^{\infty} \frac{a_j}{\sinh(kh)} d\Phi(k, \theta, \omega) e^{i(kx \cos \theta + ky \sin \theta - \omega t)},
\]

where

\[
a_x = i \cos \theta \cosh[k(z + h)],
\]

\[
a_y = i \sin \theta \cosh[k(z + h)],
\]

\[
a_z = \sinh[k(z + h)],
\]

\( h \) is the mean water depth and \( j = x, y, z \). Invoking the properties of \( \{d\Phi\} \) we can express

\[
f_z(\omega; z) = \left( \frac{A_z}{\sinh(Kh)} \right)^2 f_\eta(\omega),
\]

where \( f_z \) is the vertical displacement spectra and \( A_z = a_z|_{k=K} \) where \( K \) is a solution of \( \omega^2 = gK \tanh(Kh) \). Thus, replacing \( f_\eta(\omega) \) with \( f_z(\omega; z) \) in equation (3), we can calculate the diffusion tensor \( D_{ij} \) at any depth for any appropriate surface spectrum. We note here that the diffusion arises from considering the higher-order Stokes-drift term while the expression for \( f_z(\omega; z) \) is only considered in the linear limit. This is a valid approach since higher-order terms will only have a small affect on the form of the displacement spectra below the surface and hence on the calculated diffusion terms.

For the Pierson-Moskowitz surface spectrum the diffusion tensor at the surface can be written

\[
D_{ij} \propto \omega_m^{-3} D_{ij}^s \quad \text{where} \quad D_{ij}^s \text{ is a non-dimensional function of } S(\theta).
\]

The peak frequency, \( \omega_m \), is given by \( \omega_m = 0.280 \pi g/U \) where \( U \) is the wind speed measured 19.5 m above the sea height. This means that once the surface diffusion coefficients have been calculated for one velocity, for a given \( S \), they can be found for any other velocity using the scaling relationship \( D_{ij}(U_1) = (U_2/U_1)^3 D_{ij}(U_2) \). In three dimensions the same surface relation

\[
\text{COASTAL ENGINEERING 1998} \quad 3555
\]
Figure 1: The value of $D_{xx}$ and $D_{yy}$ calculated for a Pierson-Meslowitz surface spectrum with $S(\theta) = 2 \cos^2(\theta)/\pi$ for a wind speed $U = 20 \text{ ms}^{-1}$ and a water depth of 100 m. Also shown are results calculated for wind speeds $U = 25, 15, 10$ and 5 $\text{ms}^{-1}$ after they have been scaled by equation (9) to align them with the results for $U = 20 \text{ ms}^{-1}$.

must hold for $D(U, z = 0)$. Below the surface we note that the $z$-dependence appears only in the integral

$$\int_0^\infty \omega^6 f^2(\omega; z) d\omega \quad (8)$$

as a product $kz$ which in deep water can be expressed $\omega^2 z/g$. In this integral the function $f(\omega; z)$ is negligible except close to $\omega_m$ so we find, to a good approximation, the following scaling relation for different values of $U$:

$$D(U_2; z) = \left[ \frac{U_2}{U_1} \right]^3 D(U_1; \left[ \frac{U_1}{U_2} \right]^2 z) \quad (9)$$

This allows us to predict the value of $D$ at different depths and different wind speeds from a knowledge of $D$ for any $U$. Figure 1 shows $D_{xx}$ and $D_{yy}$ plotted against $z$ for a wind speed $U = 20 \text{ ms}^{-1}$ in water of depth 100 m. Also shown are the values of $D_{xx}$ calculated
for $U = 5, 10, 15$ and $25 \text{ ms}^{-1}$ after they have been scaled according to equation (9) to align them with the $U = 20$ result. The good agreement validates the use of equation (9). Also shown in figure 1 is the difference between $D_{xx}$ and $D_{yy}$ for the spreading function $S(\theta) = 2 \cos^2(\theta)/\pi$, where $D_{xx}$ describes diffusion in the mean wind direction and $D_{yy}$ in the direction perpendicular to the mean wind. As expected $D_{xx} > D_{yy}$ for all values of $z$. In fact, for any $z$ the ratio $D_{xx}/D_{yy}$ is a function of $S(\theta)$ and independent of $z$. Thus the good agreement of $D_{xx}$ between the results for different wind speeds is also true for $D_{yy}$.

**Diffusion of Particles Denser Than Water in a Random Sea**

The above theory allows us to calculate diffusion rates for particles on the sea surface or at a fixed depth below the surface. We now wish to consider particles which do not remain at a fixed depth. To demonstrate how this can be done we consider, as an example, a particle denser than water falling through the sea under gravity. A particle with density $\rho > \rho_w$, the density of water, initially at the sea surface, will sink to the bottom. As it does so it will diffuse in the horizontal directions according to the diffusion tensor $D_{ij}(z(t))$ where $z(t)$ is the particle’s vertical position as a function of time. Neglecting any vertical motion due to the wave action, since there is no vertical drift or diffusion (Herterich and Hasselmann 1982), the vertical velocity $w$ of a spherical particle of radius $a$ can be found by considering the forces acting on it. Gravity is acting with force $-4\pi a^3 \rho g/3$, there is a buoyancy force $4\pi a^3 \rho_w/3$ and there is a drag force $-6\pi \mu a w$, where $\mu$ is the fluid viscosity. This gives

$$w(t) = A_{\rho w} \frac{\rho_w - \rho}{\rho} g \left(1 - e^{-t/A}\right)$$

where

$$A_{\rho w} = \frac{2 a^2}{9 \mu}.$$  \hspace{1cm} (10)

The vertical position of the particle is therefore given by

$$z(t) = A_{\rho w} \frac{\rho_w - \rho}{\rho} g t + A_{\rho w}^2 \frac{\rho_w - \rho}{\rho} g \left(e^{-t/A} - 1\right)$$

for $t < t^*$ where $z(t^*) = -h$. Thus we can calculate the vertical position $z(t)$ and the ensemble average of the square of the difference between the components of the particles horizontal position at time $t$ and it’s ensemble position at time $t$, $\langle (x(t) - \langle x(t) \rangle)^2 \rangle$ and $\langle (y(t) - \langle y(t) \rangle)^2 \rangle$, which are given by

$$\left( \frac{\langle (x(t) - \langle x(t) \rangle)^2 \rangle}{\langle (y(t) - \langle y(t) \rangle)^2 \rangle} \right) = \frac{\pi}{2 g^2} \int_0^t d t_1 \int_0^\infty d \omega \int_{-\pi}^\pi d \theta_1 \int_{-\pi}^\pi d \theta_2 \left[ \frac{\sinh \{k[z(t_1) + d]\}}{\sinh (kd)} \right]^4 f^2_\eta(\omega) S(\theta_1) S(\theta_2)$$

$$\times [1 + \cos(\theta_1 - \theta_2)]^2 \left( \frac{\cos \theta_1 + \cos \theta_2}{\sin \theta_1 + \sin \theta_2} \right)^2.$$  \hspace{1cm} (13)
Figure 2: The value of \(\langle (x(t) - \langle x(t) \rangle)^2 \rangle\) for diffusion parallel to the mean wind direction and \(\langle (y(t) - \langle y(t) \rangle)^2 \rangle\) perpendicular to the mean wind direction for a single particle with radius \(a = 1\) mm falling through the ocean plotted as a function of the vertical position for a random sea state described by a Pierson-Moskowitz spectrum with a wind speed \(U = 10\) ms\(^{-1}\) and spreading function \(S(\theta) = 2\cos^2(\theta)/\pi\). The particle densities considered were 1001, 1005 and 1010 kgm\(^{-3}\) and the density of the ocean was taken to be 1000 kgm\(^{-3}\).

Figure 2 shows the value of \(\langle (x(t) - \langle x(t) \rangle)^2 \rangle\) and \(\langle (y(t) - \langle y(t) \rangle)^2 \rangle\) plotted against the vertical position of the particle for a particle with density 100.1\%, 100.5\% and 101\% of the density of water and radius 1 mm. The surface spectrum is a Pierson-Moskowitz spectrum with \(U = 10\) ms\(^{-1}\), the spreading function used was \(S(\theta) = 2\cos^2(\theta)/\pi\). The water depth is 100 m but only the top 20 m are shown since there is only negligible horizontal motion below this depth and the particle falls vertically to the ocean bed. The graph shows that the majority of the dispersion occurs in the top 10 m (for our choice of wind speed). This is to be expected since the horizontal wave velocities are maximum at the surface and decay exponentially below it. Clearly, the slower the particle falls through the top 10 m of the sea, the longer it is subject to the larger random velocities and so the larger its potential to be dispersed. Thus the closer the particle density is to the density of water, the slower it sinks and the larger its potential to be diffused by the wave motion.
**Conclusion and Discussion**

The dispersion of particles due to random wave motion have been studied. Consideration has been given to buoyant particles on the surface, neutrally buoyant particles suspended in the sea and particles moving through the fluid under the action of gravity. It has been seen that diffusion due to random waves can have a significant affect on the dispersion of particles or pollutants in the ocean. An approximate scaling relationship has been found which relates the diffusion tensor at different depths and different wind speeds. The validity of this relationship has been tested by calculating the diffusion tensor explicitly at different values of $U$ and $z$ and comparing them to the values obtained using the scaling relationship. Of the three cases considered, buoyant particles on the surface, neutrally buoyant particles suspended in the sea and particles dropping through the sea under gravity, particles on the sea surface were subject to the greatest dispersion. Particles suspended (at a constant depth) beneath the surface can also be dispersed by a significant amount if they are close to the surface (within the top 10 m for the values considered here). Particles falling through the ocean are only subject to significant dispersion, due to surface waves, during the time they are in the top 0-10 m of the ocean. Since they are only in this region for a limited time any dispersion is also limited. Below this region particles are virtually unaffected by the surface waves, however, other influences such as currents (Sanderson and Pal 1990) and internal waves (Sanderson and Okumbo 1988) may produce dispersion.

PREDICTING AND EVALUATING TURBIDITY CAUSED BY DREDGING IN THE ENVIRONMENTALLY SENSITIVE SALDANHA BAY

S A Luger¹, J S Schoonees¹, G P Mocke¹ and F Smit¹

Abstract

Extension to the oil jetty at the Port of Saldanha will necessitate dredging of the entrance channel. This study was undertaken to determine the turbidity caused by the dredging and also the transport/dispersion of the dredging plumes. Hydrodynamic and water quality modelling were performed in order to determine the environmental impact of the dredging on the nearby mariculture activities, as well as to investigate possible deposition of mud in the Langebaan Lagoon. Turbidity levels due to storms and shipping were compared with the turbidity caused by the dredging. The environmental impact of the plumes is found to be within acceptable ecological limits and only insignificant sediment deposition is predicted in the Langebaan Lagoon.

1. Introduction

The environmental impact of dredging has recently come under increased public scrutiny within South Africa, especially when dredging is planned in an environmentally sensitive area like Saldanha Bay. The Port of Saldanha, situated 120 km north-west of Cape Town, was constructed mainly for the export of iron ore. Shelter from the swell conditions that occur there was obtained by building a sand (or spending beach) breakwater between the mainland and Marcus Island (Figure 1). A causeway and a jetty (extending 4 km offshore) were built in the lee of this breakwater for the loading of ore and loading/offloading of oil. This causeway divides Saldanha Bay into two: Small Bay and Big Bay (Figure 1). The adjacent Langebaan Lagoon, located some 9 km south of the oil and ore jetty of the Port of Saldanha, is a site of international (Ramsar) ecological significance. Mussel farming is practised within 1 km from the oil jetty, while commercial sea grass production areas are also in close proximity (Figure 1).

Plans to extend the oil jetty will entail dredging of up to 2.5 million m³ of material in order to widen and deepen the entrance channel. Although the dredged material is to be disposed of in a confined disposal area, it is anticipated that "leakage" associated with the dredging will place a quantity of fine sediment into suspension. Transported by the ambient flow regime, the suspended material could conceivably

¹Research engineers, CSIR, P. O. Box 320, 7599 Stellenbosch, South Africa
move throughout the bay in the form of turbid plumes and so impair water quality and the surrounding habitat. An assessment of turbidity phenomena as a result of the proposed dredging operations constituted a specialist study (Mocke et al., 1996) as part of a comprehensive environmental impact assessment.

This paper describes how the anticipated turbidity loading due to the dredging was determined and how the associated suspended sediment concentrations compared with ecological thresholds and estimated turbidity levels due to storms and shipping. (The turbidity loading (in kg/s) is the rate at which sediment is released into the water during dredging.) Also described are the mathematical modelling of the water circulation, wave refraction-diffraction and the dispersion of plumes which were performed to predict the extent and fate of the dredging induced plumes. In general, conservative assumptions were made and conservative values were applied in the study. The rationale behind this approach is that, if the severest or most extreme scenario produces acceptable environmental impacts, then a less severe scenario will be even more acceptable.

2. Environmental Conditions

Saldanha falls in a semi-arid region with mild (air) temperatures. Fog, which may influence dredging operations, occurs between 88 and 111 days throughout the year. The wind regime is dominated by the south-westerly to south-easterly winds (about 57% in total) while the opposing north-easterly to north-westerly winds occur much less frequently (about 24% in total). Wind velocities are below 4 m/s for about 39% of the time and above 10 m/s for about 13% of the time.

A Waverider buoy is situated within Saldanha Bay across from Marcus Island next to the entrance channel. These nearshore measured data show that seasonal differences in wave heights are fairly small. The majority of $H_{\text{rms}}$ measurements (89%) fall within the range 0.5 m to 2 m and the majority of $T$ measurements (73%) within the range 10.7 s to 13.5 s. The wave heights measured in Saldanha Bay are significantly smaller than those measured offshore. Wave directions estimated by voluntary observations from ships in deep water, the so-called VOS data, showed that southerly to south-westerly wave directions are dominant. Wave directions inside Saldanha Bay do not vary as much as those outside the bay.

The tidal range at Saldanha Bay is relatively limited, with neap and spring tidal ranges of 0.5 m and 1.5 m respectively. There are no river inputs into Saldanha Bay.

Wind forcing is the dominant mechanism controlling current direction and magnitudes in both Small and Big Bay. Current speeds are generally low, with some 80% of surface currents less than 0.12 m/s. Current directions are found to be closely aligned with wind direction, except for surface flow in Small Bay, which is mainly clockwise.

Upwelling occurs from spring to autumn. Surface waters attain a maximum temperature of around 19 °C and the thermocline (at 13 °C) is generally found to be at a depth of between 3 m and 6 m below the surface.

Essentially three sediment types were found, namely, a greyish, medium sand (the most commonly occurring type), silty fine sand and calcrete (limestone). It was found that about 15.5% of the bottom material was fine gravel (between 2 mm and 4
mm) and 72% is relatively fine sand with an average median grain size of around 0.23 mm. The mean percentage of silt/clay (mud) in the bottom material is estimated to be 12.5%, with a median grain size of around 4 micron. The only hard material to contend with during the dredging is hardpan calcrite, which occurs in layers between 0.3 m and 3 m thick. The uniaxial compressive strengths (UCS) of the calcrite varied from 3 MPa to 42.8 MPa with a mean UCS of 18.1 MPa.

3. Conceptual Dredging Plan

3.1 General

A conceptual dredging plan was drawn up so that the turbidity loading caused by the dredging can be determined. This is relevant because the type of dredging and the operation influence the generation of turbidity.

3.2 Dredging Required

The entrance channel to the port needs to be widened and deepened in order to provide access to larger ships. Up to 2.5 million m$^3$ of material has to be dredged in order to deepen the channel between 0.8 m and 1.3 m (the depth of cut for the dredger varies between 0.8 m and 10 m).

3.3 Physical Conditions Affecting the Dredging

The sediment type has a profound influence on the performance of the dredger and is thus a key element in deciding what type(s) of dredger should be used. The bottom material consists mainly of medium to fine sand interspersed between "moderately strong" calcrite layers. It is important to note that the thickness of these layers is on average 1.5 m. This means that they will not be broken out easily.

Wave action mainly adversely affects the vertical movement of the dredger. This is a problem particularly when cutting hard material because vertical movement causes damage to the cutting device. A $H_{max}$ of 0.8 m will be exceeded between 10% (protected part of the channel) to 80% (outer part of the channel). Currents make marine operations more awkward due to the difficulty of maneuvering and of obtaining good anchorage for the dredger. Normally the current velocities are between 0.10 m/s and 0.20 m/s. Weather conditions such as rain and temperature should not cause problems with the dredging. This is because Saldanha lies in the semi-arid region which does not experience extreme temperatures. Wind makes the manoeuvring of all vessels more difficult and it can cause the dragging of anchors. Wind speeds exceeding 10 m/s occur about 13% of the time. Fog could influence dredging operations because of the limited visibility for about 88 to 111 days per year. However, because of modern position fixing systems and radar, it is unlikely that dredging operations would have to be suspended due to fog.

3.4 Spoil Disposal

The bottom material, being mainly medium to fine sand and calcrite, is generally suitable as fill material. The dredger spoil is thus considered a valuable resource which should be stored for later use during port extensions. The disposal of the dredger spoil will most probably be a land-based operation. It has been assumed that
special precautions will be taken such as using stilling ponds. Therefore virtually no sediment-laden water will reach the sea. The marine environmental impact of plumes from the disposal area will therefore be negligible and will not be considered further.

3.5 Conceptual Dredging Plan

The conceptual dredging plan proposed is that a medium to large cutter suction dredger be used to dredge the medium to fine sand and the calcrete (blasting the calcrete will not be necessary). Dredging is expected to be done 24 h a day at a rate of about 1 100 m³/h (a high production rate is required to limit the dredging period to 3 to 4 months). The down-time for a large cutter suction dredger was estimated to be between 10% and 80%, depending on where you dredge along the entrance channel. Disposal will take place by means of a pipeline to the reclamation site from where virtually no sediment-laden water will reach the sea. All the dredger spoil will be stored to be used as fill. The first section of pipe from the dredger will be a floating line to a large pontoon from where the rest of the pipeline will be submerged up to the causeway/ore jetty. From there the pipeline will run on land. A booster pump station will be necessary because of the distance between the dredger and the disposal site.

An alternative way of dredging could be by using a combination of a trailing suction hopper dredger and a cutter suction dredger. In this assessment only the most obvious dredging method, namely, of using a cutter suction dredger, has been analysed further.

4. Turbidity

4.1 General

The main purpose of this chapter is to determine the turbidity loading as caused by the dredging. The secondary purpose is to compare the turbidity caused by the dredging with the background turbidity and the estimated turbidity levels due to storms and shipping. It is believed that the background turbidity levels in Saldanha Bay are quite low (usually below 20 mg/l); however, this is based on very limited data which do not cover extreme conditions.

In order to determine the turbidity loading, it is necessary to know the settling velocities of the sediment fractions (Section 4.2) and the turbidity that will be generated at the dredger (Section 4.3) respectively. The turbidity loading is addressed in Section 4.4. Section 4.5 is a comparison of the turbidity caused by shipping and storms with turbidity due to dredging.

4.2 Settling Velocities

The settling velocity distributions of the sand were obtained in a standard settling tube. The average median settling velocity of the sand fraction was 0.023 m/s.

Laboratory tests were done to determine the settling velocity of the mud (silt and clay) fraction. These tests were done for a range of initial concentrations from 100 mg/l to 10 000 mg/l, with most of the tests done at 150 mg/l and at an average water temperature near the seabed of 13 °C. The 150 mg/l is the ecological threshold, determined from the level at which negligible effects on the mariculture will be found (Carter, 1995). All the tests were done in seawater taken from the site so as to ensure
the correct salinity and typical background turbidity (and thus typical organic material in the water). A pipette withdrawal tube was used to determine the distributions of the settling velocity. Because limited variation in the settling velocity distributions was found, it was decided to schematise the settling velocity of the mud into three parts:

<table>
<thead>
<tr>
<th>Fraction of the mud</th>
<th>% of the mud</th>
<th>Mean settling velocity (mm/s)</th>
<th>Conservative settling velocity (mm/s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Part 1</td>
<td>30</td>
<td>0.05</td>
<td>0.005</td>
</tr>
<tr>
<td>Part 2</td>
<td>40</td>
<td>0.50</td>
<td>0.19</td>
</tr>
<tr>
<td>Part 3</td>
<td>30</td>
<td>2.00</td>
<td>1.25</td>
</tr>
<tr>

<td>0.45</td>
</tr>
</tbody>
</table>

These values correlate well with the typical range of values (0.01 mm/s to 10 mm/s) given by Berlamont et al. (1993) and the typical value (0.21 mm/s) for the Øresund link (Broker et al., 1994) given for chalk/limestone (supposedly similar to the Saldanha calcrete).

4.3 Turbidity at the Dredger

The turbidity at the dredger was determined in two different ways: (1) measurements of turbidities around cutter suction dredgers at other sites around the world were used and compared with the environment at Saldanha; and (2) a comparison with the turbidity caused by different types of dredgers was used. According to Van Wijck et al. (1991), a cutter suction dredger causes about twice the turbidity associated with bucket-ladder and trailing suction hopper dredgers. For a seabed grab the ratio is 2.7. In this way the measurements of turbidity caused by other types of dredgers could be used to estimate roughly the turbidity that could be found around a cutter suction dredger.

Van Raalte and Blokland (1988) and Pennekamp and Quaak (1990) defined a number of variables related to turbidity:

\[ t = \text{time for the turbidity to decline to the background levels after cessation of dredging} \]

\[ S = \text{the amount of sediment which is lost by suspension from the immediate vicinity of the dredger (kg of dry material per m}^3\text{dredged).} \]

Typical values for these variables are discussed below.

Kirby and Land (1991) did a comprehensive study of the turbidity generated by different dredgers. For cutter suction dredgers they found that a maximum of 1 100 mg/l was measured immediately adjacent to the cutter head. The turbidity decreased rapidly from the dredger to only a few tens of mg/l (20 mg/l to 90 mg/l) at a distance of 50 m away from the dredger. The turbidity was not influenced by the size of the cutter suction dredger. For normal operations, S is about 6 kg/m^3 while it is approximately 3 kg/m^3 if the dredger works with reduced swing and rotation speeds. Huston (1976) found in a series of tests an increase in turbidity (which varied considerably) above background levels only in the immediate vicinity of the cutter head. Little turbidity reached the water surface, especially from depths of 12 m and more. Yagi et al. (1976) recorded turbidity of generally less than 210 mg/l with a depth-averaged value of approximately 70 mg/l.
If one applies the ratios of 2 and 2.7 for the respective dredgers by Van Wijck et al. (1991) and calculate the equivalent turbidities that can be expected for cutter suction dredgers, one obtains a mean turbidity of about 250 mg/l. This corresponds reasonably with the values derived from measurements for cutter suction dredgers.

Based on these findings and also on the measurements reported by Kuo et al. (1985) and Nichols et al. (1990), the turbidity and the initial diameter of the sediment plumes were estimated. The conditions of the sites at which the above-mentioned turbidities were measured were compared to the conditions at Saldanha Bay. For example, the currents of between 0.10 m/s and 0.20 m/s at these sites correspond well to the Saldanha case. The following table was compiled for Saldanha as input to the plume modelling:

<table>
<thead>
<tr>
<th>Plume scenario</th>
<th>Mean concentration over height of the water column (mg/l)</th>
<th>Height of plume column* (m)</th>
<th>Initial plume diameter (m)</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>100</td>
<td>10-15</td>
<td>50</td>
<td>best estimate; still somewhat extreme</td>
</tr>
<tr>
<td>2</td>
<td>300</td>
<td>15</td>
<td>100-250</td>
<td>best estimate of extreme turbidity duration</td>
</tr>
</tbody>
</table>

*The height of the plume column is the height above the sea bottom up to where the suspended sediment extends (which can be less than the water depth).

The turbidity caused by previous cutter suction dredging during two previous projects in Saldanha Bay has not been measured before. Photographs, however, show light coloured plumes which were mainly confined to the vicinity of the dredgers. These plumes were mainly caused by chalk particles being suspended in the water during the cutting of the calcrete layers.

Van Raalte and Blokland (1988) and Pennekamp and Quaak (1990) found that within about 0.5 h to 1 h after dredging (of mainly mud), the turbidity returned to the background levels. Aerial photographs and observations by the port pilots confirmed these values of t: within about 0.5 h to an absolute maximum of 2 h, the plumes caused by shipping in Saldanha Bay are no longer visible.

Using the S values of 3 kg/m$^3$ to 6 kg/m$^3$ given by Kirby and Land (1991) for cutter suction dredgers, the percentage leakage can be determined if the $in situ$ density of the bottom material is known. Assuming typical densities between 1 600 kg/m$^3$ and 1 800 kg/m$^3$, leakages of 0.2% to 0.4% were obtained. Kuo and Hayes (1991) give leakage percentages for bucket-ladder dredgers of 0.11% to 3%. Nichols et al. (1990) recorded a value of 12% for a trailing suction hopper dredger. Broker et al. (1994) quoted an upper limit value of 5% based on test dredging; this is a combined figure for the whole dredging operation (the type of dredging is not given). Based on these values the following leakage scenarios have been assumed for Saldanha: (1) 0.4% - 2% (best estimate, still somewhat conservative); and (2) 12.5% (best estimate of extreme turbidity generation, assumes that all fines will be lost).
4.4 Turbidity Loading

Four different approaches were used to determine the turbidity loading at the dredger, namely:

1. A sediment balance (based on continuity considerations) was drawn up to calculate the loading required to achieve the turbidities obtained in the two plume scenarios given above. Essentially the method supposes that the sediment entering a cylindrical element of the water at the dredger is balanced by settling and transport of material out of the cylindrical zone of initial mixing. Lateral mixing is ignored, which is slightly conservative. It is also assumed that an equilibrium will be reached soon after the start of dredging.

2. The percentages of leakage were combined with the possible production rate of the dredger to obtain the turbidity loading. Note that this method is independent of the turbidities that have been estimated to occur around the dredger.

3. The behaviour of the turbidity plumes was considered in two dimensions and averaged over depth by using the advection-diffusion equation. This equation was solved with the modelling approach of Kuo and Hayes (1991) by assuming different loadings to obtain the required turbidity in the plume as given above as the plume scenarios (Section 4.3).

4. The results acquired with the above-mentioned three approaches were correlated with turbidity loadings given in the literature. This was done to verify the results from other methods.

Two turbidity loadings were recommended for use in the plume modelling, namely: (1) 9 kg/s (best estimate loading, still somewhat conservative); and (2) 70 kg/s (best estimate of extreme loading). The 70 kg/s was determined by assuming pipeline failure (which is unlikely), the duration thereof and where it will occur. The turbidity loading was determined by assuming that all the fines (12.5% of the material) will stay in suspension whilst the sand and gravel will settle out. By using the production rate of 1 100 m$^3$/h, the turbidity loading of 70 kg/s quoted above was obtained. This value was checked by computing the pumping rate in the pipeline. Good agreement was found. Very conservatively, it was determined that the duration of the turbidity loading is 12 h. The place where pipeline failure would have the biggest impact is in the turning circle of the entrance channel because it is the closest to the mussel rafts. It was assumed in the modelling that the failure will occur in this most critical area.

4.5 Turbidity Caused by Shipping and Storms

Shipping

It is expected that, after the expansion of the oil transfer operations, about 297 ships will visit the port annually, that is, about one ship every 1.2 days.

Detailed turbidity measurements at Rotterdam during the normal passage of a bulk carrier (of similar size as the ships expected at Saldanha), revealed no increase in the turbidity (Pennekamp et al., 1991). This is despite the fact that the bottom sediment is predominantly mud. Kirby and Land (1991) found, during the passage of a vessel in the Lower Rhine with a muddy bottom, that the disturbed sediment soon settled. This is in accordance with the results by Hochstein and Adams (1989) in St Mary's River in the
USA/Canada. The bottom material there was smaller than 0.075 mm and yet they found no noticeable degradation of water quality. This they attributed to the sediment settling within the 34 minutes before another ship passes. Recalling from above that for dredging, it took about 0.5 h to 1 h for the turbidity to decline to background levels. Compare these values to the 1.2 days between ships expected at the port. This means that most of the material in suspension will settle before the next ship arrives. It can therefore be concluded that normal sailing contributes very little to turbidity (Kirby and Land, 1991).

Because turbidity is mainly caused during manoeuvring such as turning and berthing, this aspect should be considered further. From the literature, measurements at 5 sites (including Saldanha) show that the increase in the turbidity due to shipping is typically between 100 mg/l and 210 mg/l (Pennekamp et al., 1991, Pennekamp and Quaak, 1990 and Kirby and Land, 1991). These values show that the increase in turbidity is not very large despite the fact that the bottom material is mud. The bottom material in the enlarged turning circle will be medium sand with some calcrete layers present. Comparing this material with the soft mud that was encountered during the above-mentioned measurements (except possibly Saldanha), it is clear that turbidities will generally be lower at Saldanha than the values quoted above. This is enhanced by the calcrete layers which armour the sea bottom and reduce the suspension of material.

It can therefore be concluded that it is unlikely that the turbidity caused by shipping, even during manoeuvring, will be significant at Saldanha during the operation of the extended oil jetty. Most of the time the turbidity caused by shipping in its immediate vicinity will be below the ecological threshold of 150 mg/l.

**Storms**

For a large number of sites from around the world, depth-averaged sand concentrations (turbidities) that were measured outside the surf zone ranged from 29 mg/l to 901 mg/l (Van Rijn, 1991). In a review Appleby and Scarratt (1989) found natural turbidity levels in estuaries of up to 1 200 mg/l. High turbidities therefore occur naturally. Sand concentrations were computed for 4 typical storms. Two different models were applied to calculate the sand concentration, namely, those of Van Rijn (1989) and Schoonees (1998). Most of the depth-averaged concentrations ranged between 8 mg/l and 80 mg/l. The two approaches yielded reasonably similar results although the Van Rijn (1989) formulation showed a wider range. Typical turbidities due to the suspension of the fine fraction were estimated by assuming that all the fines will be washed out of a layer of material on the sea bottom. These fines are then supposed to be redistributed in the water above the layers from where they originated. Typically the increase in turbidity due to the fines (mud) will range between approximately 10 mg/l and 60 mg/l.

In the study in the Thames River and the eastern Long Island Sound, Sosnowski (1984) found that the concentrations during storms are nearly an order of magnitude larger than those due to dredging. Dredging induced suspension was found to be a near-field or local phenomenon while storms have a regional impact. When comparing the dredging induced turbidity at the dredger at Saldanha with natural fluctuations during storms, it is clear that the concentrations are of the same order of magnitude. It can therefore be concluded that the turbidity that will be encountered during dredging...
will be similar to that occurring naturally during storms.

5. Modelling of Wave and Current Regimes

5.1 Waves

Modelling of the wave refraction/diffraction was done for two reasons: (1) to determine what effect the deepening and widening of the entrance channel would have on wave conditions throughout Saldanha Bay and therefore if the coastline would be affected by the dredging; and (2) the wave regime inside the bay was required in order to be able to calculate bed shear stresses due to wave and current action. Because the effect of the dredging on the coastline does not form part of this paper, only results related to the second objective will be considered.

The scope of the study did not allow for a comprehensive numerical refraction/diffraction study of the total deep water wave climate. Instead a number of average and extreme wave conditions was modelled using both the present bathymetry and a post dredging bathymetry as input. Wave conditions were decided upon based on the wave data described in Chapter 2.

A widely used wave refraction model, Hiswa (Holthuijzen et al., 1989), was used to transform the deep-water waves through nested grids up to the entrance of Saldanha Bay. As Hiswa allows only for wave refraction to be calculated and not wave diffraction, a wave refraction/diffraction model based on the mild slope equation was used to transform waves from the entrance into the bay.

Figure 2 contains a plot of wave heights for an average deep-water wave condition of $H_m = 2 \text{m}, T_p = 12 \text{s}$ and a deep-sea direction of south-west. From this figure it can be seen that wave heights along the south-eastern beaches of Big Bay are for the most part less than 1.2 m with the highest waves occurring opposite the entrance to the bay. Diffraction around the sand breakwater ensures that waves with heights in the order of 0.2 m to 0.4 m enter Small Bay.

5.2 Currents

The Delft3D-FLOW hydrodynamic model (WL|Delft hydraulics, 1996a) was used to simulate the three-dimensional flow regime in the semi-enclosed Saldanha Bay system. The processes included in the model were tidal forcing, wind forcing, Coriolis effects, baroclinic flows due to thermal stratification and the drying and flooding of tidal flats in the lagoon. The model uses constant eddy viscosity and diffusivity coefficients in the horizontal direction while a k-ε turbulence model is used in the vertical direction. An orthogonal curvilinear grid with cell sizes ranging from 200 m in the areas of interest to 1 000 m near the model boundary was used in the horizontal direction, with eight o-coordinate layers used in the vertical.

The model was calibrated based on current and water temperature data measured at four locations in the bay for a 12 day period. Measured wind, water level and thermistor string data were used at the model boundaries. The following coefficients were found to give the best correlation to the measured data: Chezy coefficient for bottom friction = 65 m$^0$Vs, horizontal eddy viscosity = 1 m$^2$/s, horizontal eddy diffusivity = 0.5 m$^2$/s, wind coefficient = $6.3 \times 10^{-4} + 6.6 \times 10^{-5} U_{10}$ (Smith and Blanke, 1975) where $U_{10}$ is the wind speed 10 m above the water surface. Figure 3
indicates a good comparison between the measured data and model currents. The water temperature is modelled less accurately since in this case the air-sea interaction module was not used and the thermal stratification is driven by the imposed open boundary conditions only.

Figure 4 depicts the predicted three-dimensional current structure at outgoing and incoming tides with a 10 m/s south-westerly wind under non-stratified conditions. The predicted current magnitudes are generally below 0.5 m/s, except in the constriction at the entrance to Langebaan Lagoon where currents may exceed 1.0 m/s at spring tide. Under stratified conditions and the dominant southerly winds, the exchange between the bay and the adjacent shelf revealed cold water entering the bay near the seabed on the incoming tide and warmer water leaving the bay near the surface on the outgoing tide. This phenomenon will have a significant impact on the supply of nutrients to the primary producers and thus the mariculture activities in the bay as well as on the residence time of pollutants in the bay.

6. Turbid Plume Dispersion

The Delft3D-WAQ water quality model (WL|Delft hydraulics, 1995, 1996b) was used to simulate the advection, dispersion, settling and deposition of the turbid plumes arising from the dredging operations. This model solves the advection-diffusion equation in three dimensions including settling of particles and deposition or erosion based on specified critical shear stresses. The bed shear stress is computed as the sum of the stress due to currents and waves. The hydrodynamic database is obtained from the Delft3D-FLOW simulation via an offline coupling.

The silt/clay material (< 63 microns) was subdivided by mass into three fractions each with a characteristic settling velocity and a critical shear stress for deposition. Settling velocities of 0.05 mm/s, 0.5 mm/s and 2.0 mm/s (Section 4.2) and corresponding critical deposition shear stresses of 0.1 Pa, 0.2 Pa and 0.3 Pa were used in the simulations.

As discussed in Section 4.4, a best estimate loading of 9 kg/s for material less than 63 microns and an extreme loading of 70 kg/s due to a failure of the pipeline from the dredger were simulated. Based on occurrence statistics, a representative range of winds, tides and wave heights was selected. The model was used to obtain the following output: contour plots of the maximum turbidity for each scenario, maximum turbidity and exposure times at the ecologically-sensitive sites in the bay as well as contour plots of the deposition thickness throughout the bay upon completion of dredging. Figure 5 shows the predicted turbidity plume due to the extreme loading case of 70 kg/s.

The turbidity at the ecologically sensitive sites was predicted to be below 25 mg/l, which is within the range of the natural background turbidity. Wave-generated bottom shear stresses were found to have a significant influence on the results by inhibiting deposition of the finer mud fractions in the exposed areas of the bay and thus causing a pervasive spreading of these particles into the lagoon and also out to sea. The maximum deposition thickness in the lagoon, however, totalled less than 2 mm over the dredging duration of 4 months. Based on these results the ecological impact of the proposed dredging was predicted to be low.
7. **Conclusions and Recommendations**

The turbidity loading caused by the proposed dredging could be determined with reasonable accuracy. The circulation in Saldanha Bay was well modelled, with predicted currents generally below 0.5 m/s, except at the entrance to Langebaan Lagoon where currents may exceed 1 m/s under spring tidal conditions. The turbidity at the ecologically sensitive sites was predicted to be below 25 mg/l, which is within the range of the natural background turbidity and far below the ecological threshold of 150 mg/l. Wave action will inhibit deposition of the finer mud factions in the exposed areas of the bay, thus causing a pervasive spreading of these particles into the lagoon and also out to sea. The maximum deposition thickness in the lagoon will, however, be insignificant. These results showed that the environmental impact of the plumes will be within acceptable limits.

It was found that the turbidity caused by the dredging (having a local effect) will be of a similar order to that occurring naturally during storms (a widespread effect). The turbidity caused by shipping is short-lived and not significant.

It has been recommended that the background turbidity levels be monitored before commencement of the dredging, particularly under storm conditions. In addition, it is required to measure the turbidity levels in the vicinity of the dredging and in the ecologically sensitive areas while dredging is taking place.

SIMULATION OF THE BEHAVIOR OF OXYGEN-DEFICIT WATER IN TOKYO BAY BY THREE-DIMENSIONAL WATER QUALITY MODEL

Nobuo Mimura¹, Member ASCE, Mitsuhiro Tsukada² and Masaharu Suzuki³

ABSTRACT

Semi-enclosed bays have been suffering from eutrophication in many countries. The present study deals with simulation of this problem focusing on Tokyo Bay, Japan. Tokyo Bay faces blue tides and fish death events caused by the oxygen-deficit water formed in the bottom layer during summer. To study the formation of the oxygen-deficit water, a model is developed to simultaneously simulate the flow, density stratification, and the material circulation in the ecosystem. The behavior of oxygen-deficit water, such as formation, growth, and stagnation, in Tokyo Bay is reproduced and examined by the model. The present model is effective in studying the temporal and spatial changes in water quality in a detailed manner. Moreover, countermeasures such as reduction of the land-based pollutant loads and sand capping on the polluted bottom mud are also examined.

1. Introduction

Semi-enclosed bay such as Tokyo Bay, Japan, have been suffering from water pollution. Tokyo Bay is about 65km and 25km long in the longitudinal and transverse directions, and 1,200km² in surface area. The inner part is occupied by shallow sea of less than 20m deep. The bay is surrounded by the Tokyo metropolitan area, where about 30 million people live, and major ports and industrial belts exist. Six major rivers flow into the bay, and the total fresh water inflow is about 325m³/s including these rivers. From these settings, the organic nutrients loads to Tokyo Bay are extremely large(Fig.1).

¹ Professor and ² Graduate Student, Center for Water Environment Studies, Ibaraki University, 4-12-1 Nakanarusawa, Hitachi, Ibaraki 316-8511, Japan

One of the major problems in Tokyo Bay is the formation of the oxygen-deficit water in the bottom layer during summer, which often causes blue tides and fish death by suffocation. The oxygen-deficit water is generated under specific combinations of the flow, density stratification, and the material circulation in the ecosystem. Therefore, a model with simultaneous equations for flows, density distribution, and ecosystem is needed to realistically calculate the processes related with water quality.

In this paper, a three-dimensional numerical model is developed to simulate the formation, growth, and stagnation of the oxygen-deficit water in Tokyo Bay. Then the spatial and temporal changes in water quality in 1993 are reproduced to trace the detailed behavior of the oxygen-deficit water mass.

2. Three-Dimensional Water Quality Model

The present model consists of three sub-models for flow field, density field, and material circulation in the ecosystem.
(1) Flow and density fields
The equations of continuity and momentum conservation are discretized by an FDM scheme on a three-dimensional grid system (Mimura et al., 1993; Kobayashi et al., 1995). Since the period of simulation often exceeds a year, an effective and stable method of computation is required. For this purpose, a special scheme to implicitly solve the terms of vertical turbulent transfer of momentum and pressure gradient is used (Sato et al., 1993). As boundary conditions, temporal records of tidal elevation at the bay mouth, wind stresses, and river discharges are given from field observations.

The density sub-model consists of the diffusion equations of heat and salinity. At the water surface, heat exchange by solar radiation, long-wave radiation, and sensible and latent heat transfer by evaporation are taken into consideration. Inflows of freshwater by rainfall and river discharge are also included. These terms are calculated by giving the time histories of the observed data for atmospheric temperature, solar radiation, wind etc as mentioned later.

(2) Material circulation in the ecosystem
In this sub-model, ecosystem is represented as a network of material flows among the components of phytoplankton, zooplankton, detritus, dissolved organic matter, phosphate, and inorganic nitrogen as shown in Fig. 2. The key elements and nutrients, such as carbon, nitrogen and phosphorus, are stored in these components, and transported among them. As a result of such material flow, water quality changes. Chemical oxygen demand (COD) and dissolved oxygen (DO) are taken as the indices of water quality. The governing equations of the ecosystem sub-model are the diffusion equations with bio-chemical process terms.

\[
\frac{\partial B}{\partial t} + U \frac{\partial B}{\partial x} + V \frac{\partial B}{\partial y} + W \frac{\partial B}{\partial z} = \frac{\partial}{\partial x} \left( K_x \frac{\partial B}{\partial x} \right) + \frac{\partial}{\partial y} \left( K_y \frac{\partial B}{\partial y} \right) + \frac{\partial}{\partial z} \left( K_z \frac{\partial B}{\partial z} \right) + \Delta B
\]

where, \(U, V\) and \(W\) are velocity components, and \(K_i\) is diffusion coefficient in \(x, y,\) and \(z\) directions.

The bio-chemical process term, \(\Delta B\), expresses the temporal change in the concentration of each component. In the case of phytoplankton, this term includes photosynthesis, respiration, extracellular release, and grazing by zooplanktons. These processes are modeled by empirical and semi-theoretical relationships obtained in the existing studies. Equations to represent the relationships are shown in Fig.3 in a conceptual manner (Nakata, 1993). The factors controlling the rates of changes are given as empirical equations. Regarding the material flow, changes in carbon (C) flows are calculated first, then the contents of other nutrients, i.e. nitrogen (N) and phosphorus (P),
Figure 2 Material flow in the ecosystem

are determined based on the empirical ratios of N/C and P/C. The DO consumption of each bio-chemical reaction is calculated by the ratio between the theoretical oxygen demand and carbon content (TOD/C).

These equations include the terms for release of nutrients from bottom mud and consumption of DO in the bottom. It was pointed out that such exchange between bottom water and mud is very important, for the bottom mud play a role of significant nutrients' stock. These processes are controlled by the concentration difference of each component between bottom water and mud, water temperature and DO concentration. In this model, equations given by Matsunashi (1993) are used to represent these relationships.

3. Simulation for Tokyo Bay

(1) Grid system
Tokyo Bay is about 65 km long and 25 km wide, and the water depth decreases sharply from 200 m at the bay mouth to less than 20 m in the inner half of the bay. A three-dimensional grid was set in Tokyo Bay as shown in Fig.1. The horizontal grid is 1 km × 1 km, and water depth was divided into 20 layers with variable height. The layer height is 2 m each for the upper layers to reproduce the vertical density distributions precisely, while it is 30 m beyond the depth of 60 m. The time step of the calculation, Δt, is 4 minutes.
Phytoplankton (Phy)
\[ \frac{\partial \text{Phy}}{\partial t} = \text{Photosynthesis} - \text{Extracellular Release} - \text{Respiration} \]

(2) Target year and field data
A serious problem which we faced during the study was lack of observed data. Though the present model can calculate the temporal and spatial changes very in detail, it is difficult to find data obtained in a similar manner for the calibration of the model. After gathering as much data as possible, the data set in 1993 was found to be relatively complete, then 1993 was chosen as the target for the calculation. In 1993, the oxygen-deficit water began to form in the middle of May, and seven blue tide events were recorded from June to September. Therefore, it was tried to hindcast the temporal change of water quality from April to September in 1993.

Initial and boundary conditions used for this calculation were as follows.

1) Water density: Salinity and water temperature were set as 34.3‰ and 14°C respectively, uniform for all grid points.
2) Tide: Observed tidal elevation was given along the boundary of the bay mouth.
3) Climate: Rainfall, solar radiation, cloudiness, direction and speed of wind observed hourly in Tokyo were used.
4) River discharge: Daily records of the discharges were given for six major rivers (Edo R., Ex-Edo R., Ara R., Sumida R., Tama R., Tsurumi R.; Japan River Association, 1995). The salinity of the discharge was assumed 0 ‰, and the concentration of COD and other nutrients were set to be the yearly mean values, i.e. constant.
5) Bio-chemical terms: The bio-chemical components were set as the data observed on March 23, 1993.

4. Comparison of Simulation and Field Data
As mentioned above, there are no data set of water quality obtained continuously for a sufficiently long period of time. The longest record for salinity, water temperature, and DO was found for a month, from August 30 to September 28 in 1993. In order to verify the present model, the simulated results were compared with the observed data. The point of the comparison was Point B in Fig.1.

The comparisons are shown in Fig.4, 5 and 6 for salinity, water temperature, and DO, respectively. Overall agreements between the simulation and observed data are good, indicating that the present model could reproduce the real changes in water quality.

The observation of salinity and water temperature shows that strong density stratification formed in this period, while the difference of salinity and temperature between the surface and bottom layer disappeared on September 4, 13, 17, and 23. This indicates that strong vertical mixing took place during these days. This disruption of the
Figure 4  Comparison between observed and calculated results (Salinity)

Figure 5  Comparison between observed and calculated results
(Water temperature)
density stratification corresponded to the wind condition; it occurred when the speed of southerly or south-westerly wind exceeded 5m/s. This means that such strong vertical mixing might be induced by the breaking of wind waves. On the other hand, the vertical mixing are relatively weak in the simulated results. In the model, the vertical mixing is expressed by the eddy viscosity and diffusivity, and the density effect is represented by a stratification function based on the Richardson Number. Therefore, the mixing term of the present model cannot represent the effect of turbulent mixing from water surface caused by wave breaking.

Regarding DO, the concentration over 10mg/l were observed on September 1, 6, 12, and 17. These events are considered to be supersaturation caused by the blooming of phytoplanktons. During the disruption of the density stratification on September 4, 14, and 18, DO also became uniform in the vertical direction. Though such vertical uniformity was not reproduced, the overall temporal change of DO shows good
agreement with the observed data. The blue tide occurrence corresponded to the upwelling of the oxygen-deficit water from the bottom layer to the shore along Chiba Coast.

5. Behavior of the Oxygen-Deficit Water

(1) Formation and expansion of oxygen-deficit water

From the simulation by the present model, the behavior of the oxygen-deficit water in Tokyo Bay can be examined. Figure 7 shows two different distributions of DO in Tokyo Bay; one is the planar distribution in the bottom layer and the other is the vertical distribution along the A-A' section indicated in Fig.3. The period is from early May to mid June. There have been several definitions of the oxygen-deficit water depending

![Figure 7 Formation and growth of the oxygen-deficit water](image-url)
on the degree of harmfulness to the marine organisms. In the present study, DO of less than 3mg/l was taken as the criterion for the oxygen-deficit water.

On May 3, no significant oxygen-deficit water formed, though there was a water mass with 4mg/l of DO off Chiba Coast. Water mass with 3mg/l of DO appeared for the first time on May 5. It expanded on May 7, and the water mass with 4mg/l of DO covered a large portion of the inner bay surrounding the oxygen-deficit water. On May 11, the water mass with 3mg/l of DO expanded in the inner bay, and water mass with 2mg/l of DO appeared in the middle of it. Until June 12, such expansion of the oxygen-deficit water continued, and the bottom layer of the inner bay was finally covered by strong oxygen-deficit water with less than 1mg/l of DO. After this period, the oxygen-deficit water has been stagnant until September, the end of the computation.

The history of the vertical distribution also shows the formation and growth of the oxygen-deficit water very clearly. It was produced around the innermost place of 10 to 20m deep off Chiba Coast. The expansion of the oxygen deficit water was very quick. After May 5, the density stratification started to be intensified. This is due to the climatic conditions; the atmospheric temperature suddenly increased to 24°C on May 11, and it kept above 20°C during the daytime after then. This climatic condition is the major cause for the rapid formation and stagnation of the oxygen-deficit water in the inner part of Tokyo Bay.

Figure 8 shows the changes in the total volume of the oxygen deficit water mass for the complete period of the simulation. The volume of the oxygen deficit water mass was defined as the volume of water in which DO concentration is less than 3mg/l. The history of the atmospheric temperature for the same period is shown in Fig.9. From these figures, the history of the oxygen-deficit water formation can be understood again. As the water temperature increases in May, the oxygen-deficit water started to form. The volume reached its maximum in early July, then tended to decrease with fluctuation. Amazing thing is that the water mass still exist even at the end of September. These tendency is similar with the real situation qualitatively. However, more accurate quantitative verification needs more data densely measured both in time and space.
Figure 8 Changes in the total volume of the oxygen-deficit water (from April to September, 1993)

Figure 9 Changes in atmospheric temperature (from April to September, 1993)

(2) Up-welling of the bottom water and formation of blue tide
Figure 10 shows the temporal changes of the DO distribution in the surface and bottom layers during 22 to 30 in September. Throughout this period, the bottom layer of the inner bay was covered by strong oxygen-deficit water, while the appearance of the oxygen-deficit water in the surface layer was intermittent. Though DO was almost saturated on September 22, strong oxygen-deficit water suddenly appeared on the next
day, September 23. This is because wind changed to northerly on September 23, then up-welling was brought about by this wind in front of the north-east coast of Tokyo Bay. Actually blue tide occurred in the same area on September 23.

(3) Effect of countermeasures
The usefulness of such model is that it enables to examine the effects of countermeasures. The possible countermeasures for improving the water quality in Tokyo Bay are reduction of the inflow loads and sand capping over to depress oxygen consumption and nutrients release by bottom mud. In the present study, two trials were made for 50% reduction of the inflow loads and sand capping on the area shallower than 10m. Both countermeasures were not effective to improve the formation of oxygen-deficit water. However, they may be effective if the calculation is continued for several years. Since complete boundary conditions for climate, river discharge, tide, etc. are needed for longer simulation, such attempts are left for future studies.

Figure 10 Up-welling of the oxygen-deficit water by wind
6. Conclusions

It is proved that the present model can reproduce the observed spatial and temporal changes in water temperature, salinity and DO rather well. The tendencies of the temporal changes in these parameters are quite similar between calculation and field data through the simulation period of 6 months.

In Tokyo Bay, oxygen-deficit water is generated even in early May in the bottom layer. Once a small mass of the oxygen-deficit water is generated, it expands very quickly to cover the wide area of the innermost part of the bay. During mid-summer, the bottom layer of a half of the bay is covered by strong oxygen-deficit water with DO concentration of less than 1 mg/l. Up-welling of such water occurs when north winds are strong, which in turn brings about blue tide along the north coasts of Tokyo Bay.

When the pollutants discharged from rivers is reduced by 50%, the concentration of nutrients such as phosphate and nitrogen decreases apparently, while the oxygen-deficit water continues to take place. Same tendency was observed, when the effects of sand capping work on the bottom mud was calculated. This indicates the difficulty to improve water quality in Tokyo Bay in a short time. For assessing the effects of such countermeasures, the present model is expected to be useful.

Watertable Fluctuations in a Sandy Ocean Beach

B. Raubenheimer\textsuperscript{1}, R.T. Guza\textsuperscript{1}, and Steve Elgar\textsuperscript{2}

Abstract

Fluctuations of the watertable level within a fine-grained beach were observed for 2 months in Fall 1996. The magnitude of fluctuations at diurnal and semi-diurnal frequencies decayed rapidly inland, but fluctuations at spring-neap frequencies remained significant nearly 100 m inland of the mean shoreline location. During two storms that coincided with spring tides, overtopping and ponding of water behind the berm resulted in increased watertable levels that persisted for several days. Beach erosion during the second storm resulted in landward displacement of the shoreline location, and subsequent watertable fluctuations also extended farther inland. Numerical solutions of the nonlinear Boussinesq equation, with the seaward boundary condition given by the observed shoreline location, agree well with the observations. The landward attenuation and phase shifting of tidal watertable fluctuations are predicted well, as is the location of the seepage face.

Introduction

Beach watertable levels are believed to affect swash zone fluid motions (e.g., Packwood, 1983) and sediment transport (e.g., Grant, 1948; Duncan, 1964; Eliot and Clarke, 1988). Tidal watertable fluctuations in shallow (relative to the wavelength of the fluctuations) aquifers are often modeled with the nonlinear Boussinesq equation

\[ \frac{\partial \eta}{\partial t} = \frac{K}{N} \frac{\partial}{\partial x} \left( (D + \eta) \frac{\partial \eta}{\partial x} \right) \tag{1} \]

where \( t \) is time, \( x \) is the cross-shore coordinate, \( \eta \) and \( D \) are, respectively, the deviation of the watertable elevation and the depth of the impermeable stratum relative to mean sea level, \( K \) is the hydraulic conductivity in the saturated beach, and \( N \) is the effective porosity. The observed asymmetry (the beach fills more rapidly than it drains) and

overheight (the mean inland watertable elevation is higher than mean sea-level) of tidal watertable fluctuations (e.g., Emery and Foster, 1948; Harrison et al., 1971; Waddell, 1976; Lanyon et al., 1982) that result from the moving intersection of the waterline with the sloping beach are predicted qualitatively by analytical solutions of (1) for small tidal excursions on a planar beach (Nielsen, 1991). However, the tidal overheight is underpredicted, possibly because the model neglects the effects of the seepage face, the decoupling of the watertable and offshore water level that occurs on fine-grained beaches near low tide (Turner, 1993). Comparisons of numerical solutions of (1) with watertable fluctuations observed over one or two tidal cycles suggest the seepage face and wave-driven setup at the shoreline are important to watertable fluctuations (Kang and Nielsen, 1996; Baird et al., 1998).

Here, watertable fluctuations observed along a densely instrumented cross-shore transect are used to extend the previous studies. The 2 months of observations span several spring-neap tidal cycles and include a storm that modified the beach profile. Comparisons of the observations with numerical solutions of (1) are used to identify processes important to watertable fluctuations and the seepage face location.

Observations

Waves, runup, tides, and watertable fluctuations were sampled nearly continuously at 2 Hz for two months during Fall 1996 at Torrey Pines Beach, CA (Figure 1). Surf zone waves and runup were measured with 16 pressure sensors located near the sand surface, and watertable fluctuations were measured with 22 buried pressure sensors. Runup and watertable sensors were stacked vertically to estimate vertical infiltration and to detect capillary effects. Beach profiles landward of about 2-m water depth were measured daily throughout September and October and approximately every other day during November. Other than erosion during a storm in late October (Figure 1), foreshore profile changes were small (< 10 cm). At the beginning, middle, and end of the experiment the profile was measured to about 5-m water depth. Offshore wave heights measured in 10-m water depth about 35 km north of the experiment site ranged from 40 to 330 cm and peak periods ranged from 5 to 20 s (Figure 2B). These offshore observations agreed well with measurements made at Torrey Pines Beach in about 3.5-m water depth at cross-shore distance 165 m (Figure 1), except during the storms when the shallower sensor was in the surf zone. Rainfall of 0.76 and 1.62 cm were recorded on Oct 26 and 30, respectively.

At fifteen locations between cross-shore distances 10 and 100 m, 8-m deep holes were drilled to collect sediment cores and to determine the beach stratigraphy. Sieve analysis was conducted on eleven cores to determine grain sizes, and five cores were used to determine porosity. Hydraulic conductivity was estimated from pumping tests (Bouwer and Rice, 1976) conducted at cross-shore distances 60 and 91 m. The beach is composed of approximately 2 to 4 m of uniform fine to medium sand with traces of silt \( (d_{50} \approx 0.23 \text{ mm}, \text{porosity} \approx 37\%, \text{ and hydraulic conductivity} \approx 0.07 \text{ cm/s}) \) overlying about 1 m of Scripps formation composed of dense, silty fine sand with traces of gravel \( (d_{50} \approx 0.15 \text{ mm}, \text{porosity} \approx 33\%, \text{ and hydraulic conductivity} \approx 0.03 \text{ cm/s}) \) on top of low permeability Ardath Shale \( (d_{50} \approx 0.004 \text{ mm}, \text{porosity} \approx 32\%, \text{ and hydraulic conductivity} \approx 0.0005 \text{ cm/s}) \). All pressure sensors were located above the Scripps formation and are identified by their distance (in m) inland from the mean shoreline location, defined as the intersection of the beach profile and mean
Figure 1: Pressure sensor locations (solid circles) and beach profiles measured at Torrey Pines Beach before (thin solid curve) and after (thin dashed curve) a storm on Oct 25. The thick solid and dotted curves at the bottom of the figure represent the measured upper surface of the Ardath Shale and the (unmeasured) offshore shale position used in the numerical model, respectively.

The observed mean watertable levels usually increased in the landward direction, suggesting that water usually flowed toward the ocean (Figure 2A). Tidal watertable and offshore fluctuations were dominated by waves with 25 and 12 hr periods (Figure 3). Similar to previous observations (e.g., Emery and Foster, 1948; Harrison et al., 1971; Waddell, 1976; Lanyon et al., 1982), tidal watertable fluctuations were asymmetrical in time (not shown), and decreased rapidly in magnitude in the landward direction (Figures 2 and 3). Offshore tidal amplitudes ranged from about 0.5 m during neap tides to 1 m during spring tides (Figure 2C), whereas watertable fluctuation amplitudes at cross-shore distance 60 m were usually less than about 10 cm (Figure 2A). At the most landward sensor, 98 m inland of the mean shoreline, diurnal and semi-diurnal tidal fluctuations were strongly damped, but fluctuations at the frequency of the spring-neap tidal cycle remained significant (Figure 2A). Spring-neap watertable fluctuations have not been observed previously, possibly because most observations spanned only a few days. For similar offshore tidal fluctuations and wave heights, watertable fluctuations near the berm were smaller in September than in November (Figure 2) because beach erosion (Figure 1) on Oct 26 reduced the distance from the berm to the mean shoreline.
Wind waves had a significant effect on the observed watertable fluctuations. During two storms (offshore wave heights greater than about 130 cm) that occurred during spring tides (Oct 15 and Oct 25 in Figure 2) runup overtopped the berm, resulting in large (up to 70 cm) increases in the berm watertable level. High watertable levels persisted for several days after each storm. However, tidal levels modulated the effect of storm waves on watertable fluctuations. For instance, although offshore wave heights exceeded 130 cm during the neap tides (Figure 2, Oct 20), berm overtopping did not occur and the berm watertable response was small.

Figure 2: Observed (A) 10-min averaged watertable levels at cross-shore locations 98 (dotted curve), 60 (thick solid curve), and 46 m (thin solid curve) inland of the mean shoreline, (B) offshore hourly significant wave heights (solid curve) and peak wave periods (dotted curve), and (C) 34-min averaged offshore sea-surface levels versus time.
Figure 3: Energy spectra (24 dof) of offshore water-level (solid curve) and watertable fluctuations at 46 (dashed curve), 60 (dotted curve), and 80 m (dash-dot curve) inland of the mean shoreline.

Numerical Model

The observations are compared with numerical solutions of the nonlinear Boussinesq equation (1). A no flow bottom boundary condition is imposed at the top of the Ardath Shale (Figure 1), which is assumed to be horizontal both landward and seaward of the measured positions. Above the impermeable boundary, the beach material is assumed homogeneous and isotropic, with an average hydraulic conductivity $K$ of 0.07 cm/s. The effective porosity $N$, determined using a least squares fit of the predictions to the observations, is 0.215. The model is initialized with the watertable level observed at the start of the experiment. Initial levels inland of the most landward sensor are estimated using a natural cubic spline extrapolation. The location of the inland boundary (250 m landward of the mean shoreline) was determined iteratively to ensure it was sufficiently far onshore that predicted watertable fluctuations were negligible. In the results presented below, a constant head (Dirichlet) condition is imposed at the inland boundary of the model domain. The model results are sensitive to the ratio $K/N$ and to the aquifer thickness $D$, but are insensitive to the inland boundary condition.
The beach is assumed to be saturated at, and offshore of, the model seaward boundary, which is given by the shoreline location (e.g., the beach-ocean intersection). The moving locations of the shoreline and the watertable outcrop at the sand surface were estimated using water levels observed with the closely spaced foreshore sensors and measured beach profiles. The cross-shore structure of the mean water level was estimated by fitting a cubic spline to 10-min averaged observations at all sensors. Sand levels at each time step were determined by fitting a cubic spline to the measured beach profiles. The shoreline location was defined as the most seaward location where the water depth above the beach profile was less than a small number \( \delta_s \). The watertable outcrop location was estimated from the observations as the most landward position where the measured water level was less than \( \delta_w \) below sand level. Owing to errors of a few cm in the measured mean pressure and beach profiles, nonzero values are used for \( \delta_s \) and \( \delta_w \). The results shown below correspond to \( \delta_s = \delta_w = 2 \) cm and are not sensitive to values of \( \delta_s \) and \( \delta_w \) between 1 and 5 cm. Following van Gent (1994) and Baird et al. (1996), when the predicted watertable level exceeds the sand level within the model domain (landward of the shoreline), the watertable is reset to sand level and the excess water is assumed to be run-off.

The Boussinesq equation (1) is based on the assumption that horizontal flows \( u \) are much larger than the vertical flows \( w \). The flow through saturated sand was estimated using observed gradients of hydraulic head \( (p_w/\rho g + z_R) \), where \( p_w \) is measured pressure, \( z_R \) is the vertical sensor location relative to a fixed datum, \( \rho \) is water density, and \( g \) is gravitational acceleration) and Darcy's law for laminar flow,

\[
u = \frac{K \partial (p_w/\rho g - z_R)}{N} \frac{\partial x}{\partial x} \tag{2}
\]

\[
w = -\frac{K \partial (p_w/\rho g - z_R)}{N} \frac{\partial z}{\partial z} \tag{3}
\]

where \( z \) is vertical distance positive upward. Consistent with the model assumptions horizontal velocities are on average about 10 times larger than the vertical velocities (Figure 4). Vertical and horizontal velocities had similar magnitudes only during spring high tides when wave runup ran onto the beach above the watertable sensors, resulting in relatively large downward (negative) velocities on the rising tides and relatively large upward velocities as the watertable drained on the falling tides (Figure 4, Sep 24 to 31). However, 10-min-averaged vertical velocities were smaller than horizontal velocities 95% of the time. The vertical velocities corresponding to individual wave uprushes will be considered elsewhere.

Model-Data Comparisons

The model, driven with the observed 10-min-averaged shoreline location, predicts the observed watertable levels, except during and immediately after the two October storms (Figure 5). The fluctuations at the spring-neap frequency and the increased watertable fluctuations near the berm following the beach erosion on Oct 26 (Figure 1) are modeled qualitatively well. Consistent with previous results (Baird et al., 1998), breaking-wave-driven setup is important to the watertable fluctuations. Driving the model with the observed offshore water level fluctuations rather than the shoreline location results in underprediction of both the mean watertable levels and
Figure 4: Normalized horizontal \((u/K\), solid curve\) and vertical \((w/K\), dotted curve\) velocities versus time. Velocities were estimated from 10-min averaged hydraulic heads measured with horizontally separated sensors at 39 and 53 m and vertically separated sensors at 46 m and elevations 0.6 and -2.2 m, respectively.

The fluctuation amplitudes, primarily because the shoreline is farther offshore when setup is not included (Figure 5).

The strong onshore decay and significant phase delays of diurnal, semi-diurnal, and higher frequency tidal watertable fluctuations are also predicted accurately (Figure 6). There is little energy at tidal harmonic frequencies in offshore tidal fluctuations (8 and 6 hr periods in Figure 3) and the increased energy in watertable fluctuations at these harmonics appears to be generated nonlinearly in the vicinity of the moving shoreline (Raubenheimer et al., in prep.). However, inland of the most onshore locations of the shoreline \((x \approx 35\) m), the watertable fluctuations are described well by solutions to the linearized Boussinesq equation, which have the form

\[
\eta(x, t) = \eta_0 e^{-k_R x} \cos(\omega t - k_I x) \tag{4}
\]

where \(\eta_0\) is the shoreline fluctuation amplitude, \(\omega\) is the frequency in radians, and \(k_R\) and \(k_I\) are the real and imaginary parts of the wavenumber, respectively, given by

\[
k_R = k_I = \sqrt{\frac{N\omega}{2KD_{av}}} \tag{5}
\]

where \(D_{av}\) is the average aquifer depth. Similar to observations, the linearized equation (4) predicts that the amplitudes decay exponentially, and the phase lags vary linearly with distance inland (Figure 6).

The Boussinesq model (1) does not predict the increase in the watertable elevation landward of the berm \((x > 50\) m) observed during the October storms.
Figure 5: Watertable fluctuations observed (solid curves) and predicted by the numerical model (1) driven with the observed shoreline location (dotted curves) and offshore water level (dashed curves) versus time. Cross-shore distances are (A) 98, (B) 60, and (C) 46 m.
Figure 6: (A) Root-mean-square amplitudes and (B) phase lags relative to the shoreline for watertable fluctuations with periods of 25 (circles) and 8 hr (triangles) versus cross-shore distance inland from the mean shoreline location. Solid symbols with solid curves and open symbols with dotted curves are observed and predicted (with the nonlinear model) values, respectively, calculated from cross-spectra with 48 dof. Dashed lines represent linear theory predictions calculated using (4), (5), and observations at 39 m. Results for 6 and 12 hr periods are similar.
that coincided with spring tides (e.g., Figure 5, Oct 15 and 25). For the simplified case of no tides and monochromatic waves, the inland overheight of the watertable is independent of grain size and beach hydraulic conductivity (Kang et al., 1994). Using laboratory observations of watertable fluctuations owing to random breaking sea-swell waves, Kang et al. (1994) determined an empirical formula for $\eta_w$, the time-averaged wave-driven overheight

$$\eta_w = 0.62 \frac{H}{L} \tan \beta_f$$

where $H$ and $L$ are the offshore significant wave height and wavelength, respectively, and $\beta_f$ is the foreshore slope. The estimated (with (6)) wave-driven overheight ranges from 9 to 47 cm, but maxima of $\eta_w$ do not coincide with the storm events during which offshore wave heights increased, but wavelengths ($L = gT^2/2\pi$) decreased (Figure 2B). Presumably, to predict the storm-induced watertable increases it is necessary to account for the effects of ponding water behind the berm (and the resulting infiltration) and the runup of (nonbreaking) infragravity waves. Differences between model predictions and observations may also result from neglecting the effects of the capillary fringe (e.g., Gillham, 1984; Li et al., 1997; Turner and Nielsen, 1997), trapped air within the watertable, and salinity (density) gradients (e.g., Nielsen, 1998). Despite the model simplifications and inaccuracies during the storms, model errors are small when the seaward boundary condition is given by the observed shoreline location (including setup). The 2 month average (and standard deviation) of differences between modeled and observed watertable levels are less than 6±7 cm for all sensors landward of the maximum shoreline.

Figure 7: Cross-shore position of the 10-min averaged observed shoreline (solid curve) and observed and predicted watertable outcrop (dashed and dotted curves, respectively) versus time. The seepage face is located between the shoreline and the watertable outcrop.
When the tide falls more rapidly than the beach can drain, a seepage face forms between the watertable outcrop and the shoreline (Figure 7). The observed outcrop locations are predicted well by the nonlinear Boussinesq equation (1). Previous studies have suggested that the seepage face width on macrotidal beaches can be estimated assuming that the watertable outcrop position is independent of the pressure distribution within the beach, and depends only on the rate that the tide falls, the beach slope, and the value of $K/N$ (Dracos, 1963; Turner, 1993). However reasonable agreement between the simple model of Dracos (1963) and the present outcrop observations is possible only if the ratio $K/N$ is increased unrealistically (by a factor of 8) relative to that used in the numerical Boussinesq model.

Conclusions

Watertable levels observed for 2 months within a sandy beach depended on tidal levels, wind-waves and wave-driven setup, and the beach profile. Overtopping during spring high tides resulted in increased watertable levels for several days (Figure 2). Wind-waves of similar offshore height during neap tides had less effect on the watertable. Similar to previous observations, diurnal and semi-diurnal watertable fluctuations decreased inland (Figures 2, 3, 5, and 6). Although diurnal and semi-diurnal watertable fluctuations were damped almost completely 100 m inland of the mean shoreline location, fluctuations at spring-neap frequencies remained significant. Beach erosion during a storm resulted in larger tidal watertable fluctuations owing to the landward displacement of the shoreline. The observed horizontal flow in the watertable was usually much larger than the vertical flow (Figure 4), consistent with the assumptions in the nonlinear Boussinesq equation for watertable fluctuations in shallow aquifers.

The observed watertable levels (Figures 5 and 6) and seepage face width (Figure 7) are predicted accurately by a numerical model based on the nonlinear Boussinesq equation and driven with the observed 10-min averaged shoreline location (which includes wave-driven setup). When the model is driven with the offshore water levels (without setup), mean watertable levels and fluctuations are underpredicted. Watertable fluctuations (Figure 3) at harmonics of the tidal frequencies are nonlinearly generated near the moving shoreline location, but farther onshore the amplitudes and phases of watertable fluctuations are predicted well by solutions to the linearized Boussinesq equation (Figure 6).

SEEPAGE EFFECTS ON SEDIMENT TRANSPORT BY WAVES AND CURRENTS.

T. E. Baldock¹ and P. Holmes²

Abstract

This paper considers the influence of seepage on the motion and transport of sediment. Under wave motion, steady upwards seepage (injection) increased erosion, while downwards seepage (suction) stabilised the bed. Conversely, seepage in the presence of a steady flow produced negligible changes in the sediment motion. A theoretical analysis examines the stability of the sediment particles and sediment bed under these conditions and provides an explanation for the different seepage effects. Seepage across the sediment/fluid interface also had a strong influence on the growth of sand ripples, even at pressure gradients of order 0.1. These results suggest that ripple dynamics in the nearshore may be affected by the watertable level and drainage within a beach.

1) Introduction

The stability of sediment particles under the influence of pressure gradients within the sediment bed is considered to be important with respect to the type and rate of sediment transport under both steady and oscillatory flows (Nielsen, 1992) However, previous work has provided conflicting results (Martin, 1970; Willets and Drossos, 1975; Oldenziel and Brink, 1974; Rao et al., 1994) and the effects of pressure gradients on sediment dynamics are not immediately obvious (Oh and Dean, 1994).

The rate and nature of sediment transport under steady flows and wave induced motions is generally considered to be dependent on the forces on the individual sediment particles. These include gravity forces, the surface drag force, pressure forces due to pressure gradients within the fluid, a lift force due to flow over the sediment particle and a seepage force due to flow across the fluid/sediment interface (Sleath, 1984). It may also be necessary to consider the stability of the sediment bed as a whole. In this instance the

¹ Research Fellow, School of Civil and Structural Engineering, University of Plymouth, PL1 2DE, UK.
² Professor, Department of Civil Engineering, Imperial College of Science, Technology and Medicine, London, SW7 2BU, UK.
Effective stresses within the sediment may be increased, reduced or vanish completely (fluidisation) due to pressure gradients within the sediment. However, the effects of these pressure gradients on sediment transport are unclear and previous work has provided conflicting results. For example, in steady flows, Martin (1970), Watters and Rao (1971) and Willets and Drossos (1975) found that seepage did not affect sediment motion, while Oldenziel and Brink (1974) found the opposite to be true. The only experimental evidence under oscillatory flow in a water tunnel appears to be that from Krujit (1976), who again found no significant effects. These results all pertain to steady vertical seepage, and as far as the authors are aware, no study has been carried out under oscillatory wave motion.

Surface gravity waves and bores will induce both vertical and horizontal transient pressure gradients within a sediment bed. The vertical pressure gradients induce flow into the bed under wave crests (suction) and upwards out of the bed under the wave troughs (injection). However, as noted by Packwood and Peregrine (1983), the vertical wave induced pressure gradients are approximately linearly proportional to the bed thickness. Consequently, scale modelling of sediment motion may be influenced by the relatively thin beds generally used in laboratory studies. Indeed, evidence to this effect was found by Conley and Inman (1992), who suggested that differences in bed ventilation might be responsible. Madsen (1974) showed experimentally that horizontal pressure gradients could be sufficient to fluidise a sediment bed under breaking waves while Yamamoto (1978) suggested that large steep waves and tsunamis transport huge amounts of sediment because the bed is fluidised by horizontal pressure gradients.

Previous work has also suggested that the pressure gradients and the seepage flow induced within beaches may be an important factor governing both long term beach morphology and short term (storm duration) beach evolution (Oh and Dean, 1994; Turner, 1995). In these instances, an unsaturated beach face appears to promote steepening of the profile, while a saturated beach face tends to result in a flattening of the beach profile. However, the mechanism by which the watertable influences the beach dynamics is not obvious. For example, Oh and Dean (1994) found that a raised water table increased shoreward transport, contrary to most previous studies (e.g. Emery and Foster, 1948; Waddell, 1976), while a lower water table appeared to result in increased stability and little profile change. Numerical calculations also suggested that the pressure gradients induced by the change in watertable were too small to influence the stability of the sediment.

2) Theory

The pressure distribution within sediments was first considered by Putnam (1949) and later expanded upon by Sleath (1970) and others. Sleath's (1970) solution was based on the assumption of an incompressible fluid, grain particles and grain skeleton. Flow velocities were then derived assuming Darcy's law for flow in a porous medium. A number of more exact solutions include the effects of fluid compressibility and the deformation of the grain skeleton (e.g. Yamamoto et al, 1978; Madsen, 1978). Darcy's law gives flow velocities in a porous medium as:

\[ u = -k \frac{x}{z}, \quad v = -k \frac{y}{y} \]  

(1)
An explanation for this anomaly may be found by comparing the fall velocity of the sediment particles with the velocity of the flow across the fluid/sediment interface. If Darcy flow applies, then the flow rate across the interface is given by equation (1). Prior to piping, the maximum possible flow velocity, $V_s$, out of a sand bed will therefore be approximately equal to the bed permeability, $k$, and of the order 0.25$k$ for lightweight anthracite beds. This flow velocity is generally much smaller than the fall velocity of the sediment, $w$. For example, for a sand with $d_{50}=0.2$mm, the permeability will be of order $10^{-4}$m/s but the fall velocity is of order $10^{-2}$m/s (van Rijn, 1989).

This difference of two orders of magnitude remains much the same for coarser sand. Consequently, once a sediment particle lifts out of its bed recess and the seepage force no longer acts, the fall velocity of the particle, $w$, will dominate over the vertical flow velocity $V_s$ (figure 1). The effect of vertical seepage on a sediment particle rolling over the surface of the bed will therefore be minimal. The same argument applies in reverse in the case of downwards seepage and the fall velocity of the sediment particle again dominates the process. Note that the effect of boundary layer changes due to the seepage flow are not considered separately in this study. Consequently, the experimental results include both the effects of seepage and boundary layer changes together. Therefore, extrapolating the results from these flow conditions to radically different flow conditions or sediment sizes should be viewed with caution.

**Figure 1.** Forces and fluid velocities acting on particles on and just above a sediment bed at incipient fluidisation:
- $F_g$ - gravity force,
- $F_s$ - seepage force,
- $F_d$ - drag force,
- $F_{LS}$ - lift force due to seepage velocity,
- $u$ - free stream velocity,
- $w$ - particle fall velocity,
- $V_s$ - seepage velocity.

A: $F_g=F_p$, B: $F_g>F_{LS}$, $w>>V_s$. 
3) Experimental Method And Instrumentation.

The experiments were conducted in a 12m long combined wave-current flume in the Civil Engineering Department at Imperial College (figure 2). Waves can be absorbed at any position within the flume by a block of polyether foam and the reflection coefficient under these conditions was found to be less than 10%. In order to allow the thickness of the sediment bed to be varied whilst maintaining the same flow conditions in the flume, a raised bed was additionally installed. Vertical seepage was induced by means of a seepage box installed within the sediment bed, allowing a seepage flow over a length of 1m across the full width of the flume. The seepage box comprised a lower section 50mm deep, overlain by a baffle plate and 30mm of polyether foam. The foam was then covered with fine wire gauze to prevent the ingress of sediment. The seepage flow was induced through a pipe running under the raised bed. Upwards seepage was controlled through a tap and valve connected to a large constant head tank, while downwards seepage was induced by siphoning to a sump, the discharge in either case being proportional to the head across the sediment bed. During this phase of the investigation the depth of sediment above the box was kept constant at 70mm. For convenience, the origin of the horizontal co-ordinate in all figures is taken at the upstream end of the box.

Both the dynamic and steady pressure gradients were measured by a technique developed by Baldock and Holmes (1996). This uses probes connected to pressure transducers via semi-rigid flexible tubing to determine the pressure at any location quickly and easily, with minimal disturbance of either the fluid or sediment bed. When determining steady pressure gradients, the probe system requires no calibration and errors in the measurements are of order 5%. Baldock and Holmes (1996) also show the dynamic response of the probe system is good when measuring transient pressure gradients, with errors of order 10%-15%.

![Figure 2. Wave and current flume.](image)
where $k$ is the coefficient of permeability, $i_x$ and $i_y$ are the dimensionless pressure gradients in the horizontal and vertical directions respectively, and $u$ and $v$ the corresponding flow velocities. Note that flow into the bed (suction) corresponds to a positive vertical pressure gradient. Fluidisation, or liquefaction, of the sediment bed occurs when the pressure gradient reduces the effective stress within the sediment to zero (e.g. Smith, 1968). For vertical seepage this occurs when the vertical pressure gradient exceeds the critical value $i_{cy}$ given by:

$$i_{cy} = -(s-1)(1-n)$$

where $s$ is the specific gravity of the sediment and $n$ is the porosity, typically of order 0.4-0.6. For sand, this critical value is generally found to be approximately equal to 1, while for anthracite ($s=1.4$), the critical value is of order 0.2. The critical horizontal pressure gradient, $i_{cx}$, required for bed fluidisation is smaller than that needed with vertical seepage (Madsen, 1974):

$$i_{cx} = (s-1)(1-n) \tan \phi$$

where $\phi$ is the internal angle of friction. For typical values of $\phi$ of 35°, the critical horizontal pressure gradient is of order 0.5-0.6 for natural sand and 0.14 for anthracite. If both a vertical and horizontal pressure gradient act simultaneously, then failure of the bed material will occur earlier. In this instance the horizontal pressure gradient required for fluidisation of the bed will reduce to:

$$i_{cx} = (s-1)(1-n) \tan \phi \left(1 - i_{cy}/i_{cx}\right)$$

Hence, if a steady and critical vertical pressure exists ($i_y=i_{yc}$), then the sediment bed will be unable to resist any additional horizontal pressure gradients. Therefore, even the smallest degree of wave motion or turbulence will shear the sediment layers within the bed. If, however, the free fluid flow is steady (i.e. a current), there will be no significant additional horizontal pressure gradient and no horizontal shearing within the bed.

The stability of the interfacial particles is generally considered to be dominated by the drag force and is expressed in terms of the Shields parameter, $\Theta$. Considering flow conditions where the sediment bed is on the point of incipient fluidisation, then the particles within the bed are completely supported by the upwards seepage, although the interfacial particles might experience a smaller seepage force (e.g. Martin 1970). A modified Shields parameter could therefore be written in the form:

$$\Theta' = \frac{\Theta}{(1 - i_{y}/i_{yc})}$$

As a result, the Shields parameter becomes large as the bed approaches fluidisation and we might expect the interfacial particles to become highly unstable. Indeed, Loveless (1994) suggests that the particles will be ejected into the flow. Incipient sediment motion should therefore occur at very much smaller flow velocities than normal, contrary to most of the previous experimental work discussed above.
A series of preliminary measurements were made in order to determine the properties of the sediment bed and the flume set-up. The sediment bed was laid underwater and then repeatedly stirred in order to exclude as much air as possible, subsequently remaining submerged for the duration of each test. The bed permeability was measured in-situ at a number of locations with a falling head permeability test. The porosity of the bed material was also measured under conditions that approximated those within the flume. Sand ripple growth was promoted by introducing artificial disturbances. Ripple growth rates could therefore be measured under different seepage conditions. Both sand and lightweight anthracite particles were used in this study, the latter chosen to highlight seepage effects and aid visual and video observations. Table 1 shows the relevant sediment properties. Finally, as a check on the pressure measurement system and the method of laying the sediment bed, the pressures within a sand and anthracite bed were compared to the solution presented by Sleath (1970), with good agreement (figure 3).

4) Experimental Results

Bed thickness

The influence of wave induced vertical pressure gradients was examined by comparing the conditions required for incipient motion of lightweight anthracite particles over a thin (10mm) and thick (150mm) sediment bed. Three different wave periods were selected and the tests were carried out by slowly increasing the wave height until incipient motion commenced. At incipient motion, the measured vertical pressure
gradients, $i_y$, just below the surface of the thick bed were about 0.08, approximately half those required for complete fluidisation of the anthracite, and negligible for the thin bed. Careful observation suggested that incipient motion of the anthracite particles commenced at the same wave height ($h=0.06$), regardless of the bed thickness. Vertical wave induced pressure gradients therefore appear to have no significant effect on incipient sediment motion, and are also unlikely to affect sediment transport rates, at least prior to sheet flow conditions. This is consistent with the discussion in section 2, since at the time of maximum and minimum bed stability wave induced horizontal pressure gradients are zero.

The effects of a steady vertical seepage across the fluid/sediment interface were examined under conditions of both suction and injection using the seepage box arrangement (figure 2). For the fine sand, a vertical pressure gradient, $i_y$, of 0.6 was used in both instances. The effective stress within the bed was therefore reduced to close to zero during injection and nearly doubled under suction. The vertical pressure gradients were reduced to 0.2 for the anthracite bed, approximating the same effective stress conditions within the bed. In each case the experimental conditions remained identical except for the seepage across the sediment/fluid interface.

With a steady seepage across the sediment bed, a current was introduced within the flume and then slowly increased until the threshold of sediment motion was reached. For both the sand and anthracite beds, incipient sediment motion started at Shields numbers of about 0.045, irrespective of the seepage direction. These results are again in agreement with the argument set out in section 2 and consistent with a number of previous studies (e.g. Martin, 1970; Willets and Drossos 1975; Kruijt 1976). However, in order to examine the effects of the seepage flow in more detail, a closer examination of the bed material during piping was carried out using the larger anthracite particles.

Initially, in the absence of a current, the seepage flow was slowly increased until piping first occurred over a small region of the bed. Under these conditions, sediment particles were not ejected into the body of the fluid but appeared very unstable within their bed recesses. In fact, close inspection suggested that the particles within the piped area appeared to vibrate. This is entirely consistent with transient nature of the seepage force as particles start to lift out of their bed recesses and then re-settle under their own weight. Furthermore, on the re-introduction of the steady current, incipient motion of the particles within the piped area occurred at the same flow velocity as previously and at the same time as incipient motion commenced at adjacent areas of the bed that were not piped. This therefore shows that as soon as a particle moves out of its bed recess, the gravity force completely dominates the lift force due to the small seepage velocity out of the bed. Consequently, steady seepage has very little effect on the stability of the interfacial particles.

Wave motion

Under wave motion, the sediment bed is subject to both vertical and horizontal pressure gradients, the latter being independent of the bed thickness. The effects of an additional steady seepage on the net sediment transport rate were now examined, initially using anthracite particles. Waves with a height of 38mm and wave period of 1s were selected for use in these and all subsequent tests, corresponding to a Shields number of about 0.12 and giving maximum measured horizontal pressure gradients, $i_x$, of 0.14, very
close to the conditions required for local fluidisation of the bed. Net sediment transport rates were inferred from bed level changes.

Figure 4a compares the bed level changes found without seepage with those obtained during injection. With no seepage, the net sediment transport was positive due to the shallow water wave conditions but tended to accumulate at the anti-nodes of the weak standing wave system within the flume, i.e. where the wave induced horizontal velocity was a minimum. The results obtained during injection show a significant change, with erosion occurring over the weakest area of the bed (0<x<50cm) and further upstream. The steady vertical seepage was found to have an effect at pressure gradients, i_y, as low as 0.05 and the net positive sediment transport rate increased fourfold when the bed was on the point of fluidisation (i_y=-0.2, figure 4c).

Close inspection of the bed using video analysis showed that the seepage had a clear effect on the sediment transport mechanism. The sediment within the bed tended to lift during the passage of a wave trough and the upper layers of the bed were then sheared by the horizontal pressure gradient and positive horizontal velocity induced by the approaching wave crest. Sediment was therefore transported in the direction of wave motion. The flow into the bed under the crest subsequently reduced the effect of the upwards seepage, stabilising the bed. However, although the wave induced horizontal pressure gradients were symmetric about the wave crest, a similar mechanism was not observed following the passage of a wave crest. This appears to confirm the results of Takahashi et al (1994), who suggested that the phase difference between the bed motion and wave motion is less than 180°.

![Figure 4a](image)

Figure 4a. Evolution of an anthracite bed under wave motion with steady vertical seepage (injection).

--- i_y=0, --- i_y=-0.2, ---- i_y=-0.1, ------- i_y=-0.05.

The behaviour of the sediment within a locally piped region was again closely observed. This also showed that even under wave motion the interfacial particles were largely unaffected by the seepage flow, with no relative movement between these particles and those within the bed. However, the sediment bed within the piped area behaved largely as a fluid, oscillating to a considerable depth under the smallest wave induced pressure gradients. Note that the piped bed had zero effective strength and, consequently, was unable to sustain a slope, leading to negligible net sediment transport.
The experiment was then repeated with suction applied across the fluid/sediment interface. In this instance the steady pressure gradients were in the range $i_y=0-0.15$, approximately doubling the effective strength of the bed. Suction was found to increase the stability of the sediment bed and consequently the shearing of the upper layers of the bed was prevented. The net positive sediment transport rate was therefore reduced (figures 4b&c). It is, however, very important to note that this reduction in the transport rate was not a result of an increase in the stability of the interfacial particles. The transport rate of these particles did not appear significantly affected by the applied suction, even when $i_y=0.15$. This is consistent with the data obtained previously under steady flows. In these instances the reduction in the transport rate compared to the case without seepage predominantly arose due to the reduced shearing of the upper layers of the sediment bed.

Figure 4c. Variations in the net positive sediment transport rate for anthracite under wave motion with steady vertical seepage.

Sand ripple dynamics

Seepage across the fluid/sediment interface was also found to have a significant effect on the formation and growth of sand ripples. For example, figure 5 shows the evolution of a fine sand bed after five hours of wave action. With no seepage, bed level
changes occurred due to the gradual formation of ripples, leading to suspended sediment transport and eventually the generation of larger scale features. Little change was observed when repeating the experiment with an upwards seepage flow (injection); however a considerable difference arose when suction was applied. In this instance, the sand bed over the seepage area (0<x<100cm) remained plane during five hours of wave action, with no ripple formation occurring, despite ripple formation either side of this region. It has been drawn to the authors' attention that Sakai and Gotoh (1996) found that the bed configuration and ripple regime could be changed by an oscillating pressure gradient across the bed.

The growth rate of sand ripples on the fine sand bed with additional suction and injection was therefore compared to that over an adjacent region of the bed without seepage. Two discontinuities were introduced to promote ripple growth at specific positions on the bed. The first was at x=50cm, in the centre of the seepage area. The second, which acted as a control, was positioned at x=150cm, downstream from the seepage area.

Each discontinuity consisted of a hollow approximately 5mm wide and 1-2mm deep across the full width of the flume, formed by pushing a perspex wedge a fixed distance into the bed. After the onset of fluid motion, ripples started to grow from these discontinuities, spreading in both directions under wave motion and downstream in the presence of a steady current. The ripples could initially be classified as rolling grain ripples but subsequently grew to form vortex ripples. The effect of the seepage was then investigated by comparing the ripple growth rates at the two positions (the ripple growth rate at the two positions was the same when there was no seepage flow).

During injection, the upwards seepage started to have a significant effect at pressure gradients, \( i_y \), as low as -0.2, with the ripple growth rate increasing nearly threefold as the bed approached conditions of local piping, \( i_y=-0.6 \), figure 6a. Close inspection of the bed showed that the ripple growth rate increased due to the increased instability of the bed surface as a whole, with small ridges of sediment forming across the flume. Indeed, at very high pressure gradients, the bed tended to ripple spontaneously all over the seepage area and not just at the position of the initial discontinuity. This is
consistent with the analysis outlined in section 2 and was due to the local shearing of the surface layers of the sediment bed by the additional wave induced pressure gradients. This shearing of the bed caused small distortions in the bed surface, prompting the formation of sand ripples.

In contrast, suction prevented the formation of ripples and took effect at steady pressure gradients as low as $i_y = 0.05$ (figure 6b). Furthermore, at gradients in excess of 0.1, ripples did not grow at all, which confirmed the results obtained previously (figure 5). It is, however, important to note that the suction did not prevent the motion of the interfacial particles, the motion of which was similar at both the control section and over the seepage area. Seepage effects on ripple formation under steady flows appeared minimal, again due to the lack of additional wave induced pressure gradients and hence minimal shearing and deformation of the bed surface (figures 7a&b).

--- control (t=5mins), ■ t=5mins, --- control (t=10mins), ▲ t=10mins, ---- control (t=15mins), ▲ t=15mins.
The effect of suction on existing ripples (relic bedforms) was also examined. If the ripples were initially very small (i.e. rolling grain ripples) then they were slowly washed out by the wave motion and the bed tended to return to the initial plane state. If, however, the ratio of the ripple height to wavelength exceeded a value of about 0.1, then the ripples were not washed out, but neither did they continue to grow. These effects will, however, be dependent on the relative magnitude of the applied suction, the sediment grain size and the wave induced orbital velocity. Nevertheless, the results suggest that both the watertable level and/or the presence of a beach drain could influence the formation and growth of ripples within the nearshore region. This might then affect the quantity of both the bed load transport and the amount of sediment put into suspension.
6) Conclusions

On a plane sediment bed, vertical wave induced pressure gradients, \( i_y \), were found to have no direct effect on the conditions required for incipient sediment motion. Steady vertical seepage across the sediment/fluid interface was also found to have no discernible effect on the threshold of motion of the sediment particles in the presence of a current, even when the sediment bed was locally fluidised. In contrast, steady vertical seepage in combination with wave motion had a significant effect on net sediment transport rates. Injection was found to promote erosion of the sediment, through shearing of the upper layers of the weakened bed by the additional wave induced horizontal pressure gradients. Conversely, suction stabilised the bed material, reducing wave induced shearing and reducing the net transport rate.

At low Shields numbers, seepage flow across the sediment/fluid interface appears to have very little effect on the threshold of motion or sediment transport rates. This is because the seepage force no longer acts on sediment particles rolling or saltating over the bed. Consequently, the vertical forces on moving sediment particles are little changed in the presence of a seepage flow. However, although sheet flow conditions could not be modelled in this study, the results do suggest that injection will enhance sediment transport by sheet flow, while suction will tend to reduce the occurrence of sheet flow conditions (neglecting boundary layer changes). In this instance, the sheet flow layer may act as a fluid/sediment matrix, within which a seepage force can exist. Seepage will therefore alter the effective weight of the sheet flow layer, enhancing or reducing mobility. In practical circumstances, such as in the swash zone, the experimental results therefore appear consistent with the suggestion that the sediment transport rate will differ over saturated and unsaturated beach faces. Further work is therefore required to identify if a modified Shields parameter will describe sediment transport rates under these conditions.

Vertical seepage greatly influenced the formation and growth rate of ripples on a sand bed at pressure gradients typically induced within beaches due to changes in watertable levels, infiltration/exfiltration and beach drainage. Therefore, since both bed load and suspended load sediment transport are influenced by the ripple regime, the effects of seepage on ripple dynamics may have important implications for net sediment transport rates in the nearshore. This, however, requires further work and should isolate the effects of turbulence and boundary layer changes (e.g. Turcotte, 1960).

1. Abstract

The degree of sand beds compaction affects the accumulation and erosion of shorelines, and the population of creatures which live in sandy beach. The properties of the settlement, hardness and liquefaction of sand beds due to fluctuating water pressure were experimentally studied. The settlement of a sand bed was accelerated by liquefaction. The thickness of liquefaction layer which is estimated from the measured values of excess pore water pressure agreed well with one from the measured values of the rate of settlement. The hardness of sand bed was determined only by void ratio independent of liquefaction or non-liquefaction beds.

2. Introduction

Sand beds are repeatedly densified and sparsified due to wave action, and loose sand beds gradually settle and become compacted. Kraus et al. (1994) experimentally showed that the erosion of compacted sand on shorelines due to waves is less than that of loose sand, and Nishi et al. reported from the results of their field study that the degree of sand compaction affects the accumulation and erosion of sandhills and shorelines. Field studies have also been conducted on the effects of the degree of sand compaction on aquatic animals; Hodgin et al. (1992) showed that the degree of sand compaction affects the life of turtles, and Akutu et al. (1996) showed that, as it is difficult for bivalves to burrow into hard sand, the population of burrowing bivalves in compacted sand beds is less than that in loose sand beds. Although clarification of wave-induced settlement and compaction of sand beds is important from both engineering and biological points of view, there have been very few systematic studies of these

phenomena. On the other hand, it is known that the amount of settlement is greater if liquefaction of the sand bed occurs due to wave action (Zen et al., 1987).

In this study, the characteristics of settlement, hardness and liquefaction of a sand bed due to fluctuating water pressure were experimentally investigated, and the interrelationships between settlement, hardness and liquefaction were quantitatively determined.

3. Experiments

Experiments were carried out using a fluctuating pressure-type liquefaction test apparatus (Fig. 1). A two-meter-high acrylic cylinder was made by joining together cylindrical rings of 40 cm in diameter and 10, 20 and 40 cm in height. The sand bed was a loose sand layer with a void ratio of 0.85 and a sand particle diameter of 0.15 mm. Sand beds of four thicknesses were used in the experiments: L=0.7 m, L=1.2 m, L=1.5 m, and L=1.8 m. A sand container filled with water was set at a higher location than that of the experimental cylinder, and, using a hose, the cylinder was filled with water and sand by suction force generated due to the head gap between the container and the cylinder. The amount of air in a sand bed affects the properties of the sand bed, however, sand beds with same property containing very little air can be made by using this method. Table 1 shows experimental conditions. In all cases, the period and average pressure of fluctuating water pressure were 5 sec and 10 m, respectively. All experiments were first conducted at total head H=1.2 m under conditions in which liquefaction does not occur, in order to determine the properties of a sand bed. For the theoretical analysis of pore water pressure, we used the theory of Zen et al. (1987). Underwater pressure and pore water pressure in the sand bed were measured at 11 points (see Fig. 1) and at sampling intervals of 0.01 sec, and the amount of settlement was determined by measuring the position of colored sand

(maker) at depth intervals of 10cm or 20cm. The surface hardness of the sand bed was determined by measurement of the depth penetration of a cone penetrometer (weighing 800g) that was dropped from the surface of the sand bed. The above three measurements were repeated 6 times under conditions of fluctuating water pressure of 3,000 waves.

4. Experimental Results and Discussion

4.1 Fluctuating pore water pressure

Fig. 2(a) and (b) show the distributions of depth direction of phase delay $\Delta T/T$ ($=\text{time difference between surface water pressure peak and pore water pressure peak} / \text{period}$) and the ratio of amplitude of pore water pressure to surface water pressure $P_m/P_0$. $Z$ is positive in a downward direction with the sand-bed surface as the origin. The theoretical values calculated according to the method of Zen et al. (1987) are shown in figures. In the case of the same period, the theoretical values are not affected by the amplitude of fluctuating pore water pressure. The parameters used for the theoretical calculation are the coefficient of transmission ($\alpha$) and the coefficient of consolidation (C). The values of $\alpha=1.25$ and $C=0.35$ were used for the theoretical calculation to coincide with the experimental results of pore water pressure under conditions in which liquefaction does not occur. The figure shows that the deeper the location of the pore water pressure gauge is, the smaller is the ratio of amplitude of pore water pressure to surface water pressure and the larger is the phase delay. Thus, the surface water pressure is transmitted throughout the sand bed accompanying attenuation and phase delay. Under conditions in which liquefaction of the sand bed does not occur ($H=1.2m$), the tendencies of the experimental values (i.e., decrease in $P_m/P_0$ and increase in $\Delta T/T$ with increases in $Z$) agreed well with the theory of Zen et al. On the other hand, under conditions in which liquefaction of the sand bed occur ($H=6.0m$), the decrease in $P_m/P_0$ and increase in $\Delta T/T$ with increases in $Z$ were smaller than those of the theoretical values of Zen et al. This is thought to be due to the improvement in transmission properties of pore water pressure caused

---

**Fig 2.** The ratio of amplitude of pore water pressure to surface water pressure and the phase delay
by liquefaction.

In order to see the effect of thickness of the sand bed on transmission properties of pore water pressure, Fig. 3(a) and (b) show the distributions of depth direction of the ratio of amplitude of pore water pressure to surface water pressure and phase delay for each thickness of the sand bed under conditions in which liquefaction does not occur. The depth distribution of \( \frac{P_m}{P_0} \) in Fig. 3(a) shows that the ratio of amplitude of pore water pressure to surface water pressure decreases with increases in the sand bed depth and sand bed thickness, which agrees with the properties of the theoretical values of Zen et al. In Fig. 3(b), the phase delay \( \Delta T/T \) increases with increases in the sand bed depth and sand bed thickness, which also agrees with the properties of the theoretical values of Zen et al. In other words, the larger the sand bed thickness is, the greater is the effect on the transmission properties of pore water pressure.

![Graphs showing the ratio of amplitude of pore water pressure to surface water pressure and the phase delay](image)

**Fig 3.** The ratio of amplitude of pore water pressure to surface water pressure and the phase delay

### 4.2 Distribution of excess pore water pressure

Fig. 4(a) and (b) show examples of the distribution of excess pore water pressure \( P_e \) obtained by measurement and by the theoretical calculation of Zen et al. (solid line) in the case of a total head of 6.0 m. The phase where the fluctuating water pressure changes from negative to positive was made zero. The distributions of earth pressure (\( \sigma \)) are also shown in the figures. L=1.5m in both figures. In Fig.4(a), \( \alpha = 1.15 \) and the excess pore water pressure is smaller than the earth pressure, which are conditions under which liquefaction of the sand bed does not occur. Under these conditions, the measured values and theoretical values are very similar in all phases. It was found that in the phases 180° ~ 270°, in which surface water pressure decreases from zero, positive excess pore water pressure increases, while in the phases 0° ~ 90°, in which surface water pressure increases from zero, negative excess pore water pressure increases. Maximum excess pore water pressure occurs at phase 225°. Also, excess pore water pressure increases with depth.

A comparison of the earth pressure and excess pore water pressure in Fig. 4(b) shows that the excess pore water pressure is greater than the earth pressure in the phases 180° ~ 270°, which is the condition under which liquefaction of the sand bed occurs. In phases 0° ~
90°, in which the measured values are very similar to the theoretical values, the density of the sand bed is higher due to the large negative excess pore water pressure. However, in the phases in which liquefaction occurs (225° and 270°), the measured values are smaller than the theoretical values. This is thought to be due to the improvement in transmission properties of pore water pressure caused by liquefaction. As can be seen in the figure, under this condition, liquefaction occurs down to a depth of 40cm at phases 225° and 270°.

Fig 4. The distribution of depth direction of excess pore water pressure

**4.3 Settlement properties**

Fig.5 show the experimental results of amount of settlement \( \Delta L \) at each depth of the sand bed in the case of fluctuating water pressure of 3,000 waves. Arrows in the figure show the depth of liquefaction obtained from experimental values of excess pore water pressure. Under conditions in which liquefaction of the sand bed does not occur (unshaded portion), the amount of settlement on the surface layer of the sand bed increases with increases in thickness of the sand bed, but the average rate of settlement \( \Delta L/L \) (amount of settlement / thickness of sand bed) does not change regardless of the thickness of the sand bed. The similar degrees of settlement in every layer were thought to be due to the good transmission of pressure throughout the sand bed because of the small value of \( \alpha \) (1.15) and the fact that the ratio of amplitude of pore water pressure to surface water pressure was over 0.9 in every layer, as can be seen in Fig. 3. More detailed examination of the distribution of depth direction of the ratio of settlement \( \Delta L/1 \) (amount of settlement...
of each layer / thickness of each layer) shows that \( Z \approx 40 \text{cm} \) in the case of \( L=1.2 \text{m} \) and \( Z \approx 70 \text{cm} \) in the case of \( L=1.5 \text{m} \), the ratio of settlement decreases slightly. These regions agree with the regions in which phase delay (Fig. 3) and an increase in excess pore pressure (for example, \( \theta =225^\circ \)) to depth direction (Fig. 4) become smaller. Next, a comparison of a liquefying sand bed (black-colored symbols) with a non-liquefying sand bed shows that the rate of settlement in the liquefying region of the sand bed (above the arrows) is about two-times greater than that in the non-liquefying region of the sand bed. This result suggests that the settlement of a sand bed is accelerated by liquefaction. The region with a higher rate of settlement coincides well with the liquefying region calculated from excess pore pressure, indicating that the liquefying region can also be estimated from the distribution of depth direction of the rate of settlement. Moreover, in the non-liquefying region (under the arrows), the rates of settlement are very similar in both sand beds. This is thought to be because liquefaction of the surface of the sand bed at a thickness such as that in Fig. 2 or Fig. 4 has little effect on the transmission of pore water pressure to deeper layers.

Fig. 6 shows changes in the wave number \( N \) of the average rate of settlement in each thickness of sand bed in the case of a liquefying sand bed and non-liquefying sand bed. In the case of a liquefying sand bed, the average rate of settlement is that only in the liquefying region. As can be seen in the figure, in our experimental range of up to 1.8m in sand bed thickness, the average rate of settlement is not affected by the thickness of the sand bed in either the liquefying or non-liquefying sand bed, but the average rate of settlement in the liquefying sand bed is two-times greater than that in the non-liquefying sand bed. Also, the increase in the average rate of settlement in the liquefying sand bed is greater than that in the non-liquefying sand bed until about 100 waves; thus, settlement is accelerated by liquefaction of the sand bed, and the increase in the settlement rate later becomes smaller.

Fig. 7 shows the relationship between the average rate of settlement and the total head of fluctuating pressure of 1,000 waves for each sand bed thickness. As can be seen in this figure, in our experimental range of up to 1.8m in sand bed thickness, the average rate of settlement is almost the
same in every thickness of sand bed that has the same total head regardless of whether the sand bed is liquefying or non-liquefying, indicating that the average rate of settlement is not affected by the thickness of the sand bed. In the non-liquefying sand bed, the average rate of settlement is almost proportional to H. Also, as stated before, the average rate of settlement in the liquefying region is two-times greater than that in the non-liquefying sand bed.

4.4 Effect of settlement on transmission properties of pore water pressure

In order to see the effect of settlement on the transmission properties of pore water pressure, examples of change in the wave number of the ratio of amplitude of pore water pressure to surface water pressure and phase delay are shown in Fig. 8(a) and (b). These examples are for the case in which liquefaction occurs in the sand bed and the surface layer of the sand bed has sunk by 4.5cm. The ratio of amplitude of pore water pressure to surface water pressure and the phase delay remain almost constant regardless of the wave number, indicating that settlement has very little effect on the transmission properties of pore water pressure. This agrees with the results reported by Zen et al. (1987) and Yamashita et al. (1996).

4.5 Liquefaction region

Fig. 9 shows the liquefaction depth obtained from measured values and theoretical values of excess pore pressure (see Fig. 4) and the depth of liquefaction obtained from the amount of settlement of the sand bed (see Fig. 5). In the case of \( \alpha = 1.15 \), liquefaction of a sand bed theoretically does not occur if the thickness of the sand bed is less than 1.8m. In this figure, it is quantitatively shown that the larger the thickness of the sand bed and the value of \( \alpha \) are, the larger is the liquefaction depth obtained by theoretical values of excess pore water pressure. The liquefaction depths obtained by measured values of excess pore pressure and by the
amount of settlement are almost the same. The measured values and theoretical values of excess pore water pressure and the amount of settlement are very similar when the liquefaction depth is small, but when the liquefaction depth is large, (for example, the line and ▼ of L=1.8 in the figure), the measured values become smaller than theoretical values. This tendency for the measured values to be smaller than the theoretical values becomes larger as the liquefaction depth increases. This is thought to be due to the improvement in transmission properties of pore water pressure as the liquefaction depth increases (and the phase of liquefaction becomes longer).

4.6 Hardness of the sand bed

Fig. 10 shows the relationship between void ratio $e$ of the surface layer of the sand bed and the penetration depth $D_p$ measured by a cone penetrometer in the case of a liquefying sand bed and non-liquefying sand bed. The void ratio $e$ is obtained from the rate of settlement of the surface layer. As can be seen in the figure, the penetration depth is determined only by the void ratio $e$, and there is almost no difference in penetration depth of the liquefying and non-liquefying sand bed. In other words, it has been quantitatively shown that the penetration depth becomes smaller and the sand bed becomes harder with settlement of the sand bed.

5. Conclusions

The following is a summary of the results obtained in this study:
① The values of pore water pressure in the sand bed subjected to fluctuating water pressure under conditions in which liquefaction does not occur agreed well with the theoretical values of Zen et al. (1987).
② Under conditions in which liquefaction occurs, in the phases in which the density of the sand bed is high (0° ~90°), the negative values of excess pore water pressure were similar to the
theoretical values of Zen et al. (1987), but in the phases in which liquefaction occurs (225° and 270°), the measured values of excess pore water pressure were smaller than the estimated values.

The rate of settlement in the liquefying region was about two-times greater than that in the non-liquefying region, indicating that settlement of a sand bed is accelerated by liquefaction.

In our experimental range of up to 1.8m in total thickness of the sand bed, the average rate of settlement was almost proportional to the total head of fluctuating water pressure in all thicknesses of the sand bed.

Settlement had very little effect on the transmission properties of pore water pressure.

It was quantitatively shown that the larger the thickness of sand bed and the value of α are, the larger is the liquefaction depth obtained by theoretical values of excess pore water pressure.

Liquefaction depths obtained from measured values of excess pore water pressure and from the amount of settlement were very similar.

In the case where the liquefaction region is small, the measured values of excess pore water pressure and amount of settlement agreed well with the theoretical values. However, the measured values became smaller than the theoretical values as the liquefaction region became larger.

The penetration depth measured by a cone penetrometer is determined only by the void ratio \( e \) regardless of whether the sand bed is liquefying or non-liquefying, and it was quantitatively clarified that the sand bed becomes harder with settlement of the sand bed.

A method for estimating the bed velocities produced by a ship’s propeller wash influenced by a rudder.

G.A. Hamill 1, J. A. Mc Garvey 2, P.A. Mackinnon 3

Introduction

When a ship manoeuvres within the confines of a harbour it does so with minimal bed clearance and at near to maximum power. The propeller produces thrust by drawing in water and accelerating it. This accelerated flow is discharged from the propeller in the form of a jet or wash. Under these circumstances the wash can impact on the bed with velocities in excess of 8 m/sec. These high velocities erode the seabed, and where this occurs near to quay structures serious damage may result. Bergh and Magnusson (1987) Chait (1987) and Johnston (1985) are among many who have given specific details of problems which have occurred world-wide.

In order that an engineer may provide adequate protection to the bed form the erosive power contained within the propeller wash a full understanding of the magnitude and distribution of the velocities within it must be known. Stewart (1983), Fuehrer (1977) and Berger (1981), among others, have studied the wash and have provided predictive equations for velocity calculations. However, they have not included the influence of the rudder on the formation and distribution of the wash.

Related Research

Robakiewicz (1966), Verhey (1983) and Fuehrer et al. (1987) carried out investigations which allowed for the presence of the rudder, and they presented methods by which the velocities on the sea bed could be calculated. These equations are limited in that a full velocity distribution cannot be calculated and they are related to an efflux velocity equation which has been found to be up to 20% in error.

Hamill and McGarvey (1996) presented the initial findings from a study aimed at providing a method for designing for propeller action in harbours and this paper contains information which extends that already presented at ICCE'96.

**Experimental set-up**

A number of model propellers, operating at up to four speeds of rotation, have been tested in an experimental tank 7.5m x 4m x 1 m deep. Rudders were manufactured in accordance with the Ship Design Manual, and these were tested within the normal range of operation, at angles of up to 35 degrees on either side of the propeller axis. Velocity measurements, in both the axial and radial directions, were taken on a fine 3D grid within the wash using a twin component Laser Doppler Anemometer and an array of Pitot static tubes.

**Rudder effect**

Hamill and McGarvey (1996) discussed the influence of the rudder, on the propeller wash. The wash was found to split into two different jets, one directed towards the free surface the other directed towards the seabed, as shown in figure 1. It was found that there was an increase in the magnitude of the axial velocity by as much as 30% with the rudder present when compared to the jet without a rudder. A method by which the velocity distribution on the face of the propeller could be calculated was given. This has been shown to provide a more accurate value for the efflux velocity.

As the rudder turns into either the bottom jet, or surface jet, it changes the resulting velocity magnitudes and distributions which prevails within the wash. This can be seen in figure 2 which represents the same situations as figure 1 but with the rudder turned -15 degrees into the bottom jet. The bottom jet has now been moved in both the vertical ‘y’ and transverse ‘z’ plane when compared to the zero rudder location.

![Figure 1 Isovels at zero rudder angle](image1)

![Figure 2 Isovels at -15 degree rudder angle](image2)
The equations presented by Hamill & McGarvey (1996) provide a method for calculating the position of the maximum velocity in the ‘y’ plane only. It is clear from figure 2 that transverse diffusion is also present within the wash.

The ability to locate the position of maximum velocity in the three dimensional space behind the propeller, along with a method for predicting its magnitude, allows the calculation of the velocity distribution around that value to be attempted. Previous distribution equations have been based on an axis-symmetrical approach. However, as the rudder angle changes it becomes clear that within the bottom stream a symmetric assumption would be invalid and as a consequence separate distribution equations have been developed which describe the velocities vertically and transversely within the jet, allowing for changes in rudder position.

**Propeller wash characteristics**

Having already established a relationship for the velocities on the ‘y’ (vertical) plane, Hamill and Mc Garvey (1996), the location of the maximum velocity along the ‘z’ plane was then observed. It was expected that this would be more influenced by altering the rudder angle due to the deflection of the jets by the rudder which provides directional control for a ship.

The location of the maximum velocity within the bottom stream in the ‘z’ direction of the jet was tracked and plotted. It was found that the rudder had a significant effect in controlling the direction of the bottom stream. The location of the maximum velocity within the bottom stream of a typical wash is as shown in figure 3. The general trend of the surface stream showed that with a change in rudder position there was a corresponding change in the stream which tended in the general direction of the rudder, for all of the angles tested. Figure 3 shows however that this trend does not continue for the bottom stream. It can be seen that with an increase in the rudder angle from 15 to 35 degrees there is in fact a reduction of the diffusion angle of the bottom stream. Figure 4 shows the location of the maximum velocity in the bottom stream of another wash, for all of the angles tested. It can be seen that for the negative rudder angles the streams diffuse in the
direction of the rudder however once again it can be seen that there is a reduction of the horizontal diffusion angle as the rudder angle is increased from 15 to 35 degrees. The explanation for this ambiguous trend lies in the initial formation stages of the jet, and is the result of the direction of rotation of the propeller and increasing positive rudder angles.

**Equation for location of maximum velocity on Z-plane**

As was the case for the vertical plane, the location of the maximum velocity in the ‘z’-direction is best described by a linear decay equation of the type:

\[
\frac{R_{mx}}{R_{mo}} = Const \left( \frac{X}{D_p} \right)
\]

1

where \(R_{mx}\) is the location of maximum velocity in the ‘z’ plane at any axial distance ‘X’ from the propeller. Figure 4 showed the location of the maximum velocity in the Z-direction for a typical test propeller, for all of the rudder angles tested. It can be seen that for the zero rudder angle position the bottom stream moves towards and crosses the propeller centreline. It has been shown that the bottom stream tends in the direction of the rudder and as the rudder angle varies there is a corresponding variation in the direction of the bottom stream. There was a change in this trend observed for the +35 degree rudder angle in which there is a reduction of the jet deflection as the rudder is turned from +15 to +35 degrees.

With reference to figure 4 it is clear that the magnitude of the constant term in equation 1 is some function of the rudder angle. The magnitudes of these constants for each propeller, propeller speed of rotation and rudder angle combination was obtained by a simple regression analysis, and these are compared to the change in rudder angle in figure 5.

![Spline smoothing curve](image)

**Figure 5** Measure slope for location of maximum velocity on Z plane at various rudder angles.
It can be seen that there is a gradual decrease in the slopes from the -35 degree rudder position to the +15 degree rudder angle and then as expected there is a reduction in the slope from +15 to +35 degrees. A spline curve was then fitted to determine if a mathematical relationship existed between the slopes and the rudder angle, and is plotted as shown in figure 5. It can be seen that the curve peaks at some position between +15 and +20 degrees and thereafter there is a reduction in slope and without further tests this rudder angle remains ambiguous. It was therefore decided to develop a relationship between the slope and rudder angle within the range of -35 and +15 degrees. It was found that the following linear relationship provided the best correlation for the data,

\[ m_z = -0.27 - 0.04(\theta) \]

which achieved a correlation of 0.98 where \( \theta \) is the rudder angle in radians. The location of the maximum velocity along the Z-plane may therefore be determined using the following equation, within the range -35<\( \theta \)<+15 degrees,

\[ \frac{R_{nx}}{R_{no}} = 1 + m_z \left( \frac{X}{D_p} \right) \]

It would be recommended that further tests be carried to clear the ambiguity surrounding the location of the maximum velocity on the Z-plane when the rudder is located between +15 and +35 degrees. It appears that at some angle within this range the general trend changes where there is in fact a decrease in the rate of diffusion with increasing rudder angle.

This equation when used with those for the vertical plane position, \( R_{ny} \), reported in Hamill & McGarvey (1996), enable the location of the position of the maximum velocity in the 3D space behind the propeller to be determined.

### The velocity distributions within the propeller jet.

A method has already been reported by which the magnitude of the maximum axial velocity, at any axial distance \( X \) within a propeller jet, can be determined, Hamill & McGarvey (1996). It is also necessary to predict accurately the velocity distributions around this maximum value so that adequate bed protection can be designed to protect quay structures.

The velocity distributions, within the zone of established flow, for a free expanding jet without a rudder present are symmetrical about the axis of the propeller. The velocity distributions at any point within the jet have been shown to follow the normal probability curve as proposed by Albertson (1950), and modified by Fuehrer and Romisch (1977). Their equation has been successfully used by several authors and was found to describe quite accurately the velocity distributions within a propeller jet without a rudder present.
Influence of rudder on velocity profiles

The rudder has been shown to split the flow into two high velocity streams, one directed towards the surface and the other directed towards the bottom. It was decided to investigate the velocity distributions within the bottom stream as this is the jet which induces bed velocities, and as a result, can lead to erosion of the bed. It has previously been shown that a variation in rudder angle significantly alters the diffusion characteristics of the bottom stream, with a confining and an elongation effect within the stream, resulting in a loss in the symmetry common to the free expanding wash.

Velocity distribution on vertical Y-plane.

The velocity profiles along the Y-plane through the jet axis, at increasing distance from the propeller, were plotted for the bottom stream. Figure 6 shows the axial velocity distributions for a typical jet with a zero rudder angle. It can be seen that with distance from the propeller there is a decay in magnitude of the velocity profiles and an increase in the distance to the location of the maximum velocity. It can be seen that they appear quite similar to the normal probability distributions suggested by previous authors. It can be seen that the distributions are approximately symmetrical through the stream axis, although the velocities are slightly greater along the profile above the stream axis that is due to the proximity of the surface stream close to the propeller. As the distance from the propeller increases, the distances between the streams also increase and the influence of the surface stream becomes less significant. This was found to be the general trend of all the results obtained for the zero rudder angle position.

\[
\frac{V_{yr}}{V_{max}} = \exp \left[ -0.5 \left( \frac{V}{\sigma} \right)^2 \right]
\]

Figure 6 Axial velocity distributions on the Y plane measured from the location of maximum velocity within the bottom stream.

In order to describe the velocity distribution it is necessary to consider the normal probability curve proposed by Albertson to describe the velocity profiles,
where $V_{XR}$ is the velocity at the point under consideration and $y$ is the distance from the propeller axis to the point. The term $\sigma$ is the standard deviation of velocity and is the distance from the axis to the point at which the velocity has a value of 0.605 $V_{max}$ and this term depicts the depth of the profile. It was therefore required to determine the location of the standard deviation of velocity so the velocity distributions within the propeller jet could be established.

The location of the maximum velocity, and the velocity distributions on the Y-plane within the propeller jet, were found to be dependent on rudder angle. Therefore, as the shape of the distribution profile depends on the standard deviation of velocity, it would be reasonable to assume that the standard deviation of velocity is dependent on the magnitude of rudder angle. The location of the maximum velocity on the Y-plane has been established in terms of the distance below the propeller axis. It was therefore decided to establish a point one standard deviation of velocity below the maximum as the distance below the propeller axis, $R_{GY}$. It was observed that there was a gradual increase in the distance to this point with distance from the propeller and this can be observed when plotted as shown in figure 7. The location of the maximum velocity on the Y-plane is also plotted for comparison.

\[
R_{GY} = -0.8 R_{mo}(-0.322 + 0.00126)X
\]

The velocity distribution can be established based on equation 4 proposed by Albertson where $y$ is the distance from the location of the maximum velocity on the profile and is equal to $R_{any} - y_m$ in which $y_m$ is the distance from the propeller axis to the point under consideration. Figure 8 shows a schematic view of the velocity profiles within the propeller jet to avoid confusion. The standard deviation of velocity, $\sigma$, as shown in figure 8 is equal
The velocity distribution within the propeller jet can therefore be described as follows,

\[
\frac{V_{yr}}{V_{\text{max}}} = \text{EXP} \left[ -0.5 \left( \frac{R_{my} - y_m}{R_{my} - R_{my}} \right)^2 \right]
\]

where \( R_{cy} \) is calculated from equation 5.

This equation will predict quite accurately the velocity distributions within the propeller jet for a given rudder angle at distances up to 10 \( D_p \).

**Velocity distribution on the Z-plane**

In a similar manner to that employed for the analysis of the locus of one standard deviation on the 'y' plane, a relationship for the 'z' plane was also established. Thus \( R_{cz} \) can be calculated from

\[
R_{cz} = 0.2R_{m0} + (-0.141 - 0.014\theta)X
\]

The velocity distribution along the Z-plane can now be established based on the normal probability equation where the distance along the profile, \( z \), is equal to \( R_{mz} - z_m \), in which \( z_m \) is the distance from the propeller axis to the point under consideration, and \( R_{mz} \) is the distance to the maximum velocity. For clarity this is shown in figure 9. The standard deviation of velocity, \( \sigma \), is equal to \( R_{cz} - R_{mz} \), therefore the axial velocity distribution on the z axis may be expressed as follows,

\[
\frac{V_{xz}}{V_{\text{max}}} = \text{EXP} \left[ -0.5 \left( \frac{R_{mz} - z_m}{R_{cz} - R_{mz}} \right)^2 \right]
\]

where \( R_{cz} \) is calculated from equation 7.
The present investigation has studied the influence of the rudder within a ship's propeller jet, and has confirmed the formation of two high velocity streams, one directed upwards to the surface and the other directed downwards towards the bottom.

The influence of the rudder on the maximum velocity at the face of the propeller i.e. the efflux velocity, was found to be insignificant, although at high propeller speeds and large rudder angles some confinement was observed with a variation of approximately 8% noticed.

It was found that there was an increase in magnitude of the axial velocities by as much as 30% with the rudder present when compared to the jet without a rudder.

The location of the maximum velocity within the propeller jet was on the axis of each stream which were established from the position of the rudder. The location of the maximum velocity within the jet was found to be independent of propeller speed however, there were significant changes in the location of the maximum velocity due to variations in rudder position. Equations are presented which locate the maximum velocity in the vertical and transverse directions allowing for changes in rudder position.

The velocity distributions were found to change dramatically when compared to the jet without a rudder. Investigations showed that the equations used to predict the velocity distributions within the jet without a rudder present cannot successfully be applied to the jet with a rudder. The rudder position significantly changed the diffusion characteristics of the propeller jet and as a consequence distribution equations were developed to describe the velocities vertically and transversely within the jet, allowing for changes in rudder position, based on the normal probability curve suggested by Albertson (1950).

The velocities at any point within the jet can be determined using the equations presented. They are first approximation equations and further work should consider a greater number of rudder positions. Having established knowledge of the velocities within the propeller jet, it is now possible to design adequate scour protection.

DESIGN OF SCOUR PROTECTION FOR THE BRIDGE PIERS OF THE ØRESUND LINK

Lars Kirkegaard¹, Mogens Hebsgaard² and Ole Juul Jensen³

Abstract

The Øresund Link between Denmark and Sweden consists of a cable stayed bridge, a man-made island and an immersed tunnel. The engineering design of the scour protection of the 45 approach bridge piers was made on the basis of numerical and physical modelling. The numerical studies included determination of the hydrographic design conditions and wave/current induced bed shear stresses along the bridge alignment, enabling the selection of the most exposed piers for each bridge segment and pier type. Physical model tests were then performed with the selected piers to investigate the necessary scour protection. This article describes the methods applied and the conclusions and resulting scour protection design.

Introduction

The 16 km long fixed link across the straight between Denmark and Sweden, the Øresund Link, will consist of three main elements: 1) an immersed tunnel, 2) a man-made island, and 3) a cable stayed high bridge. The immersed tunnel crosses the eastern channel between Kastrup on the Danish coast and the man-made island Peberholm just south of Saltholm. The cable stayed high bridge, including approach bridges, crosses the main shipping route in Øresund, Flinterenden, and reaches the Swedish coast at Lernacken. The location of the bridge is shown in Figure 1.

This article concerns the design of the scour protection for the approach bridge piers, which has been investigated through both numerical and physical model tests carried out by Danish Hydraulic Institute (DHI).

Bridge Design

The approach bridges are founded on 45 concrete piers at water depths less than 10 m. The cross-sections of the piers are prismatic with slightly streamlined up- and down-stream ends as shown in Figure 2.b. The dimensions of the pier shafts at seabed level are approximately 6 m x 18 m, and those of the supporting caissons 6 m x 18 to 22 m.

Due to a strict environmental requirement of zero blocking of the water exchange between the North Sea and the Baltic Sea, it was decided to place the pier caissons in excavated pits in the sea bed, see Figure 2.a. The zero blocking requirement further implied that only a few of the supporting caisson walls were allowed to protrude above the original sea bed level, and that the scour protection had to be placed flush with the sea bed.

Figure 2       (a) Vertical cross-section of bridge pier placed in excavation
                 (b) Horizontal cross-section of streamlined pier shaft.

Placing the caissons in the excavated pits and founding them directly on the hard Copenhagen Limestone further enabled the bridge to withstand the large forces of ice
and design ship impacts, but also eliminated the risk of undermining of the caissons, which is usually the major risk of bridge scour.

To ensure the necessary geotechnical stability of the piers, backfilling of the excavated pits was required. The main purpose of the scour protection was thus to contain the backfill inside the excavation.

The geotechnical conditions vary along the bridge alignment, with a seabed consisting of hard non-erodible limestone covered by a layer of clay till or sand/gravel. The thickness of the erodible top layers varies between 0 and 4 m along the bridge alignment. Large differences are even found from one side of the excavation to the other at each pier location.

**Numerical Studies**

The hydrographic conditions in the region has been derived from intensive measuring campaigns and numerical model studies prior to the scour investigations and model testing, and these have been used to define the Design Requirements. From the previous studies and the specifications in the design requirements, the relevant design conditions for waves, currents and water levels along the bridge alignment have been established.

The wave conditions varies along the alignment and are relatively directional. The maximum significant design wave height, $H_s$, is up to 2.7 m for southerly wind directions. The wave heights are generally lower for the near-shore piers due to depth limited breaking of waves. The design wave heights for events with a 100 and 10,000 year return period (yrp) are shown in Table 1 (intervals).

The current conditions are nearly bi-directional, with the angle between the main current direction and pier orientation varied between 10 and 20°. The maximum design current velocity was found to be 3.8 m/s close to the navigation channel for southward currents. The design currents velocities (intervals) are shown in Table 2.

*Table 2 Design Current Velocities.*
There is an inherent correlation between extreme wave and current events, as these events are primarily caused by the same meteorological conditions, and it was subsequently decided to use a straightforward combination of wave and current conditions in the design.

As the correlation between water levels and wind directions showed a rather large scatter and since the scour protection is most exposed at low water, assuming equal wave and current conditions, it was decided to adapt a conservative most probable low water level in the design. This level varied between -0.5 m and +0.5 m.

Based on the data described above, the bed shear stress distribution along the bridge alignment was computed using the numerical sediment transport programme STP, which is a part of LITPACK, DHI's deterministic modelling system for littoral processes. All relevant combinations of wave and current directions were calculated using a bed grain size of 0.2 mm. The resulting shear stresses are shown in Figure 3.

The limited variation in the size of the maximum shear stress for the various wave directions indicate that the bed shear stress is largely dominated by the current. This is even more clear from the direction of the maximum shear stress, as the waves are only able to deflect the maximum shear stress direction approx. ±10-15° away from the main current direction. This fact was important for the selection of set-up of the physical model and definition of the test programme.

The shear stresses shown in Figure 3 are not representative of the shear stresses actually experienced by the scour protection once the bridge piers and the protection have been placed, as the piers and the rocky protection themselves alter the flow pattern fundamentally by amplification and by generation of turbulence.

However, the figure enables the selection of the most exposed piers of each pier type to be tested in the hydraulic model along with the corresponding design conditions to be used in the model.

Three types of pier caissons exist, viz. Type A, B and C. These types are characterised by the number of supporting caisson walls and whether these protruded above sea bed/scour protection level. Type A (W11-W4 and E4-E11) have seven supporting walls terminated just below original sea bed level, Type B (W20-W12 and E12-E26) have
five supporting walls that protrude up to 1.0 m above original sea bed level, and Type C (W23-W21 and E27-E28) have seven walls that protrude up to 1.0 m above sea bed level.

The piers closest to the Swedish coast were placed in a 100 m wide excavated construction channel. The local bed levels were thus lower than those used for the computation of the bed shear stresses above. Using the actual bed levels significantly reduced the bed shear stresses, as indicated with • marks on Figure 3, and these piers could therefore be designed as the less exposed western piers.

Based on Figure 3, the following piers were selected for further investigation in the physical model:

- E11, representing all Type A piers
- E17, representing the eastern Type B piers
- W12, representing the western Type B piers

No tests were performed on Type C piers, as these were all relatively sheltered.

Physical Model Tests and Scour Protection Design

A physical 2D model was constructed to a linear scale of 1:40 in a 5.5 m wide flume in which unidirectional irregular waves and current could be generated simultaneously. The model set-up is shown in Figure 4.

![Figure 4 Two-dimensional model flume set-up.](image-url)

The conditions created in the 2D model, combining extreme waves and currents from different directions into one single direction, is estimated to create more critical
conditions for the scour protection, as the amplification patterns of shear stresses from waves and currents coincide.

A total of fourteen test series were carried out on three different pier types in order to investigate the stability of the scour protection. Each test series included three standard tests: 1) 100 y waves and current, 2) 10,000 y waves and 100 y current, and 3) 10,000 y waves and current. Each test had a duration corresponding to four hours in nature.

Three different current (and wave) directions relative to the pier were studied. The first tests with current directions of 10° and 40° showed that the damage pattern is rather sensitive to the direction. The tests yielded acceptable damage and collapse respectively for otherwise identical situations. As the current was found to dominate the scour process outside the protection, it was concluded that a current direction of 20° relative to the pier should be applied in the design.

![Figure 5 Typical damage pattern for 20° and 40° pier alignment.](image)

Two types of damage were observed, viz. direct and indirect damage. Direct damage is caused by the direct action of waves and current on the surface of the protection, whereas indirect damage at the edges of the protection is a result of the scouring of the seabed just outside the protection resulting in stones being moved into the down-stream scour holes by wave action. Figure 5 shows some typical patterns of scour outside the protection and the resulting damage at the edges.

Indirect damage occurred along the downstream side and downstream end of the protection. The direct damage occurred in three areas: At the downstream side, the downstream end, and in the upstream cells (between the supporting walls) or all cells along the pier. Figure 6 shows the areas where damage occurred for a successful test.
To prevent any damage from impacting stones on the concrete, it was specified to use the largest stones of each fraction in the upstream cells and to place these with great caution. In the downstream area the stone size was slightly increased to reduce the number of stones being moved.

As a consequence of the results of the first test series showing larger damage than originally estimated, the test programme was currently changed and very often the layout of the scour protection in a test series was defined from the results of the previous test series in order to optimise the design.

![Figure 6 Typical damages observed in the physical model (looking upstream).](image)

In addition to the traditional stability tests, it was decided to carry out tests to investigate the effects of a thin layer of erodible material on top of the limestone. This test showed that the extent of the protection could be reduced significantly for piers placed in areas where the limestone is only covered by a thin layer of erodible soil. Figure 7 shows a photo taken after Test 3 (10,000 yrp). The dark areas is the limestone surface being exposed where the erodible material has been washed away.

Finally a test was carried out to investigate the time scale for the scouring in sand/gravel and clay till outside the protection. Analysis of the results indicated that the scour outside the protection would develop rapidly if the sea bed consisted of sand, whereas it would not exceed 1.0 m within an average 10 year period, if the sea bed consisted of 30 mm gravel. For clay till the scour was found to be in the order of 0.4 m for an average 10 year period, but this value could vary between 0.1 m and 3-4 m corresponding to fully developed scour holes. It is important to note that the values above are determined assuming homogeneous conditions. In reality the sea bed
consists of a mixture of sand, gravel, clay till and boulders. The sea bed will therefore to a certain extend tend to be self-armouring if erosion occurs.

The uncertainties of estimating the parameters for the clay till were considered too large to facilitate in the design, but indicated that it might be possible to include this in the design if more intensive studies and possibly a comparison of the results with available field observations were carried out.

The final layouts of the scour protection were derived by comparing the damage patterns of each test series with the design requirements and taking the local soil conditions into consideration. An example of the protection layout is shown in Figure 8 and Figure 9.

It has further been specified in the design that the protection shall be adjusted according to the actual conditions found on site in the construction phase.

The most important change in the design concerned the back fill. It was originally foreseen that the caissons were to be back filled with the sound friction materials
recovered during excavation of the pits, and to place a filter layer between the back fill and the scour protection. However, the large difficulties experienced by the contractor keeping the back fill in place while placing the filter layer, caused him to substitute the native back fill with imported, coarse quarry run. This change in the original design has further increased the safety of the scour protection, and in case the protection is damaged, the maintenance costs will reduced significantly.

Figure 9  Cross-section of scour protection around Type A piers.

Conclusion
The detailed hydrographic design data were used in the design of the scour protection, including numerical calculations and hydraulic model tests. The test programme was continuously changed to optimise the design. This resulted in a differentiated design of the scour protection along the bridge alignment that fulfils the given requirements, taking both the pier specific hydrographic, geometrical and geotechnical conditions into account.

EXPERIMENTAL ANALYSIS OF WAVE-INDUCED LIQUEFACTION IN A FINE SANDBED

Kojiro Suzuki¹, Shigeo Takahashi² and Yoon-Koo Kang¹

Abstract

A series of experiments were conducted to examine wave-induced liquefaction in a loosely packed fine sandbed, which was specifically used to ensure the presence of residual excess pore pressure. Also observed was the compaction of a liquefied sandbed in response to cyclic wave loading; a phenomenon thought to reduce the possibility of liquefaction. In addition, pore water was supplied from the bottom of the sandbed such that the effect of underground water pressure on liquefaction could be clarified.

1. INTRODUCTION

Wave actions are known to produce the phenomenon of sand liquefaction. One type of sand liquefaction is caused by seepage flow due to differences in water pressure, which typically occurs in the vicinity of a sheet pile (Figure 1), although it can also be caused by waves generating a pore pressure gradient in the sandbed. Such behavior is termed as "momentary wave liquefaction," and has been simulated by Zen et al. (1990) using a fluctuating pressure-type liquefaction test apparatus. Another type of liquefaction occurs during an earthquake (Figure 2), where in this case, pore pressure builds up due to shear stress in the sandbed such that the residual pore pressure produces liquefaction. Foda et al. (1991) simulated this behavior using a wave flume experiment, while Sekiguchi et al. (1995) did so using a centrifuge experiment.

Due to the unusual nature of sand boiling, which can cause devastating failure of coastal breakwaters, elucidating its mechanisms is a key task in breakwater design processes. This led to the present study that describes the results of experiments in which the following phenomena were observed: (1) liquefaction behavior of a loosely packed, fine sandbed due to residual excess pore pressure, (2)

compaction behavior of a fine sandbed due to cyclic wave loading, (3) the softening effect of a fine sandbed due to large standing waves, and (4) liquefaction behavior due to bottom-supplied feedwater.

2. EXPERIMENTAL SETUP

A large wave flume (105 m × 0.8 m) (Figure 3) was used to generate sand liquefaction. Water depth was changed from 0.35 to 1.0 m. The sandbed, which consisted of a mixture of silt and fine sand, was 6.0 m long and 1.0 m deep (Fig. 4). A feedwater system supplied water to the bottom of the sandbed, being used to produce an initially loose sandbed condition and to generate seepage flow liquefaction. The 50% sieve diameter of fine sand was 0.08 mm. We measured water surface displacement and pore pressure in the sandbed. Regular waves were mainly applied to sandbed without a structure, although a caisson was installed in order to investigate a standing wave condition.

The sandbed is equipped with a feedwater system to supply water from the bottom of the sandbed; a system used to produce an initially loose sandbed condition, and to generate seepage flow liquefaction.

3. EXPERIMENTAL RESULTS

**Loose Sand under Progressive Waves**

As can be seen in Photo 1, very loose sand behaves like a thick liquid. At the same time, the motion of the sand induces wave breaking and damping. Figure 5 shows typical pore pressures generated in the sandbed, where after just several waves the pore pressure oscillates and rapidly increases due to the wave-induced residual pore pressure. The magnitude of this pressure corresponds to the submerged weight of the sand.

![Photo 1](Image)

**Photo 1** Effect of progressive waves on a loose sandbed.

![Figure 5](Image)

**Figure 5** Pore pressure profile in a loose sandbed hit by progressive waves.
In the case of a loosely deposited sandbed (Fig. 6), the weight of sand is supported by both the pore water and the skeleton structure of the sandbed. Thus, when a wave acts on the bed, the sand skeleton structure breaks due to the shear stress such that only the pore water remains for supporting the sand's weight which corresponds to the increase in residual pressure.

It should be noted that this phenomenon only occurs when the permeability of the sand is low, i.e., if permeability is high, such as in a coarse sandbed, the excess pore pressure easily escapes and the increase in residual pore pressure never occurs. Immediately after wave loading, sand boiling occurs (Photo 2) due to the excess pore water being squeezed out from the sandbed up to the sandbed surface. Such boiling is produced by residual pore pressure and lasts 2–3 min.

![Diagram representing residual pore pressure](image)

Figure 6 Diagram representing residual pore pressure

![Photo 2 Sand boiling phenomenon](image)
Compaction Due To Cyclic Wave Loading

Because substantial settlement was observed in a fine sandbed, we investigated this compaction effect using series of cyclic loading tests in which a group of monochromatic waves was applied at 10-min intervals (figure 7). Wave period \( T \) was 2.08 s, wave height \( H \) was 48.8 cm, and each group consisted of 37 waves.

![Monochromatic wave \( T=2.08s, H=48.8cm \)](image)

**Figure 7** Applied cyclic loading scenario.

Figure 8(a) shows sandbed settlement after applying cyclic loading, where the effect of boiling forces the pore water out of the sandbed such that cyclic wave loading causes the bed to gradually settle. In fact, after the 14th loading, total settlement reaches about 13 cm; a substantial decrease in bed thickness.

Due to the presence of a loose sandbed during the 1st cyclic loading, sand particle motion is very large and vertical displacement is about 9 cm (Fig. 8(b)). However, the ensuing compaction effect with each loading subsequently reduces sand motion such that the 14th loading produces a displacement of only 0.3 mm, after which sand particle movement is not reduced by further loading, although sand ripples do appear such a compacted sandbed.

The compaction effect due to cyclic loading also leads to a reduction in residual pore pressure. Figure 8(b) shows the residual pore pressure \( P_r \) at different heights in the sandbed, where \( P_r \) gradually decreases such that after the 14th loading it vanishes.

Figure 9(a) shows the oscillatory component of pore pressure produced by 1st-loading water surface oscillations, where pore pressures have nearly the same amplitude and show no time lag. This result indicates that loose sand behaves like a thick liquid. At the 4th loading (Fig. 9(b)), however, a very sharp negative peak appears in the pore pressure, being is due to the “dilatancy” effect which will be explained later. At the 14th loading (Fig. 9(c)), it is obvious that pore pressure decreases with respect to the depth of the sandbed, and that a significant time lag is present; an effect produced by compaction of the sandbed.
Figure 8 Compaction effect due to cyclic wave loading.

Figure 9 Profile of oscillatory pore pressure.
Sand Particle Motion after Compacted

Figure 10 shows the amplitude of sand particle motion after the sandbed is compacted, where only those waves larger than a certain height produce visible movement of the sand particles. In this case, large long-period waves acting on the sandbed increase sand particle motion and generate a large shear strain which in general results in the sand having small shear modulus. In other words, larger waves soften the sandbed.

When feedwater is applied from the bottom of the sandbed, the amplitude of the sand particle motion becomes much larger. That is, a 200-cm water head makes the sandbed boil and the amplitude of sand particle movement reaches 5 cm.

Figure 10 Sand particle movement after sandbed compaction.

Effect of Preceding Loading

Another interesting phenomena that occurred is re-liquefaction of the compacted sandbed. Figure 11 shows the change in residual pore pressure due to cyclic loading, where for smaller waves \( T = 1.6 \) s, \( H = 12.7 \) cm liquefaction does not occur until the 5th loading and residual pore pressure diminishes. However, after applying larger waves at the 11th loading, liquefaction reappears; a behavior we call “re-liquefaction.”

Re-liquefaction probably occurs due to compaction by small waves being limited to near the sandbed surface, whereas the increase in shear stress produced by larger waves is sufficient to once again liquefy the bed. When larger waves were continually applied, the compaction expanded deep into the sandbed.
Figure 11 Effect of preceding loading (re-liquefaction).

Loose Sand under Standing Wave

Photo 3 shows a standing wave in front of a caisson model. When the sand bed is loose, it is easily liquefied due to the larger wave pressure compared to that by progressive waves. At the loop of standing wave, sand moves vertically in phase with the movement of surface water and at the node sand moves horizontally in phase with movement of water particles. On the other hand, for a compacted sandbed, its surface moves out of phase, that is lagging by 180 degrees.
Compaction due to Cyclic Wave Loading (Standing Wave Condition)

Figure 12 shows compaction of the sandbed under standing waves, where residual pore pressures are the same at the node and loop of the wave. On the other hand, oscillatory pore pressure is different. In particular, pore pressure at the node is quite large ($\approx 1.7w_dH$) from the 2nd–5th loading.

Figure 13 shows the oscillatory pore pressure profiles at the node of standing wave, where very sharp negative peaks appear. Since such peaks are not present at the loop of a standing wave, this indicates that they are caused by shear stress at the node of the wave. Such sharp negative pressure is surmised to be caused by the dilatancy effect, i.e., shear stress acting on the sand expands the volume of sand containing porous areas which in turn causes sharp negative peaks in pore pressure.

![Diagram showing compaction due to cyclic wave loading by standing waves.](image-url)
Figure 13 Pore pressure profiles at the node of standing wave at the 5th loading.

**Softening Effect**

Figure 14 (a)–(c) shows pore pressure profiles at the loop of a standing wave after it hits a fully compacted sandbed. For small waves (14(a)), the pore pressure lags out of phase and is damped out in the direction of sand bed depth; whereas for larger ones (Figure 14(b)), it penetrates deeper into the sand and is in phase. When feedwater is supplied (Figure 14(c)), this phenomena can be seen more clearly in that there is no lagging out of phase and no damping of pressure.

We call this phenomenon the "softening effect" because it exhibits the same characteristic as the shear modulus of soil. Namely, if the shear strain becomes large, the shear modulus of soil is reduced. Large shear strain is generated by strong wave pressure and amplified by upward seepage flow.

**4. FEM SIMULATIONS**

Using FEM in conjunction with Biot's equations (Park et al (1996)), pore pressure was numerically simulated for a standing wave \( (T = 2.08 \text{ s}, H = 48.8 \text{ cm}) \). Figure 15(a) shows results for compacted sand in which the strain is small with a large shear modulus \( G \) of 10000 kN/m\(^2\), where in this case the oscillatory pore pressure lags out of phase and dampens out in the direction of sandbed depth. Figure 15(b) shows results for lower \( G = 1000 \text{ kN/m}^2 \), a large wave, and feedwater being supplied, where due to the softening effect, pore water penetrates deeper into the sandbed and no time lag or damping occurs. Finally, Fig. 15(c) shows \( G = 10 \text{ kN/m}^2 \) for loose sand, where it should be noted that such substantial lowering of \( G \) produces behavior similar to that observed in Fig. 15(b) with feedwater being supplied.
Figure 14 Pore pressure profile at the loop of a standing wave.

Figure 15 FEM simulation of pore pressure distribution along sandbed depth.
5. SUMMARY

Using model experiments, we observed the following phenomena:

1) When waves act on a loosely packed fine sandbed: 
   (i) the skeleton structure of the sandbed easily breaks and it behaves like a thick liquid, and 
   (ii) the internal pore pressure builds up within it, i.e., sandbed liquefaction occurs due to the excess pore pressure.

2) Waves acting on a sandbed gradually squeeze out the excess pore pressure such that a compaction effects occurs.

3) For small waves, compaction is limited to near the sandbed surface. However, as the waves get larger, the sandbed is again liquefied and compaction substantially expands into deeper depths.

4) Once fully compacted, large waves produce large shear strain due to a corresponding decrease in the shear modulus, i.e., a softening effect occurs allowing the pore pressure, which is in phase in the direction of sandbed depth, to penetrate deeper into the sandbed.

While it is important to gain experimental insights elucidating the effects of waves acting on a fine sandbed, our future work will be directed at developing methods to quantitatively evaluate the effects of such phenomena; as only in this manner can we assuredly prevent associated damage to coastal breakwaters.

LONG-PERIOD OSCILLATIONS IN A HARBOUR WITH FLUID MUD BOTTOM

Wataru KIOKA\textsuperscript{1}, M. Akter HOSSAIN\textsuperscript{2} and Kenji KASHIHARA\textsuperscript{3}

ABSTRACT

Non-linear dynamic responses of fluid mud to the oscillating surface waves in a harbour basin and their consequential effects on the long-period harbour excitations are investigated. A set of Boussinesq-type equations based on the weakly nonlinear, dispersive and viscous wave theories is developed for coupled two-layer density stratified system, incorporating the boundary layer corrections for the interfacial shear and mud viscosity. Laboratory experiments are also conducted with fluid mud for different wave periods, and the generation, behavior and different propagation modes of the interfacial waves are examined. Both experimental and numerical results demonstrate that the amplification of water surface displacements is significantly reduced near the first peak of resonance oscillations in the harbour where the internal mode of the interfacial waves governs the surface mode in the motion of the interface. Near the second peak of resonance oscillations the surface mode of the interfacial waves dominates and the interface oscillates nearly in phase of surface waves. The amplification of water surface displacements at the second peak is also reduced to some extent.

1. INTRODUCTION

In many harbours with silty sediment bed, the stratified system of water waves overlying a fluid mud layer or suspended sediment layer frequently occurs. Such dense lower layer may have significant effects on the harbour excitations induced by

\textsuperscript{1}Professor, \textsuperscript{2}Graduate Student and \textsuperscript{3}Research Associate: Department of Civil Engineering, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466-8555, Japan
Many studies have so far been conducted addressing the long-period excitations in harbours, but all the previous studies were based on the assumption that the bottom of the harbour is rigid and non-responsive to the surface waves. The behavior of soft mud bed in a harbour and its interaction with water surface waves are yet to be understood. In this study, the excitations induced by long-period waves in a harbour with soft mud bed are investigated. Generation of interfacial waves, their behaviors and different propagation modes are examined. Effects of bottom mud on the harbour excitations induced by the long-period waves are also analyzed.

For theoretical formulations, we adopted here a two-layer density stratified fluid system with lower layer as the fluid mud, and a set of Boussinesq-type equations based on the weakly nonlinear, dispersive and viscous wave theories is developed describing the nonlinear interaction of fluid mud with the propagating surface waves. The behavior of mud depends on the wave induced internal stresses, and the soft mud can behave elastically at very low strain, visco-elastically at intermediate strain and viscously at the high strain level (Foda et al., 1993). Since the resonant long-period oscillations may induce relatively high oscillatory strains in the mud, the present model assumes that the mud becomes fluidized and behaves like a viscous fluid (Dalrymple and Liu, 1978). For the verification of numerically predicted results from the adopted model, laboratory experiments are also conducted with fluid mud for different incident wave periods.

Long-period oscillations in a harbour are of concern because such oscillations are often responsible for disturbing the operations of ship terminals, for breaking the mooring of vessels and for flooding on the wharf. Countermeasure against such harbour excitations is however not yet established owing to the difficulty of controlling the incident long waves by means of conventional breakwaters. The present study is also aimed to investigate the behavior of fluidized mud inside the harbour, and thereby addresses the possible means of controlling the harbour excitations using fluidized mud. Since the wave heights inside the harbour are usually too small to liquefy the silty harbour bed, a fluidized sediment bed may be artificially generated by boiling (see Takahashi et al., 1994).

2. THEORETICAL FORMULATION

2.1 Governing Equations

A definition sketch of the two-layer fluid system adopted for the theoretical model is presented in Fig. 1. The surface wave is propagating in water depth $h$ over a dense mud layer of thickness $d$. Beneath the lower denser fluid mud, we assumed a rigid impermeable bed. In the analysis, the density-stratified fluid is confined to a harbour basin. The density and viscosity are respectively denoted by $\rho$ and $\nu$, and the subscripts 1 and 2 stand for upper and lower layers respectively. The governing equations for the fluid motion are the continuity and Navier-Stokes equations for an
incompressible fluid. For the simplicity, the mathematical formulations described hereinafter are only for the two-dimensional motion.

The dynamic and kinematic boundary conditions at the free-surface are given by

\[ p_1 = 0 \quad (z = \zeta) \]  
\[ w = \zeta_x + u \zeta_x \quad (z = \zeta) \]

where \( p_1 \) is the pressure, \( u \) and \( w \) are respectively the horizontal and vertical velocities in the upper layer, and \( \zeta \) is the free-surface displacement. The subscripts \( x \) and \( t \) indicate the partial derivatives. At the water-mud interface, the following boundary conditions are imposed:

\[ p_1 - 2\rho_1 v_1 w_x = p_2 - 2\rho_2 v_2 (W + \tilde{W})_x \quad (z = -h + \xi) \]  
\[ \{u - (U + \tilde{U})\} \xi_x - \{w - (W + \tilde{W})\} = 0 \quad (z = -h + \xi) \]  
\[ (U + \tilde{U})_x + (W + \tilde{W})_x = 0 \quad (z = -h + \xi) \]  
\[ u = U + \tilde{U} \quad (z = -h + \xi) \]

where \( U \) and \( W \) are the horizontal and vertical velocities in the lower layer respectively, \( \tilde{U} \) and \( \tilde{W} \) are the horizontal and vertical rotational velocities at the interface for the lower layer respectively, \( \xi \) is the interfacial displacement, and \( p_2 \) is the pressure in the lower layer. The subscripts \( x \) and \( z \) indicate the partial derivatives. Eqs. (3), (4), (5) and (6) are respectively the condition for normal stress continuity, the usual kinematic condition, the condition for shear stress continuity and the continuity of horizontal velocity. The viscous effects of upper fluid are assumed very small, and the rotational velocities at the interface are disregarded in the upper layer. This assumption will be discussed in the following section.

The boundary condition on the fixed impermeable bottom of the lower layer is imposed as

\[ W + Ud_x = 0 \quad (z = -h - d) \]

Based on the assumption of weak viscosity, the rotational velocities are neglected entirely near the bottom boundary.
2.2 Derivation of Boussinesq Equations

The continuity and Navier-Stockes equations for the two-layer density stratified system of flow of the incompressible fluids and the boundary conditions cited in the previous section provide a complete description of the present model. A perturbation from long wave theory to include the effects of frequency dispersion and viscosity, consistent with Boussinesq theory, is carried out to facilitate the approximate solutions to the above equations. As a first step of formulations, the following non-dimensional variables are introduced in terms of characteristic frequency \( \omega \), characteristic wave amplitude \( a_0 \), and characteristic water depth \( h_0 \):

\[
x' = \frac{ax}{\sqrt{gh_0}}, \quad y' = \frac{ay}{\sqrt{gh_0}}, \quad z' = \frac{z}{h_0}, \quad t' = \alpha t, \quad u' = \frac{h_0 u}{a_0 \sqrt{gh_0}}, \quad U' = \frac{h_0 U}{a_0 \sqrt{gh_0}}
\]

\[
h' = \frac{h}{h_0}, \quad a' = \frac{d}{h_0}, \quad \xi' = \frac{\xi}{a_0}, \quad \xi'' = \frac{\xi''}{a_0}, \quad p_1' = \frac{p_1}{\rho_1 g a_0}, \quad p_2' = \frac{p_2}{\rho_2 g a_0}
\]

In addition, the following two length ratios are defined:

\[
\varepsilon = \frac{a_0}{h_0}, \quad \mu = \frac{\omega^2 h_0}{g}
\]

Introducing the potential \( \phi \) for the upper layer and \( \Phi \) for the lower layer, and substitution of these variables into the governing equations reduces to the following non-dimensional forms after some manipulations:

\[
\mu^2 \phi_{xx} + \phi_{zz} = 0 \quad (-h + \varepsilon \xi \leq z \leq \varepsilon \xi)
\]

\[
\mu^2 \Phi_{xx} + \Phi_{zz} = 0 \quad (-d - h \leq z \leq -h + \varepsilon \xi)
\]

\[
\varepsilon \phi_t + z + \frac{1}{2} \varepsilon \left[ \phi_x^2 + \frac{1}{\mu^2} \phi_z^2 \right] = -p_1 \quad (-h + \varepsilon \xi \leq z \leq \varepsilon \xi)
\]

\[
\varepsilon \Phi_t + z + \frac{1}{2} \varepsilon \left[ \Phi_x^2 + \frac{1}{\mu^2} \Phi_z^2 \right] = -p_2 \quad (-d - h \leq z \leq -h + \varepsilon \xi)
\]

\[
p_1 = 0 \quad (z = \varepsilon \xi)
\]

\[
p_2 = 0 \quad (z = \varepsilon \xi)
\]

\[
\varepsilon \zeta_t + \varepsilon \mu^2 \zeta \phi_x - \phi_z = 0 \quad (z = \varepsilon \xi)
\]

\[
p_1 - \frac{2}{\mu^2} \rho_1 V_1 \phi_{xx} = p_2 - \frac{2}{\mu^2} \rho_2 V_2 \Phi_{xx} \quad (z = -h + \varepsilon \xi)
\]

\[
\phi_{xx} + \Phi_{xx} = 0 \quad (z = -h + \varepsilon \xi)
\]

\[
\mu^2 d_x \phi_x + \phi_t = 0 \quad (z = -d - h)
\]
For convenience the primes will be dropped from here on. The smallness parameters \( \varepsilon \) and \( \mu \) are the measures of non-linearity and frequency dispersion respectively, and \( \varepsilon \) and \( \mu^2 \) are assumed to be of the same order. This implies that the scales of water and mud depths are small compared to the horizontal scale, and that the free surface and interface displacements are also small compared to the depths of upper and lower layers respectively. The effect of viscosity is considered to be relatively weak in both layers and of the order of \( \varepsilon \). The upper fluid is further assumed much less viscous than the lower mud such that the ratio of kinematic viscosity \( \nu_1/\nu_2 = O(\varepsilon^2) \). This condition leads that the shear in the lower layer is entirely negligible at the interface (Hill and Foda, 1996). The vertical rotational velocity is zero to the leading order at the interface.

Integrating the continuity equations from the solid bottom to the interface, and from interface to the free surface, and applying the kinematic boundary conditions we get

\[
\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x} \left( \varepsilon \frac{\partial}{\partial x} - h \right) \int_0^z U \, dz = 0
\]

\[
\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x} \left( \varepsilon \frac{\partial}{\partial x} - h \right) \int_0^z U \, dz = 0
\]

Similarly the momentum equations can be integrated over each fluid layer to give (see Mei, 1983)

\[
\frac{\partial}{\partial t} \int_0^z w \, dz + \varepsilon \frac{\partial}{\partial x} \int_0^z u w \, dz - \frac{\varepsilon}{\mu^2} w^2 + g(\zeta - z) - p_1 = 0
\]

\[
\frac{\partial}{\partial t} \int_0^z W \, dz + \varepsilon \frac{\partial}{\partial x} \int_0^z U W \, dz - \frac{\varepsilon}{\mu^2} W^2 + g\left(\frac{h}{\varepsilon} + \xi - \frac{z}{\varepsilon}\right) + p_2 = 0
\]

The horizontal velocities \( u \) and \( U \) may be expanded as Taylor series about the interface and the solid bottom respectively. The resultant horizontal velocities can be expressed in terms of layer-averaged velocities \( \bar{u} \) and \( \bar{U} \) for both layers as

\[
u = \bar{u} - \mu^2 \left[ \frac{1}{2} (z + h)^3 - \frac{1}{6} h^3 \right] \frac{\partial^2 \bar{u}}{\partial z^2} + \mu^2 \left[ \left( z + h \right) - \frac{1}{2} h \right] \frac{\partial^2 (d \bar{U})}{\partial z^2} \right] + O(\mu^4)
\]
The horizontal velocities vary quadratically over each layer to this order. The corresponding expressions for vertical velocities are obtained from the continuity equation as

$$w = \frac{\partial \zeta}{\partial t} - \mu^2 (z + h) \frac{\partial \vec{u}}{\partial x} + O(\mu^4)$$  

(27)

$$W = -\mu^2 \left( (z + h + d) \frac{\partial \vec{U}}{\partial x} + \vec{U} \frac{\partial d}{\partial x} \right) + O(\mu^4)$$  

(28)

Substituting Eq.(25) to Eq.(28) into the layer-integrated continuity and momentum equations (19)-(24) and retaining the terms up to $O(\varepsilon)$ and $O(\mu^4)$, a set of Boussinesq-type equations can be obtained for the adopted coupled two-layer density stratified system. This set of equations is given in terms of physical variables for the three-dimensional problem as

$$\zeta_t + \nabla \cdot [(h + \zeta - \xi) \vec{u}] + \nabla \cdot [(d + \xi) \vec{U}] = 0$$  

(29)

$$\zeta_t + \nabla \cdot [(d + \xi) \vec{U}] = 0$$  

(30)

$$\vec{u}_t + (\vec{u} \cdot \nabla) \vec{u} + g \nabla \zeta - \left[ \frac{1}{3} h^2 \nabla \cdot (\vec{u}_t) + \frac{1}{2} h \nabla \cdot (d \vec{U}_t) \right] = 0$$  

(31)

$$\vec{U}_t + (\vec{U} \cdot \nabla) \vec{U} + (1 - \frac{1}{\gamma}) g \nabla \zeta + \frac{1}{\gamma} g \nabla \zeta + \left[ \frac{1}{6} d^2 \nabla \cdot (\vec{U}_t) - \frac{1}{2} d \nabla \cdot (d \vec{U}_t) \right]$$

$$- \frac{1}{\gamma} \left[ h \nabla \cdot (d \vec{U}_t) + \frac{1}{2} h^2 \nabla \cdot (\vec{u}_t) \right] - 2(\nu_2 - \frac{1}{\gamma} \nu_1) \nabla \cdot (\nabla \cdot \vec{U}) = 0$$  

(32)

where $\gamma$ is the density ratio defined as $\gamma = \rho_2/\rho_1$, and $\vec{u}$ and $\vec{U}$ are the velocity vectors in upper and lower layers respectively. The model equations (29)-(32) yield the standard Boussinesq equations if all the terms involving $\vec{U}$ are omitted.

3. NUMERICAL SIMULATION

Eq.(29) to Eq.(32) are solved using a finite difference scheme. The spatial derivatives in one direction are approximated using a 5-grid-points centered differences with fourth-order accuracy, leading to a truncation error that is sufficiently small relative to all the terms retained in the equations. For the temporal integral, an iterative scheme based on Adams-Bashforth-Moulton method is employed. The free surface displacement $\zeta$ and interfacial displacement $\xi$ are
computed explicitly from the continuity equations (29) and (30). The velocity components in x-direction are computed implicitly from the momentum equations (31) and (32), treating the derivatives of $\bar{u}$ and $\bar{U}$ in y-direction as explicit. Similarly, the computations of velocities in y-direction are done implicitly from momentum equations, treating the derivatives of $\bar{v}$ and $\bar{V}$ in x-direction as explicit.

At the incident boundary, both $\zeta$ and $\bar{u}$ are assumed to be given as input, and all the outgoing waves are absorbed applying radiation condition prescribed from the linear long wave theories. A harbour with fully reflective boundaries is treated as the solid walls and the velocity normal to the wall is taken as zero.

4. EXPERIMENTAL INVESTIGATION

Experiments were conducted to investigate the behavior of fluid mud in the harbour. The detailed experimental setup is shown in Fig.2. A laboratory wave flume of 26.0 m long, 0.60 m wide and 1.20 m high with glass walls throughout was used for the experiments. A model of rectangular harbour was installed on the horizontal bottom at 5.2 m apart from the step of the flume. A harbour basin, 50 cm long and 20 cm wide has straight breakwaters at both sides of its entrance. The experiments were also conducted for the rectangular harbour without breakwater. The harbour walls were made of acrylic fiber, so that the motions of the water surface and interface can be observed using a video camera through glass walls of the wave flume. A false bottom inside the harbour was lower than the horizontal bottom by 5cm. The hollow 5cm deep was filled up with mud.

![Fig.2. Experimental setup](image)

The commercially available fine silts of mean diameter 50 $\mu$m were used to prepare the fluid mud for the experiments. Silts were mixed with water to make a well-mixed slurry of density about $\rho_2 = 1.2$ g/cm$^3$. The slurry was then gently poured into the harbour to fill the requisite depth of 5.0 cm. The harbour mouth was tightly fenced from the outside before filling up water to the required depth. After filling, the mud layer in the harbour was stirred again and allowed to settle half a day. The muddy water above the interface was removed before experiments. This procedure was repeated for each experimental run to keep the requisite depth of fluid mud. By taking samples through the mud layer, only the depth-averaged density $\rho_2$ is measured during the experiment.
The water depth over the fluid mud bed was kept at \( h = 12\text{cm} \). A monochromatic wave with the wave height \( H = 1.5\text{ cm} \) was used as an incident wave for wave periods \( T \) ranging from 0.8 s to 2.0 s. Wave gauges were used to record the temporal surface wave profiles at several locations of the flume including the corner of the harbour. At the same time, the spatial profiles of the free surface and interfacial waves over the longer side of the harbour were recorded with a digital video camera through the glass walls. The interfacial displacements at the corner of the harbour were read out from the enlarged video pictures.

5. MOTION OF FLUID MUD
The observed responses of fluid mud in the harbour for various wave periods were compared with the numerical predictions for the purposes of model evaluation. In the numerical calculations the measured water surface profiles \( \zeta \) were used as input data on the upwave control surface, and the corresponding horizontal velocities \( \bar{u} \) were given from the linear long wave theory. The results were, however, essentially identical to the predictions based on sinusoidal profiles \( \zeta \) as input. Viscosity measurements of fluid mud were not made in the laboratory experiments. Ting and Lemasson (1996) showed from rheological tests that the viscosity of fluid mud confined within a submerged rectangular trench was not significantly affected by shear rate and time of shearing in the low strain-rate region. Since the strain rates in fluid mud under the present wave conditions were still relatively small, the viscosity \( \nu_2 \) was determined from their rheological tests using the asymptotic values at low shear rate as a function of mud density.

Fig.3 shows the snapshot of the computed free-surface and interfacial displacements in the harbour without breakwater. The line \( X=0 \) in the figure indicates the end of the harbour. The figure is plotted for \( T=0.8\text{s} \), \( \rho_2=1.19 \text{ g/cm}^3 \), \( \nu_2=16.4 \text{ cm}^2/\text{s} \)
Fig. 4 shows the comparison of spatial profiles of the free-surface and the interfacial displacements along the longer side of the harbour. Upper and lower figures show the images respectively when the water surface displacements become maximum at the corner of the harbour and $\frac{T}{2}$ after that time. The surface mode of the interfacial waves governs the motion of the interface and the interface oscillates nearly in phase of surface waves. At the entrance of the harbour, small internal waves out of phase are observed both in the experimental and numerical results, but they quickly absorb their energy within a very short distance from the harbour mouth.
Fig. 5. Spatial profiles ($T=1.2 s$, $\rho_2=1.19 \text{ g/cm}^3$, $\nu_2=16.4 \text{ cm}^2/\text{s}$)
The sequence of pictures at intervals of 0.1s for the wave period of 1.2s is shown to demonstrate the motion of fluid mud inside the harbour in Fig.5. It is observed from both experimental and numerical profiles that the interfacial waves are first generated at the harbour mouth, and propagate at internal phase speed towards the harbour end. The amplitudes of the interfacial waves are substantially reduced in course of their propagation due to the energy dissipation. The phase of the numerically simulated profiles is slightly delayed from the experimental profiles.

Fig.6 shows the comparison of spatial profiles for $T=1.6s$ which corresponds nearly to the first peak of resonant oscillations in the harbour without breakwater. Distinct
internal waves at the interface are observed in this case and the internal mode of the interfacial waves dominates the motion of the interface. Both the experimental and numerical results indicate that the internal wave generated at the harbour mouth propagates towards the harbour end without much dissipation. The amplification of the free-surface displacements inside the harbour is significantly reduced in this case. As shown in Fig.6 (a), the mud bed is strongly stirred up due to the vortex formed at the harbour mouth. The response of fluid mud to wave action may no longer be described by the two-layer model due to this suspended sediment. The present model must be modified for quantitative accuracy.

6. AMPLIFICATION FACTOR

The experimental and numerical results for the amplification factor of the water surface and interfacial displacements are shown in Fig.7 for the harbour without breakwater. The amplification factor is defined as the ratio of wave height $H$ at the corner of the harbour to the incident surface wave height $H_i$ and plotted as a function of the ratio of the harbour length $l$ to the length of incident wave $L$, with $L$ being determined from linear wave theory. The results for the harbour with breakwaters at the entrance are shown in Fig.8. Two peaks observed near the first mode of the resonant oscillations without fluid mud bed is due to the effects of side walls of the wave flume. The amplifications of the water surface waves are significantly reduced
near the first peak of the resonant oscillations where the interfacial displacements governed by the internal mode increase to the maximum. At the secondary peak, the surface mode governs the motion of the interfacial waves, and thus the interface oscillates nearly in phase of the surface wave. In this case, the secondary peak for the water surface displacements shifts to the higher frequency with the apparent increase in water depth by the thickness of mud layer. The amplification factors decrease to a limited extent at the secondary peak.

7. CONCLUDING REMARKS
Behaviors of fluid mud in a harbour basin for various wave periods are investigated both experimentally and numerically. The study reveals that the amplification of water surface waves is significantly reduced near the fundamental peak of long-period oscillations, where the internal mode governs the motion of fluid mud. In the frequency range higher than secondary peak, the surface mode governs the motion of the interface, yielding an insignificant reduction in the amplification factor.

Abstract

Empirical results which show the existence of a relationship among the probabilistic behaviour of the sea surface elevation, the statistical properties of the phase spectral estimates and the sea surface bispectra are presented. Furthermore, some theoretical relations proposed to characterise the marginal density function of the waves phase for the linear and non-linear wave records are examined.

Introduction

The free sea surface elevation in deep waters is generally considered to be the result of the superposition of a large number of sinusoidal waves of different frequencies, amplitudes and phases. Besides, it is usually assumed that the phase angles are mutually independent and are uniformly distributed in the interval $(0, 2\pi)$. Hence, the free surface elevation at a given point can be represented as

\[
\eta(t) = \sum_{n=1}^{\infty} a_n \cos(\omega_n t) + b_n \sin(\omega_n t) = \sum_{n=1}^{\infty} C_n \cos(\omega_n t + \epsilon_n)
\]  

where directionality of waves has not been considered. In Eq. (1), \(a_n\) and \(b_n\) are the Fourier coefficients, assumed normally distributed, \(C_n = (a_n^2 + b_n^2)^{1/2}\) are the wave amplitudes, \(\omega_n\) the frequencies, ranging from 0 to infinity and \(\epsilon_n = \tan^{-1}\left(-\frac{b_n}{a_n}\right)\) the

phases, uniformly random.

Under these assumptions it can be shown, by invoking the central limit theorem, that \( \eta(t) \) posses a Gaussian distribution,

\[
p(\eta) = \frac{1}{\sigma_n \sqrt{2\pi}} \exp \left[ -\frac{\eta^2}{2 \sigma_n^2} \right]
\]

For waves of low steepness there is a reasonable agreement between this linear model and observations and the free surface is very nearly Gaussian. However, various authors (e.g. Huang and Long, 1980) have reported significant deviations from the Normal distribution for steeper waves, with the free surface displaying sharper peaks and shallower troughs. The observed deviations from Gaussianity can only be explained by the existence of nonlinear interactions among wave components. The first author dealing with this problem was Longuet-Higgins (1963), who suggested that the free surface elevations should be considered as a weakly non-linear process. In other words, surface elevations can be considered as a quasi-normal process. Given that wave-wave non-linear interactions are consequence of the existence of phase relationships, or phase coupling between wave components, deviations from the Gaussian distribution for \( \eta(t) \) must be reflected on the probability distribution of phase angles. It can be shown that for a stationary process with a narrow spectral bandwidth the phase distribution can be uniform only if the probability density of the free surface elevations is strictly Gaussian (e.g. Bitner, 1980).

In this paper, the relations between the bispectrum and the statistical behaviour of the sea surface elevation and the phases of the wave components are analysed. Furthermore, the effects of the phase statistical properties on wave groupiness are investigated. Finally, some features of the probability density function of the wave phases are examined.

**Probability distribution of wave envelope and phase**

Upon the assumption of narrow band random function, the sea surface elevation can be expressed as

\[
\eta(t) = A(t) \cos \phi(t)
\]

where \( A(t) = (\eta^2 + \hat{\eta}^2)^{1/2} \) is the wave envelope, \( \phi(t) = \tan^{-1} \left( \frac{\hat{\eta}}{\eta} \right) \) the phase and \( \hat{\eta} \) is the Hilbert transform of \( \eta(t) \). Then, introducing the normalised variable \( \xi = \frac{A}{A_{rms}} \), where \( A_{rms} = \sqrt{2\eta_{rms}} \) is the root mean square of the wave envelope amplitude, it can be shown (e.g. Bitner, 1980, Tayfun, 1993) that the joint distribution of \( A \) and \( \phi \) is given by the product of the corresponding marginal probability densities,

\[
p(\xi, \phi) = p(\xi)p(\phi) = \left[ 2\xi \exp \left( -\xi^2 \right) \right] \left[ \frac{1}{2\pi} \right]
\]
This result reveals that for a linear narrow banded wave field both variables are statistically independent, with the amplitudes following a Rayleigh distribution and the phases uniformly distributed in $(0, 2\pi)$.

From the above discussion it should be expected that, except for very low sea states, the probability density function of phase angles deviate from the uniformity, reflecting the existence of privileged phases. However, this fact is still controversial, with various authors presenting contradictory results.

On the other hand, the importance of phase information in the Fourier representation of wind generated waves have received very little attention because the phase spectrum contains no relevant information under the assumption of a Gaussian random process. However, phase information for non-Gaussian waves may result of vital importance in practical applications. Thus, for example, the presence of phase coupling among the various component wave frequencies results in a non-Gaussian signal which is capable of significantly alter the response of a system thought to be subject to a Gaussian input.

The present interest on the phase information has raised mainly in relation with the wave grouping phenomenon. Also, this subject is far from solved. Thus, while some authors consider that phase information is necessary for a good description of wave groups. (e.g. Johnson et al., 1978 and Burcharth, 1978), some other authors (e.g. Rye and Lervik 1981 and Goda, 1983) support that the phases of the spectral components for wind waves can be considered as independent and uniformly distributed on the interval $(0, 2\pi)$.

Following the work by Longuet-Higgins (1963), Tayfun and Lo (1989, 1990) and Tayfun (1993, 1994) have examined the representation of second-order random waves in terms of the effect of second-order nonlinearities on the wave envelope and phase. These authors assumed that, in general, in deep water nonlinearities are relatively weak so that its statistical and spectral characteristics can be adequately described by a two-term perturbational solution to the governing nonlinear equations of motion.

Tayfun (1994), expressed the sea surface displacement from the mean level as the superposition of a first order solution $\eta_1$, given by (1), and a second order solution $\eta_2$, which includes the nonlinear nonresonant components of frequencies $\omega_m + \omega_n$ and $\omega_m - \omega_n$ generated by any two components of $\eta_1$ with frequencies $\omega_m$ and $\omega_n$. Thus, the sea surface elevation at a given point can be expressed as

$$\eta(t) = \eta_1 + \eta_2 = \eta_1 + (\eta_2^+ + \eta_2^-)$$

where,

$$\eta_2^\pm = \lim_{N \to \infty} \frac{1}{4} \sum_{m=1}^{N} \sum_{n=1}^{N} C_mC_n K_{m,n}^\pm \cos[(\omega_m \pm \omega_n) + (\epsilon_m \pm \epsilon_n)]$$

and

$$K_{m,n}^\pm = K^\pm(k_m, k_n, \cos(\theta_m - \theta_n))$$
with $\vec{k}_m, \vec{k}_n$ the horizontal wave-number vectors with moduli $k_m$ and $k_n$; and directions $\theta_m, \theta_n$, measured positive counterclockwise from the $x$ axis. $K^\pm$ represents the interaction coefficients (e.g., Longuet-Higgins, 1963, Tayfun, 1990).

In this context, the Gaussian law is not useful to characterise the probability distribution of $\eta(t)$. For this, some authors (e.g. Longuet-Higgins, 1963; Huang et al., 1983) have suggested alternative expressions for $p(\eta)$ by considering weak interactions among wave components. Besides, in this case, the wave envelope amplitude $\xi$ and the phase $\phi$ are no more statistically independent (Tayfun, 1994). The marginal density function of $\xi$ has the same expression as in (4) whereas the marginal density of $\phi$ is given by

$$p(\phi) = \frac{1}{2\pi} \left( 1 - \frac{1}{6} \sqrt{\frac{\pi}{2}} \lambda_3 \cos \phi \right)$$

(8)

and the joint distribution function of these variables is given now by

$$p(\xi, \phi) = \frac{\xi}{\pi} \exp \left( - \frac{\xi^2}{2} \right) \left( 1 + \frac{\sqrt{2}}{3} \lambda_3 \xi (\xi^2 - 2) \cos \phi \right)$$

(9)

where $\lambda_3$ is the coefficient of skewness. Under oceanic conditions this coefficient should be usually $\lambda_3 < 0.75$ (Srokosz and Longuet-Higgins, 1986). An asymptotic expression useful to estimate this parameter in terms of the zero $m_0$ and second order $m_2$ spectral moment is (Tayfun, 1990)

$$\lambda_3 = \frac{12\pi^2}{g} \left( \frac{m_2}{\sqrt{m_0}} \right)$$

(10)

From equation (4) it is easy to show (Tayfun, 1994) that in the linear case the mean value and variance of the wave phases are given by,

$$\langle \phi \rangle = \pi; \quad \text{Var}(\phi) = \frac{\pi^2}{3}$$

(11)

From Equation 8, in the nonlinear case the mean value of $\phi$ is equal to that in the linear one. However, the variance depends on the coefficient of skewness, and is given by,

$$\text{Var}(\phi) = \frac{\pi^2}{3} - \frac{1}{3\sqrt{2}} \lambda_3$$

(12)

**Measurements and Data analysis**

The analysed wave records were measured, by using a Waverider buoy deployed at deep waters in the Stajfiord oil platform (Norway continental shelf). The sampling frequency was $2H_z$ and the total record length close to 20 minutes with 2048 digitised values. The overall period analysed covers from January to February 1989.
Since the pioneering paper by Hasselmann et al. (1963), bispectral analysis has been considered as a useful tool for investigating the nonlinear properties of random waves and to identify phase characteristics of non-Gaussian wind generated wave records. According to these authors, if the surface elevation \( \eta(t) \) is a stationary zero mean valued random process, the spectra \( S(\omega) \) and the bispectra \( S(\omega_1,\omega_2) \) are defined respectively as

\[
S(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R(\tau) e^{-i\omega \tau} d\tau
\]

(13)

\[
S(\omega_1,\omega_2) = \frac{1}{(2\pi)^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R(\tau_1,\tau_2) e^{-i(\omega_1 \tau_1 + \omega_2 \tau_2)} d\tau_1 d\tau_2
\]

(14)

where

\[
R(\tau) = E[\eta(t) + \eta(t + \tau)]
\]

(15)

\[
R(\tau_1,\tau_2) = E[\eta(t) + \eta(t + \tau_1) + \eta(t + \tau_2)]
\]

(16)

and \( E[\cdot] \) denotes the mathematical expectation. The bispectra has been estimated by using the method suggested by Kim and Powers (1979). That is, by segmenting the wave records into \( N \) segments to obtain the following smoothed estimation of the bispectra,

\[
B(k,l) = \frac{1}{N} \sum_{n=1}^{N} X_n(k) X_n(l) X_n(k + l)
\]

(17)

where \( k \) and \( l \) are the frequencies of the interacting wave components and \( X \) are the complex Fourier coefficients, which can be computed efficiently by means of the Fast Fourier Transform (FFT) algorithm.

Assuming the linear wave theory, the sea surface elevation should be symmetric. Thus, the asymmetry of wave record profiles implies the existence of nonlinearities. Furthermore, the vertical asymmetry of the sea surface profile with respect to the mean water level can be characterised by the coefficient of skewness \( \lambda_3 \) of the sea surface elevation probability distribution. It can be shown (e.g., Kim et al., 1980) that for a stationary process with zero mean \( \lambda_3 \) and \( S(\omega_1,\omega_2) \) are related through the following relationship

\[
\lambda_3 = \frac{1}{(E[\eta^2(t)])^{3/2}} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} S(\omega_1,\omega_2) d\omega_1 d\omega_2
\]

(18)

Taking into account that \( \lambda_3 \) must be null for a Gaussian process and that it is proportional to the zero order moment of the bispectrum, a value different from zero for the bispectrum implies a non-zero value of the skewness and some deviation of the sea surface elevation probability function from the Gaussian distribution or equivalently asymmetries in the wave record. As a consequence, statistically significant deviations of \( S(\omega_1,\omega_2) \) from zero can be interpreted as the existence on nonlinearities in the process being examined.
Results and Discussion

The sea surface displacement and the wave phase probability distributions have been obtained for each one of the wave time series recorded at the Stajfiord oil field. The phase spectrum was computed as a previous step to estimate the phase distributions. The Chi-square (with a significance level \( \alpha = 0.05 \)) and Kolmogorov Smirnov tests were applied to examine the statistical significance of the possible deviations from the Gaussian and the uniform distributions.

From a total of 412 wave records analysed, the percentage of rejection of the hypothesis of the Gaussian distribution adequacy to describe the statistical structure of the sea surface elevation was of 64\% and 59\% for the \( \chi^2 \) and the K-S tests, respectively. The goodness of fit of the uniform probability function to the wave phase distribution was rejected in a 60\% of the cases for both tests. In addition, the probability distribution function given by equation (8) (Tayfun, 1994). Paradoxically, though this model depends on the coefficient of skewness, which represents a measure of nonlinearity, the percentage of rejection was of 66\% and 62\% for the \( \chi^2 \) and the K-S tests, respectively. That is, greater than the obtained for the uniform distribution.

Figure 1 shows the sea surface elevation (1a) and wave phase (1b) distributions, and the bispectral density corresponding to a wave record with a very small value of skewness (-0.002) and kurtosis (fourth statistical moment) (-0.004), such as is revealed by the associated low bispectral density. In this case, the Gaussianity and the uniformity were accepted by the two statistical tests. Furthermore, the Tayfun’s distribution, which tends to present a maximum at \( \pi \) and minima at 0 and 2\( \pi \), was also accepted. In this example, the coefficient of skewness computed by means of (10) is 0.133. Note the difference with that computed directly from the wave record which is slightly negative.

It should be remarked that, while the bispectra have been displayed in all the range of positive frequencies, it only needs to be represented between the origin, the line \( f_1 = f_2 \) and the Nyquist frequency due to its symmetry properties, which can be easily observed in the figure.

In contrast with the low values observed for the bispectrum of the first example, the bispectral density represented in figure 2 presents a large peak revealing an important contribution of nonlinearities, mainly from the auto-interactions of the peak frequency. This effect is reflected in the deviations of the sea surface elevation from the Gaussian distribution, which was rejected by the two statistical goodness of fit tests applied. Such as expected, the probability distribution of wave phases deviate significantly from the uniformity, displaying a maximum at \( \pi \) and minima at 0 and 2\( \pi \) (the coefficient of skewness is 0.356). Hence, the goodness of fit is rejected for the uniform distribution and accepted for the Tayfun’s model.

In various cases the wave phase distribution presents an inverse pattern to that expected. That is, the phase probability density presents a maximum at \( \phi = 0 \) and another at \( \phi = 2\pi \) and a minimum near to \( \phi = \pi \). An example of this kind of phase distribution is shown in figure 3. In this example, the Gaussian hypothesis was accepted but the goodness of fit of the wave phase distribution to the uniform distribution and to the Tayfun’s model was rejected. In fact, the relatively large percentage of this kind of phase
distribution is the motive for the above mentioned large quantity of rejections for the Tayfun's model, greater than the obtained for the uniform distribution. In some of these cases, the deviation from uniformity is relatively small but the Tayfun's model tend to fit a distribution with an inverse structure to that displayed by the measurements and, as a consequence, it is rejected. Note that in this case the bispectrum presents a moderate amplitude and the coefficient of skewness is 0.356.

Wave phases distributions with a similar structure have been presented (but not discussed) by some authors (eg. Bitner, 1980; Mase et al., 1983). The properties of this wave records are being studied now in detail.

Figure 1. Sea surface elevation (a) and wave phase (b) probability distributions and bispectrum associated to a Gaussian and uniform wave phases distribution wave record.
Figure 2. Sea surface elevation (a) and wave phase (b) probability distributions and bispectrum associated to a non-Gaussian and non-uniform wave phases distribution wave record.

In general, there is a trend of the coefficient of skewness to increase with the significant wave height (see Fig. 4a), such as expected according to the comments above and in agreement with results reported by various authors. On the other hand, according to Mase et al., (1983) if the groupiness factor GF, computed in terms of the SIWEH (smoothed instantaneous wave energy history) and proposed by Funke and Mansard (1980), is larger than 0.7, the phase distribution is not uniform, but the appearance frequency becomes large at the phases close to π. Similarly, Yuxiu and Manhai (1996) used a different groupiness parameter named group height factor (GFH) and expressed in terms of the standard deviation and the mean value of the wave envelope, which is estimated directly from the wave records with the Hilbert transform technique. These
authors analysed three sets of field wave data and observed that when GFH is large, the phase distribution is not uniform, but concentrated around \( \pi \).

The values of the groupiness factor are represented versus the coefficient of skewness in Figure 4b. It can be observed that GF presents a large scatter and that there is not a clear trend of GF to increase with the coefficient of skewness. Thus, the observed results do not support the idea of an increase of the wave groupiness as the nonlinear interactions become more significant.

Figure 3. Sea surface elevation (a) and wave phase (b) probability distributions and bispectrum associated to a Gaussian and non-uniform wave phases distribution wave record.
Figure 4. Coefficient of skewness computed by using Eq. 10 versus significant wave height (a) and the groupiness factor (Funke and Mansard, 1980), for the whole data set analysed.

In relation to the mean and variance of the wave phase distribution, Figure 5 displays the values of these parameters obtained for each one of the 412 wave records analysed. Figure 5a represents the observed values for the mean, together with the theoretical value, \( \pi \), derived for the linear and nonlinear wave models. It can be observed that the theoretical mean value is coincident with that empirically observed only for very low values of the coefficient of skewness, but there is an increasing scatter as \( \lambda_3 \) increases.

Similar results are observed for the variance of the wave phase distribution, which are represented together with the theoretical values predicted for the linear and the nonlinear wave model by Tayfun (1994).

Figure 5. Variability of the wave phase mean value and variance with the coefficient of skewness for the whole data set analysed, and theoretical values for the linear and nonlinear cases, according to Tayfun (1994).
Conclusions

Bispectral analysis of measured wave records has been used to detect the presence of phase coupling among the various component wave frequencies. It is shown that when bispectral density function is statistically insignificant, sea surface displacements are distributed according to the Gaussian law and the angle phases are uniformly distributed. On the other hand, a non zero bispectrum is related to non Gaussian sea surface displacements and non uniformly distributed phases.

It is observed that, in most cases, the phase distribution deviations from uniformity are characterised by a higher relative frequency of angles in the range from $0.5\pi$ to $1.5\pi$. That is, it presents a maximum near $\phi=\pi$ and minima at $\phi=0$ and $\phi=2\pi$.

These results agree with those reported by Tayfun (1994) who analysed data from hurricane Camille and observed a similar behaviour in phase distributions. However, in same cases, our results display an inverse structure to that expected according to this author. In other words, phase probability density presents a maximum at $\phi=0$ and another at $\phi=2\pi$ and a minimum near to $\phi=\pi$.

There is not a clear trend of the wave groupiness to increase with the deviation of phase angles from uniformity, in contrast with the results previously reported by some authors.

The theoretical values of the mean and the variance of the wave phase distribution agree with the empirically observed values only for low values of the coefficient of skewness.

Acknowledgements

This work has been partially supported by the project HP, 1997-0009 “Stochastic characterization and digital simulation of random waves in deep and shallow waters” under the programe of the bilateral cooperation between Portugal and Spain. The authors would like to thank STATOIL for provision of field data.
