sources, whether or not they are historically active. It is likely that the major cause of catastrophic tsunamis is underwater shallow focus earthquakes of Richter magnitude 5.0 or greater (Iida, 1970, 1963). However, not all such earthquakes produce tsunamis since the generation mechanism is usually associated with vertical dislocations of the sea floor in dip-slip faults normal or reverse faults.

**Neotectonic features**

The Alborán Sea in the southwestern Mediterranean is a very active region of the wide area of continental collision generated by the northward movement of the African plate relative to the European plate (Dewey et al., 1989). The unusual tectonic situation of a small sea caught between two major plates is characterized by a complex sea floor physiography, with several basins separated by structural highs and ridges (Maldonado et al., 1992a, c; Woodside et al., 1992). Furthermore, some authors (Udías et al., 1976; Buform, 1988b, c; Udías et al., 1992 and Mezcua et al., 1997) have proposed different geodynamic models based on source mechanisms of earthquakes, that permit the determining of the fault system in the Alborán Sea. The tectonic features are characterized by a fault system composed of short strike-slip faults and short dip-slip faults, as shown in figure 2. This short fault system is due to the crustal shocks of the African and European plates, where a beniof or subduction zone is not evidenced.

![Figure 2. Schematic summary of principal neotectonic and geomorphologic elements in the Alborán Sea](image-url)
Seismic pattern

The spatial distribution of seismicity could be considered a manifestation of the lithospheric weakness zone where the stresses applied are released, that, joined with some seismic parameters, permit the choice of potential tsunamigenic sources. The Alborán Sea presents high seismic activity, with moderate earthquake magnitudes and shallow epicenters. The earthquakes are associated with the local fault system.

The data for the earthquakes were taken from: (1) the Spanish National Seismic Catalog from the period 1916-1996; (2) the Spanish seismic risk maps from the National Geographic Institute (NGI) from the period 1320-1920. In figure 3, different Richter magnitudes of the earthquakes from the 1916-1996 period are shown for $M_s \geq 5.0$.

![Figure 3. Relocated seismicity ($M_s \geq 5$), for the period 1916 - 1996 and potential tsunamigenic sources](image)

Potential faults

Five potential tsunamigenic sources have been selected for the Alborán Sea, taking into account: (1) the historical tsunami data (figure 1); (2) the analysis of the dip-slip faults (normal and reverse); and (3) analysis of seismicity. This kind of analysis is used as an important tool to estimate the potential for tsunamigenic earthquakes (Alami and Tinti, 1991). Only the seismic data with magnitude greater than 5.0 on the Richter scale with focal depths less than 50 km and greater than 20 km, are included in the analysis (Iida, 1963, 1970).

Tsunamis of distant origin (Italian and Greek sources) are not considered a threat to the study area. Furthermore, although the Atlantic Ocean sources (Azores - Gibraltar fault system) can generate great tsunamis, they do not cause any perceivable perturbations in the Alborán Sea. Historical events and numerical simulations confirm that the Strait of Gibraltar acts as an important tsunami filter. In figures 3 and 5, the five potential tsunamigenic sources
selected for the Alborán Sea area are shown.

**Tsunami Source Model**

In this study, the offset is assumed to be a vertical ascendant movement generated by submarine earthquakes of tectonic origin, which are associated with the five selected potential sources. It is also assumed that the sources are simple straight faults with a focus located in the middle point (see figure 5). The bed displacement is defined by: (1) the source location; (2) the plane area of the ground displacement, $S$; (3) the average offset or vertical dislocation, $D$; and (4) the velocity of the displacement, $\zeta(t)$. Figure 4 shows a diagram of the bed movement.

![Figure 4. Schematic sea bottom displacement](image)

![Figure 5. Location map showing global and detailed grids and potential tsunamigenic sources](image)
The most widely used quantitative measure of the strength of an earthquake has been its magnitude ($M_s$). However, it is well-known that there is difficulty in relating magnitude with other important source characteristics such as strain-energy release, fault offset, stress drop and source dimensions, etc. (Kanamori and Anderson, 1975). For large earthquakes, the seismic moment denoted $M_o$, is defined as:

$$M_o = \mu SD$$ (1)

In which $\mu$ = rigidity of the medium ($\mu = 2 - 3 \cdot 10^{11}$ dyne - cm²).

Tsunamigenic earthquakes of tectonic origin are those submarine earthquakes on shallow faults and of large magnitude. As such, tsunamigenic earthquakes are most conveniently measured by seismic moment. In fact, tsunami records in the Pacific have been correlated with and used to calibrate seismic moments (Kanamori, 1977).

The number of occurrences of earthquakes with seismic moment, $M_o$, greater than or equal to $m_o$ has been shown to be given as:

$$N(m_o) = a \cdot m_o^{-\beta}$$ (2)

where $\alpha$ and $\beta$ are numerical constants determined from earthquake records. Discussion of values of these quantities is given by Molnar (1979) as well as by Kanamori and Anderson (1975) and the Fundación Leonardo Torres Quevedo (1997). Equation (2) will be used to determine the probability distribution function of seismic moment in the section “Risk model for tsunamis”.

Important physical dimensions of an earthquake are the offset: vertical dislocations and, length and width of ground dislocation. Based on earthquake data, Kanamori and Anderson (1975) obtained the empirical relation between the seismic moment $M_o$ and the source, $S$, given as:

$$M_o = C_1 S^{-2}$$ (3)

In which $C_1 = 1.23 \cdot 10^7$ dyne - cm² width $S$ measured in km².

In order to relate seismic moment, $M_o$, with Richter magnitude, $M_s$, different authors have proposed empirical relations. Mezcua et al. (1991) obtained for the Azores-Gibraltar-Alborán Sea, the following empirical relationship:

$$\log M_o = 1.16 M_s + 17.93$$ (4)
An expression that can be used to relate $M_s$ with source parameters.

In this study an elliptical ground displacement in plan view is assumed, with an exponential time-displacement function which Hammack (1972) defined as:

$$\xi(t) = D(1 - e^{-\alpha t}) \quad 0 < t < t_G$$

with $\alpha = 1.1/t_c$, where $t_c$ is the time to rise $2/3$ D ($t_c \sim 1 - 20$ g.) and $t_G$ is the total generation time ($1 - 2$ min.).

In accordance with the tsunami source model, the most important parameters that have to be determined are the source location and the seismic moment, $M_s$.

**Hydrodynamic Numerical Models**

In order to simulate tsunami generation and propagation a coupled numerical model was applied. The run-up in some cross-shore locations was estimated matching the coupled model with a one-dimensional, time-dependent numerical model.

**Tsunami Generation numerical model**

Many authors have applied an elliptical water surface shape similar to the ground displacement for the waves near the source (Houston et al., 1980; Lin et al., 1986; Camfield, 1992). This kind of surface water displacement has also been applied in this study, defined as:

$$\eta(x, y, t) = \xi(t) \left[ I - \left( \frac{x}{a} \right)^2 - \left( \frac{y}{b} \right)^2 \right]^{1/2}$$

where $\xi(t)$ is the equation (5), and the coordinate system origin for the x and y axes is located in the middle of the ellipsoid (or source area).

**Tsunami Propagation numerical model**

Nonlinear, nondispersive, shallow water equations were used to model the propagation of tsunamis in the Alborán Sea.

For a distant tsunami, traveling distance could be much greater than the characteristic wave length of the tsunami. In these cases, both the frequency dispersion and coriolis terms
could play an important role (Liu et al., 1994). However, due to morphological characteristics of the Alborán Sea (see figure 5) which is a small basin (approximately 400 km length, 200 km width and water depth less than 2 km) these two terms can be neglected.

As tsunamis propagate into the shallow water region, wave amplitude increases and wave length decreases due to shoaling. The nonlinear convective inertia force becomes increasingly important while the importance of frequency dispersion diminishes (Liu et al., 1994).

The model equations are solved by an implicit finite difference method. The finite difference scheme is similar to that presented by Leendertse (1970). The model used, as a temporal initial condition, the elliptical deformation of the water surface presented by the relations (5) and (6). An absorbing boundary condition is employed for the seaward boundary and a reflecting condition in the coastline.

A global propagation grid 440 x 290 km$^2$ was adopted (see figure 5). The numerical computational mesh size and time-step size were fixed, $\Delta x = \Delta y = 1000$ m, $\Delta t = 5$ s. for propagation and $\Delta t = 0.5$ s. for the wave generation. In order to reduce numerical errors, the spatial grid size should be such that one local wave length includes more than 20 grid points. Therefore, a finer spatial grid size was adopted, $\Delta x = \Delta y = 200$ m for water depth less than 50 m. Three finer grids between Adra and Almería are shown in figure 5.

A propagation tsunami example generated in fault 5 ($M_s = 7.5$), is shown in figure 6, where the computed water surface appears at $t = 18$ min. and $t = 33$ min.

![Figure 6. Propagation example tsunami wave elevation (t = 18 and 33 min.), epicenter at fault 5, with $M_s = 7.5$](image_url)
**Tsunami Run-up Numerical Model**

A one-dimensional, time-dependent numerical model (Kobayashi et al., 1994 a), is used to simulate the tsunami's flow over some cross-shore profiles along the coast between Adra and Almeria. The finite amplitude shallow-water equations (mass, momentum and energy) including the effects of bottom friction over rough permeable cross-shore slopes, are solved numerically in the time domain using an explicit dissipative lax-wendroff finite-difference method (Kobayashi and Otta, 1987). The run-up model used, as seaward boundary, the tsunami-wave elevation recorded at a numerical gauge in the finer grid. Several cross-shore profiles were selected, starting seaward in 10 m water depth and including the topography of high and low coastal areas.

The bottom friction factor \( f \) was not considered constant along a cross-shore profile. In profile areas with smooth slopes, as is the case in sandy beaches a \( f = 0.005 \) was used. On the other hand, a \( f = 0.01 \) was used in rough slopes, for example in urban areas and step structure slopes.

**Risk Model**

The tsunamigenic earthquake is not a deterministic phenomenon; both source location and seismic moment, \( M_0 \), have to be defined as random variables. Since the occurrence of future tsunamis is difficult to predict, risk analyses must be based on probabilistic considerations. One of the elements involved is the probability of tsunami inundation of various levels at a given place in a given return period. This probability is generally referred to as hazard or risk.

Eight points (see figure 5) of the Alborán seacoast and some cross-shore profiles between Adra and Almeria were selected to perform the risk analysis. The risk analysis consists of: (1) A Monte Carlo simulation, which is based on a probabilistic model in order to obtain the synthesized record of tectonic deformations of the seabed; (2) The tsunami source model, which permits us to relate the physical dimensions \( (S, D) \) of the displaced bottom source \([\text{eq. (1) and (3)}]\); and (3) the hydrodynamic numerical models which are used to simulate propagation and run-up of the tsunami caused by each of the synthetic seabed deformations.

**Probabilistic model for tsunamigenic earthquakes**

In order to obtain the synthesized record of seabed deformations, it is necessary to define the three basic random variables involved in risk analysis: (1) the occurrence of tsunamigenic earthquakes events; (2) the earthquake source; and (3) the seismic moment, \( M_0 \).

The tsunamiic mean frequency of occurrence was obtained based on the eight events which occurred in the last 200 years, due to the fact that there is no historical catalog of tsunamis before 1800. Therefore, it is assumed that one tsunami event occurs once every 25 years on average.
As stated previously, five potential individual faults, were selected. However, the probability of occurrence of tsunamigenic earthquakes in each one of these is different. In order to obtain these probabilities, the following hypothesis are assumed: (1) the faults are independent and once every 25 years one event occurs in one of the five faults; (2) a tsunamigenic earthquake originates from a single, well-defined, straight fault; (3) earthquakes can occur anywhere along a fault with equal likelihood but the focal point is located in the middle of a straight fault (see figure 5); and (4) the probability of occurrence of tsunamigenic earthquakes of a specific fault increases, with the number of events with Richter magnitudes ($M_s > 5$) and focal depths ($D_f < 50$ km). Figure 7 shows the probability function obtained for each one of the potential faults.

The probability distribution function, $F_{Mo}(m_o)$ of $M_o$ was determined, using equation (2) by Lin and Tang (1982), as:

$$F_{Mo}(m_o) = \left[ 1 - \left( \frac{m_{ol}}{m_o} \right)^6 \right] \cdot \left[ 1 - \left( \frac{m_{ol}}{m_{eu}} \right)^6 \right] m_{ol} \leq m_o \leq m_{eu}$$

(7)

where $m_{ol}$ is the lower magnitude of seismic moment, in accordance with (Iida, 1970, 1963), $m_{ol} = 10^{23.73}$ dyne-cm ($M_s = 5.0$ on Richter scale). The maximal energy released by a earthquake in a fault, is limited depending on the neotectonic and the geodynamic of the potential fault. Due to the characteristics of the Alborán Sea, $m_{eu}$ was defined as $m_{eu} = 10^{26.65}$ dyne-cm ($M_s = 7.5$). Equation (7) was applied for the five potential faults (see figure 8), taking into account the seismological data to obtain $\beta$, and the empirical relation between $M_s$ and $M_o$ (equation 4).

Results

The risk analysis due to tsunamis is represented by curves which permit us to obtain the maximal tsunami-wave elevation in given sites along the Alborán seacoast for two confidence levels (50% and 99.99%) and return period (years).

As an example of these curves, figures 9 and 10 show the risk analysis in the city of Adra. Figure 9 shows the run-up in a cross-shore city profile and the figure 10 represents the horizontal flooded landward distance, measured from local mean water level. In figure 11, for a return period of 2,500 years, the risk analysis for different places along the Alborán Sea in water depths of 6 m is shown. This figure shows a higher risk in areas near Adra, Málaga and Melilla. The complete results and propagation details can be found in Fundación Leonardo Torres Quevedo (1997).
Conclusions

- Given the global neotectonic setting, the geodynamic processes as well as the seismicity of the Alborán Sea, the tsunamis generated in the area present a medium-to-low intensity.
- Five potential tsunamigenic faults have been determined in the area (figure 5).
- Using simple tsunami source, hydrodynamic and risk models, tsunami risk in different sites along the Alborán Sea has been computed.
- Due to morphological characteristics and the setting of potential faults, zones close to Málaga, Adra and Melilla have a greater tsunami wave elevation than the rest of the Alborán Sea locations.

Long-Period Wave Responses in a Harbor with Narrow Mouth

Weon Mu Jeong¹, Kil Seong Lee² and Woo Sun Park¹

Abstract

Field measurements of long-period wave have been preformed for the Gamcheon Harbor in Korea. A Galerkin finite element model based on the extended mild-slope equation has been developed for simulating harbor oscillation more accurately. Infinite and joint elements are introduced to accomodate radiation condition at infinity and matching conditions at harbor mouth for the consideration of the energy loss due to flow separation, respectively. Comparisons with the results obtained by hydraulic experiments by Lepelletier (1980) show that the present model gives fairly good results. Model results reveal that the influence of entrance loss at the harbor mouth is considerably significant. From the application to the Gamcheon Harbor it is seen that the computed resonant periods and amplification ratios well agree with the measured results. The entrance loss effects were found to be insignificant unless the incident wave height is large.

Introduction

Long-period harbor oscillations could create unacceptable vessel movements leading to the downtime of moored ships. It is practically very difficult to prevent long-period harbor oscillations, but extension of breakwaters at the harbor mouth could be a countermeasure in part. Narrowing a harbor mouth might give rise to increase in the energy loss due to flow separation near the mouth, which in turn makes resonant periods of the harbor become longer, especially for the Helmholtz resonant mode. Referring to Lepelletier (1980), the reduction of a harbor mouth can reduce the amplification ratios of Helmholtz mode considerably.
This study includes field measurements for short- and long-period waves around the Gamcheon Harbor in Korea, and the development of a finite element model based on the extended mild-slope equation, which incorporates the bottom frictional dissipation and the entrance loss due to flow separation. The present model can also handle the harbor resonance problems in a harbor with non-straight coastlines. The model is verified through the comparisons with Lepelletier (1980)'s experimental results. Finally, the model is applied to the Gamcheon Harbor with narrow mouth and compared with field measurements.

Field Measurement

Field measurements for short- and long-period waves have been performed around Gamcheon Harbor which is located at the east-southern coast of Korea. The harbor is 4,000 m long, 1,150 m wide and has entrance of 240 m wide. In spite of narrow mouth, this commercial harbor is suffering from severe downtime problems in summer season. The measurement period was from November 27 to December 13 in 1997. Four pressure-type wave gauges (PWG), and one Aanderaa RCM-9 current meter were deployed at locations shown in Figure 1. Sampling intervals for the pressures at Sts. P1 and P4 were set to 5 seconds, while pressure data at Sts. P2 and P3 were gathered in the interval of 1 second. Current velocities from RCM-9 were averaged over 1 minute.

Figure 1. Location Map of Field Measurements.
After filtering tidal components from pressure signals using a Butterworth high-pass filter in MATLAB, spectral analyses of the 16 sets of filtered pressure data were performed. Figure 3 shows the power spectral densities of long-period wave data set no. 6 obtained at the four stations. We can find the first and second resonant modes appear near 2,000 seconds and 600~700 seconds, respectively. It is noted that the period of Helmholtz resonant mode of Gamcheon Harbor is 27.0~33.3 minutes, and the second and third resonant periods appear at 9.4~12.1 and 5.2~6.2 minutes, respectively. Figure 3 shows the power spectral densities of current velocity normal to the harbor mouth. It is noted that the maximum value appears around 28.2~31.9 minutes corresponding to the Helmholtz mode.

Galerkin Finite Element Model

Theoretical Formulation

A Cartesian coordinate system \((x, y)\) and a cylindrical coordinate system \((r, \theta)\) are employed for mathematical formulation. The domain in the model is divided into two regions as shown in Figure 4. One is a near field region \((\Omega_1)\) that is modeled as conventional finite elements and the other is a far field region \((\Omega_2)\) that is represented as infinite elements of which shape functions satisfy the radiation condition at infinity. In the far field region, the water depth is assumed to be constant in the radial direction, but the depth in the circumferential direction varies with the value of the interface between the far and near field regions, \(\Gamma_f\). To take into account the entrance loss at the narrow harbor mouth, the near field region is again divided into two sub-regions, that is inner \((\Omega_{1i})\) and outer regions \((\Omega_{1o})\) of the harbor (see Figure 4).

![Figure 4. Definition Sketch for Boundary Value Problem.](image-url)
The monochromatic and simple time harmonic waves propagating over a steeply sloped sea bed with variable depths in both regions may be described as follows (Massel, 1993; Suh et al., 1997).

\[ \nabla \cdot (C_C \nabla \phi_i) + \frac{C_g}{C} \omega^2 \phi_i - \omega^2 \left\{ R_1 (\nabla h)^2 + R_2 \nabla^2 h \right\} \phi_i = 0 \]  

(1)

in which \( \nabla = (\partial / \partial x) \hat{i} + (\partial / \partial y) \hat{j} \), \( \hat{i} \) and \( \hat{j} \) are unit vectors in the directions of \( x \) and \( y \), respectively, \( \phi_i \) is the two-dimensional spatial complex valued velocity potential, the subscript \( i \) denotes the near field region for \( i = 1 \) and the far field region for \( i = 2 \), \( \omega \) is the angular frequency, \( h(x, y) \) is the water depth, \( R_1 \) and \( R_2 \) are coefficients for second-order bottom effects corresponding to the squared bottom slope \( (\nabla h)^2 \) and the bottom curvature \( \nabla^2 h \) (see Suh et al., 1997). Wave celerity, \( C \) and group velocity, \( C_g \) are given as

\[ C = \sqrt{\frac{g}{k} \tanh kh} \]  

(2)

\[ C_g = \frac{C}{2} \left( 1 + \frac{2kh}{\sinh 2kh} \right) \]  

(3)

in which \( k \) is the wave number.

To consider the effects of wave absorbing, the partial reflection boundary condition is introduced along the solid boundaries, which was proposed by Mei and Chen (1975) as a function of an empirical reflection coefficient, \( K_r \) normal to the solid boundaries. This boundary condition is represented as

\[ \frac{\partial \phi_1}{\partial n} = \alpha \phi_1 \quad \text{on } \Gamma_1 \]  

(4a)

\[ \frac{\partial (\phi_2 + \phi_i)}{\partial n} = \alpha (\phi_2 + \phi_i) \quad \text{on } \Gamma_2 \]  

(4b)

in which \( \phi_1 \) is the total velocity potential in the near field region, \( \phi_2 \) is the scattered wave potential in the far field region, \( \phi_i \) is the incident wave potential, \( n \) is outward normal to the solid boundary, and \( \alpha \) is expressed as

\[ \alpha = ik \cos \theta_i \frac{1 - K_r}{1 + K_r} \]  

(5)

in which \( \theta_i \) is the angle of the incident wave normal to the solid boundary.
The matching boundary condition on \( \Gamma \) can be expressed as

\[
\phi_1 = \phi_2 + \phi_I \\
\frac{\partial \phi_1}{\partial n} = -\frac{\partial (\phi_2 + \phi_I)}{\partial n}
\]  

(6a) (6b)

The scattered wave potential, \( \phi_2 \) in the far field region must satisfy the Sommerfeld radiation condition at infinity.

\[
\lim_{r \to \infty} \sqrt{r} \left( \frac{\partial \phi_2}{\partial r} - ik\phi_2 \right) = 0
\]

(7)

The incident wave potential is given as

\[
\phi_I = -\frac{ig a_0}{\omega} e^{i k r \cos(\theta - \theta_i)}
\]

(8)

in which \( a_0 \) is the amplitude of incident wave and \( \theta_i \) is the attack angle of incident wave.

Two matching conditions were introduced on the interface boundary of two sub-regions, i.e., velocity and pressure continuity conditions at the harbor mouth (Unluata and Mei, 1975). For the entrance loss effects, the following matching conditions are introduced.

\[
u_i = u_o
\]

(9)

\[
\frac{p_i}{\rho} = \frac{p_o}{\rho} + \frac{1}{2} f_e \frac{g}{u_o} u_o |u_o| + \frac{l_j}{g} \frac{\partial u_o}{\partial t}
\]

(10)

where, \( u \) is the flow velocity, \( p \) is the pressure, the subscript \( i \) denotes the inner region and \( o \) denotes the outer region, \( \rho \) is the fluid density, \( f_e \) is the loss coefficient and \( l_j \) is the jet length. The quadratic non-linear energy loss term was linearized by using Lorentz transformation and equating depth averaged power, that is,

\[
\frac{1}{2} \frac{f_e}{g} u_o |u_o| = \frac{1}{2} \alpha u_o
\]

(11)

where, the linearized loss coefficient \( \alpha \) is given by

\[
\alpha = \frac{8}{9\pi} \frac{f_e}{g} u_o \tanh kh \frac{5 + \cosh 2kh}{2kh + \sinh 2kh}
\]

(12)
where, \( \overline{u_o} \) indicates the wave mean velocity.

In the above equations, \( f_e \) and \( l_j \) are determined by hydraulic experiments for various cross-sections. We used \( f_e \) based on the inverse Strouhal number, \( u_e/a \omega \) suggested by Lepelletier (1980). Then the linearized matching condition can be given by

\[
\frac{\partial \phi_{1i}}{\partial n} = - \frac{\partial \phi_{1o}}{\partial n} \tag{13}
\]

\[
\frac{\partial \phi_{1i}}{\partial n} = \frac{1}{ia + \frac{l_j}{\omega g}} (\phi_{1o} - \phi_{1i}) \tag{14}
\]

in which \( \phi_{1i} \) and \( \phi_{1o} \) are complex velocity potentials of the inner and outer regions, respectively. For the jet length, a simple formula suggested by Morse and Ingard (1968) is used.

**Finite Element Formulation**

- **Discretization of Fluid Domain**

To discretize the fluid domain in the standard finite element manner, it is necessary to describe the unknown potential, \( \phi_i \), in terms of the nodal potential vector, \( \{ \phi_i^N \} \), for an element \( (e) \), and the prescribed shape function vector, \( \{ N \} \), as follows:

\[
\phi_i = \{ N \}^T \{ \phi_i^e \} \tag{15}
\]

Using Galerkin’s technique, the boundary value problem can be re-formulated as integral equations. Using following definition of the residual for each element

\[
\{ R^e \} = - \int_{\Omega_e} \{ N \} \left[ \nabla \cdot (CC_e \phi_i) + \frac{C_e}{C} \omega^2 \phi_i - \omega^2 \left( R_1 (\nabla h)^2 + R_2 \nabla^2 h \right) \phi_i \right] d\Omega_e \tag{16}
\]

and Green's second identity, and introducing the above boundary conditions, the system equation can be obtained for each element. Taking the residual as zero gives following simultaneous equations:

\[
\sum_e \{ ( [K_e^r] + [K_e^w] + [K_e^z]) \{ \phi_i^e \} + \{ F_i^e \} + \{ F_i^e \} + \{ F_i^e \} \} = \{ 0 \} \tag{17}
\]
in which \([K^e_Ω], [K^e_Γ], [K^e_Γ_m], \{F^e_Γ\}, \{F^e_Γ_m\}, \text{ and } \{F^e_Ω\}\) are the element system matrices given by for the near field region:

\[
[K^e_Ω] = \int_{Ω^e_1} \begin{bmatrix} CC_Ω \left( \begin{array}{c} \frac{∂N}{∂x} \\ \frac{∂N}{∂y} \end{array} \right) \\ \frac{∂N}{∂y} \end{bmatrix}^T + \begin{bmatrix} \frac{∂N}{∂x} \\ \frac{∂N}{∂y} \end{bmatrix}^T \\
- \omega^2 \left( \frac{C_Ω}{C} - \{R_1(∇h)^2 + R_2(∇^2h)\} \{N\} \{N\}^T \right) dΩ^e_1
\]

\[
[K^e_Γ] = \int_{Γ^e_1} CC_Γ a \{N\} \{N\}^T dΓ^e_1
\]

\[
[K^e_Γ_m] = \int_{Γ^e_1} CC_Γ \frac{∂φ_m}{∂n} \{N\} dΓ^e_{1m} + \int_{Γ^e_{m1}} CC_Γ \frac{∂φ_m}{∂n} \{N\} dΓ^e_{m1}
\]

\[
\{F^e_Γ\} = \{0\}
\]

\[
\{F^e_Γ_m\} = -\int_{Γ^e_1} CC_Γ \frac{∂(φ_1 + φ)}{∂n} \{N\} dΓ^e_1
\]

and for the far field region:

\[
[K^e_Ω] = \int_{Ω^e_2} \begin{bmatrix} CC_Ω \left( \begin{array}{c} \frac{∂N}{∂r} \\ \frac{∂N}{∂θ} \end{array} \right) \\ \frac{∂N}{∂θ} \end{bmatrix}^T + \frac{1}{r^2} \begin{bmatrix} \frac{∂N}{∂r} \\ \frac{∂N}{∂θ} \end{bmatrix}^T \\
- \omega^2 \left( \frac{C_Ω}{C} - \{R_1(∇h)^2 + R_2(∇^2h)\} \{N\} \{N\}^T \right) dΩ^e_2
\]

\[
[K^e_Γ] = \int_{Γ^e_2} CC_Γ a \{N\} \{N\}^T dΓ^e_2
\]

\[
[K^e_Γ_m] = 0
\]

\[
\{F^e_Γ\} = \int_{Γ^e_2} CC_Γ \left( αϕ_1 - \frac{∂φ_1}{∂n} \right) \{N\} dΓ^e_2
\]

\[
\{F^e_Γ_m\} = -\int_{Γ^e_1} CC_Γ \frac{∂(ϕ_1 - φ)}{∂n} \{N\} dΓ^e_1
\]

- Finite, Infinite and Joint Elements

The inner region is modeled by using three-noded triangular elements, in which the water depth \(h\), the square of bottom slope \((∇h)^2\), and the curvature \(∇^2h\) are assumed to be constant for the convenience of numerical calculation. In order to model efficiently the radiation condition at infinity, a two-noded infinite element is developed. The shape function of the element is given by
\[ \{N\} = N_r(\xi)\{N_\theta(\eta)\} \quad \text{for} \quad 0 \leq \xi \leq \infty, \quad -1 \leq \eta \leq 1 \quad (20a) \]

\[ \{N\} = N_r(\xi) \quad \text{for} \quad 0 \leq \xi \leq \infty \quad (20b) \]

in which \( \{N_\theta(\eta)\} \) is the Lagrange shape function, and \( N_r(\xi) \) is the shape function in the radial direction given by

\[
N_r(\xi) = \frac{\sqrt{r_{r_i}}}{\sqrt{\xi^2 + r_{r_i}}} e^{(ik-\varepsilon)\xi} \quad (21)
\]

in which \( \varepsilon \) is the artificial damping parameter (\( \varepsilon < k \)), and \( r_{r_i} \) is the distance to the infinite elements from the origin as shown in Figure 4. The artificial damping parameter has been introduced to make the integration in Eq. (19e) in the radial direction bounded. After the integration is completed analytically, the value of \( \varepsilon \) is taken to be zero. The shape function, \( N_r(\xi) \), in the radial direction, except for the artificial damping parameter, have been derived from the asymptotic expression for the first kind of Hankel's function in the analytical boundary series solutions such as

\[
\phi_s \sim \frac{1}{\sqrt{r}} e^{ikr} \quad (22)
\]

The above shape functions satisfy the radiation condition at infinity.

- Matching the Inner and Outer Regions

Using the matching boundary conditions in Eq. (6), the total system matrices can be assembled as

\[
\sum_\alpha \left\{ \left[ K^e_{\Omega} \right] + \left[ K^e_{r_i} \right] \right\} \{\phi^e_{\Omega}\} + \{ F^e_{r_i}\} = \{0\} \quad (23)
\]

in which

\[
\left[ K^e_{\Omega} \right] = \left[ K^e_{\Omega_i} \right], \quad \left[ K^e_{\Omega_i} \right] \quad (24)
\]

\[
\left[ K^e_{r_i} \right] = \left[ K^e_{r_i} \right], \quad \left[ K^e_{r_i} \right], \quad \left[ K^e_{r_i} \right] \quad (25)
\]

\[
\{ F^e_{r_i}\} = \{ F^e_{r_i}\} \quad (26)
\]

\[
\{ F^e_{r_i}\} = -\int_{\Gamma_i} CC_s \frac{\partial \phi^e_{\Omega}}{\partial n} \{N\} d\Gamma_i - \left( \left[ K^e_{\Omega_i} \right] + \left[ K^e_{\Omega_i} \right] \right) \{\phi^e_{\Omega}\} \quad (27)
\]
Numerical Analyses and Discussions

Verification of the present model

To prove the validity of the present model, numerical analyses have been performed for a rectangular harbor used by Lepelletier (1980) in hydraulic experiments. Two types of rectangular harbor have been tested. One is a fully open harbor \((a/b = 1.0, a\) is width of a harbor entrance, \(b\) is width of harbor) and the other is a partially open one \((a/b = 0.2)\). In Figures 6 and 7, numerical results without and with entrance losses are presented with the experimental results by Lepelletier (1980), respectively. As shown in figures, the calculated amplification ratios considering energy loss effects due to flow separation coincide very well with the experimental results. Neglecting energy loss effects obviously over-estimates the ratio.

In general, the length of jet-flow, \(l_j\) has been taken to be zero. As the \(l_j\) increases, the resonant periods move toward longer periods and amplification ratios at the resonant conditions increase. These phenomena have been confirmed in this verification. As shown in Figure 7, amplification ratios for the case with \(l_j = 0.0284\) m are smaller than those for the case with \(l_j = 0\). This is due to shifting of the first resonant condition. The results considering the effects of the jet-flow are better fitted to the measured results. As mentioned before, the length of the jet-flow is estimated from the theoretical formula proposed by Morse and Ingard (1968) which was derived for the narrow channel with a thin gate. It may be required to develop a new formula for estimating the length of jet-flow at the harbor mouth more accurately.

Application of the present model

To prove the applicability of the present model to the real case and to investigate the characteristics of long-period oscillations in a harbor with narrow mouth, numerical analysis was performed for the Gamcheon Harbor shown in Figure 1. As previously mentioned, field measurements were carried out using four PWGs and one RCM-9. For the direct comparison of the field measurements and calculated results, the informations for the incident waves such as wave heights and directions are estimated. However, it is nearly impossible to obtain the accurate informations from the limited set of field measurements, especially for long-period waves. Therefore, the incident wave angles were assumed to be equal to the main direction of short-period waves previously measured. A wave height for each wave frequency was determined from comparisons of the estimated and measured results at two stations, P1 and P2 at the outside of the
The estimated incident long-period wave heights were in the range of 0.03 - 0.07 m.

The amplification ratios at the innermost station, P4 are plotted in Figure 8. In this figure, hollow black circles indicate 13 measured data and black squares indicate the estimated results. The resonant periods and amplification ratios simulated by the present model are well agree with the measured results. To investigate the effects of the entrance losses in the real situation, the numerical analysis without considering the entrance losses was performed. The effects of the entrance losses were however almost insignificant in the whole tested range, except for the slight difference near the first resonant condition. This may be due to the fact that the incident wave heights are small in the present case. The entrance losses might be effective when the incident wave height is large as the case of attacking of tsunami.

![Figure 6. Variation in Amplification Ratios with respect to Incident Wave Heights for a Fully Open Rectangular Harbor (a/b = 1.0).](image)
Figure 7. Variation in Amplification Ratios with respect to Incident Wave Heights for a Partially Open Rectangular Harbor ($a/b = 0.2$).

Conclusions

In this paper, the long-period wave oscillations in a harbor with narrow mouth has been studied. Field measurements were performed for a harbor with narrow mouth, Gamcheon Harbor in Korea. A Galerkin finite element model based on the extended mild-slope equation was developed which can handle the entrance losses due to flow separation. Verification of the present model was proved through the comparison of the estimated and experimental results. Comparisons of estimated and measured data in field shows that the present model gives quite reasonable results.

The effects of the entrance losses are insignificant unless the incident wave height is large. This may be true for tsunami. It was also found that strong jet-flow can affect the resonant condition, i.e., the resonant periods are moving toward longer period and amplification ratios are amplifying especially for the resonant conditions, as the jet-flow is being strong.

APPLICATION OF COMPUTER MODELING FOR HARBOR RESONANCE STUDIES OF LONG BEACH & LOS ANGELES HARBOR BASINS

Jiin-Jen Lee¹, Member, Ching-Piau Lai², Member, and Yigong Li³, Member

ABSTRACT

One of the major engineering problems for large harbors with container ship operation is the motion of moored ships due to long wave activity. In order that the wave-induced ship-motions may be effectively controlled, the response characteristics of the harbor basin due to incident waves must be accurately determined. This study focuses on the application of a computer model in the harbor resonance study in connection with modification of harbor basins. The computer model used is a finite element model with the mild-slope equations as the governing equations. Various boundary conditions are incorporated in the model: fully and partially reflecting boundaries, permeable boundary. Energy losses across the harbor entrance due to flow separation and frictional loss at the bottom are also incorporated in the model. Good comparison between the computer model results and the physical model data of the Los Angeles-Long Beach harbor basin has been obtained.

The computer model has been applied to the large scale harbor basin of Los Angeles & Long Beach Harbors. Effects on response characteristics due to incident wave system with and without breakwater at Pier J in Long Beach Harbor have been determined. The construction of the proposed breakwater outside Pier J in Long Beach Harbor appears to be effective in reducing the wave amplification for wave period less than 140 sec. The wave period associated with resonant peak has been shifted to 170 sec. or higher. With the advancement of computing power, it is found that computer model offers a very powerful alternative to physical model in the study of wave response characteristics. All the computation reported herein are done by Pentium 2-300 MHz personal computer.

1. INTRODUCTION

One of the most important engineering tasks in the planning and design of a new harbor or modification of an existing harbor is the determination of the response characteristics of the harbor basin to the incident wave system. The long wave induced harbor resonance may cause unwanted motion of berthed ships, delaying the loading or unloading of cargo. It may even damage the ship or dock facilities and cause breaking of mooring lines and fenders. The response characteristics could be determined by either physical modeling or by computer modeling. Advancement in the computer modeling technique has progressed to the point that a convenient computer model can be applied to model a complicated harbor basins using personal computer including incident wave system of relatively short wave period range.

This study focuses on the effect of the proposed breakwater at Pier J on the response characteristics of the harbor basin.

2. THEORY OF THE COMPUTER MODEL

The computer model used for the present study is a finite element model. The governing equation is the well known mild-slope equation with appropriate boundary conditions as specified in the following:

Mild-slope wave equation:

\[ \nabla \cdot \left( C C \nabla \Phi \right) + \frac{C_s \omega^2 \Phi}{C} = 0 \]  

(1)

Boundary conditions:

\[ \frac{\partial \Phi}{\partial n} = 0 \]  

(for fully reflecting boundary)  

(2)

\[ \frac{\partial \Phi}{\partial n} = -i \alpha k \Phi - i \alpha \frac{\partial^2 \Phi}{2k \partial S^2} \]  

(for partially absorbing boundary)  

(3)

\[ \frac{\partial \Phi_1}{\partial n} = i k k_1 \Phi_1 \]  

(for permeable boundary)  

(4)

\[ \Phi_1 = \Phi_2 + \Delta \Phi = \Phi_2 + \frac{g}{\omega} \int_{S}^{U} \frac{\partial^2 \Phi}{\partial S^2} \]  

(for entrance boundary)  

(5)
\lim_{r \to \infty} \sqrt{r} \left( \frac{\partial}{\partial r} - ik \right) \Phi_S = 0 \quad \text{where} \quad \Phi_S = \Phi - \Phi_1 \quad \text{(at infinity)} \quad (6)

The energy dissipation due to bottom friction is described as an instantaneous complex energy flux, \( E_f \), out through the bed under the water,

\[ E_f = \tau_b U_b \quad (7) \]

where \( \tau_b \) is the instantaneous complex shear stress at the bed.

\( \tau_b \) can be expressed in terms of the water particle velocity near the bed as follows:

\[ \tau_b = \frac{1}{2} \rho K_b |U_b| U_b \quad (8) \]

Here \( K_b \) is a dimensionless frictional coefficient, \( U_b \) is the near-bottom water particle velocity and can be expressed in terms of the velocity potential \( \Phi \) as follows:

\[ U_b = (\frac{\partial \Phi}{\partial z})_b = \nabla \Phi \frac{1}{\cosh kh} \quad (9) \]

Insert (9) into (7), we obtain

\[ E_f = \frac{\rho}{g} e^{-2i\omega} f_a \left( \frac{1}{\cosh kh} \right)^2 (\nabla \Phi)^2 \quad (10) \]

Upon integrating (10), we introduce a new bottom friction coefficient, \( f_w = \frac{1}{2} g K_b |U_b| \).

Thus the resulting equation can be written as:

\[ \int_A [E_f dt] dA = \frac{\rho}{g} e^{-2i\omega} \int_A f_a \left( \frac{1}{\cosh kh} \right)^2 (\nabla \Phi)^2 dA \quad (11) \]

We introduce a quadratic headloss law at the harbor entrance. It is convenient to define \( K_e = \frac{f_e}{2g} |U_o| \), where \( |U_o| \) is taken as the average velocity at the harbor entrance computed based on the case of no entrance loss, and express the entrance loss, \( \Delta H \), as follows:

\[ \Delta H = f_e \frac{U^2}{2g} = f_o \frac{|U_o| U}{2g} = K_e U \quad (12) \]

where \( U \) is the new entrance velocity to be computed in the model, and \( f_e \) is the entrance loss coefficient similar to the one defined by Lapelletier (1980).
The Galerkin's method and shape function are used to transform the governing's equation and boundary conditions into a matrix form by discretizing the domain of interest into a finite number of elements. The Gaussian quadrature method is used for numerical integration terms.

By using \( \Phi = N_1 \Phi_1, \ \nabla \Phi = \nabla N_1 \Phi_1 = B_1 \Phi_1 \) and \( \Phi_s = N_s c, \ \frac{\partial \Phi_s}{\partial \tau} = P_s c \), the finite element weak formulation can be obtained as follows:

\[
[K][\Psi] + [Q] = [0]
\] (13)

where \( \Psi \) are all unknown matrices, and

\[
K = \begin{bmatrix}
[[M]] & [[M_2]] \\
[[M_2]]' & [[M_1]]
\end{bmatrix}
\]

\[
[M] = \int_A \left( C_2 B^T B - \frac{\partial \omega}{\partial C} 2 N^T N \right) dx dy - \int_{\partial a} i \omega C_3 e N_T N ds + \int_{\partial b} i \omega C_5 K_t (N^T N) ds
\]

\[
- \int_A \frac{i \omega}{\cosh^2 \kappa h} B^T B dx dy - \int_{\partial c} i \omega C_7 e [(1-K)] N^T B - K_e B^T B ds
\]

\[
[M_1] = \int_{\partial a} C_8 e P_s N_T N ds
\]

\[
[M_2] = \int_{\partial a} C_8 e N_T P_s ds
\]

\[
[Q_1] = \int_{\partial a} C_8 e N_T \frac{\partial \Phi_1}{\partial A} ds
\]

\[
[Q_2] = \int_{\partial a} C_8 e P_s^T \Phi_1 ds
\]

\[
K_e = \frac{f_e |U_0|}{2g}
\]

This computer model takes into account the diffraction, refraction, reflection, boundary absorption, bottom friction, and separation losses at harbor entrance or other entrance to inner basins. Especially noteworthy is the ability of this computer model to obtain responses in the relatively short wave period range which was considered prohibitive heretofore. This was accomplished by the use of "substructuring technique" and "automatic mesh generation" system. The substructuring technique has been developed by dividing the entire modeling basin into several irregular shaped basin with solutions
matched at each of the imaginary common boundaries. The automatic mesh generation program is incorporated so that this computer model could be used as an effective iteration design tool to arrive at the desirable harbor geometry for a given permissible wave response within the harbor.

3. RESULTS AND DISCUSSIONS

One of the major objectives of this study is to use the computer model to investigate the basin response characteristics to incident waves which are related to any proposed modification of the harbor layout with the ultimate objective of reducing the dependence on physical model in reaching engineering decisions. At the very least, the computer model could be used to guide the use of physical model so that the physical models could be more efficiently conducted.

The layout of the Long Beach / Los Angeles harbor model basin is presented in Figure 1. This physical model basin was constructed by the Coastal Engineering Research Center of the Waterways Experiment Station of the U.S. Army Corps of Engineers. Also included in the figure are the location of all the wave height measuring gages used in the model basin.

Two computer model grid systems have been used and are shown in Figure 2 and Figure 3. Figure 2 is a smaller model which covers the harbor basin mostly in Long Beach Harbor region. This model grid has 14,895 nodal points with 6,325 elements. Also indicated in the grid layout are three of the incident waves directions.

Figure 3 shows the grid layout of a larger model it contains the entire model basin used in the physical model (as shown in Figure 1). It consists of 31,538 nodal points and 13,263 elements. One of the motivations of using this huge model is to utilize of the results of the physical model for verification of the computer model.

It should be noted that because of the nature of the long period wave, the wave length is long compared with characteristic length of the harbor basin, a true incident wave system for an open sea condition can not be achieved in the physical model. Instead, it is a wave generator system at one end of the harbor model basin surrounded by reflecting walls at the model boundaries.

Thus, in order to compare the computer model results with the physical model data, it is necessary to construct the computer model so that it will be identical to the physical model (that is a wave generator is placed at one end of the model basin, with reflecting boundaries comprising the three walls of the model basin).

An attempt has been made to compare the results of a computer model with a wave
Figure 1: Layout of Long Beach & Los Angeles harbors and locations of gauge stations

Figure 3  The finite element grid layout of large scale model (13263 elements, 31538 nodal points)
Figure 4  Comparison of response curves between the present numerical results and WES experimental results at gage #81 (Pier J)

Figure 5  Comparison of response curve between the present numerical results and WES experimental results at gage #43 (West Basin)
generator system with the physical model data using the exact wave generator strokes registered by the physical models. This comparison is presented in Figures 4 and 5 for two gaging stations. These two figures show the comparison of the computed and measured wave heights at the specified stations as a function of the model wave periods. Gage #81 is located at the inner corner of the Pier J basin in Long Beach Harbor. Gage #43 is located at the left corner of the Long Beach West Basin. It can be seen that the comparisons are good in general further verifying the usefulness of the computer models.

The computer model with large grid layout covering a wide area of the harbor basin as shown in Figure 3 has been applied to study the effect of basin modification on long period wave response characteristics.

Figure 6 shows the plan view of the harbor modification at Pier J. The sketch on the left shows the Pier J basin without the breakwater (the basin layout prior to the construction of the breakwater). The sketch on the right of Figure 6 shows the layout for the breakwater. It is clear that the introduction of the breakwater modifies the characteristic length of the harbor basin. The longitudinal length of the Pier J basin is increased by approximately 44%.

The response curves for four different gaging stations are presented in Figures 7 through 10 for Gage #81, #85, #82 and #94. Gage #81 and #85 are located at the back end of Pier J basin. Since the variations of water surface elevation for the wave period range under study is mainly in the longitudinal direction; thus, response curves for Figure 7 & 8 are almost identical. Comparing the two curves in both Figure 7 & 8 two major effects of the breakwater can be clearly shown: (1) The amplification factors for wave periods less than 140 sec. has been greatly reduced due to the introduction of the breakwater. (2) The major resonant mode at T=130 sec. has been shifted to T=170 sec.
Wave Dir. 2, at Gage #81

- with Breakwater
- without Breakwater

Figure 7 Comparison of computed response curves with and without breakwater at gage #81

Wave Dir. 2, at Gage #85

Figure 8 Comparison of computed response curves with and without breakwater at gage #85
Figure 9  Comparison of computed response curves with and without breakwater at gage #82

Figure 10  Comparison of computed response curves with and without breakwater at gage #94
By comparing the response curves shown in Figures 9 & 10 for the conditions with and without breakwater, it is also found that the two key features just mentioned also hold true here. Therefore, the introduction of the breakwater clearly shift the resonant wave period to higher values hopefully into the region not relevant to periods associated with possible ship motions.

Comparison of the computer model results with available field data at a location corresponding to that for gage #81 is presented in Figure 11.

Field data were obtained during a three months period, December 1997, January and February 1998. Five sets of field data are included in Figure 11. Obviously without knowing the actual incident wave direction it is not certain what definitive conclusion can be drawn from them. However, it appears that some of the resonant modes are captured in the computer model even though the field data show considerable scatter. It should be noted that the computer results shown are for incident wave direction #2, with breakwater at Pier J Basin and with large scale grid layout (as that shown in Figure 3).
4. CONCLUDING REMARKS

Computer models by nature are an approximate solution to the more complicated prototype conditions. For important engineering projects one should use both the computer models and physical models. However, at the present time the computer model has been advanced to a degree that it can largely reduce (although not eliminate) the need for physical models. At the very least, the computer model can be used effectively for preliminary planning work and to serve as a guide to the use of physical model if the latter is still needed for important projects.

The results presented herein show that the computer model nicely reproduces the data obtained from the physical model. The introduction of the breakwater at Pier J at Long Beach Harbor effectively reduces the wave amplitude response for wave period less than 140 sec. It also shifted the resonant wave period to period larger than 170 sec., hopeful this will be in the wave period range not very significant for ship motion problem.

5. ACKNOWLEDGEMENT

The authors are appreciative of the funding support of the Port of Long Beach and Port of Los Angeles. The helpful comments of Professors Robert Dean, C.C. Mei and Fredric Raichlen during the course of this study are greatly appreciated. ATTENUATION OF VERY LONG WAVES BY A LARGE RESONATOR AS AN OUTER HARBOR

Takayuki Nakamura¹, M. ASCE and Satoshi Morita²

Abstract

A large resonator which has a similar size of the outer basin of a double-basin type harbor is designed by the Wave Filter Theory. This resonator aims to protect an inner basin from incoming very long waves which may cause long-period motions of moored ships at piers. Performance of the designed resonator is examined by the physical and numerical experiments. It was confirmed that the large resonator designed by the Wave Filter Theory is effective for protecting the inner basin from very long waves with a period of 30s or longer. However, the aspect ratio of the resonant basin should be nearly equal to 2:1 for the effective reduction as pointed out by Valembois(1953).

Introduction

It has become known that infragravity waves having a period of about one minute or longer may cause long-period ship motions in a harbor. Especially, a moored ship at piers sometimes experiences large amplitude motions by these long-period waves. In this study, a large resonator that is presumed as the outer basin of a double-basin type harbor is proposed as one of countermeasures to reduce such long-period ship motions.

Valembois(1953) has already presented an idea of resonators to reduce incoming waves to harbors and canals by installing resonators at the entrance. Recently, Nakamura et al(1996) have shown a rational method to design a resonator, which is called the Wave Filter Theory. They also reported that the theory is useful for designing a resonator that is effective for the specified wave conditions. However, the designed resonator is mainly for wind waves having a wave period of 10s or so.

In this study, by using the Wave Filter Theory, a resonator that is effective for very long waves is first obtained. The resonator as the outer harbor of a double-basin type is assumed. Laboratory and numerical experiments were carried out to examine the effectiveness of the resonator.

Large Resonators Designed by the Wave Filter Theory

In the Wave Filter Theory, a rectangular resonator as shown in Fig. 1 is assumed. Based on the theory (Nakamura et al 1996), we can estimate the necessary dimensions of $l_2$, $l_1$ and $b_3$ for given $b_0$ and the required effective frequency band as follows.

\[ b_3 = \frac{mb_0}{\sqrt{2(1-m^2)}} \]

\[ l_2 = \frac{1}{\pi f_c} \sqrt{\frac{gh(1-m^2)}{2}} \]

\[ l_1 = \frac{m\sqrt{gh}}{2\pi f_c} \]

where $g$ is the gravitational acceleration, $h$ is a water depth, and $m$ is a function of the critical frequency $f_c$ and the pole frequency $f_w$ of an effective frequency band ($f_c < f < f_w$) of a wave resonator and is given by

\[ m = \sqrt{1 - \left(\frac{f_c}{f_w}\right)^2} \]

The pole frequency \(f_p\) corresponds to a frequency at which wave transmission through a resonator becomes the lowest.

Table 1 shows typical results on the horizontal dimensions of resonators for various design conditions. Resonators with a wide entrance are presumed for passing ships. The aspect ratio of a resonant basin of these resonators, \(b_2/l_2\), ranges from 1.8 to 3.5. Valembois (1953) pointed out that the aspect ratio of the resonant basin should be about 2 for the effective protection.

**Effects of the Aspect Ratio of a Resonant Basin on the Wave Transmission**

To examine the effectiveness of the designed resonators specified in Table 1, we calculated wave transmission characteristics through a linear array of the resonators by the vertical line source Green's function method (Nakamura 1994). This numerical method takes into account the effect of an infinite array of bodies by considering an infinite number of mirror image sources. In the computation, the reflection coefficient of the wall of resonators is assumed to be 0.8 for modeling the practical situations.

Figs. 2~4 show the computation results on the wave transmission through an infinite array of the resonators, Type (A), (B) and (C) in Table 1, respectively. The wave transmission characteristic is specified by the wave height ratio \(K_T\), which is defined by

\[
K_T = \frac{(H_T)_{rms}}{H}
\]

where \((H_T)_{rms}\) is a root-mean-square value of transmitted wave height along the array direction, and \(H\) is an incident wave height. The rms value of transmitted wave height is necessary to account for the short-crested wave pattern about an array of resonators, especially under the condition \(\lambda/L > 1\) (\(\lambda\): center-to-center distance between the adjacent resonators, \(L\): wave length). It has become known that wave patterns about an infinite array of identical bodies under the condition \(\lambda/L > 1\) are short-crested even though in the region far from the array (Dalymple & Martin 1990 and Nakamura 1994). In other condition \(\lambda/L < 1\), the wave pattern is long-crested and the definition of \(K_T\) coincides with that of a well known transmission coefficient.

From these figures, it is seen that the value of \(K_T\) for each array of resonators, Type (A), (B) and (C), is comparatively small for the presumed effective range of wave period as shown in Table 1. The spike-like variation of \(K_T\) is due to the wave resonance in the transverse direction. Under the transverse resonant condition, a center-to-center length of the adjacent resonators \(\lambda\) is equal to a wave length \(L\). In the numerical computation, this resonant condition corresponds to the singular point at which one of eigenfunctions of the Green’s function becomes indefinite.
Fig. 2 Dimensionless transmitted wave height through the arrayed resonators of Type (A); water depth h = 30m.

Fig. 3 Dimensionless transmitted wave height through the arrayed resonators of Type (B); water depth h = 30m.
From inter-comparison among these figures, we can see some difference with the performance of the resonators. For instance, Type (A) and (B) resonators show the much lower $K_T$ value than Type (C) resonator in the presumed effective wave period range. It may be caused by the difference of aspect ratios of a resonant basin $b_3/l_2$. The aspect ratio is about 2 for Type(A) and (B) resonators, which is equal to the aspect ratio recommended by Valembois (1953). On the other hand, the aspect ratio of Type (C) resonator is 3.5. Therefore, it is better to design a resonator in such a way that the aspect ratio of a resonant basin is about 2. However, it is noted that the entrance width $b_0$ of a resonator is also an important factor to determine the performance.

As a result, we can use the Wave Filter Theory to get a rough estimate of geometrical dimensions of a wave resonator that is effective for the given frequency range. However, it is hard to know the degree of effectiveness of the resonator by the theory. In this case, we have to rely on the numerical computation method.

**Experimental Results in a Channel for Regular and Irregular Waves**

In order to check the validity of the design results by the Wave Filter Theory, we carried out model tests in a long channel. The channel is 1.2m heigh, 1m wide and 26m long. The distorted model was applied to avoid the difficulties arising from the wave nonlinearities. The model scale is 1/324 in the horizontal dimensions and 1/167 in the vertical dimension. Type (A) resonator in Table 1 was basically used. The setup of a model resonator is shown in Fig.5. Considering the mirror image effect of both side walls, only a half of the resonator was placed in a long channel. The wave field in this channel is equivalent to the one around an infinite array of identical resonators when the wave reflection from side walls is perfect. In the experiment, the allocation pitch length $\lambda$ of the arrayed resonators is equal to double of a channel width, i.e. 2m.

We used two different types of model resonators with the same dimensions, but having different reflection characteristics. One model is made of plywood and has a high reflective
nature. The other model consists of low-reflective walls covered with porous materials on the surface. It was confirmed by the other experiment that the reflection coefficient of the low-reflective wall is approximately 0.8.

In order to be able to analyze the short-crested wave pattern around a resonator in the channel, we set a linear array of five wave gauges in the transverse direction to measure transmitted waves through a resonator. Wave conditions used in the experiment are largely classified into two categories, i.e. regular and irregular waves.

In the case of regular waves, wave period $T_m$ ranges from 1.2 s to 3.5s (in prototype scale $T=22\sim64$s) and wave height $H_m$ is fixed at about 3cm (in prototype scale $H=5$m).

Fig. 5 Experimental setup; Type (A) resonator.

(In case of low reflective walls)

Fig. 6 Dimensionless transmitted wave height through the arrayed resonator for regular waves.
For the case of irregular waves, the Bretschneider spectrum was used as a target frequency spectrum. At present, the frequency characteristic of infragravity waves has not been clarified. Therefore, we just account for the irregular nature of wave trains in the field.

Fig. 6 shows typical results for regular waves, where the rms transmitted wave height ratio $K_T$ is plotted as a function of wave period $T$ in the prototype scale. The parameter $\lambda/L$ is also plotted as a second horizontal axis.

![Figure 6](image1)

Fig. 7 Variations of $K_T$ of Type(A) resonator with water depth.

![Figure 7](image2)

Fig. 8 Dimensionless transmitted wave height through the arrayed resonator for irregular waves.

![Figure 8](image3)
In the figure, two different results are shown. One is for the resonator consisting of high reflective walls and the other consists of dissipative walls covered with porous materials. Further, in the figure, the computed result by the Green's function method is also plotted. In the computations, the distorted model was used as a real structure. Hence the water depth is assumed to be 60m in the prototype scale.

Except the condition near the transverse resonance at $\lambda/L=1$, we can see the reasonable agreement between the computed and experimental results. However, for longer wave period conditions, the measured value of $K_T$ is smaller than the computed one. It may be partly caused by the frictional damping on the sea bed.

From the comparison between the two experimental results for the low- and high-reflective wall cases, it is seen that there is little influence of the different wall types on the wave transmission.

Fig.7 shows the effect of water depth on the performance of resonators. In the figure, the computed results of $K_T$ for the arrayed resonators with the same horizontal dimensions (Type (A)), but for three different water depths, are shown. It is apparent that the effective range of wave period shifts to the side of longer waves with deceasing water depth $h$. This is caused by the decrease of wave length with water depth. This tendency can also be predicted by Eq.(1).

Fig.8 shows the result of $K_T$ for irregular waves with different significant wave periods $T_{1/3}$, where $K_T$ is defined as a transfer function in the frequency domain. We can see the similar tendency to the result of regular waves. From the examinations described above, we can say that the large resonator is effective for reducing very long waves of both regular and irregular wave trains.

![Fig.9 Layout of a model harbor and reflection coefficients on the boundary.](image_url)
Numerical Experiment on the Harbor Tranquility

In order to confirm the effectiveness of the resonator as an outer harbor of a double-basin type, we carried out numerical experiments based on the vertical line source Green's function method (Isaacson 1978 and Nakamura et al 1985).

Fig. 10 Wave height distributions around the original harbor (T=35s, normal incidence).

Fig. 11 Wave height distributions around the harbor with a resonator (T=35s, normal incidence).
Fig. 9 shows a layout of an original harbor adopted in the numerical experiment. It is assumed that the water depth $h$ is constant around the harbor and is equal to 30m. Reflection characteristics of harbor boundaries are specified in the figure by the reflection coefficients $C_R$. When we add two jetties in a harbor as shown in dashed lines in the figure, the harbor becomes a double-basin type with the resonator of Type (A) as an outer basin.

Fig. 10 and 11 show the comparisons of wave height distributions between two different models, i.e., the original harbor and the one with the type (A) resonator as an outer harbor as seen in Fig. 9, respectively. In these figures, the dimensionless wave height ratio to an incident wave height is plotted. The normal incidence of waves to the harbor entrance is presumed.

We can see that the resonator designed by the Wave Filter Theory is very effective to reduce long-period waves incoming to the inner basin. However, we can also see a subsidiary effect of the resonator, i.e., higher waves in the resonator including at the harbor entrance. It may be thought that there is little or no influence on passing ships because of a small amplitude of very long waves. Fig. 12 shows another example, where the wave period $T$ is longer than the case of Fig. 11. It is again confirmed that the resonator plays an effective protector for incoming waves to the inner basin.

Finally, Fig. 13 shows the result of wave height distributions in case of obliquely incident waves to the harbor entrance. The inclination angle is 30-degree from the normal incident direction. It can be seen that the performance of a resonator is not affected by the incident angle of waves.
Conclusion

The Wave Filter Theory is very useful to design a large resonator as the outer basin of a double-basin type harbor for protecting the inner basin from very long waves, which may cause long period motions of a moored ship at the piers. It was confirmed experimentally that the large resonator as the outer basin is effective for reducing both regular and irregular waves in the inner basin.

It is suggested that the aspect ratio of a resonant basin should be the order of 2:1 for the effective protection of the inner basin from incoming waves. However, it is noted that the entrance width of a resonator is also an important factor to determine the performance.

Application of Physical Model in Long Wave Studies for The Port of Long Beach
Ying-Keung Poon¹, Frederic Raichlen², and James (Kimo) Walker³

INTRODUCTION

The increase in container shipping demand has lead to rapid expansion of container terminal facilities. The Port of Long Beach have expanded their operations by landfills in areas more exposed to waves in less protected areas of the harbors. At the same time, container ships have been increasing in size and more rapid cycle time of cargo transfers by container cranes have demanded tranquil berths to minimize vessel motions. The availability of tranquil water and the need for faster crane cycle times have been in conflict.

The Port of Long Beach constructed a container terminal near the entrance to the harbor in 1992 for Maersk shipping lines. The 2,300 ft wharf is backed by over 100 acre of terminal and gate area and has four post panamax size container cranes. The terminal operates with a trucking and rail facility. Immediately after construction of the terminal in 1992, the first ships of over 900-ft size experienced excessive ship motions. These motions produced a surge measured up to 10 ft with periods on the order of one minute. Sway motions were about 20 to 40 seconds, and when coupled with the surge caused damage to fenders, represented a safety issue by mooring line breakage, and substantially reduced container crane productivity.

This paper summarizes the use of physical model studies in the design of a breakwater to attenuate vessel surge motions at Pier J berths to acceptable levels. In assessing the performance of a breakwater configuration, two different criteria were considered. The

¹ Senior Coastal Engineer, Moffatt & Nichol Engineers, 250 W. Wardlow Road, P.O. Box 7707, Long Beach, CA 90807, USA
² Professor, Civil & Mechanical Engineering Dept., California Institute of Technology, Pasadena, CA 91125, USA
³ Senior Vice President, Moffatt & Nichol Engineers
first criterion was based on comparing the long wave energy in Pier J with a proposed breakwater arrangement in place to the wave energy at existing conditions. This criterion was used to quantify the improvement in wave conditions in Pier J and hence to compare the performance of different alternatives. The second criterion was based on comparing the long waves at Pier J with those at the South East Basin at the Port of Long Beach, at where container ship operations had not experienced major ship motion. The long wave attenuation criterion selected for the Pier J Breakwater design was therefore set to match or be below the existing wave conditions within South East Basin.

**EXPERIMENTAL PROGRAM**

*Model Description*

The effectiveness of the Pier J Breakwater in reducing the long wave in Pier J was tested at the US Army Engineer Waterways Experiment Station (WES) Los Angeles and Long Beach Harbors (LA/LB) model. The LA/LB model was originally constructed to conditions in the early 1970's and has been periodically updated to account for changes in the LA/LB Harbors. The model has a vertical scale of 1:100 and a horizontal scale of 1:400. The model shoreline extends from 2 miles northwest of Point Fermin to Huntington Beach, and reproduces the Pacific Ocean bathymetry seaward of the harbor out to the -300 ft MLLW contour. The total model area covers about 44,000 ft$^2$, which represents 253 sq. miles in prototype.

A wave generator composed of 13 individual segments, each independently controlled by a computer, was located at the far end of the wave basin. Details of the generator design and modes of operation can be found in Outlaw et al. (1997). A sketch of the physical model basin, wave generators and offshore wave gages is shown in Figure 1.

*Breakwater Configurations*

Seventeen different breakwater configurations were tested. These configurations are shown in Figure 2, and represent modifications from the original “J6” configuration identified in a prior study by Sargent and Thomas (1995) as effective in reducing the long wave energy at Pier J.

A total of twenty-three sets of tests were conducted. These include the seventeen different configurations, two tests for the existing (base) conditions, and four additional tests for construction phasing (J20, J21, J22 and J23).

Detailed descriptions of each breakwater configuration are not provided herein. However, the rationale in selecting these different test configurations is summarized as follows:
1. Compare the performance of the breakwaters with a rectangular layout (J6 and J8) with those breakwaters with a triangular layout (J9 and J11);

2. Optimize the performance of the rectangular layout by varying the length of the breakwaters (J6, J8, and J12 through J19);

3. Test the importance of the permeability of the breakwaters (J6, J15 and J19) in reducing the long wave energy in Pier J; and

4. Identify the importance of different long wave attenuation mechanisms such as blocking the incident wave (O1), enhancing the separation losses (P1, O1 and J18), and reducing the trapped long wave energy (J11).

**Test Conditions**

Both monochromatic waves and random wave spectra were tested. Eleven wave periods were selected for most of the monochromatic wave tests which included 151.5, 128.3, 110.3, 99.0, 80.2, 72.3, 60.2, 47.8, 41.9, 37.2 and 32.7 seconds. These wave periods were chosen based on the response of the basin during an initial test with a uniform random wave. Some of the test configurations shown in Figure 2 (BS2, J10, J11, N1, O1 and P1) were tested with only four wave periods (151.5, 128.3, 110.3 and 37.2 seconds). The final configuration J19 was tested with five additional wave periods (160.0, 141.1, 120.0, 106.0 and 91.0 seconds), which results in a total of sixteen periods tested.

Ten wave gages were used for data collection. These included five in Pier J, two in the South East Basin, one at the Queen’s Gate entrance, and two offshore gages (one near Platform Edith). The gage locations and their designated numbers are shown in Figure 3. For the final test for J19, an additional gage was placed near the entrance to the Pier J. Wave gages were also deployed in other locations in the Port of Long Beach and Port of Los Angeles to investigate whether proposed modifications would exacerbate any existing surge conditions outside the Pier J project site.

**Data Analysis**

The monochromatic wave test results revealed that the incident wave conditions measured at a gage near Platform Edith location are subject to multiple wave reflections within the model basin. Reflected waves from the breakwaters, reflected waves from other model boundaries, and re-reflected waves from the wave machine contaminated the wave record at Platform Edith after a short time.

An example time series of recorded waves at four different gage locations is shown in Figure 4. In the figure, Gage 16 is at Platform Edith; Gage 42 is at the Queen’s Gate entrance; Gage 81 is near the end of Pier J; and Gage 29 is in the South East Basin. This
example record shows that it takes about 5 seconds for the waves to reach Platform Edith and about another 25 seconds for the waves to travel from Edith to Queen's Gate. This means that it takes about 50 seconds for the reflected waves from the Federal Breakwaters to reach Edith. In another 10 seconds, the reflected waves will travel to the wave generator and be re-reflected to Edith. The effect of these reflected and re-reflected waves to the wave record at Edith is clearly shown in the figure.

In calculating the wave amplification factor – the ratio of the measured wave height at a specified location to that at Edith, only the uncontaminated (before wave reflection affects the Edith reading) wave record was used in the calculation.

The test with the uniform spectrum, which requires a long wave record for spectral analysis, is inherently contaminated and therefore not suitable in defining wave amplifications. In this study, the optimized breakwater configuration was therefore chosen based on the results of the monochromatic wave tests. The spectral wave results were used only for studying the general response of the basin over a range of wave periods.

MODEL RESULTS

In general, the monochromatic wave tests showed that for similar total breakwater lengths, the rectangular layout is more efficient in attenuating the long waves than the triangular layout. For the rectangular layout, the longer the breakwater segments the better the performance. In addition, the permeability of the breakwater was found to be an important factor in determining the performance of the breakwaters. The less permeable breakwater cross section performs better than the more permeable sections.

Due to the large number of tests and large amount of analyzed data, only the most relevant and important test results are presented here. These results were chosen to illustrate and elaborate the general conclusions stated above. In addition, only measurements at Gages 81 (located near the end of Pier J, which usually shows the greatest long wave amplification within Pier J, are shown. However, wave measurements at all gages were analyzed and their results were evaluated in determining the best breakwater configurations.

Effect of Permeability

The amplification factors measured at Gage 81 for configurations J6 and M1 are shown in Figures 5. The two test configurations used identical breakwater layouts. While J6 has permeable breakwater cross-sections, M1 has impermeable breakwater sections. The results showed that in general, the impermeable breakwater performs better in attenuating the long waves. Data taken at other gage locations showed the same general trend.
Since the breakwater permeability was found to be an important factor in the performance of the breakwaters, proper modeling of long wave transmission through a breakwater in a distorted scale model was further evaluated in a two-dimensional flume. The model stone size providing the best match of permeability of the prototype design (determined from a 1:30 undistorted scale flume model test) was specified for use in the final test with Configuration J19.

**Effect of Breakwater Length**

The length of the breakwater segments for the rectangular layout was found to be important. In general, wave amplifications in Pier J were found to be less for the breakwater configurations with longer segments. However, this improvement in performance is less sensitive to the length of the breakwater segments running in the north-south direction (i.e., parallel to the Pier J entrance) compared to the lengths of the breakwater segments extending eastward from the Pier J Berth (i.e. parallel to the berthing slips). In the following discussions, the average length of the two north-south breakwater segments is designated as $L_1$, while the average length for the two east-west sections is designated as $L_2$. A definition sketch of $L_1$ and $L_2$ is shown on the last configuration in Figure 2.

**Effect of $L_1$**

The amplification factors measured at Gage 81 for configurations J08 and J15 are shown in Figure 6. These two configurations have roughly the same $L_2$ of about 600 feet but $L_1$ differs by about 200 feet. The results show that J08 with longer $L_1$ of 1,000 feet has slightly less amplification factors compared to those for J15 with $L_1$ of about 800 feet. However, the differences in the amplification factors are in general very small.

**Effect of $L_2$**

Amplification factors at Gages 81 configurations J12, J14, J15 and J17 are shown in Figure 7. For these four tests, the shortest $L_2$ is about 370 feet (J12) and the longest $L_2$ is about 965 feet (J17). Note that these four test configurations do not have the same $L_1$, the latter ranges between 600 to 800 feet. As discussed above, the length $L_1$ does have some effect on long wave attenuation in Pier J, but not to a great extent.

In Figure 7, the dot-dash line connects the amplification factors for J12, which has the shortest $L_2$ of 370 feet. The solid line represents results for J17, which has the longest $L_2$ of 965 feet. The results show that there is a great difference in the amplification factors between these two configurations. In most of the tested wave periods, J17 has amplification factors of only about half or less of those amplification factors for J12.
The effects of $L_2$ on long wave attenuation at Pier J were further examined by comparing their performance relative to the existing condition (base case) for five critical wave periods. These include three longer periods of 151.5, 128.3 and 110.3 seconds which are important for ship surge motions; and two shorter periods of 41.9 and 37.2 seconds which are important for ship sway motions.

Figure 8 plots the amplification factors relative to the base case versus the length of the east-west breakwater segment $L_2$ at Gage 81. The amplification factors are taken from test results for breakwater configurations J12, J15, J14 and J17; which have different $L_2$ of 370, 600, 810 and 965 feet, respectively. Except for the longest period of 151.5 seconds, all the four configurations resulted in substantial reduction in wave amplification factors compared to the existing conditions. There is also a general trend of reduced amplifications with the increase in $L_2$. The reductions in the amplification factors are substantial when the breakwater length $L_2$ extends from 360 to 600 feet. When the breakwater extends beyond 600 feet, the amplification factors reduce less rapidly and seem to level off when the $L_2$ approaches about 1,000 feet.

**Separation Loss**

Exploratory tests were conducted by visual observations for a few selected wave periods for configurations P1 and O1. These tests were designed to determine whether enhancement of the separation losses would have measurable impact on surge. The results of these very basic tests, however, did not support the importance of the separation losses in attenuating the long waves in Pier J. After J17 was chosen for the final test, a full test with all the eleven wave periods was conducted to further examine the importance of separation losses. The test was conducted with configuration J18, which has similar layout as J17. The only difference between J17 and J18 is that while J17 has the traditional sloping breakwater head sections, J18 has vertical sheet piles installed at the breakwater head sections leading to the Pier J basin. These vertical sheet piles for J18 were intended to increase the flow separation at the basin entrance and hence should have induced greater separation loss compared to J17.

Figure 9 compares the amplification factors at Gage 81 for J17 and J18. The methodology and results did not indicate that it would be warranted to investigate alternatives based on increasing separation losses.

**FINAL TEST WITH J19**

After reviewing all the results, it was determined that J17 had the best performance among all the configurations tested. A final test was therefore conducted with Configuration J19, which was a modification of J17. This final configuration J19 differs from J17 in two major aspects. First, the lengths of the breakwater segments were
extended to the maximum allowable for the site as limited by dredging and ship maneuvering room. Second, a less permeable breakwater cross-section was specified.

The performance of J19 was compared to J17 in Figure 10. This figure shows the wave amplification factors measured at Gages 81 for J17 and J19. The results show that the less permeable J19 breakwater did result in smaller wave amplifications at Gage 81. Similar results were found for other gage locations.

As mentioned earlier, the criterion for long wave attenuation at Pier J is set to be the same or less long wave energy compared to those long wave energy at the South East Basin. The wave amplification factors measured at Pier J with the final test configuration J19 in place are therefore compared with those amplification factors measured at the South East Basin. These comparisons are shown in Figure 11. In the figure, solid symbols denote wave amplification factors measured in Pier J (Gages 81, 82, 85, 53 and 54), while open symbols are used to show measured results in the South East Basin (Gages 29 and 30). The wave amplification factors at Gage 81 for existing condition (base case) are also shown in the figure for comparison.

In general, with the J19 breakwater configuration in place, wave amplification factors at Pier J are comparable to those at the South East Basin. For the shorter wave periods between 30 to 70 seconds, the amplification factors at Pier J are close to those at the South East Basin. For the longer wave periods of between 90 to 130 seconds, waves at Pier J are slightly higher than those at the South East Basin. However, these wave amplifications at Pier J already represent reduction by a factor 1/2 to 1/3 compared with existing conditions. Even longer wave periods, of between 140 and 160 seconds, waves amplifications at Pier J are in general smaller than those at the South East Basin.

**SUMMARY**

In summary, although configuration J19 does not completely meet the criterion of reducing the long waves in Pier J to be the same as or lesser than the wave conditions at the South East Basin, it is the most effective among all the tested configurations and also represents substantial improvement over existing conditions. Hence, the J19 Breakwater configuration was selected. The Pier J layout with the J19 Breakwater (hatched) is shown in Figure 12.

ABSTRACT

Detailed studies have been undertaken to assist in the design of major extensions to the port of Haifa. Both numerical and physical model studies were done to optimise the mooring conditions vis á vis the harbour approach and entrance layout. The adopted layout deviates from the normal straight approach to the harbour entrance. This layout, together with suitable aids to navigation, was found to be nautically acceptable, and generally better with regard to mooring conditions, on the basis of extensive nautical design studies.

INTRODUCTION

The Port of Haifa is situated at the southern end of Haifa Bay, which is about 12 km long by 6 km wide, with Mount Carmel at the south and Akko at its north end (see Figure 1). The original main breakwater with a length of 2.25 km was built in 1931. It was extended by 600 m during 1978/79 to protect the newly constructed container or eastern quay. At the same time, the harbour entrance area was dredged to a nominal depth of -14 m LSD (Land Survey Datum). In recent years, the eastern quay has been extended by 300 m and a piled passenger jetty has just been completed at the western end of the harbour.

The Kishon harbour is situated east of the main port area close to Haifa’s main industrial area. The harbour entrance is dredged to a depth of -12 m LSD and it is protected by a 400 m long rubble mound breakwater. It is the home of the Israeli shipyard and repair industry.

As part of the Master Plan for the development of the Port of Haifa a 500 m main breakwater extension and several new container, general cargo and bulk quays are planned together with a new approach and entrance channel. Initial numerical wave agitation studies showed unacceptably high downtimes for the original layout, particularly for Quay no. 4 (re. Figure 2). Further studies were therefore undertaken to increase the operability of all the new

berths to acceptable levels but, at the same time, to ensure good navigational conditions in the approach and entrance to the port.

These studies included:
- studies of the main breakwater layout giving the best protection against wave penetration
- a desk study of the nautical design of the entrance
- preliminary full-mission manoeuvring simulations
- a full simulation programme for the accepted layout.

The results of these studies are briefly described in the following sections.

![Fig. 1 Haifa Port in Haifa Bay](image-url)
HAIFA PORT EXTENSION

The Haifa Port Area Development Plan was prepared by the Israeli Ports and Railways Authority (IPRA), with the assistance of Israeli and international experts in various fields. The primary goals of the development are to prepare Haifa Port to meet operational demands which require a high level of service efficiency. This is intended to be accomplished by staged development through the year 2020, as required by demand. The primary goals are as follows:

• furnish a high level of service which means an average waiting time for berths of not more than one hour per vessel
• develop the western part of the Haifa Port as a passenger port
• assure port accessibility by various transport modes (roads and railway)
• optimize integration of the port complex into the metropolitan area by coordinated development planning with surrounding systems
• develop the port hinterland for industrial, commercial and port services
• ensure environmental protection, quality of life and maximum safety.

The three primary components of the development plan are breakwaters, layout & designated usage of quays and port operational areas. The development of Haifa East will be implemented in the following phases (refer Figure 2):

Phase I - Haifa East "A" and Haifa East "B" by the year 2003.
Phase II - Haifa East "C" and "D" future developments based on demand.
With the completion of works envisioned under the development plan, the port would have a total of 6 500 m of operational quays (plus another 900 m of service quays) and 245 ha of operational area.

**Phase I** calls for the construction of 700 meter of container quay and 1 900 meter of general and dry bulk cargo quays in Haifa East "B". Container operational areas will be expanded by 50 ha, general and dry bulk cargo areas by 15 ha. The quays in the western sector of the port (1 600 m) are to be used by passenger ships and ships serving the Dagon grain silos. The western end of the port will then be designated as a passenger ship port and will be integrated into the city's urban fabric. This transformation will have a sweeping impact on the development of the City of Haifa.

The main breakwater must be extended by 500 m to allow Phase I development. The existing Kishon north breakwater must be removed and replaced along a new alignment, with a 200 m long breakwater, refer Figure 2.

Upon the completion of Phase I, the container terminal will be centralized in the area including Haifa East "A" and the western side of Haifa East "B". The western end of the Port will no longer be used for container handling operations. General cargo will be handled in the Kishon Port (as it is currently) and on the northern and eastern quays of Haifa East "B". A transport corridor physically connecting the Kishon Port with the main Haifa Port is planned. The water inlet of the Electric Power Station's cooling basin will be maintained as a bridge in the transport corridor. The warm water from the Electric Power Station will be canalized in a closed conduit and its outlet will be located between Quays nos 1 and 2.

**Phase II** is intended for expansion of the existing chemical terminal as an alternative to the fuel jetty and tankfarm and for handling general cargo and bulks by grabs (Haifa East "C" and "D"). Expansion of the existing airport is planned, as shown in Figure 2.

The mix of ships using the Port, has impact on two primary aspects of the port development plans:

- the physical layout of the port including quay length, water depth, basin size, operational areas, breakwaters and entrance channel dimensions
- the design of the operational concept, including personnel and handling equipment plans and work procedures.

The following **design vessels** (LoaxBxT) were used by the planners for the Haifa Port extensions:

a) Post Panamax Container Vessels up to 84 000 dwt (318x42,8x14).

b) Bulk Ships 60 000 dwt (225x32x12,5), Bulk Ships 100 000 dwt (280x40x15) and Coal Ships 150 000 dwt (295x44x17).
c) General Cargo Ships 25 000 dwt (190x25x10,6).
d) Chemical Tankers 12 000 dwt (160x18,4x8,3).
e) LPG Tankers 22,000 dwt (170x23x9,7).

The following development plan characteristics were set based on the above design vessel assumptions:
- entrance channel water depths (max. 20 m);
- quayside water depths, 14 and 16,5 m for Bulk and General Cargo Ships, 15,5 m for Post Panamax Container Ships, 19 m for Coal Carriers, 12 and 10 m in the Kishon Port to be used by smaller Bulk Carriers and General Cargo Ships;
- basin width between quays 250 m;
- turning circle diameter 600 m.

WAVE PENETRATION AND MOORING STUDIES

Both numerical and physical model studies were done to optimise the harbour layout with respect to limiting wave agitation. Due to the semi-protected position of the Port of Haifa (see Figure 1), storm waves from the dominant W'ly and WNW'ly directions become mainly NW'ly but also NNW'ly. Because ships must approach from the same NW'ly direction, due to the presence of the Talbot Reef, protection against wave penetration becomes rather problematic and several layouts have been studied in the numerical model before physical model tests were done.

The numerical model studies employed three separate modules, a non-linear shoaling module, the linear DHI agitation model MIKE 21 EMS and a linear wave-ship interaction module developed by the Coastal and Marine Engineering Research Institute (CAMERI) in Haifa. For more details on this approach, refer to Di Castro et al (1997). The physical model was built to a scale of 1 in 150 at the CAMERI laboratory in Haifa. As a first step, the numerical model results were compared with those of the physical model for the existing harbour conditions. Acceptable agreement was found, both in the short and long wave heights and in the downtimes for the 60 000 dwt bulk carrier and the 30 000 dwt container ship moored at the existing eastern quay (refer Di Castro et al). Operabilities were found to be 97,0 % and 96,1 % for the numerical model and 97,9 % and 96,7 % for the physical model (limited prototype data suggests 2 % to 4 % downtime which is in close agreement).

After calibration, three basic layouts were modelled in the numerical model, namely the 'original' design (Figure 3) with four different alignments of Quay no. 4 from maximum skew (kinked extension of Quay no. 5) to 90° square (parallel to Quay no. 2), the 'alternative' design which provides maximum protection against wave penetration (Figure 4) and the 'final' design (Figures 4, insert, and Figure 2).
The test results for the original layout showed that the 'parallel' Quay no. 4 has the lowest downtimes and this quay-wall layout was therefor used for all further modelling. The 'alternative' design, with the head of the breakwater extension moved about 150 m east, was found to be significantly better in the eastern part of the port extension, including the Kishon Port, although conditions at Quays nos 1 and 2 became slightly worse. Mainly based on navigational considerations the entrance channel of the 'alternative' layout was revised, without changing the position of the breakwater head, which resulted in the 'final' design. The 'final' layout was studied, both with the numerical models and the physical model and the results showed generally acceptable downtimes for all the berths of Haifa East "B", namely operabilities for the various design ships moored at the relevant Quays nos 1 to 5 from 95.2 % to 98.3 % for the numerical model and from 96.6 % to 99.6 for the physical model. Considering that these operabilities assume 100 % occupancy of design ships (sensitivity studies showed that downtimes for smaller ships are generally significantly less), these results were considered acceptable, based on present experience in the port.

NAUTICAL HARBOUR ENTRANCE DESIGN

The nautical design efforts were concentrated on the Post Panamax container vessel of 84 000 dwt (maximum draught 14.0) loaded to 12.5 m draught (71 900 dwt) to berth at Quay no. 2, a 150 000 dwt coal carrier to be berthed at Quay no. 3, the 100 000 dwt bulk carrier to berth at Quay no. 4 (north) and the 25 000 dwt general cargo ship entering the Kishon Port.
Wave conditions in the approach and entrance area are rather mild and the swell direction is mainly NW. The following refracted design data (in %) apply to the entrance area in 16 m depth (the 'long term' data are largely visually recorded data):

<table>
<thead>
<tr>
<th>Wave Direction</th>
<th>( H_{\text{m0}} &gt; 1.5 \text{ m} )</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>'Long term' wave data '58 -'96</td>
</tr>
<tr>
<td>NW</td>
<td>3.43</td>
</tr>
<tr>
<td>NNW</td>
<td>0.53</td>
</tr>
<tr>
<td>All directions</td>
<td>3.96</td>
</tr>
</tbody>
</table>

Thus, since the available 30 t bollard pull Voith-Schneider tractor tugs can be made fast in waves up to \( H_{\text{m0}} = 1.5 \) to 1.8 m (refer Halber et al., 1985), these tugs could assist outside the protection of the breakwaters for at least 96% of the time.

The dominant wind directions are W, NW and SE while the strongest winds come mainly from W'ly, E'ly and SE'ly directions. Wind speeds in excess of 10 m/s (20 knots) occur only 2.9% of the time (all directions) while speeds in excess of 15 m/s (30 knots), which limits ship handling and crane operation, occur less than 3 days per year.

The 'original' channel alignment shown in Figure 3 was 345° with an approach route of 307°. This design was based on the accepted criterion of a straight harbour entrance channel (refer PIANC, 1997 and also Halber et al., 1985). However, a more easterly position of the breakwater extension would provide better protection against the NW'ly waves and the 'Alternative' entrance design shown in Figure 4 was developed with the breakwater head moved about 150 m east, an entry channel at 10° with the same approach route of 307° and a nominal 63°-radius bend of 900 m or about 3 ship lengths. PIANC (1997) quotes a minimum of 2.8 lengths for unassisted entry but in the case of Haifa, tug assistance in the bend area would anyhow be possible up to at least 96% of the time.

This layout proved to be superior from a wave protection point of view but further improvements were made as follows (see insert Figure 4):

- the head of the breakwater extension remained unchanged but the 500 m extension was made straight
- the turning circle and the head of the future Haifa D breakwater were moved 50 m west
- the entrance channel was revised to have a single-radius (1100 m) bend of 53°
- the channel design allows a further lengthening of the breakwater due north of 200 m, if found necessary (see Figure 2).

This provided a single-radius entry route into the main port area (container basin) of ample
radius. No change was so far made to the original approach route of 307° into Haifa Bay because it is virtually fixed by the presence of the Talbot Reef and the future air corridor (refer Figures 1 and 3). However, when considering the aids to navigation, it was found that by making a minor change in the approach route from 307° to 306°, the back leading light could be fixed to a very prominent grain elevator building (refer Figure 2).

This 'final' layout was used for the preliminary and detailed ship manoeuvring studies described below.

FULL-MISSION MANOEUVRING SIMULATOR

The MSCN real-time simulator with the full mission bridge and a 360° visual image was used for the Haifa Port extension manoeuvring simulation studies. This facility consists of a real ship bridge located in the centre of a cylindrical projection wall on which the graphics image is projected. A separate wing console is available for manoeuvring close to berth. Among the standard equipment of the bridge is a software controlled radar with full ARPA functionality.

Behind the bridge is the simulation manager's position. He can follow the manoeuvres directly as he has a view on the bridge, but he also controls all aspects of the simulations using a dual-headed workstation. On the left hand screen a birds-eye view of the simulation is presented. All environmental conditions can be called up on this screen. The track following target vessels are also controlled from this screen with respect to track and velocity. The right hand screen is used for the control of the simulation. It is used for the selection of conditions, control of tugs, control of environmental settings (visibility, wave heights and wind speed/direction) and it gives information about the status of the own ship (velocity, rate of turn and relative wind speed). At any time the simulation manager can halt the simulation and, if required, reposition the vessel. It is even possible to play-back a manoeuvre. During the simulations the simulation manager can follow the conversation on the bridge using the intercom. Tug orders are normally transmitted by VHF.

During the simulation studies the following instruments were available on the 'bridge':

- RPM indicators of engine and bow thrusters;
- rate of turn indicator(s);
- rudder indicator(s);
- compass and course indicator;
- dopplerlog;
- sallog;
- wind indicator (speed and direction);
- VHF and intercom.

The data base includes information regarding the new lay-out of the port according to existing data of surveys, sea charts, local maps and the design drawings of the new situation. Both the 'original' and 'final' designs were included with access channel depths of 16, 18.5 and 20 m, depending on the design ship. All data regarding the critical environmental conditions were made available by the Israel Ports and Railways Authority and these data were digitized and imported into the database. For the environment (waves, wind and currents) it
is possible to include a so called grid in order to take into account the spatial variation of the environment. Furthermore effects of variations in time are also included in the simulations, for instance, wind gusting and slowly varying drift forces. These variations in time are, like in nature, stochastic which makes every simulation unique.

The visual image was prepared using photographs, maps, charts and drawings. For each situation two outside views were prepared, a day and a night version. In the night version special emphasis was laid on the so-called cultural lights. Lights on the quays and in town, producing backlight but also giving additional position information to the pilot. Of course also the aids to navigation, buoys and leading lights, were implemented. A so called 'minimum scheme' was applied in order to find out which aids had to be added in order to secure safe manoeuvring. For a number of destinations, moored ships were included at various quays thus reducing the available space and making the manoeuvres more complicated.

The mathematical models applied are waterdepth/draft sensitive, consequently the manoeuvring characteristics are depending on the waterdepth, an important aspect of manoeuvring in shallow water. Special emphasis was paid to the wave drift forces calculated for the various ship types. When the vessel runs aground in the simulator the simulation halts so that the reason for this can be evaluated. A realistic collision behaviour with spring action, damping and longitudinal friction, depending on the properties of the fendering, was included along the quay walls. Bank suction was only included in the Kishon area, as this is a relatively narrow passage with restricted width and depth.

Most realistic is a simulation with tugs as own ships sailed from other available bridges. However the own-ship tugs are not always practical and in the Haifa simulation tugs operated by the simulator manager were used. All tug forces are modelled realistically and the transitions between the pulling/pushing directions conform with reality. The forces are dependent of speed, pulling/pushing direction, velocity of own ship and current. The tugs can be positioned in a realistic position awaiting the approach of the vessel. They are also visible in the visual image. When the pilot requests assistance, the tugs will approach and upon command they will make fast. All this is performed with realistic time delays including stochastic variation. Pulling/pushing will be effected on order. In the Haifa simulations four 30t bollard pull Voith-Schneider tugs were available for assisting the vessel.

For a new port development, the selection of the pilots who should execute the simulations is an important issue. It is beyond doubt that experienced pilots must be used. Local pilots have the advantage that they are familiar with the port and the procedures normally applied. However in case of an increase in maximum ship size they lack the experience with the specific vessels. To overcome this problem in the Haifa port study we have worked with one local pilot and one Dutch pilot who has experience with the specific ship size. This was a successful approach also with regard to knowledge/experience transfer.
PRELIMINARY MANOEUVRING SIMULATIONS

Although tug assistance in the channel bend is considered feasible most of the time, it was decided by the IPRA to carry out a preliminary programme of manoeuvring simulations to check on the nautical feasibility of the curved entrance channel which goes against normal harbour entrance design rules.

These preliminary simulations were done on the full-mission simulator at MSCN/MARIN, Wageningen over a period of three days by a Dutch and an Israeli pilot. Only the largest ships were used, namely the Post Panamax container vessel (84 000 dwt) loaded to 71 900 dwt and the 150 000 dwt bulk carrier. Also, rather extreme conditions were used, namely: Condition 1 with 10 m/s (20 knots) W wind, 1 m/7 s NW waves and 0.2 m/s E'ly current, and Condition 2 with 20 m/s (40 knots) W wind, 2 m/9 s NW waves and 0.4 m/s E'ly current.

Leading lights were used to define the approach route, the back light being 4.7 km from the start of the bend at a height of 30 m above sea level and the front one 2.9 km away at a height of 15 m (see Figure 2). Four navigation buoys were used, no. 1 at the Talbot Reef, nos 2 and 4 at the start of the bend and no. 3 at the entrance, opposite the new breakwater head.

The preliminary simulations included 15 entry manoeuvres (both during daylight and at night) and 4 departures with the container vessel (T = 12.5 m) and 8 entries and 1 departure with the 150 000 dwt bulk carrier (T = 17.0 m). Thus, a total of 28 actual test runs, excluding 5 familiarisation runs. The runs started about ½ mile (900 m) seaward of buoy no. 1 and it was assumed that the pilot had boarded before buoy no. 1. The container vessel was berthed at Quay no. 2 (north) and the bulk carrier at Quay no. 3 (centre). Two 30 t tugs joined the ship in the bend area. For condition 1 (H = 1 m) the tugs could start to make fast outside, for Condition 2 (H = 2 m), they could only make fast when the wave height had reduced to H = 1.5 m. It was assumed to take 5 minutes to fasten one tug. Two more tugs were waiting inside and could be used, if required.

Although it was intended to also check the 'original' layout, the early results with the 'final' layout were very positive and all the preliminary runs were done for this layout. On the basis of this limited simulation programme it was found that the 'final' layout was indeed feasible. Rudder and propeller use were moderate and three tugs should be sufficient, except for the 40 knot (20 m/s) wind condition when the tug capacity was considered marginal for the container vessel. It was therefore decided to reduce this test condition for the further simulations to a more realistic wind speed of 30 knots (15, 0 m/s). Even when the container ship's power was reduced by 25 per cent for some runs, no particular problems were encountered.
Based on the preliminary three-day simulation study it was concluded that the 'final' layout was, not only nautically acceptable, but probably preferable to the original layout with the straight entrance channel section. This is because the single bend design is such that the entry manoeuvre becomes quite 'natural'. It was also found that the aids to navigation (leading lights and 4 buoys) appeared sufficient but necessary for safe navigation.

On the basis of these results it was decided to continue with the main simulation study using the 'final' entrance design.

**COMPREHENSIVE MANOEUVRING SIMULATION STUDY**

The main simulation study consisted of two weeks of simulations at MSCN/MARIN by two Israeli and two Dutch pilots. The purpose of these studies was to check on the nautical design of the extended port, according to the 'final' design, with particular emphasis on:

- the approach, entrance and turning area layouts and the channel widths
- the location and extent of the manoeuvring areas and mooring basins
- the need for and adequacy of the aids to navigation
- the minimum required tug use and the overall manoeuvring safety vis-à-vis weather conditions.

The simulations were done with the following ships:
- Post Panamax Container Vessel (T = 12.5 m) to be berthed at Quay no. 2;
- 150 000 dwt Bulk Carrier (T = 17 m and 11.8 m) to be berthed at Quay no. 3;
- 100 000 dwt Bulk Carrier (T = 15 m and 10 m) to be berthed at Quay no. 4;
- 25 000 dwt General Cargo Ship (T = 10.6 m) to be berthed at Quay no. 5 (Kishon).

The following environmental conditions were used in the simulations:

<table>
<thead>
<tr>
<th>Swell</th>
<th>Direction</th>
<th>-</th>
<th>-</th>
<th>NW</th>
<th>NNW</th>
</tr>
</thead>
<tbody>

</table>

| Starting Speed (knots) | 5 | 6 | 5 | 6 | 7 | 6 | 7 |
| Condition | 1 | 2 | 4 | 5 | 7 | 8 | 9 | 10 |

In total, 102 manoeuvring runs were performed as follows (outbound in ballast):
The results of the simulations are shown in Figure 5 where the results are combined for the different wind directions W, E, SE and NW and for the three main design ships (excluding the 100 000 dwt bulk carrier). Some minor channel boundary transgressions are noted on the inside of the bend and near the head of the future Haifa D breakwater. MSCN/MARIN recommended straightening of the western channel boundary but since this would come in the way of a possible further main breakwater extension, it was decided to anchor an additional buoy, no. 6, here. Also, an additional buoy, no. 5, is anticipated to avoid possible transgression of the eastern channel boundary (refer Figure 6).

Apart from these minor changes, the harbour entrance design was found to be effective and nautically safe.

**FINAL LAYOUT AND AIDS TO NAVIGATION**

Based on the design studies and the preliminary and detailed ship manoeuvring simulations it was found that:

- the approach, entrance, turning and mooring areas are satisfactory for safe operation for waves up to $H_{mo} = 2 \text{ m}$ and 20 to 30 knots (10 to 15 m/s) wind for the container vessel and up to 40 knots (20 m/s) for the bulk carriers
- the limiting conditions for operation will be bringing aboard of pilots and the use of service craft, not the channel design
- the revised Kishon entrance was found to be satisfactory although, due to the change from the present entry conditions, pilot training on a simulator will be advisable
- under adverse conditions, only the bow-out manoeuvre of the container vessel is sufficiently safe but for the bulk carriers both the bow-out and bow-in manoeuvres can be made safely
- normally two tugs, used inside the port, are sufficient although for some conditions three and even four tugs are advisable (also depending on the type of ship and for speed of operation)
- the aids to navigation as used in the simulations are generally sufficient but necessary for safe navigation and manoeuvring although two additional buoys are envisaged based on the minor transgressions
- the pilot boarding and manoeuvre starting points used are satisfactory
pilot training is envisaged for the new conditions, particularly for manoeuvring into the container basin and the new Kishon entrance and to confirm the need and effectiveness of the additional buoys nos 5 and 6.

The 'final' design, including all the envisaged aids to navigation are shown in Figure 6. This layout was also used for the detailed numerical and physical model tests described above for the mooring conditions. Preliminary numerical model studies did indicate that a longer breakwater extension (600m) would indeed further reduce wave heights inside the port so that this remains a future option, if needed.

Fig. 5 Combined Simulation Tracks per Wind Direction
CONCLUSIONS

Forced by circumstances, a curved approach to the entrance of the planned extensions to the Port of Haifa, was designed in the 'final' layout. Detailed nautical studies not only proved the adequacy of this layout but they showed the distinct advantages of this particular design. At the same time, maximum protection against wave penetration was achieved.

These satisfactory results were reached by an integrated design process which included a nautical desk study design supported by an extensive programme of full mission manoeuvring simulations and detailed numerical and physical model studies.

Wave Propagation Modeling for Pusan New Harbor

Jang-Won Chae¹ and Weon Mu Jeong²

Abstract

For the basic design of Pusan New Harbor that will be the third largest container hub-port in the world, extensive wave measurements and wave propagation modeling were made. They are mainly for estimating shallow-water design wave height and determining breakwater alignment to acquire harbor tranquility. The directionality of short crested waves is proved to be very important when they propagate through the waterway. Bounded long-period waves with a small amplification were observed in the shallow water area, which might cause horizontal motions of the container ship moored at a berth aligned to the south. Modified and extended numerical wave models are found to be reasonably good at simulating the measured wave propagation phenomena. Hybrid modeling was made to evaluate harbor tranquility combining numerical and physical modeling results.

Introduction

With the rapid economic growth in the region of North-East Asia, Pusan New Harbor, which is located at the south-east end of the Korean Peninsula, is to be developed in order to cope with massive annual increase of trading goods (51 million tons in 1995). Then it will be the third largest container hub-port in the world and handle nine million TEUs per year (Ministry of Maritime and Fisheries, 1996). The proposed harbor site is located at the area of very shallow water of depth less than 5 m in which tidal flat is well developed due to the sediments from the Nakdong river as shown in Figure 1. The harbor basin and approaching channel are to be dredged up to 15 m below the chart datum.

¹Director, Coastal and Harbor Engineering Research Center, Korea Ocean Research and Development Institute, 1270 Sa-dong, Ansan, Kyeonggi-do, 425-170, Korea
²Senior Research Scientist, Coastal and Harbor Engineering Research Center, KORDI, Korea
Even though the site is sheltered from typhoon attacks in summer, both the waves coming from the south and long-period waves bounded in swell waves can penetrate into the harbor. The short-period waves might be strongly influenced by the complex bottom topography, reflections by the irregular coastal line and small islands, and tidal currents. Numerical modeling of the waves propagating through the waterway and penetrating into the harbor is essential for the determination of breakwater alignment which guarantees a harbor tranquility.

The concerned area is so large that it was divided into three regions for the numerical analysis. Short-period wave models were chosen to calculate effectively the irregular wave propagation because of their computational accuracy and efficiency. Hybrid modeling was done for the harbor tranquility analysis in combination with numerical and physical modeling results. The modified Chen's model (Jeong et al., 1996) was used for the long-period harbor oscillation. Extensive field measurements of short- and long-period waves were made in order to analyze wave propagation and statistical characteristics.
Field Measurement and Data Analysis

In order to analyze irregular wave propagations, the relationship between short- and long-period waves and harbor oscillations, extensive field measurements were carried out at five reference stations for three months as shown in Figure 1. Using two Datawell directional waverider buoys, short-period waves were measured at Sts. DW and SW for about 27 min. at every hour. Long-period waves were also measured simultaneously at Sts. S1~S3 for three months at the interval of 5 s.

Directional frequency spectra of the short-period waves were obtained using the maximum entropy method (Kobune and Hashimoto, 1986). After filtering low frequency waves using the Butterworth high-pass filter, spectral analyses were made for each record of 16,384 data points (about 22.8 hours) using the standard FFT method. The spectrum was obtained by averaging over 64 raw harmonics.

Significant wave heights at St. SW were 40~60% of those at St. DW as shown in Figure 2. But the wave periods are almost the same each other at the two stations. Waves are narrow-banded at St. DW while waves are broad-banded and have non-negligible reflection components at St. SW. More details of the spectral changes can be seen in Figures 3~5. The frequency spectra have a very narrow-banded and single sharp peak, which is a typical shape of swell waves (see Figure 3). Even though swell waves, which have a narrow-banded spectrum, propagated through the waterway of about 8 km in the main direction (SSE), its significant wave height reduced half in average.

![Figure 2. Variation of Significant Wave Height ($H_s$) at Stations DW and SW.](image-url)
When the waves propagated from St. DW to St. SW, they were also affected by the tidal currents. The maximum current speed was about 60 cm/s. At high water (no current) spectral shape change was very small but energy level was decreased by half mainly due to refraction (Figure 3). However, in the following current condition, spectrum became wide in both direction and frequency bands, and wave height decreased by 60%. In the opposing current condition (Figure 4), the spectrum were less broad-banded than one in the following current (Figure 5). Significant wave height at St. DW decreased at St. SW by 40%. Reflected wave components were appeared, which might be due to currents or mooring line.

Figure 3. Frequency and Directional Wave Spectra Measured at Stations DW (Left) and SW (Right) (12:00~12:27, Aug. 2, 1996).

Figure 4. Directional Wave Spectra Measured at Stations DW (Left) and SW (Right) (14:00~14:27, Aug. 2, 1996).
system of the buoy. The mooring line was slightly modified by substituting a part of the polypropylene rope with thin steel wire of 10 m long in order to prevent the rope from cutting by fishing activities.

From this analysis it can be said that the wave height increased about 10% by the opposing current effects. The major factor on the wave transformation through the channel is the refraction of waves due to its bathymetry. To some extent current is responsible. Therefore consideration of directional distribution of the waves is most important for the refraction in the calculation of the wave propagation through the channel.

It is shown that long-period waves were observed at St. S1 and slightly amplified at St. S3. As shown in Figure 6 the spectrum has major peak in the short-period band and bounded waves are in the periods of 60 s to 150 s. The long-period waves were slightly amplified at St. S3 in shallow water area. Those waves might induce the ship moored at the berth to surge and sway because the periods are close to those of resonant modes of the ship and mooring system.

Short-Period Wave Propagation Modeling

As the modeling area of 49 km × 31 km shown in Figure 7 is so large that it was divided into three regions depending on the phenomena of wave transformation and the limitation of wave propagation models. With given deep-water wave height $H_s$ and frequency-directional spectrum $S(f, \theta)$ the irregular waves at the input boundary can be generated (Goda, 1985). Additional wave growth was ignored during their propagation in the modeling area. The wave model was used to calculate 286 discrete spectral components. The total wave height can be obtained by adding each components.

For the calculation of wave propagation in the large offshore region in Figure 7, the RCPWAVE model (Ebersole et al., 1986) was used because of its
computational efficiency and sufficient accuracy. The area was divided into \(195 \times 124\) rectangular cells and the grid size was 250 m.

**Estimation of Shallow-Water Design Wave Height for Breakwater**

For the calculation of short-crested wave propagating in the complex coastal waterway (subregion A) and penetrating into the harbor (subregion B), a hyperbolic-type wave model HCORD (eg. Copeland, 1985) based on the mild-slope equation was used.

The HCORD is modified in order to simulate partial wave reflection by
Figure 7. Map Showing Computational Domains for Short-Period Wave Propagation Modeling, and Location of Wave Paddles in the Physical Modelling.

absorbing wave energy normal to the solid boundary. The method is not correct in theory but gives numerical results within 10% error compared with the field data (Jeong et al., 1997).

Input wave conditions were provided at the boundary of the subregion B by the RCPWAVE results. The HCORD was applied to 5 discrete directional components ($\Delta \theta = 22.5^\circ$) with a representative frequency of the waves (Goda, 1985). It is mainly because of the grid size limitation (herein 1/10 wavelength) and computational capacity of engineering workstation. The subregion A was divided into 1,650,000 grids and the size is 10 m x 10 m. It took about 6 hours for computing one irregular wave propagation by engineering workstation.

The computation results agree well with the measured data in terms of wave height and direction. They were also compared with the data obtained from three-dimensional hydraulic model tests which used a JONSWAP (multi-frequency) spectrum with one direction. The physical model produced larger waves than the field data and it was tuned with the data. One of the calculation results is shown in Figure 8, where shallow water design wave heights were obtained for various breakwater alignments.
Harbor Tranquility Analysis

Harbor tranquility is essentially to reduce motions of ships moored at anchorage or along a wharf. Even though physical factors are involved for the analysis of harbor tranquility (Goda, 1985), a practical approach of wave height evaluation was used for simplicity in the designing stage. Harbor tranquility should be maintained above a certain level of harbor operation rate (95—97.5% in Korea) in order to have feasibility with respect to safety of loading/unloading and operational efficiency. Combined numerical and physical modeling results were used in order to estimate wave height distribution in the harbor. The limiting wave height criteria for loading/unloading were chosen as 0.3 m for small vessel, 0.5 m for general cargo, and 0.3 m for north and south container ship terminals.

Four-year data of six hourly hindcasted waves at deepwater were used, which are in the form of the joint distribution of significant wave height, period and direction. They were further reanalyzed to know the days of exceedance of the significant wave height above certain levels during a year at the container and cargo terminals in the harbor. Among the data set 12 cases of waves were chosen...
for the calculation because only limited number of directional wave components can propagate into the harbor. Those waves are in the direction of SSW, S and SSE with periods of 7 s, 9 s, 12 s, and 15 s.

Two wave models of RCPWAVE and HCORD were used to calculate the wave propagation from deep water (large region) to shallow water (subregions A, B) shown in Figure 7. One of the computational results is shown in Figure 9, which is the wave heights in meter at the final harbor layout for the design wave condition. Hydraulic modeling results were adopted to estimate the wave heights inside the harbor depending on the wave condition at the entrance of the harbor given by HCORD. In order to reduce the strong wave reflection from the vertical wall with right angle to the north end of the general cargo terminal a beach with 1/3 slope was applied. As shown in Table 1 harbor operation rates were
evaluated for small vessel, general cargo, and container terminals. Mean annual rate of the harbor operation is estimated at 98.7%.

Long-Period Wave Modeling

Long-period wave oscillations in a harbor may cause unacceptable vessel motions, excessive mooring forces and fender reactions leading to the breaking of mooring lines and fender system. The typical natural periods of a reasonable harbor or moored vessel are of the order of magnitude of minutes (Nagai et al., 1994). One of the sources that generate the offshore long-period waves of 2—3 minutes is the wave set-down traveling with the wave group velocity.

For the analysis of harbor oscillations a long-period wave model HOMETA was developed, which is similar to Chen (1986)’s HARBD but improved with the extended mild-slope equation (Massel, 1992). Some details of the model equations and calculation method are given in Jeong et al. (1996). The model application to new harbor oscillation is focused herein.

The modified model was applied to calculate the wave amplification due to group bounded and free long waves, which were generated during the storm wave condition and resonated in the new harbor. The calculation area was taken large enough to cover offshore measurement station S1 as shown in Figure 1. The water depth of the far-field area (analytic solution region in HARBD model) is assumed to be constant. Reflection coefficients vary from 0.95 (natural beach) to 0.99 (vertical sea wall) and also vary depending on the magnitude of frequency (i.e., from 0.4 for 15 s to 0.98 for 180 s waves at energy absorbing boundary). The numbers of triangular elements are 22,222 and its size is small enough to
resolve 30 s period wave in the water of 15 m depth. Numerical computation has been made for the 54 component waves of period ranging from 60 s to 1,400 s and comparisons were made with experimental data. The amplification ratio is $\sqrt{S_i(f)/S(f)}$, where $S_i(f)$ is the spectral density at the $i$-th point in the domain and $S(f)$ at offshore station.

The model was validated with the measured data, and then it was applied to predict harbor amplification by dominant frequency wave components observed at St. S1. Figures 10 and 11 show the amplification ratios at Sts. C12 (south), C13 (center), and C14 (north) of general cargo terminal, and Sts. C26 (west), C28 (center), and C30 (east) of north container terminal. First and second modes of the harbor oscillations are expected to be amplified but their energy levels are so low that they can not generate large water level variation and strong current. However the bounded waves of period from 100 s to 200 s will be amplified at St. C12 in the general cargo terminal. As the waves might be critical for the surging motion of ship sized several 10,000 DWG, this should be considered for the mooring line and fender system in the detail design stage.

Conclusion

From the field measured directional wave spectra and numerical modeling, the directionality of short crested waves is proved to be very important when they
propagate through the complex coastal waters. Bounded long-period waves were observed in the shallow water area with a small amplification. These might cause horizontal motions of a container ship moored at a berth aligned to the south. Both the modified and extended numerical wave models are accurate enough to simulate the measured wave propagation phenomena. Based on the computational results of short/long-period waves, proper counter-measures were recommended.

The Studies for the Resonance of Hwa-Lian Harbour
Agitated by Typhoon Waves

Chien-Kee Chang
Chung-Ching Chien
Hsiang-Maw Tzeng

Abstract

Hwa-Lian Harbour is located at the north-eastern coast of Taiwan, where is relatively exposed to the threat of typhoon waves from the Pacific Ocean. In the summer season, harbour resonance caused by typhoon waves which generated at the eastern ocean of the Philippine. In order to obtain a better understanding of the existing problem and find out a feasible solution to improve harbour instability. Typhoon waves measurement, wave characteristics analysis, down-time evaluation for harbour operation, hydraulic model tests are carried out in this program.

Under the action of typhoon waves, the wave spectra show that inside the harbors short period energy component has been damped by breakwater, but the long period energy increased by resonance hundred times. The hydraulic model test can reproduce the prototype phenomena successfully. The result of model tests indicate that by constructing a jetty at the harbour entrance or building a short groin at the corner of terminal #25, the long period wave height amplification agitated by typhoon waves can be eliminated about 50%. The width of harbour basin 800m is about one half of wave length in the basin for period 140sec which occurs the maximum wave amplification.

I. Introduction

Hwa-Lian Harbour is an artificial harbour built on a steep and narrow east coast of Taiwan. More than 4000m long breakwater was constructed to protect the harbour basin against incident waves from the Pacific Ocean. Figure 1 shows the location and layout of the harbour, which has 25 wharves after the fourth stage expansion. In the summer season, harbour resonance may be agitated by typhoon waves which generated at the east of the Philippine. Harbour resonance, may cause down time for harbour operation, or even break the ship mooring lines.

Institute of Harbour Marine Technology(IHMT)

Field investigation has been carried out since 1989, a waverider has been deployed at the outside of the harbour. In 21 June 1990, Typhoon Ofelia formed at the eastern ocean of the Philippine, and moved toward Taiwan in NNW direction. Finally made landfall with the eye of typhoon striking at 17km south of Hwa-Lian Harbour. One hour before landfall, the maximum wave height 20.5m, period 16.0sec was recorded; The corresponding significant wave height and period were 13.9m and 14.1 sec respectively. Time series of wave height and period are plotted as shown in figure 2. Four commercial vessels were berthed at the terminal, two of them escaped for survival when significant wave height was greater than 4m; the mooring lines of two other ships were broken and the harbour facilities were damaged while wave height increased rapidly.

In November 1992, there were three typhoons Elise, Hunt and Gay. The center of those typhoons were located at SE direction and more than thousand kilometers away from Hwa-Lian. But, the harbour basin was agitated by swells generated by typhoon and berthed ships were forced to leave the harbour for survival.

In order to get a better understanding of the harbour hydraulic environment during the threat of typhoon, an intensive research program had been carried out by the Institute of Harbour and Marine Technology (IHMT) since March 1993. Field investigation, hydraulic model test and numerical computation are included in this research project. This paper present field investigation wave characteristics, down time of harbour operation, model test for different amendment layouts.
II. Field Investigation

Figure 1 shows the location of wave stations. The permanent station, St.2 locates at outside of the harbour, a directional wave-rider and current meter have been installed since 1989. At the harbour entrance, St.5 and terminal stations located at water front of terminal #8, #10, #22, four pressure type wave gauges were installed prior to typhoon wave attacked Hwa-Lian Harbour. At the offshore station, St.2 offshore incident waves were recorded 20 min every two hours with sampling rate 1.28Hz. At the harbour basin and entrance stations waves were recorded 34min every hour with 1 Hz sampling rate.

III. Wave Characteristics

The paths of six typhoons which occurred in the summer of 1994 are plotted as shown in figure 3. IHMT had succeeded to obtain wave data inside and outside of the harbour synchronously during Typhoon Tim, Fred and Gladys moved toward Hwa-Lian Harbour. Figure 4 shows time series of wave height variation for the offshore station St.2, the harbour entrance station St.5 and terminal stations #22, #8, #10. The sheltering coefficient is defined as the ratio of wave height between the terminal station or the harbour entrance station and the offshore station. The sheltering coefficient and corresponding incident wave direction recorded at St.2 are plotted as shown in the upper and middle diagrams of figure 4. For a specific time, the location of typhoon center, the incident wave height, wave direction and sheltering coefficients at the harbour entrance station St.5, terminal stations #22, #8, #10 are tabulated in table 1.
Table 1 indicates that the sheltering coefficients of harbour entrance and terminal stations depend on the incident wave direction and sheltering environment. The incident wave direction have good relationship with the location of the typhoon center. For example, the center of Typhoon Tim was 600km in SE of Hwa-Lian, incident wave came from 125°, wave height coefficient reduced from 0.6 at the harbour entrance to 0.1 at the inner basin terminal #10; the center of Typhoon Fred located at 100km in ESE and moved toward Hwa-Lian in WNW direction, wave height increased from 2.6m to 4.9m, incident wave direction decreased from 115° to 95°, the sheltering coefficient decreased accordingly. But, when the center of typhoon approached Hwa-Lian, the incident wave direction and sheltering coefficients were changed rapidly by local wind field.

Energy spectra for waves recorded at the permanent station St.2 and terminal stations #22, #8 and #10 are plotted as shown in figure 5. After the sheltering of the breakwater, the short period wave energy measured at terminal stations were reduced tremendously. The degree of energy density reduction depends on the sheltering condition. At the outer basin the energy density ratio between terminal #22 and incident wave is about 1/10; at the inner basin the ratio between #8 or #10 and incident wave decreases further to 1/100. On the other hand, long period waves from 140sec to 160sec recorded in the harbour basin, the energy density were amplified hundred folds. The detail time series water surface for various wave stations are plotted in figure 6, which shows water surface recorded at harbour stations have rather long periodic motion in comparison with that of incoming wave recorded at St.2.
IV Down-time Evaluation

According to the berthing records of Hwa-Lian Harbour indicate that in the summer season, down time for harbour operation due to the action of typhoon wave has occurred at least once every year since 1985. Based on the status of berthing conditions provided by Hwa-Lian Harbour Bureau from 1990 and the corresponding paths of the typhoon, as shown in figure 7, issued by the Central Weather Bureau, table 2 shows the summary of typhoon generated swells that made harbour instability and caused down time for harbour operation.

Based on the advance typhoon path, the leaving location which listed in column 4 of table 2, is defined as the location of typhoon, while berthing ship commences to leave the harbour due to agitation of swells. By assuming the propagation velocity of swill is 50 km/hr, the initial time and location were estimated as shown in column 5 of table 2. The initial time and location are defined as the time and location that typhoon generated swells which might arrive the harbour and force ships to leave the harbour for safety. The analysis results of initial and leaving locations are plotted as shown in figure 8. The swell generated at the initial location arrives the harbour and causes ships to leave the harbour for survival, while the center of typhoon moves from initial location to leaving location.

IV. Down-time Evaluation

According to the berthing records of Hwa-Lian Harbour indicate that in the summer season, down time for harbour operation due to the action of typhoon wave has occurred at least once every year since 1985. Based on the status of berthing conditions provided by Hwa-Lian Harbour Bureau from 1990 and the corresponding paths of the typhoon, as shown in figure 7, issued by the Central Weather Bureau, table 2 shows the summary of typhoon generated swells that made harbour instability and caused down time for harbour operation.

Based on the advance typhoon path, the leaving location which listed in column 4 of table 2, is defined as the location of typhoon, while berthing ship commences to leave the harbour due to agitation of swells. By assuming the propagation velocity of swell is 50 km/hr, the initial time and location were estimated as shown in column 5 of table 2. The initial time and location are defined as the time and location that typhoon generated swells which might arrive the harbour and force ships to leave the harbour for safety. The analysis results of initial and leaving locations are plotted as shown in figure 8. The swell generated at the initial location arrives the harbour and causes ships to leave the harbour for survival, while the center of typhoon moves from initial location to leaving location.
V. Model Tests

The main purpose of model test is to find out a feasible amendment layout to eliminate long period wave energy inside the basin amplified by harbour resonance. The optimum layout will be proposed for the improvement of Hwa-Lian Harbour in the future project.

Model tests were conducted in a 62m long and 57m wide wave basin. Regular and irregular wave generator, wave gauges and data acquisition system have been equipped in the laboratory. Hwa-Lian Harbour was built in the basin by using model scale 1:150. Both regular and irregular waves were simulated in the model tests. In the primary stage, 14 layouts were tested by regular wave for qualitative analysis. Prototype incident wave height 0.75m, and wave period ranges from 10sec to 180sec were reproduced in the model tests. The existing and three amended layouts as shown in figure 9 were selected for further tests by irregular waves. The spectra of Tim typhoon waves recorded at offshore of Hwa-Lian Harbour and JONSWAP spectra were simulated in irregular wave tests.

![Figure 9: Layout of the Model Tests](image)

Wave data in front of the wave paddle (incident wave), harbour entrance and inside the basin were recorded at 30 locations in the model tests to evaluate wave disturbance of the harbour protected by breakwater. Figure 10 and 11 show wave height ratio versus incident wave period at terminal #22 of the outer basin and terminal #8 of the inner basin for primary 12 layouts. The wave height ratio is defined as the ratio of wave height between a specific location at the basin and offshore incident station. Figure 12 and 13 show the detail wave height ratio of terminal #22 and #8 for the existing and three amendment layouts. The results of the existing layout indicate that the short period wave is sheltered by breakwater, the wave height ratio at #22 of the outer basin is about 0.4 and the ratio at #8 of the inner basin is less than 0.15. But for the 140sec long period wave height ratio, the amplification factor is more than 3.4 at #22 and about 2.0 at #8. The short period wave height ratios of outer and inner basins obtained in model tests and measured in field investigation are quite consistence in case of the same direction of incident wave.
Figure 10  Wave Height Ratio of the Terminal #22 for 12 Layouts

Figure 11  Wave Height Ratio of the Terminal #8 for 12 Layouts
The amendment layout B, rebuilds the old portion of the eastern breakwater, installs perforated rubble breakwater at the north end. This layout doesn’t improve the short period wave height ratio of the outer basin. But, the ratio of the inner basin decreased, because some portion of incident wave energy of inner basin transmits through perforated breakwater. Layout B does not change the geometry of the outer basin, the resonance mechanism of the long period wave is existing. The long period wave height amplification remains the same scale as the existing layout. Layout J, a short groin is constructed at the turning corner of the terminal #25 which located beside the navigation channel. The mode of wave resonance is broken by the interaction of groin and long period wave height in the basin is eliminated by the disturbance of refraction waves. Layout Q, builds a jetty at the harbour entrance and eastern breakwater remains the same as layout B. It is obvious that the jetty and the west breakwater forms as a resonant basin at the harbour entrance, the incident long period wave energy is damped by the transverse waves in the basin. The test results show that the long period wave height amplification due to resonance decreases more than 40%. The short period wave height ratio of terminals #22 and #8 for layout J and Q are smaller in comparison with those of layout A and B.
Based on 4096 sampling data recorded at each run of model test (about 205 seconds), wave spectra were analyzed by using FFT method. The wave spectra of four layouts are plotted as shown in figure 14. In order to find out the difference of three wave spectra, which measured at incident location, terminal #22 and terminal #8, were plotted in a figure for the same layout. By simulating waves recorded in Typhoon, the spectrum has peak period 1.25sec in model or 15.3sec in prototype and no extraordinary long period wave energy component. The test results indicate that the short period wave energy density at terminal #22 and at terminal #8 is reduced by the sheltering of breakwater. There are not much difference for various layouts in the short period wave.

The spectra show that long period 11.8sec and 5.6sec in model or 144sec and 67sec respectively in prototype, the energy density at the inner and outer basins are enlarged by harbour resonance. Long wave period 144sec is quite consistency with regular wave period 140sec that caused the maximum wave amplification. Low frequency energy density at terminal #22 and #8 amplifies about 30 times for layout A and B. The shape of spectra for layout J and Q are quite similar as those of layout A and B, but low frequency energy density becomes smaller. In order to get a better quantitative understanding, the frequency is divided into two intervals, low frequency band between 0.06Hz and 0.3Hz, and main frequency band between 0.8Hz and 1.2Hz. There are corresponding to prototype wave period 204.1 sec to 40.8 sec for long period wave band and 15.3sec to 10.2sec for main period wave band. The sum of wave energy for low frequency and main frequency bands are tabulated in Table 3 and plotted as shown in figure 15 and figure 16. In all layouts, long period wave energy component contained in the incident wave measured at offshore (ch:09) is very limited. But, the terminal #22 and #8 in the harbour basin of layout A, long period wave energy component enlarged by harbour resonance. The reduction of long period wave energy component is not significant for layout B, that is similar as regular wave tests. Layout J and Q, long period wave energy component inside the basin gets much better, especially layout Q. On the other hand, figure 16 shows the main period wave energy component. The incident wave obtained at offshore station is much higher than those measured at terminal #22 and #8 in the basin.

Table 3 shows the wave height ratio computed by the viewpoint that wave height is the square root of wave energy. Because the long period wave energy for irregular wave is the sum of energy in the range of 40 sec and 204sec. Hence, the wave height ratio listed in table 3 can be considered as the average of the wave height ratio for the same period of regular wave tests. The result of irregular wave tests are quite consistency with those of regular wave tests as show in figure 12 and 13.

Note: () the wave height ratio is defined as the square root of (terminal wave energy/incident wave energy).

#### Figure 15
Wave Energy of Low Frequency Band Inside and Outside the Harbour for Different Layouts

#### Figure 16
Wave Energy of Main Frequency Band Inside and Outside the Harbour for Different Layouts
VI. Discussion

1. The spectra of the offshore permanent station shows no extraordinary long period wave energy component. Because the accelerator of wave rider can not detect low frequency motion. A pressure type wave gauge had been installed at the offshore station at typhoon season in 1996. The spectrum of waves measured by pressure type wave gauge indicates that typhoon wave has long period energy component at the offshore station.

2. Long period wave energy amplified by harbour resonance can be reproduced in hydraulic model by using either regular wave or irregular wave. The amplification ratio in prototype is larger than that in model, because the friction loss at small scale physical model is larger than in the field.

3. The shape of the outer basin is like a triangle, the maximum width is about 800m which equals a half wave length of period 140sec approximately. Hence the harbour basin is resonated in transverse direction which is consistent with the video records of ship motion under the action of typhoon wave and the visual aspect in the model test. Layout B doesn't change the harbour geometry, the resonance amplitude remains the same order of magnitude. Layout J constructs a short groin at the basin or layout builds a jetty at the harbour entrance, the long period wave energy can be eliminated by breaking the resonance mode or disturbing the incident waves.

4. Down-time harbour operation due to the berthing ship motion enlarged by the agitation of long period harbour resonance. Although, layout J and Q can reduce the long period wave energy, but it still exist in the basin. It is necessary to perform ship motion test to evaluate down-time harbour operation for various feasible layouts.

5. By taking ship maneuvering and sediment at the entrance into consideration, at this stage layout Q is proposed for the harbour improvement in the future.

APPLICATION OF MATHEMATICAL MODELING IN OPTIMIZING LAYOUT OF A LARGE INDUSTRIAL FISHERY HARBOUR

P.P. Gunaratna,1 Member, ASCE, P. Justesen2, D.S. Abeysirigunawardena3, and H-J, Scheffer4

Abstract

Mathematical modelling of nearshore oceanographic conditions was carried out, in connection with a large industrial fishery harbour planned to be implemented in a coastal stretch protected by two reefal systems, on the western coast of Sri Lanka. MIKE 21, a two dimensional mathematical modelling system with a wide range of coastal engineering applications, and LITPACK, a one dimensional coastal processes modelling system, were extensively used in this study. The major features of modelling were the successful simulation of wave transmission over reefs and wave overtopping mass flux induced currents behind the innermost reef.

The validated model under existing conditions was used to optimise the harbour layout with safe navigational access, acceptable wave agitation within the basin and adequate sediment by-pass capacity at the entrance. The wave and other hydrodynamic parameters for the economical design of harbour breakwaters were also obtained. A well calibrated hydrodynamic model covering most of the western coast of Sri Lanka also evolved as a by-product of this study.

Introduction

Dikkowita is a small coastal town located on the western coast of Sri Lanka, 6 km north of the capital city, Colombo (Figure 1.). The coastal environment around Dikkowita is characterised by the presence of two distinct sandstone reefal systems (Figure 1.). The outer reef, known as the “Offshore Reef”, is located at an average distance of 1 km from the

4Coastal Processes Expert, ADB-Sri Lanka Fisheries Sector Development Project, 22 Tickel Road, Colombo 8, Sri Lanka.
coastline, about 2.5 m to 3 m below mean sea level (MSL). This reef has a significant gap in it fronting Dikkowita. The inner reef, commonly known as the "Secondary Reef", is generally located under or in front of the beach. This reef has got disconnected from the coastline south of Dikkowita and again merges with the coastline further northwards, forming a kind of a narrow basin. The maximum distance between the coastline and the secondary reef within this basin is about 200 m. The level of the secondary reef is quite variable consisting of exposed segments above sea level, and certain submerged segments as much as 4 m below MSL. The dual protection provided by these two reefal systems has made Dikkowita an attractive site for locating a coastal fishery harbour.

Figure 1. Coastal Environment Around Dikkowita, Sri Lanka
About 2 km south of Dikkowita lies the outfall of the Kelani River, which is the major source of sediment supply to a long coastal stretch northward of it. However, due to intensive sand mining taking place in the lower reaches, the sand supply from the river to the downdrift coasts has declined. Based on the findings of a National Sand Study (Delft Hydraulics and Netherlands Economic Institute, 1992) the present rate of sand supply may be estimated to be around 100,000 m³/year compared to 400,000 m³/year in 1961. This has led to severe erosion of down drift beaches and has required the implementation of coast protection measures.

Under the Asian Development Bank (ADB) assisted Sri Lanka Fisheries Sector Development Project, the site at Dikkowita was identified as having the potential to develop an industrial fishery harbour, which will cater to large deep sea fishing vessels. The technical feasibility study in this connection was carried out by Lanka Hydraulic Institute Ltd. (LHI), Sri Lanka in association with the Danish Hydraulic Institute (DHI) and PortConsult Consulting Engineers, Denmark. Coastal Engineering Investigations formed a major component of this feasibility study.

Mathematical Modelling

Most of the coastal engineering aspects were addressed through the application of MIKE 21 and LITPACK mathematical models developed at the Danish Hydraulic Institute (DHI), Denmark. In addition, certain numerical desk calculations were carried out to supplement the model computations. A substantial volume of data acquired through a dedicated field investigation campaign (LHI et al., 1996) and from previous studies (Behnsen, 1994 and LHI, 1994), was used in the setting up and validation of the mathematical models.

MIKE 21 is a two dimensional modelling system with a wide range of coastal engineering applications. A variety of computational modules are available within MIKE 21 for simulating hydrodynamics, wave dynamics, sediment transport, advection-dispersion processes, etc. LITPACK is a one dimensional coastal processes modelling system mainly used for computation of sediment transport and associated beach profile and coastline changes.

Offshore Wave Climate and Extreme Waves

The offshore wave climate within the study area is characterised by the presence of year round swell waves, approaching from the narrow directional band 210° - 230° north and locally generated sea waves strongly influenced by the south west monsoonal winds. Based on findings of a wave study for the south west coast of Sri Lanka (Scheffer et. al., 1994) and on-site measurements (LHI, 1994), the wave climate representative around 15m water depth could be established. The average significant wave height of swell waves was found to be 0.9 m during the south west monsoon season (May to September) and 0.5m outside this period. The sea waves were seen to dominate during the south west monsoon season with an average significant wave height of 1.5 m. Apart from this, certain extreme occurrences of sea waves due to local depressional storms, with average significant wave height exceeding 3.5 m have been recorded during the intermonsoon period October to November.
The extreme occurrences of wave heights around 15m water depth were established through extrapolation of recorded significant wave heights. Several probability distributions (Fischer and Tippet, Weibull etc.) were fitted and monthly maximum wave heights as well as the actual distribution of wave heights were considered in arriving at the final estimates of extreme waves. The significant wave height \( H_{m0} \) and the mean wave period \( T_{02} \) of 100 year return period wave were determined as 5.47 m and 7.8 sec, respectively. The corresponding values established for 1 year return period wave were 2.82 m and 6.3 sec, respectively.

**Nearshore Wave Propagation Modelling**

Nearshore wave propagation modelling was carried out to establish spatial variation of wave climate within the reefal system for wave driven littoral current computations as well as for establishing wave parameters for the design of breakwater structures. For this purpose, two wave modules within MIKE 21 (NSW - Nearshore Spectral Wave and PMS - Parabolic Mild Slope) were used. Both these wave modules are based on an irregular and directional description of wave field and considers shoaling, refraction and energy dissipation due to wave breaking and bottom friction. The PMS module has the added capability to account for diffraction effects caused by coastal structures and bathymetric features.

A nested set up of NSW and PMS modules was employed with the NSW model extending offshore up to an average water depth of 15m, and the PMS model contained within it, with its offshore boundary positioned some distance outside the offshore reef. Both models were oriented with offshore boundary parallel to the general direction of shoreline in the study area (255° north). In the NSW model, the grid spacings used were 50 m in the direction parallel to offshore boundary and 10 m in the perpendicular direction. In the PMS model a 5m grid resolution was used in both directions.

The model computations with respect to wave transmission over the offshore and secondary reefs were verified using simultaneous wave recordings within and outside the reefal system. The model simulations were seen to over predict wave heights inshore of the offshore reef when compared with actual wave recordings, for moderate offshore wave heights. This discrepancy was seen to get reduced with increasing offshore wave height. The model parameters which were used to control wave transmission over the offshore reef were those which govern wave breaking.

In MIKE 21, wave breaking is governed by a maximum allowable wave height \( H_m \) given by:

\[
H_m = \gamma_1 k^{-1} \tanh \left( \frac{\gamma_2 kd}{\gamma_1} \right)
\]

where, \( k \) is the wave number, \( d \) is the water depth and \( \gamma_1 \) and \( \gamma_2 \) are wave breaking parameters. The parameter \( \gamma_1 \) which control breaking due to wave steepness was set to 1.0 (Battjes and Jensen, 1978) and \( \gamma_2 \) which controls water depth limited wave breaking was set to 0.8 (Holutuijsen et al., 1989). The wave attenuation over a steeply sloping submerged reef...
cannot be simply described by conventional breaker parameters. The main reason for simulated wave heights being somewhat higher compared to actual wave recordings can be attributed to this reason. However, since simulations provided a conservative estimate of wave heights behind the offshore reef, allowing for this discrepancy as a margin of safety, further refinement of wave transmission computations was not effected.

The wave heights behind the secondary reef was found to depend on wave heights outside of it as well as the tidal elevation. Empirical relationships were obtained for this wave height dependency through the analysis of simultaneous wave measurements on either side of the secondary reef for different water level ranges. The model simulated wave heights were seen to closely follow these wave height dependencies (Figure 2.). In order reproduce this wave transmission over the secondary reef, it was necessary to artificially lower exposed segments of the reef, as model computation ceases once an exposed "land" grid point is encountered.

![Figure 2. Verification of Wave Transmission Over the Secondary Reef](image)

The calibrated wave model setup was used to simulate wave incidences which characterise year round wave climate as well as extreme wave occurrences. The simulation of 100 year extreme wave event is illustrated in Figure 3. The proposed harbour layout is also included in this illustration. The attenuation of waves over the offshore reef and penetration of waves through the gap in this reef is clearly seen from the significant wave height contour pattern.
Hydrodynamic Modelling

MIKE 21's hydrodynamic module (MIKE 21 HD), based on the finite difference solution of full non-linear equations of conservation of mass and momentum integrated over the vertical was used to establish hydrodynamic conditions within the study area, under pre and post harbour construction stages. The hydrodynamics off the western coast of Sri Lanka is characterised by weak tidal velocities combined with intermittent wind influences. The average tide and wind combined flow velocities are in the range 0.15 to 0.25 m/s. The variation of tidal range along the coast is also found to be marginal with about 0.7 m during spring tide and 0.15 m during neap tide. In order to establish compatible boundary conditions for hydrodynamic modelling in such an environment, it was necessary to originate hydrodynamic modelling from a “Regional Model” covering a large sea area (Gunaratna et al., 1997).

The bathymetry and location of the Regional Model, which spans across most of the western coast of Sri Lanka is illustrated in Figure 4. This model was 230 km x 71 km in extent and was set up on a 1000 m x 1000 m grid. The model boundary conditions for the simulation of tidal flows was obtained through a detailed analysis of tidal wave propagation pattern of principal tidal constituents in the Indian Ocean (Gunaratna et al., 1997). The model computations were validated by comparison with tidal data available from a number of stations alongshore. Having validated the model for tidal flows, certain wind driven flow events were simulated by adjusting the wind friction coefficient.
The hydrodynamics within the study area were simulated by stepping down from the Regional Model through a set of nested sub-models. The basic details of this model setup is given in Table 1. The "transfer boundary conditions" for carrying out simulations within a sub-model were extracted by simulations within the next highest level model. The simulation of wave overtopping currents and littoral currents were carried out in the lowest level HD2 and HD3 sub-models, respectively.

Table 1. MIKE 21 Hydrodynamic Model Set Up
In the modelling of wave overtopping induced currents, the wave overtopping mass flux over reef segments was assumed to be described by the following expression for a discharge in the wave direction in the roller of a spilling breaker (Fredsøe, et al., 1992)

\[ q = \frac{k_1 H_m^2 \cos \beta}{T_{02}} \]  

where, \( q \) = wave overtopping mass flux per unit length; and \( H_m, T_{02} \) are the significant wave height and mean wave period, respectively, outside the secondary reef; \( \beta \) is the angle of wave incidence; and \( k_1 \) is a non-dimensional calibration coefficient.

The simulations were carried out at HD2 model level by employing a strategically synthesised combination of point sources behind the secondary reef that represent wave overtopping mass fluxes over reef segments. An identical number of point sinks were introduced on the other side of the reef segments for conserving the mass. An instantaneous picture of the simulated current pattern is illustrated in Figure 5. Simultaneous instrument recordings of two dimensional currents inside the reef and directional waves outside the reef were used as the basis for validation of model computations (Figure 6.).

Figure 5. Simulation of Wave Overtopping Currents Behind the Secondary Reef
A preliminary harbour layout was conceptualised by incorporating an optimal basin area of 11.7 hectares (117,000 m²) behind the secondary reef into the harbour basin. The secondary reef itself was to function as the outer toe of the main breakwaters connected by return breakwaters to land. The harbour was planned to accommodate 400 fishing craft ranging in size from 40 feet (12.2 m) to 100 feet (30.5 m).

The calibrated hydrodynamic and wave propagation models under existing conditions were used as the primary basis, to simulate post-harbour construction scenarios through additional model computations. The remaining sections of this paper outline the wave disturbance, sediment transport and sedimentation computations carried out for layout optimization.
Wave Disturbance Modeling

The wave conditions within the harbour basin and harbour entrance was modelled using MIKE 21's Boussinesq Wave Module (MIKE 21 BW). MIKE 21 BW is primarily used for modelling of wave disturbance within harbours due to penetration of regular and irregular wave trains, taking into account shoaling, refraction, diffraction, and partial reflection and absorption of wave energy by harbour structures. The input wave conditions for wave disturbance modelling were obtained by NSW/PMS model simulations.

The simulations for selected swell and sea wave incidences which characterise the year-round wave climate were carried out within the BW model set up incorporating the entire harbour basin and the approach channel. The overall wave heights were derived by combing sea and swell wave heights:

\[ H_{m0,\text{overall}}^2 = H_{m0,\text{swell}}^2 + H_{m0,\text{sea}}^2 \]  \hspace{1cm} (3)

where, \( H_{m0,\text{overall}} \), \( H_{m0,\text{swell}} \) and \( H_{m0,\text{sea}} \) are the overall, swell and sea significant wave heights, respectively.

Having established the annual wave height exceedances from model simulations, the internal layout of the harbour and the entrance configuration was suitably modified to maintain wave disturbance within acceptable limits. The allowable significant wave height limits (not to exceed 1 week per year) used were 0.4 m to 0.6 m for loading/unloading operations at a quay and 0.6 m to 0.8 m for safe mooring in the basin.

In Figure 7, the significant wave heights for a wave incidence with an estimated exceedance of 1 week per year is illustrated for the optimised harbour layout. It was necessary to effect several modifications in the basic layout to limit wave disturbance within acceptable limits. The modifications carried out included, the provision of a forebay area at the entrance and a sandy beach fronting the entrance for energy dissipation and sloping rubble mound faces as much practically possible as the internal faces of harbour structures for effective wave energy absorption.

In addition to wave disturbance due to short period waves, the possibility of harbour resonance due to long period oscillations was also examined by using a combination of MIKE 21 BW and HD models. Several simulations carried out with different wave periods indicated that undesirable wave heights due to long period oscillations will not result within the harbour basin.

At the entrance, curved breakwater arms extends up to a water depth of 5.4 m below MSL. The main operational area of the harbour is to be dredged up to 4.5m below MSL while in the southern part of the basin a depth of 3 m below MSL is to be provided. The model simulations confirmed that under the wave conditions that may be expected throughout the year, these water depths are sufficient to ensure safe navigation into and out of the harbour and safe operation within the harbour for the range of anticipated craft sizes.
Sediment Budget Computations

A sediment budget for the study area was obtained in the initial phase by quantifying different components as accurately as possible. The establishment of the sediment budget was based on LITPACK model computed sediment transport capacities across selected transects, volumetric bed level change computations based on repetitive surveys and available information on sediment supply from the Kelani River.

The analysis of all available sediment data from the study area and sediment transport mechanisms led to an identification of four distinct transport zones. These were the inner trough area behind the secondary reef, outer trough between the two reefs, the wave breaking zone on the outer slope of the secondary reef and the area around the Kelani River mouth. This analysis also identified that the average characteristics of sediments in motion due to longshore currents can be represented by that of a graded sediment mixture with a mean grain size \( d_{50} \) of 0.6 mm.

LITPACK model computations carried out using this information revealed that sediment transport capacities northwards and southwards of the proposed harbour site, where the secondary reef has merged with the coastline, are around 200,000 m\(^3\)/year. This is in excess of the present estimated sediment supply rate from Kelani River of 100,000 m\(^3\)/year. Therefore, progressive erosion of fine material can be expected to take place until bed armouring result in an equilibrium situation.
LITPACK computations indicated variable sediment transport capacities along the stretch where secondary reef has got disconnected with the coastline, but in general being in excess of the sediment supply rate. Diver inspections of the secondary reef carried out in this area revealed that it consists of fragmented sandstone with hardly any sediment accumulations within the crevices. This observation itself is an indication of the sediment transport potential being higher than the sediment supply rate.

The volumetric bed level change computations showed that on an average about 3,500 m$^3$/year of sediment is lost from the basin area planned to be occupied by the harbour. This figure represents the net difference of sediment eroded by the wave overtopping currents and the sediment spilling over the secondary reef into the basin. The construction of the harbour will result in a loss of these erosion products from the basin area to down drift coasts. However, such a moderate deficiency in sediment discharge will be unlikely to create significant erosional problems.

**Assessment of Sedimentation Impacts of the Harbour**

Two dimensional sediment transport computations were carried out for the post-harbour construction stage to ascertain whether a sufficient sediment transport capacity exist in front of the harbour entrance to by-pass the incoming sediment supply. For this purpose, MIKE 21's sediment Transport Module, MIKE 21 ST was used.

MIKE 21 ST computes sand transport capacity at each node of a rectangular grid computational domain for which hydrodynamic and wave characteristics have been established. The model could account for effects of both breaking and non-breaking waves on transport of non uniform spatially varying sediment sizes. The currents could be tidal, wind-driven, wave-driven or a combination of the three. The grain size and the gradation of sediments may vary throughout the model area.

The hydrodynamic scenarios for computing sediment transport considering selected wave incidences combined with tide and wind driven flows were established within MIKE 21 HD3 model (Figure 8.). The computed sediment transport potentials for the selected wave incidence scenarios were extrapolated considering their seasonal occurrence percentages and the fractional contribution to the transport potential as indicated by LITPACK computations. These calculations revealed that the entrance configuration of the proposed harbour with curved double breakwater arms will be able to by pass the present estimated sand supply of 100,000 m$^3$/year. This also implies that there would be no additional lee-side erosion due to the construction of the fishery harbour, apart from the first few years, which is required for the adjustment of bathymetry adjacent to the entrance.

The sedimentation within the harbour basin was assessed through desk calculations, considering three basic mechanisms of sedimentation, viz., tidal exchange, eddy exchange and long period oscillations. The calculations made under conservative assumptions estimated the annual siltation within the harbour basin to be about 5 cm. The long period oscillations was found to be the most important mechanism contributing to about 80 percent of the estimated siltation.
Figure 8. A Simulated Hydrodynamic Scenario for Sediment Transport Computations

Concluding Remarks

The hydrodynamic, wave and sediment transport phenomena in a complex reef protected coastal stretch could be successfully simulated through the application of MIKE 21 and LITPACK mathematical models. The study also resulted in the evolution of a hydrodynamic model for the western coast of Sri Lanka. This model which has undergone further refinement and validation since its initial development, has been subsequently used as the primary basis in a number of coastal engineering applications at other locations.
Acknowledgments

The work described in this paper was conducted as a part of the technical feasibility study for the proposed fishery harbour at Dikkowita, Sri Lanka. The authors of this paper wish to thank Ministry of Fisheries and Aquatic Resources Development, Sri Lanka, for providing the opportunity to be involved in this study, conducted under the ADB Sri Lanka Fisheries Sector Development Project.

1. Abstract

Studies of flows near the coast from the viewpoint of coastal engineering have focused on tidal currents and nearshore currents that are generated by waves in breaker zones. However, on-site observations have shown that there also exist strong flows with long periods of several days. As these long-period flows have a high velocity even at deep water levels outside breaker zones, they are thought to play an important role in the offshore drift-sand phenomenon and in the convection and diffusion of floating larvae of marine organisms. Through analysis of observation data on wind velocity and flow velocity recorded around Tomakomai Harbor, the temporal and spatial characteristics of long-period velocity fluctuations of these flows were clarified. We confirmed the existence of and clarified the characteristics of long-period flow velocity fluctuations around Tomakomai Harbor that have a period of 3~4 days and propagate in a westerly direction at a phase velocity of approximately 2.0km/h. These long-period flow velocity fluctuations can be estimated by the storm surge formula that assumes wind stress to be the external force and Coriolis force to be the restoring force.

2. Introduction

Studies of flows near the coast from the viewpoint of coastal engineering have focused on tidal currents and nearshore currents that are generated by waves in breaker zones. However, on-site observations have shown that there also exist strong flows with long periods of several days. Adams and Buchwald (1969) pointed out that wind stress parallel to the coastline is...
important for the occurrence of shelf waves. Nakamura (1990) showed from the results of on-site observations carried out over a period of many years on the coast of Fukushima that there exist southward-propagating flow velocity fluctuations with a period of 3 or 4 days, propagating the direction with the shoreline on the right, and he reported that these flows correspond to the second mode of shelf waves. He also pointed out that these flows affect the drifting and diffusion of floating bivalve larvae. Sato (1995) reported the existence of a strong flow at a depth of 15m off the Hokuriku coast that reaches a speed of up to 1m/s along the coastline and reported that this flow is mainly caused by wind stress and Coriolis force. Yasuda et al. (1995) pointed out that not only wind stress but also the effect of momentum transportation due to offshore breakers is important in the generation of strong flows outside the breaker zone. As these flows with long periods of several days have a high velocity even at deep water levels outside breaker zones, they are thought to play an important role in the offshore drift-sand phenomenon and in the convection and diffusion of floating larvae of marine organisms. However, there have been very few field studies conducted on these flows. Moreover, these strong flows are caused not only by a large variety of factors such as wind stress, offshore breakers, differences in density and shelf waves but also by combinations of these factors, making it difficult to clarify the physical mechanisms of flow occurrence.

Therefore, in this study, through analysis of observation data on flow velocity and wind velocity recorded around Tomakomai Harbor, we attempted to clarify the temporal and spatial characteristics of long-period velocity fluctuations of these flows, and the correlation between flow velocity and wind velocity. Next, we performed numerical calculation of these flows using a storm surge formula, and by a comparison with the observation results, we were able to investigate the mechanisms that generate these flows.

3. On-site observation data

The observation data used for the analysis were flow and wind velocities measured at the sites around Tomakomai Harbor shown in Fig. 1. Flow velocity data included long-term continuous observation data collected at one site and short-term observation data collected at multiple sites. The long-term continuous observation data of flow velocity were measured by an NC-2 current meter set at 23.5 m under the sea surface and at 1m above the sea bottom at site A, which is located 2.5km offshore from the west harbor (see Fig. 1). Velocity data (90-sec mean velocity) collected every hour from January 1990 to August 1995 were used for the analysis. The short-term data were measured by a RCM-4 current meter set at 5m below sea surface at

Fig.1 Observation sites around Tomakomai Harbor
eight observation sites (St. 1 ~ St. 8) around the east harbor (see Fig. 1). The offshore sites, St. 1 ~ St. 4, run almost parallel to the shoreline, and the water is shallower on the east side. At St. 1 ~ St. 8, 20-min mean flow velocities were measured at 20-min intervals over a period of 30 days four times a year (in June, July, October and February). Wind velocity was measured at 10m above the ground at site B (see Fig. 1). Wind velocity data obtained every hour during the same period as the recording of long-term continuous flow velocity were used for the analysis.

4. Characteristics of long-period flow velocity fluctuations

4.1 Temporal characteristics of flow velocity fluctuations

Fig. 2 shows flow velocity data obtained over a one-month period in October 1993. As can be seen in the figure, there were flow velocity fluctuations with periods of 12.5 hours and 25 hours attributed to the tides. There were also flow velocity fluctuations with shorter periods and flow velocity fluctuations with long periods of 4 ~ 6 days. The flows with long-period flow velocity fluctuations were mainly in an east-west direction, parallel to the shoreline. In the present study, we focused on these flow velocity fluctuations with along period of several days. In order to show the components of these long-period fluctuations, we calculated the 25-hour moving averages of the flow velocity raw data used in Fig. 2 and extracted the flow velocity fluctuations with periods shorter than tidal periods. The results are shown in Fig. 3. As can be seen in the figure, the periods of the flow velocity fluctuations are 4 ~ 7 days.

Next, we divided the raw data of flow velocities for October 1993 shown in Fig. 2 into two components: the component of flows in a direction parallel to the shoreline and the component of flows in a direction perpendicular to the shoreline. Fig. 4 shows the power spectrums for these
two components. The spectrums were calculated by MEM using 700 data values obtained every hour over a period of 30 days. For the flow velocity component in a parallel direction to the shoreline, the spectrum density is greatest at a period of about 150 hours (about 6 days). These long-period fluctuations correspond to the velocity fluctuations with periods of 4~7 days in Figs. 2 and 3 and were dominant flow fluctuations in October 1993. A comparison of the parallel and perpendicular components of flow velocity shows that the parallel components of these long-period flow velocity are dominant. A spectrum of flow velocity fluctuations observed every month over a period of 6 years showed that strong flow velocity fluctuations with a long period of several days were dominant throughout the year except in the early summer and mid-summer months from May to July. Nakamura (1990) reported that flow velocity fluctuations with long periods of several days could be observed off the coast of Fukushima throughout the year except for summer, when there is a great difference between daily maximum and minimum water temperatures caused by thermocline. These observation results are similar to the results of our observations of flow velocity fluctuations off the coast of Tomakomai.

4.2 Spatial characteristics of flow velocity fluctuations

Fig. 4 shows the measurements of flow velocity from September 28 to October 7, 1993 at St. 1 ~ St. 8 around the east harbor. This observation period is almost the same as the first ten days in Fig. 2. As can also be seen in this figure, the dominant flow velocity fluctuations were those with a period of several days, and most of these flows were in an east-west direction. As can be seen in Fig. 5, flow velocity fluctuations have the following spatial characteristics. St. 1 ~ St. 4 (offshore sites) showed almost the same tendencies in flow velocity fluctuations. The intensities of flow velocity fluctuations were almost the same at St. 1 and St. 4, while St. 2 and St. 3 showed larger flow velocity fluctuations. For example, on September 28, when there was a dominant eastward flow, the maximum flow velocity fluctuation at St. 1 and St. 4 was about 15 cm/s, while the flow velocity fluctuation at St. 3 reached a maximum of 30 cm/s. This difference is thought to be due to the acceleratory effect caused by the breakwater in the harbor; this effect should be considered when dealing with the issue of drift sand around a breakwater, especially in deep water around the end of the breakwater. As can be seen in the figure, St. 5 also showed similar flow velocity fluctuations to those at St. 1 ~ St. 4.

On the other hand, St. 8 showed similar flow velocity fluctuations to those at St. 1 ~ St. 4 when an eastward flow was dominant at the offshore sites, but the flow direction at St. 8 was opposite to that at St. 1 ~ St. 4 on September 29, October 4 and October 7, when an westward flow was dominant at St. 1. It is thought that a westward flow with a velocity
fluctuation period of several days changes direction at St. 8 after circling around the back of the breakwater. This type of circulatory flow around a large harbor could be effective for preventing the drifting and diffusion of floating larvae of bivalves such as surf clams. A flow in the opposite direction to that at St. 1 was rarely seen at St. 5. This is thought to be due to the shape of the breakwater, although many points still remain unclear. However, this phenomenon is thought to be an important factor in assessing the effects on the coastal environment, and especially the hydraulic environment, of large harbors, and further investigation of this phenomenon is needed. The flow velocity fluctuations at St. 6 and St. 7 (nearshore sites) are much smaller than those at other sites; most of the flow velocity fluctuations at these two sites have short periods that accord with the tides.

A comparison of the flow velocity fluctuation data from October 1 to October 7 in Figs. 2 and 5 for site A and St. 1, which are located relatively close together (see Fig. 1), shows that although these two sites have similar flow velocity fluctuations, the flow velocity at site A, where measurements were conducted near the sea bottom, is only about half that at St. 1. The vertical distribution of flow velocity fluctuations with long periods is also important for transport problems of matter such as drift sand.

Since St. 1 ~ St. 4, sites that are not affected greatly by the harbor (see Fig. 5), showed very similar flow velocity fluctuations, we calculated the correlations of east-west and north-south flows between these sites using 25-hour moving averages of the observation data obtained
at each site. Fig. 6(a) and (b) show the correlation coefficients $C(\tau)$ between flow velocities at St. 4 and those at St. 1 ~ St. 3 for a 30-day period in October 1993. The distances between St. 3 and St. 4, St. 2 and St. 4, and St. 1 and St. 4 are 4.0km, 7.5km, and 10.9km, respectively. As can be seen in the figures, the correlation coefficients between all of the sites are high (over 0.9) for both the east-west and north-south components. Also, the time lag ($\tau$) increases as the westward distance from St. 4 increases, and the correlation coefficient decreases slightly as the distance between sites increases. These results indicate that flow velocity fluctuations with long periods propagate about 10km to the south with little change in form. This property is the same as that of shelf waves along coasts in the northern hemisphere, the direction of propagation being with the shoreline on the right.

Table 1 shows the time lags between sites in various observation periods and the phase velocities of flow velocity fluctuations in these observation periods. The table shows that flow velocity fluctuations were always in an east-to-west direction and that the phase velocity ranged from 1.5~3.0 km/h.

### 4.3 Correlation between flow and wind velocities

Fig. 7 shows the raw data of wind velocities recorded during the same period in October 1993 as that in Fig. 2. As can be seen in the figure, wind velocity data also have fluctuations with periods of several days. A comparison with the data in Fig. 2 shows that there is a clear correlation between flow velocity and wind velocity fluctuations and that wind velocity fluctuations...
is slightly faster for change in phase than flow velocity fluctuations.

Fig. 8 shows the same power spectrums for wind velocity as those calculated for flow velocity in Fig. 4. The majority of winds blowing in a direction parallel to the shoreline had a velocity fluctuation period of about 150 hours. This is similar to that of the flow velocity fluctuations shown in Fig. 4.

We calculated the correlation coefficients between flow velocities at site A and wind velocities at site B. Table 2 shows the correlation coefficients that were greater than 0.8. The correlation coefficients between flow and wind velocities in the months not shown in the table were also relatively high; for example, the correlation coefficients were 0.7 ~ 0.8 for other months in 1993. The time lags of flow velocity are also shown in the table. In the case of a high correlation coefficient between flow and wind velocities, there was a time difference of 6 to 11 hours between sea flow and wind. The above results show that a sea flow is generated approximately 6 to 11 hours after a strong wind starts to blow, suggesting that tangential stress acting on the sea surface due to wind is important for the external forces that cause flow velocity fluctuations with long-term periods.

Velocity fluctuations in flows off the coast of Tomakomai with periods of 4 ~ 7 days showed a strong correlation with wind. As possible factors affecting wind, we investigated the positional relationship between low and high atmospheric pressures and the relationship between wind and flow velocities. The following results were obtained. When low and high atmospheric pressures pass over

Tomakomai together, flow velocity fluctuations with long periods occur. When there is low pressure to the west and high pressure to the east of Tomakomai, westward wind and sea flows occur, and when there is low pressure to the east and high pressure to the west of Tomakomai, eastward wind and sea flows occur. These results suggest that wind velocity, which is largely determined by the atmospheric pressure pattern, and fluctuations in the sea surface due to changes in atmospheric pressure affect flows.

5. Numerical calculation of long-period flow velocity fluctuations

A flow velocity fluctuation with a long period of several days is thought to be generated by wind stress and atmospheric pressure fluctuations accompanying the passing of a low atmospheric pressure, and Coriolis force as restoring force. At a first step, numerical calculation was performed by similar method with Sato (1995) using a basic formula for storm surge. An outline the numerical calculation is as follows:

\[
\frac{\partial M}{\partial t} + \frac{\partial}{\partial x} \left( M \frac{\partial f}{\partial y} - \frac{\partial M}{\partial y} \right) - fN + g \frac{d \eta}{d t} + \frac{d \eta}{d t} + \frac{\partial \tau_{xy}}{\partial x} - \frac{\partial \tau_{xy}}{\partial y} - \frac{\partial \tau_{xy}}{\partial z} = 0
\]

\[
\frac{\partial N}{\partial t} + \frac{\partial}{\partial x} \left( N \frac{\partial f}{\partial y} - \frac{\partial N}{\partial y} \right) - fM + g \frac{d \eta}{d t} + \frac{d \eta}{d t} + \frac{\partial \tau_{xy}}{\partial x} - \frac{\partial \tau_{xy}}{\partial y} - \frac{\partial \tau_{xy}}{\partial z} = 0
\]

\[
\frac{\partial}{\partial x} \left( \frac{\partial f}{\partial x} + \frac{\partial f}{\partial y} \right) + \frac{\partial}{\partial y} \left( \frac{\partial f}{\partial x} + \frac{\partial f}{\partial y} \right) = 0
\]

Where, \( x, y \) : the parallel and the vertical co-ordinates to shoreline, \( d \) : water depth, \( f \) : coefficient of Coriolis force, \( g \) : acceleration of gravity, \( \rho \) : density of sea water, \( \tau_x \) : shear stress on the sea surface, \( \tau_y \) : shear stress on the seabed, and \( \varepsilon \) : horizontal coefficient of eddy viscosity. Subscripts \( x \) and \( y \) represent the components of flow that are parallel to the shoreline and perpendicular to the shoreline, respectively.

The topographical conditions were simplified to a shoreline running parallel to the \( x \) direction with a 1/100 uniform slope and no harbor. Coriolis factors within the area of calculation were assumed to be constant, and we used f-plane approximation and values at 42° North Latitude. An square area of 600km \( \times \) 600km was used for the calculation. At the shoreline boundary, \( M = 0 \) and \( N = 0 \), and all other boundaries were closed. The grid width was 10km, and time steps were 30 sec. As the results of past calculation showed that fluctuation in atmospheric pressure has little effect on flows, atmospheric pressure was not included in the present calculation. Observed date of wind velocity were used as external force in this calculations.

Fig. 9 shows observed flow velocity, 25-hour moving average flow velocity, observed wind velocity, 25-hour moving average wind velocity (all at site A in Fig. 1), and calculated flow velocity 10km offshore for the period from Oct. 1 to Oct. 15, 1993. Although a direct comparison between observed and calculated flow velocities is not possible, since observation data of flow velocity were obtained at a site approximately 2.5km offshore and calculations of
flow velocity were made at a point 10km offshore, the qualitative agreement between observed and calculated flow velocities is good. Moreover, the phase velocity of the calculated flow velocity fluctuations at a point 10km offshore is 2.5 km/h, which agrees well with the results of on-site observations (see Table 1, Oct. 1993). However, there are time differences of a half day to one day between the calculated and observed flow velocities. Further study is required to resolve this discrepancy.

6. Conclusions

We confirmed the existence of and clarified the characteristics of long-period flow velocity fluctuations around Tomakomai Harbor that have a period of 3~4 days and propagate in a westerly direction at a phase velocity of approximately 2.0 km/h. These long-period flow velocity fluctuations can be estimated by the storm surge formula that assumes wind stress to be the external force and Coriolis force to be the restoring force.

Transformation of wave groups and accompanying long waves in shallow water

Mizuguchi, M. and H. Matsutate

Abstract

Interaction of short waves modulation and long waves evolution is studied. Existence of free long waves is taken into account. Laboratory experiment and numerical simulation with coupled equations are performed. Mechanism of the modulation is discussed. The distance, below which the modulation may be neglected, is evaluated.

Introduction

Figure 1 shows an example of wave record obtained in Hasaki pier, PHRI, MOT in Japan. Strong grouping of short waves is present. Long period component is filtered out numerically with cut-off frequency 0.04 Hz. Magnitude of the long waves is 1/10 of wind waves. Bounded long waves to grouping waves may be evaluated by applying the following Longuet-Higgins and Stewart (1962) solution.

\[ \eta_b = - \frac{Sxx(x-c_g t)}{p(gd-c_g^2)} \]

\( \eta \) (cm) | 波崎海洋研究施設 1996.8.29, 15:52 ～ 15:57

Fig. 1 Long waves in the field (where water is shallow and about 5m deep)
where \( \eta_b \) is the surface profile of the bound long waves, \( S_{xx} \) is the radiation stress of short waves, \( c_g \) is the group velocity of short waves, \( d \) is the water depth. Rough calculation of Eq.(1) gives 1.0 m in terms of wave height for \( \eta_b \), with \( d=5 \) m, wave period \( T=10 \) s, maximum amplitude of short waves \( a_{\text{max}}=1.1 \) m, minimum amplitude \( a_{\text{min}}=0.3 \) m. Observed long waves are much smaller than that of bound long waves as is widely pointed out.

Why is the observed long waves much smaller than that of bound long waves. A very plausible explanation may be found in Nagase and Mizuguchi(1996) that free long waves, being generated simultaneously while the bound waves developes in the process of shoaling, nearly cancels out the bound one. Then long waves observed is much smaller than the bound one unless those two are separated well as shown in Fig. 2.

![Fig. 2 Long waves accompanying a group of waves (Mizuguchi and Toita, 1996)](image)

In Fig. 2, no significant long waves is observed near the wave maker. Free long waves, which is needed to satisfy the boundary condition at the wave maker, is \( c_g/c \) times the bound waves, where \( c \) is the phase speed of the long waves. As they travel, long waves appear to be growing both in experiment and in theory. Free long waves, generated at the wave maker, propagate faster than the bound waves (or set-down waves) and start to separate each other. The separation can be observed only for this kind of single group of waves.
In this figure, one can also notice small difference between the experimental results and the theoretical one growing with the distance from the wave maker. The purpose of present study is to examine this difference. This difference is of second-order and very small in Fig. 2, but may be significant in some situation and worth to be investigated. The first-order theory assumes that short waves propagates with no change of group form. Previous nonlinear theory of wave modulation does not take into account of the free long waves. No systematic experimental investigation has not yet published, either.

Laboratory experiment

First we conducted a series of laboratory experiments to see how significant the change of wave group (or wave modulation) is. Figure 3 shows our experimental setup. Wave flume is 40m long and 30 cm wide and equipped with a piston-type wave maker.

Fig. 3 Wave flume and experimental setup

Fig. 4 An example of signal for wave maker (Case 2) Solid line is calculated by Eq.(2) and broken line after Mizuguchi and Toita(1996).
We use single group of short waves for its simplicity as in Mizuguchi and Toita (1996). An example of wave maker signal is shown in Fig. 4. Displacement of wave maker $\xi$ is obtained by numerically integrating the following equation.

$$\frac{d\xi}{dt} = u_w(0,t) + u_l(0,t) + \xi \frac{\partial u_w}{\partial x}$$

(2)

where $u_w$ and $u_l$ denote horizontal velocities of short waves and long waves respectively. $u_w$ is given by linear wave theory and $u_l$ is by

$$u_l = r \left( \frac{c_g}{d} \right) \eta_b(x,t)$$

(3)

where $r$ is the quantity to control the generation of long waves. $\xi$ is the displacement of the wave maker for long wave component and is given by

$$\xi = \int_0^t u_l(0,t) dt$$

(4)

The last term in Eq.(2) is newly added to compensate rather large value of $\xi$.

Ten cases are chosen as shown in Table 1. Standard case is Case 1, where generation of free long waves is suppressed by putting $r=1$. Finite amplitude effects may be seen in Cases 2 and 3. Effects of dispersion may be studied both in Cases 4 and 5 with different number of waves in a group and in Cases 6 and 7 with different wave period of short waves. Effects of free long waves may be observed in Cases 8, 9 and 10. Water depth is 20 cm through the experiment.

$US_{max} = 2a_{max}L^2/d^3$ , $USS_{max} = 2ga_{max}T^2/d^3$
Analytical description

In order to discuss the experimental results, knowledge on the theoretical background is very helpful. It is known that for long waves under grouping short waves, mass continuity equation is given as

$$\frac{\partial \eta}{\partial t} + \frac{\partial u_i}{\partial x} = 0 \quad (5)$$

and momentum equation is as

$$\frac{\partial u_i}{\partial t} + g \frac{\partial \eta}{\partial x} = -(n'-1/4)g\frac{\partial |A|^2}{\partial x} \quad (6)$$

where $A$ is the complex amplitude of short waves. For short waves, the complex amplitude $A$ follows

$$\frac{\partial A}{\partial t} + c_g \frac{\partial A}{\partial x} + i[\alpha \frac{\partial^2 A}{\partial x^2} + \beta' |A|^2 A + \{(k/d)(c_g/c-2)\eta_i + ku_i\}A] + \text{dissipation} = 0 \quad (7)$$

where

$$\alpha = -(\eta^2 \omega / \partial k^2)/2$$

$$\beta' = (\omega k^2 / 16 \sinh^4 kd) [2 \sinh^2 kd(1 - \tanh kd/kd)] + 9$$

Equation (7) is written explicitly for $\eta_i$ and $u_i$. Conventional form may be found in Mei(1989). Dissipation term is modeled after Mase(1987), where dissipation due to viscosity at side walls is included in addition to that at bottom. The traditional Schrädinger-type equation for wave modulation is obtained by substituting only the forced solution of Eqs.(5) and (6), while assuming the functional form of $A(x-c_g t)$, into Eq.(7) and neglecting the dissipation term.

Equations (5) to (7) may describe the second-order phenomena of long wave evolution and modulation of short waves for any initial and/or boundary condition. Standard finite difference technique is employed to solve Eqs.(5) to (7) numerically. Care is needed to give the boundary condition at the wave maker to be smooth enough.

Experimental results and comparison with theories

In the analysis of the laboratory data, long waves is simply filtered out numerically. Envelope of short waves is calculated by applying numerical filter to the absolute value of short wave surface fluctuation(List, 1992). Bound long
Fig. 5a Experimental results (Case 1 to 5)

Fig. 6b Comparison among experiment, first- and second-order theories (Case 6 to 10)
Fig. 7a Contribution of each term in Eq.(5) (case 1 to 5)

Lines in upper half of each figure show envelope profiles and those in lower half long wave profiles.
Fig. 7b Contribution of each term in Eq.(5) (case 6 to 10)
waves is calculated as LHS solution, that is by Eq.(1), with the evaluated short wave envelope. Free long waves is defined as the difference between the observed long waves and the calculated bound one.

In all cases both envelope of short waves and long wave (or set-down wave) flatten more or less as they propagate away. In Case 2, phase modulation (change of wave period of short waves) as well as amplitude modulation is clearly seen. Large velocity of bound long waves is responsible. Free second (higher) harmonics are also present, being left behind. In more linear case Case 3, change of wave group is naturally slower. In this case experimental error in long waves could be significant as its magnitude is very small. In Cases 4 and 5, effect of dispersion due to the curvature of $|A|$ is showing. In Cases 6 and 7, effect of the coefficient $\alpha (=\alpha''(k))$ for linear dispersion is evident. Cases 8, 9 and 10 show that effect of free long waves may appear in another group of waves travelling ahead.

Comparisons with first- and second-order theories are made in Figs. 6(a) and (b). They may be summarized as in the following. Near the wave maker three of them, experiment, the analytical solution of the first-order theory (Mizu\-gu\-chi and Toita, 1996) and numerical simulation of Eqs.(5) to (7), agree well for all cases. First-order theory starts to fail to agree with other two at some point. Even after the first-order theory fails, the coupled Eqs. (3) to (5) well describe experimental results.

**Discussions on wave modulation**

We evaluate degree of contribution of each term by truncating the modulation equation at different position shown below.

\[
\frac{\partial A}{\partial t} + c_g \frac{\partial A}{\partial x} + i(\alpha \frac{\partial^2 A}{\partial x^2} + \beta' |A|^2 A) + \{ (k/d)(c_g - c/2) + k u \} A] + \text{dissipation} = 0
\]

where, in Stage (3) the bound long wave solution is used in this interaction term, in practice Schrodinger-type equation is used. In Stage (5), dissipation only at bottom is included. Stage (1) corresponds to the analytical solution of first-order. Numerical results in Stage (1) to (6) are plotted together with experimental results in Figs 7(a) and (b). Comparison are made for data at x=16m, farthest measuring point from the wave maker. Overall comparison tells that the first-order theory is rather good. For second-order effects, dissipation (in particular at side wall) is always non-negligible in this scale of experiments. Other second-order effects plays their each role as is expected. In particular following points may be marked. In Case 2, the flattening effect of bound long waves on wave modulation is most
significant, as the difference between Stage (2) to (3) is largest. The cubic nonlinear term is not important as it contributes to sharpening the grouping profile. In Cases 4 and 6, especially in the latter, effect of linear dispersion term (from Stage (1) to (2)) is dominant. Small difference between the experiment and the full theory is noticeable in these magnified figures. They may come from either errors in the experiment or higher order effects in theory.

Then the distance $X^*$, below which rms difference in envelope profile between first-order theory and full second-order theory is less than 5% is calculated by using numerically simulated results with the coupled equations and plotted in Fig. 8. Free waves at the wave maker are suppressed and dissipation neglected. When $k a_{\text{max}}$ is large, flattening due to interaction with bound waves is significant and the distance is at most one-quarter of group length. When $k a_{\text{max}}$ is small, linear dispersion term $\propto \{\text{curvature}\}$ determines the distance, which is of order one wave group length. Significant shoaling of field waves occurs in rather short distance (a few km?), which is of order of one wave group length. The first-order treatment may be sufficiently accurate.

![Fig. 9 Traveling distance of negligible change in envelope](image)

$L^*_g$ is the length of the wave group

Conclusions

1) Coupled equations (5) and (7) can describe well the modulation of short wave group and evolution of long waves in a wide range of experimental results.

2) The second-order effects may be insignificant for shoaling field waves,
although the effect of free long waves could not be fully assessed as the long waves travels ahead of grouping waves.

Observation and Simulation of Low-frequency Waves on Two Natural Beaches

Satoshi NAKAMURA 1 and Nicholas DODD 2

Abstract

Field observations of low-frequency wave on natural beaches are carried out. The ratio of the wave height of low-frequency wave near the shoreline to the wind wave height at the offshore has positive correlation with the surf similarity parameter. Using the field data, a validation of a numerical model was made. The model includes basic mechanisms of low-frequency wave generation that low-frequency wave increases with shoaling of wind waves groups, they are released from wave groups due to wave breaking and wind wave period becomes longer due to run-up to the beach. The model results tend to be excessively computed against field data.

Introduction

Low-frequency waves, with wave periods in the order of minutes, appear in the surf zone most noticeably when pronounced wind wave groups exist offshore. Generation of bound or free low-frequency waves can be conclusively explained that the structure of wave group changes. Therefore the low-frequency waves are made everywhere when the wind wave groups change its shape. At the offshore, obtained wave data contain low-frequency waves of all direction from different origin such as bound low-frequency waves grown beneath wind wave group, free low-frequency waves generated near the wave breaking points and from the breakwaters and the shoreline, and low-frequency waves caused by wind wave refraction. In the surf zone, the low-frequency waves, which are mainly generated by wave breaking and become standing waves, occasionally cause rapid nearshore bar migration and berm shape changes by running-up beyond the berm crest.

In this paper, field observations are presented. The simultaneous data of offshore and nearshore low-frequency waves are obtained. A numerical model which includes mechanisms of low-frequency wave generation is used to simulate the observed dynamics.

1Marine Environment Division, Port and Harbour Research Institute, 3-1-1 Nagase, Yokosuka 239-0826, Japan
2Coastal Group, HR wallingford, Howbery Park, Wallingford, OX10 8BA, UK.
Field observation

Study sites

Field studies of low-frequency waves and wave groups have been carried out at two sites of the east coast of Japan (see fig.1).

One field observation has been carried out at a seashore site near Gamō tidal lagoon in the Sendai bay on the Pacific coast since 1997 for the study of wave run-up with the low-frequency waves on a berm and of offshore wave groups. In this observation, wave data were collected continuously with sampling 0.5s intervals using only 2 wave gages at the offshore and near the shoreline. Figure 2 shows the beach profile at Gamō and location of the wave gages. The offshore wave gage, which is set on the sea bottom at 4km offshore from the shoreline and 20m depth, measures the sea surface elevation using ultrasonic wave. The nearshore ultra-sonic wave gage is attached in the air on a scaffold at the shoreline. A highly-sensitive CCD camera and video recorder, which is set on the berm, is used to record the wave run-up and over-topping events beyond the berm crest. During observation period, an over-topping event does not record unfortunately. We do not use video data in this paper.

Another field observation was carried out at Hazaki Oceanographical Research Station (HORS) in 1989 (see Nakamura and Katoh, 1992) for the study of the propagation of incident wave groups and the low-frequency nearshore
wave motion in the storm condition. Figure 3 shows the beach profile at HORS and location of the wave gages. This data set contains simultaneous recordings of 10 wave gages from the shoreline to 3.2km offshore during a storm.

Data analysis

A set of wave record, which length is approximately 2 hours, separated in the frequency band upper 0.04Hz and the low-frequency band using FFT method. Significant wind wave heights, $H_S$, and periods, $T_S$, are calculated from the higher band wave record using zero-up-cross method. Significant low-frequency wave heights, $H_L$, and periods, $T_L$, are calculated same way. For the numerical model input, the wave energy time series is calculated from the wave envelope
Figure 4: Ratio of the low-frequency wave height in the surf zone to the significant wave height in the offshore vs. surf similarity parameter using Hilbert transform (see Hudspeth and Medina, 1988) of the wind wave record is used.

Figure 4 shows the ratio of low-frequency wave height near the shoreline, $H_{L,shore}$, to offshore wind wave height, $H_{Soff}$, against the surf similarity parameter, $\tan \beta_b/\sqrt{H_{Soff}/L_{Soff}}$, where $L_{Soff} = 1.56 \times T_{Soff}^2$ is offshore wave length and $\tan \beta_b$ is the slope of the surf zone in case of Gamo $\tan \beta_b = 1/70$ and in case of HORS $\tan \beta_b = 1/60$. In figure 4, small circles indicate the data obtained at Gamo and large circles at HORS. The ratio of $H_{L,shore}/H_{Soff}$ has positive correlation with the surf similarity parameter. In both cases, the plots seem to be scattered on a line. This fact suggests that height of low-frequency waves in the surf zone becomes large not only as height of offshore wave becomes large but on condition that beach profile and waves fill some requirements.

Figure 5 shows the ratio of low-frequency wave height at the offshore, $H_{L,off}$, to offshore wave height, $H_{Soff}$, against the surf similarity parameter. There are two groups of plots in figure 5. One is the ratio of $H_{L,off}/H_{Soff}$ has positive correlation with the surf similarity parameter. Another group is the ratio has no correlation with the surf similarity parameter. The feature of this group is that it appear in Gamo data at the calm condition several days after the storm and it does not appear in HORS data. According to the NOWPHAS
data PHRI (1996), at Sendai New Port where is nearest observation point of Gamō, the relative frequency of calm condition ($H_s \leq 0.5m$) is 24.5% and the distribution of incident wave direction is narrow (main direction is SE) and at Kashima Port where is nearest point of HORS, the relative frequency of calm condition is 2.5% and the distribution of incident wave direction is wide (main direction is E). Comparing Gamō with HORS, as Gamō beach is located at the inner part of the bay, heights of significant wind wave quickly decrease after storm due to an effect of interception of Sendai bay. I suppose that trapped small amplitude low-frequency waves in Sendai bay are observed at offshore Gamō beach.

**Numerical model**

**Low-frequency wave model**

The numerical model of low-frequency waves uses an upwind, Godunov-type finite volume method to solve the equations. This method alleviates the problem of tracking multiple shorelines, which can occur over barred beaches (see Dodd, 1998; Nakamura and Dodd, 1997). The numerical equations used in the model are the one-dimensional depth-integrated and time-averaged non-linear shallow water equations of mass (eq.1) and momentum (eq.2), in which the
radiation stress gradient is included as a forcing term, and the energy balance of fluctuating motion equation (eq.3) (see e.g. Roelvink, 1993; Zou and Dodd, 1994) includes the interaction of wind wave energy and low-frequency waves.

\[
\frac{\partial D}{\partial t} + \frac{\partial (DU)}{\partial x} = 0,
\]

\[
\frac{\partial (DU)}{\partial t} + \frac{\partial}{\partial x} \left( DU^2 + \frac{1}{2} g D^2 \right) = g D \frac{\partial h}{\partial x} - \frac{\partial}{\partial x} \left( \frac{S_{11}}{\rho} \right) - \tau_b,
\]

\[
\frac{\partial E}{\partial t} + \frac{\partial}{\partial x} \left( (c_g + U) E \right) + \frac{\partial}{\partial x} \left( U S_{11} \right) = -D,
\]

where \( D \) is the total mean water depth, \( U \) is the mean velocity, \( h \) is the still water depth, \( \tau_b \) is a bottom friction term, \( D \) is a dissipation term,

\[
E = \frac{\rho g}{8} H^2,
\]

\[
c_g = \frac{1}{2} \frac{\omega}{k} \left( 1 + \frac{2kD}{\sinh 2kD} \right),
\]

and

\[
S_{11} = E \left( 2 \frac{c_g}{c} - \frac{1}{2} \right).
\]

The interaction terms appear effective close to the shoreline where wave speed and water velocity are nearly equal. To calculate low-frequency waves generation nearshore zone, we use here the 1D model as that the wind wave was being incident on the coastline at the normal angle is supposed for reason that both of near HORS and Gamō beach topography have little change into alongshore direction. To simulate trapped low-frequency wave by alongshore topography such as edge waves, of course, the 2D model has to be used.

**Simulations**

In this model, the radiation stress gradient works as a forcing term. So, the distribution of the radiation stress seriously affects on the model results. As this model calculate radiation stress using a simple function of wave height (eqs.4-6), we compare the wave height distribution between the field data and the model result. Figure 6 is a comparison of the distribution of mean wind wave height in storm condition \( H_s = 2.4m, T_s = 11.8s \) at HORS. Solid line is a model result that is calculated from each steps of the distribution of wave energy simulated by giving a time series of wind wave energy at the offshore boundary. Roelvink’s wave dissipation model \( \gamma = 0.65 \) and following Roelvink \( \alpha = 1.0, n = 10 \) is used in this model results. Circles indicate the field data. The model results of nearshore mean wave height has a good
agreement with field data but the results of mean wave height near the wave breaking point is over estimated.

Figure 7 shows a comparison of the distribution of low-frequency wave height in same wave condition of fig.6. Bold solid line is a model results. Thin solid line is a model result of mean water level (no comparison with field data). Circles are field data. In model result, low-frequency wave height is calculated excessively. The distance between the field data of low-frequency wave height near the shoreline and the model result of that can be reduced using a large bottom friction coefficient at this region. We do not use such adjustment because it is not essential. At the shoreline (0m), low-frequency wave height in field is not calculated because run-up waves come rarely at this point.

Comparisons

Comparisons of low-frequency wave height between the field data and the model results are done with chose 13 data sets, which are embraced in the group that the ratio of $H_{Loff}/H_{Soff}$ has positive correlation with the surf similarity parameter, in Gamo data sets and 15 data sets in HORS data sets. Figure 8 shows a comparison of low-frequency wave heights near the shore-
lack of run-up events at Gamō as water invade a lagoon beyond the crest of sand dune aren't observed by video records.

At offshore Gamō beach, the small amplitude of low-frequency waves are observed in calm condition until several days after storms. Comparing Gamō with HORS, as Gamō beach is located at the inner part of the bay, heights of significant wind wave quickly decrease after storm due to an effect of interception of Sendai bay. There seems to be trapped small amplitude low-frequency waves in the bay.

Conclusions

During the observation period at Gamō, a few simultaneous observation records using offshore and nearshore wave gages were gotten. Conspicuous run-up events at Gamō as water invade a lagoon beyond the crest of sand dune aren't observed by video records.

At offshore Gamō beach, the small amplitude of low-frequency waves are observed in calm condition until several days after storms. Comparing Gamō with HORS, as Gamō beach is located at the inner part of the bay, heights of significant wind wave quickly decrease after storm due to an effect of interception of Sendai bay. There seems to be trapped small amplitude low-frequency waves in the bay.

Figure 7 shows a comparison of low-frequency wave heights in the offshore between field data and model results. Small boxes indicate the Gamō data and large boxes the HORS data. There are three under-estimated results. Except three data, the model results are well computed.

Conclusions

During the observation period at Gamō, a few simultaneous observation records using offshore and nearshore wave gages were gotten. Conspicuous run-up events at Gamō as water invade a lagoon beyond the crest of sand dune aren't observed by video records.

At offshore Gamō beach, the small amplitude of low-frequency waves are observed in calm condition until several days after storms. Comparing Gamō with HORS, as Gamō beach is located at the inner part of the bay, heights of significant wind wave quickly decrease after storm due to an effect of interception of Sendai bay. There seems to be trapped small amplitude low-frequency waves in the bay.

Figure 9: Comparison of low-frequency wave heights in the offshore between field data and model results
waves in Sendai bay.

The computation result of the low-frequency wave tends to be excessively computed. This cause is to compute the energy of the wind wave excessively. To do the better simulation, the wind wave energy dissipation and the bottom friction of the low-frequency wave must be well computed. The way to the better simulation seems to be essential difference that wind wave breaking on the surface low-frequency motion, the radiation stress in breaking waves and sediment moving by low-frequency current.

QUASI 3-D EFFECTS IN INFRAGRAVITY WAVES

A.R. Van Dongeren¹, I.A. Svendsen², and U. Putrevu³

ABSTRACT: The present paper describes a numerical study of infragravity waves forced by obliquely-incident wave groups. In this study, the depth-integrated, shortwave-averaged nearshore circulation model SHORECIRC (Van Dongeren et al., 1994), which includes the quasi three-dimensional effects, is used. The governing equations that form the basis of the model, as well as the numerical model and the boundary conditions are described. The model is applied to the case of leaky infragravity waves. The magnitude of the quasi 3-D terms and their effect on the infragravity wave envelope is analyzed, and the velocity profiles of the infragravity waves are shown.

INTRODUCTION

The depth-integrated, shortwave-averaged nearshore circulation model SHORECIRC (Van Dongeren et al., 1994) belongs to the class of quasi-3D (Q3D) models, which combine the effect of the vertical structure with the simplicity of two-dimensional horizontal (2DH) models.

Several approaches to the development of Q3D models can be found in the literature. De Vriend & Stive (1987) split the current into primary and secondary flow profiles based on the assumption that the primary velocity profiles are the same in the cross-shore and longshore direction. In a different approach, Svendsen & Lorenz (1989) determined the vertically-varying longshore and cross-shore currents separately under the assumption of weak dependence. Svendsen & Putrevu (1990) formulated a steady state version of the nearshore circulation model using analytical solutions for the 3D current profiles in combination with a numerical solution of the depth-integrated 2D horizontal equations for a long straight coast. They split the current velocity into a depth-invariant component and a component with a vertical variation with zero mean flow integrated over the central layer. Sánchez-Arcilla et al. (1990, 1992) presented a similar concept.

Putrevu & Svendsen (1992) and Svendsen & Putrevu (1994) recognized that the current-current and current-wave interactions neglected in previous investigations induce a non-linear dispersion mechanism, analogous to the dispersion of solutes (Taylor, 1954). This mechanism significantly augments the lateral turbulent mixing
and accounts for the difference in magnitude between the vertical and horizontal mixing in the case of a longshore current on a long, straight coast.

The time-dependent version of this model, called SHORECIRC, was presented in Van Dongeren et al. (1994) for the special case of longshore uniformity in both the bathymetric and hydrodynamical conditions. The generalized quasi 3-D governing equations were derived in Putrevu & Svendsen (1997a,b) and Van Dongeren & Svendsen (1997a).

Recently, SHORECIRC has been used to study a number of nearshore phenomena, such as shear instabilities over longshore-varying bathymetries (Sancho et al., 1997, 1998) and rip currents over a bar (Haas et al., 1998).

In the present paper SHORECIRC will be used to study infragravity waves forced by obliquely-incident wave groups and the associated quasi 3-D effects on a cylindrical coast.

GOVERNING EQUATIONS

The depth-integrated, time-averaged mass and momentum equations incorporated in SHORECIRC are derived from the Reynolds' equations which are integrated over depth and averaged over the shortwave period largely following the procedure outlined in Phillips (1977) and Mei (1983). In the present approach, which is given in more detail in Putrevu & Svendsen (1997a,b) and Van Dongeren & Svendsen (1997a), the total horizontal velocity of the long and short waves is further split into a depth-uniform long wave part $V_a$, a depth-varying long wave part $V_a$ and a short-wave contribution $u_{wa}$, so that

$$u_{a}(x,y,z,t) = V_{a}(x,y,t) + V_a(x,y,z,t) + u_{wa}(x,y,z,t)$$

(1)

We define $u_{wa}\equiv 0$ below trough and define the shortwave-induced volume flux above the trough level as

$$Q_{wa} \equiv \int_{\zeta-t}^{\zeta} u_{wa} \, dz$$

(2)

where $\zeta_t$ denotes the trough level of the short-wave motion. The total flux $Q_a$ can then be written as

$$Q_a \equiv \int_{-h_o}^{\zeta} u_{a} \, dz = \tilde{V}_a \, h + \int_{-h_o}^{\zeta} V_{1a} \, dz + Q_{wa}$$

(3)

where $h_o$ is the still water depth, $\zeta$ is the surface elevation of the long (or IG) wave motion, and $h = h_o + \tilde{\zeta}$ is the total depth. With this result, the depth-integrated shortwave-averaged conservation of mass can be written as

$$\frac{\partial \zeta}{\partial t} + \frac{\partial Q_{\alpha}}{\partial x_{\alpha}} = 0$$

(4)

where the index $\alpha$ represents the horizontal $x, y$ directions, and $z$ is the vertical coordinate, defined from the still water level (SWL) up.
Using the same splitting procedure, the horizontal conservation of momentum can be expressed as

\[
\frac{\partial \bar{Q}_\beta}{\partial t} + \frac{\partial}{\partial x_\alpha} \left( \frac{\bar{Q}_\alpha \bar{Q}_\beta}{h} \right) + \frac{\partial}{\partial x_\alpha} \int_{\zeta}^\infty (u_{\omega\alpha} \bar{V}_{1\beta} + u_{\omega\beta} \bar{V}_{1\alpha}) \, dz = \frac{\partial}{\partial x_\alpha} \int_{-h_o}^\zeta \bar{V}_{1\alpha} \bar{V}_{1\beta} \, dz - gh \frac{\partial}{\partial x_\alpha} \left[ S_{\alpha\beta} - \int_{-h_o}^\zeta \tau_{\alpha\beta} \, dz \right] + \frac{\tau_{\beta}^S - \tau_{\beta}^B}{\rho} \tag{5}
\]

where \( \beta \) is index notation for the horizontal \( x \) and \( y \) directions, \( \tau_{\alpha\beta} \) represents the turbulent shear stresses, \( \tau_{\beta}^S \) is the surface stress and \( \tau_{\beta}^B \) is the bottom stress. The radiation stress is defined as

\[
S_{\alpha\beta} = \int_{-h_o}^\zeta (p \delta_{\alpha\beta} + \rho u_{\omega\alpha} u_{\omega\beta}) \, dz - \delta_{\alpha\beta} \frac{1}{2} \rho g h^2 \tag{6}
\]

The governing equations (4) and (5) would be readily solvable numerically if the depth variation of the long wave velocity \( \bar{V}_{1\alpha} \) were known. However, this would require a three-dimensional grid and therefore a large computational time. In order to reduce the computational time, the depth-dependent terms can be replaced by semi-analytical solutions, which are functions of the depth-integrated terms. In this so-called quasi 3-D approach only a two-dimensional numerical model is needed. This substitution can be achieved by using the local (i.e., not depth-integrated), time-averaged momentum equations (see e.g., Svendsen & Lorenz, 1989), which after some manipulations can be written as (Putrevu & Svendsen, 1997a,b; Van Dongeren & Svendsen, 1997a)

\[
\frac{\partial \bar{V}_{1\beta}}{\partial t} - \frac{\partial}{\partial z} \left( \nu_t \frac{\partial \bar{V}_{1\beta}}{\partial z} \right) = -\beta_\beta + \left( \frac{1}{h} \frac{\partial}{\partial x_\alpha} \left( S_{\alpha\beta} - \int_{-h_o}^\zeta \tau_{\alpha\beta} \, dz \right) \right) - \frac{\tau_{\beta}^S - \tau_{\beta}^B}{\rho h} - \bar{V}_{1\alpha} \frac{\partial \bar{V}_{1\beta}}{\partial x_\alpha} - W \frac{\partial \bar{V}_{1\beta}}{\partial z} \tag{7}
\]

where

\[
\beta_\beta = \frac{\partial}{\partial x_\alpha} \left( u_{\omega\alpha} u_{\omega\beta} - \bar{w}_w^2 \right) + \frac{\partial u_{\omega\beta} \bar{w}_w}{\partial z} - \frac{\partial}{\partial x_\alpha} \left( \nu_t \left( \frac{\partial \bar{V}_a}{\partial x_\beta} + \frac{\partial \bar{V}_\beta}{\partial x_\alpha} \right) \right) \tag{8}
\]

In this expression \( \bar{w}_w \) denotes the vertical short-wave velocity and \( \nu_t \) is the turbulent eddy viscosity.

Eq. (7) can be solved more easily if we split the depth-varying velocity into two parts

\[
\bar{V}_{1\beta} = \bar{V}_{1\beta}^{(0)} + \bar{V}_{1\beta}^{(1)} \tag{9}
\]

\(^1\)This definition is symbolically similar to Mei (1983), who uses a different definition of \( u_{\omega\alpha} \), however. He requires \( \int_{-h_o}^\zeta u_{\omega\alpha} \, dz = 0 \).
where the first part is primarily the (slowly time-varying) component generated by the local external forcing, which are the first five terms on the RHS of (7), while the second, smaller contribution is generated by the advective terms (the last three terms on the RHS) in (7). Hence, we can solve for $V_{1\beta}^{(0)}$, which represents the first approximation to the depth-varying part of the infragravity velocity profiles.

In the present paper we further assume a quasi steady-state. This means that we can solve the first part of (7) by integration twice over depth with two boundary conditions: a slip boundary condition at the bottom and a conservation of mass condition over the vertical. If we define

$$f_{\beta} = \beta_{\beta} - \frac{1}{\rho h} \frac{\partial}{\partial x_{\alpha}} \left( S_{\alpha \beta} - \int_{-h_{0}}^{\xi} \tau_{\alpha \beta} \, dz \right) + \frac{\tau_{S}^{\beta}}{\rho h}$$

the solution of (7) becomes

$$V_{1\beta}^{(0)} = \frac{f_{\beta}}{2 \nu_{t}} \xi^{2} + \frac{\tau_{S}^{\beta}}{\rho} \nu_{t} \xi - \left( \frac{f_{\beta}}{6 \nu_{t}} h^{2} + \frac{\tau_{S}^{\beta}}{6 \nu_{t}} h + \frac{Q_{w\beta}}{h} \right)$$

where the vertical coordinate $z$ has been transformed to a new coordinate $\xi$, under the transformation $\xi = z + h_{0}$, which means that $\xi = 0$ at the local bottom and $\xi = h = h_{0} + \tilde{\xi}$ at the mean surface elevation.

Putrevu & Svendsen (1997a,b) show that this expression is the first approximation to the time-dependent solution of (7). Hence, in the quasi-steady approximation the velocity profiles are quadratic and known so that the quasi 3-D coefficients (12) - (15) can be expressed in terms of the coefficients of the velocity profiles.

Following the derivation of Putrevu & Svendsen (1997) and Van Dongeren & Svendsen (1997a), which is omitted here for brevity, we can define the coefficients

$$D_{\alpha \gamma} \equiv \frac{1}{h} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} V_{1\alpha}^{(0)} V_{1\beta}^{(0)} (dz)^{3}$$

$$M_{\alpha \beta} \equiv \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} V_{1\alpha}^{(0)} V_{1\beta}^{(0)} (dz)^{3}$$

$$A_{\alpha \beta \gamma} \equiv - \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} V_{1\alpha}^{(0)} V_{1\beta}^{(0)} (dz)^{3}$$

and

$$B_{\alpha \beta} \equiv \frac{1}{h} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} V_{1\alpha}^{(0)} V_{1\beta}^{(0)} (h_{0} + z) (dz)^{3}$$

$$- \frac{1}{h} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} \int_{-h_{0}}^{\xi} \frac{1}{\nu_{t}} V_{1\alpha}^{(0)} V_{1\beta}^{(0)} (h_{0} + z) (dz)^{2}$$

(15)
These expressions appear when the solution for $V_{1a}^{(0)}$ is substituted into the depth-dependent integrals in the conservation of momentum equation (5), which, after some algebra, becomes

$$\frac{\partial \tilde{Q}_\beta}{\partial t} + \frac{\partial}{\partial x_\alpha} \left( \frac{\tilde{Q}_\alpha \tilde{Q}_\beta}{h} + M_{\alpha\beta} \right) - \frac{\partial}{\partial x_\alpha} \left[ h \left( D_{\beta\gamma} \frac{\partial \tilde{V}_\alpha}{\partial x_\gamma} + D_{\alpha\gamma} \frac{\partial \tilde{V}_\beta}{\partial x_\gamma} + B_{\alpha\beta} \frac{\partial \tilde{V}_\gamma}{\partial x_\gamma} \right) \right]$$

$$+ \frac{\partial}{\partial x_\alpha} \left[ A_{\alpha\beta} \tilde{V}_\gamma \right] = -gh \frac{\partial \xi}{\partial x_\beta} - \frac{1}{\rho} \frac{\partial}{\partial x_\alpha} \left( S_{\alpha\beta} - \int_{-h_0}^{\xi} \tau_{\alpha\beta} \, dz \right) + \frac{\tau_{\beta}^S - \tau_{\beta}^B}{\rho} \tag{16}$$

where an eddy viscosity closure for the turbulent shear stresses (e.g., Rodi, 1980) is used.

**NUMERICAL MODEL**

In the version of SHORECIRC used in this paper, eqs. (4) and (16) are solved using a central finite difference scheme on a fixed spatial grid with an explicit second-order Adams-Bashforth predictor and a third-order Adams-Moulton corrector time-stepping scheme. Additionally, the program evaluates (11) in order to calculate the quasi 3-D coefficients (12) - (15).

At the seaward boundary an absorbing-generating boundary condition which is capable of simultaneously generating and absorbing obliquely-incident long waves with a minimum of reflection is implemented, see Van Dongeren & Svendsen (1997b) for details.

At the shoreline, an inundation-drainage procedure, as described in Van Dongeren & Svendsen (1997a), is used which allows for time-varying run-up and run-down of the shortwave-averaged shoreline. At the lateral (shore-normal) boundaries a periodicity condition is used.

**QUASI 3-D EFFECTS IN LEAKY INFRAGRAVITY WAVES**

In this analysis the model is applied to the case of leaky infragravity waves forced by obliquely-incident wave groups. We will focus on the effect of the quasi 3-D coefficients defined in (12) - (15) and the corresponding quasi 3-D terms in the momentum equation (16).

In our investigation we will choose a very simple bathymetry consisting of a plane beach rising from an offshore shelf, see Fig. 1a for a definition sketch. On the offshore shelf we assume that the depth varies so gently that the waves stay in local equilibrium and that at the toe of the coastal slope the set-down wave corresponds to the equilibrium bound wave found by Longuet-Higgins & Stewart (1962, 1964). This avoids the difficulty encountered by e.g. Lippmann et al. (1997) in justifying the use of long wave theory in the deep water part of their plane slope. It also enables us to specify the conditions at the toe as a simple boundary condition for the inflow to the coastal slope. In the present study we limit the analysis to a plane coastal slope to facilitate a comparison to analytical results, but it should be emphasized that the model can be run on an arbitrary bottom topography.
The incident wave groups consist of two sinusoidal short wave components that have a slightly different frequency but have the same direction of propagation as a given depth.

Given this short-wave forcing, the radiation stress $S_{\alpha\beta}$ can be written as (generalizing from Schäffer (1994))

$$S_{\alpha\beta} = \rho g P_{\alpha\beta} \begin{cases} H_1^2 (1 + 2\delta \cos(2\vartheta)) \,, & h \geq h_b \\ \gamma^2 h_0^2 (1 + 2\delta (1 - \kappa) \cos(2\vartheta)) \,, & h \leq h_b \end{cases}$$

where $H_1$ is the height of the carrier wave and the wave height modulation $\delta = H_2/H_1$ is the ratio of the wave heights of the secondary wave to the primary wave in the group. In this formulation it is assumed that $\delta$ is small. $\kappa$ is the breaking parameter, as defined by Schäffer (1994). The breaking criterion is $H_1 = \gamma h_0$, $P_{\alpha\beta}$ is the nondimensional shape parameter for the short waves, and $\vartheta$ is the phase function defined following Schäffer (1994).

As these wave groups propagate towards shore at the group speed $c_g$, they refract towards the shore-normal direction whereby it is assumed that both short wave components refract in the same way and that they do not diverge. The incoming bound infragravity wave that propagates with the groups in the same direction will
also refract in. As the wave groups shoal onto the beach and the short waves are dissipated, this incoming IG wave is modified by the wave group transformation and is released. It will then reflect off the shore and propagate and refract seawards as a free long wave, see Fig. 1 for a definition sketch.

In the following case the input parameters are: shelf depth $h_s = 3$ m and mean short-wave frequency $\omega_s = 1.8 \text{s}^{-1}$, so that the wavenumber $k_s = 0.397 \text{m}^{-1}$. The wave height of the primary short wave on the shelf $H_{1,s} = 2a_{1,s} = 0.6$ m and the wave height modulation $\delta = 0.1$. The frequency modulation is chosen as $\epsilon = 0.1$. The breaking index is $\gamma = 0.75$, and we choose first to consider a fixed breakpoint $\kappa = 0$. The beach slope is chosen as $h_x = 1/20$. Finally, the angle of incidence on the shelf is chosen as $\theta_{i,s} = 22.37^\circ$ with the normal, which corresponds to an alongshore wave length of the infragravity wave of 150 meters. The angle of incidence is less than the limiting angle of incidence $\theta_{i,s}^{max} = 37.07^\circ$, so that the infragravity wave motion is "leaky," i.e., the outgoing long waves reach the shelf and are not trapped.

On the shelf we will assume an incoming equilibrium bound long wave (Longuet-Higgins & Stewart, 1962, 1964) which propagates in the direction of the wave groups. The longshore domain length is chosen equal to the longshore projection of the infragravity wave length.

Fig. 2 shows the normalized envelope of the IG wave as a function of the cross-shore coordinate $h_0/h_s$, where the origin is at the still water shoreline and unity is at the toe of the slope. The dash-dotted lines indicate linear solution by Schäffer & Svendsen (1988). The dashed lines indicate the envelope computed by the present model without the quasi 3-D terms. It can be seen that the nonlinear terms in the equations shift the (quasi) nodes shoreward and have some effect on the amplitude of the anti-nodes. The solid lines indicate the solution computed by the full quasi 3-D model. The quasi 3-D terms change the horizontal distribution of the IG wave amplitudes, especially around the breakpoint and in the surf zone. This will be analyzed in more detail below.

In order to calculate the quasi 3-D terms in the momentum equations, we have to determine the vertical variation of the infragravity wave particle velocities from (11). It is illustrative to use this numerical output and plot the IG particle velocity profiles at various locations and at various time-instances.

Fig. 3 shows the IG particle velocity profiles for three different locations ($h_0/h_s = 0.42, 0.17$ and $0.07$) and at five time intervals of the infragravity wave period. The motion is a result of the forcing by the obliquely-incident wave groups, and of the incoming IG wave and the obliquely-reflected IG wave. It is important to notice that the steady part of the short-wave forcing drives a steady longshore current and a steady undertow, which are both included in the figure, and that the time-varying part of the forcing cause a variation of the velocity profiles over an IG period, so in essence the infragravity wave motion is riding on top of a relatively strong current.

Since the breakpoint is located at $h_0/h_s = 0.3$, the location $h_0/h_s = 0.42$ is outside the surf zone. The IG wave velocity profiles at that location show a little
The details of the variation of the velocity profiles can better be seen in Fig. 4, which shows the projections of the profiles in the longshore and cross-shore direction. Fig. 4 (a) shows the cross-shore velocity (commonly called the “undertow”) normalized by the local long-wave celerity \( c_0 = \sqrt{gh_0} \) versus normalized depth at \( h_0/h_s = 0.42 \), which is located well outside the surf zone, for ten intervals per infragravity wave period. It can be seen that the profiles are slightly curved and also that the vertical gradient varies substantially with time. This is due to the (time-varying) forcing \( f_x \) in (11), which is a function of the radiation stress gradients, the pressure gradient and the gradients in the short-wave velocities.

Fig. 4 (b) shows the longshore velocity \( V \) at the same location. Due to the relatively small angle of incidence of the short-wave groups, the forcing induced by the short waves in the \( y \) direction is also small. This leads to the profiles with only a slight curvature. The profiles exhibit a non-zero mean over depth due to the momentum that has advected out of the surf zone mostly due to the dispersive mixing (Svendsen & Putrevu, 1994).

The cross-shore profiles in Figs. 4 (c) and (e) exhibit the typical characteristic time-
varying undertow profile in the surf zone that was previously shown by Putrevu & Svendsen (1995). The longshore profiles in Figs. 4 (d) and (f) are slightly more tilted than the longshore current profile in Fig. 4 (b) because inside the surf zone a strong mean forcing is present due to the difference between the radiation stress gradient and the pressure gradient. The time variation of the longshore profiles is not very large because the short-wave groups have refracted to near normal incidence inside the surf zone.

The relative magnitude of the quasi 3-D coefficients can be calculated directly from the model results using the definitions (12) - (15). For brevity we will only present the results for the coefficients $B_{\alpha\beta}$ and $D_{\alpha\beta}$.

Fig. 5 shows the variation of the $B_{\alpha\beta}$ and $D_{\alpha\beta}$ coefficients versus the cross-shore coordinate for five time intervals of the infragravity wave period. In the figures $h_0/h_s = 0$ corresponds to the still water shoreline and $h_0/h_s = 1$ to the toe of the beach.

We see that the $B$ and $D$ coefficients exhibit a quite large variation over an IG wave period, which indicates that the local time-varying forcing is very important. It can also be seen that the magnitude of all coefficients is significantly larger than the magnitudes which would have been found for the case of no groupiness ($\delta = 0$), which is indicated by the thick solid line. The values increase significantly across the breakpoint, since the “undertow” profiles become much more curved inside the surf zone due to the increased forcing. Because of the simple short-wave modeling, this transition in curvature occurs very rapidly, which increases the cross-shore gradients of the quasi 3-D coefficients.
Figure 4: IG wave particle velocities in the cross-shore and longshore direction normalized by the longwave celerity $c_0$ vs. normalized depth for ten intervals per IG wave period: (a) Cross-shore velocity $U$ at $h_0/h_s = 0.42$. (b) Longshore velocity $V$ at $h_0/h_s = 0.42$. (c) $U$ at $h_0/h_s = 0.17$. (d) $V$ at $h_0/h_s = 0.17$. (e) $U$ at $h_0/h_s = 0.07$. (f) $V$ at $h_0/h_s = 0.07$.

We see that the $D_{xx}$ and $B_{xx}$ coefficients are larger than the $D_{xy}$ and $B_{xy}$ coefficients, which are in turn larger than the $D_{yy}$ and $B_{yy}$ coefficients. This is because the short-wave groups refract towards the shorenormal, which means the forcing $f_x$ in (11) becomes dominant over the forcing in the longshore direction. Eq. (11) also implies that the cross-shore velocities are more curved than the longshore velocities which could already be seen in Fig. 4. This curvature of the velocity profiles directly influences the magnitude of the dispersive coefficients.

An assessment of the quasi-3D effects is obtained by looking at the magnitude of the terms in the momentum equations in which these quasi 3-D coefficients appear. The analysis is performed at an arbitrary time after the periodic state of the IG waves has been reached and is strictly speaking only valid for this particular time. However, the magnitude of the terms in the equations at this time instance are
Figure 5: Magnitude of $B$ and $D$ coefficients vs. cross-shore distance $h_0/h_s$ for five intervals per IG wave period: (a) $B_{xx}$. (b) $D_{xx}$. (c) $B_{xy}$. (d) $D_{xy}$. (e) $B_{yy}$. (f) $D_{yy}$. The stillwater shoreline is located at $h_0/h_s = 0$ and the breakpoint at $h_0/h_s = 0.3$. Also shown as the thick solid line is the magnitude of the terms for the case of no groupiness $\delta = 0$. The conclusions that are drawn from this analysis are therefore considered representative for the case in question.

For reasons of clarity Fig. 6 only shows the most important terms in the equations. We first analyze the terms in the $x$ momentum equation (16) versus $h_0/h_s$, see Fig. 6 (a). The terms shown are the pressure gradient, the radiation stress gradient $\frac{\partial S_{zz}}{\partial x}$, and the local acceleration. Of the quasi 3-D terms, the $\frac{\partial M_{xx}}{\partial x}$ term is large only locally at the breakpoint. This is due to the choice of $\kappa = 0$, which causes the cross-shore velocity profiles to undergo a rapid change over a short distance around the break point. (Notice that $M_{xx}$ is equivalent to the momentum correction factor in hydraulics.) The term is positive, which leads to a negative pressure gradient in
Figure 6: Magnitude of significant terms in the momentum equations vs. cross-shore distance \( h_0/h_s \): (a) \( x \)-momentum equation: pressure gradient (solid), radiation stress gradient \( \partial S_{xx}/\partial x \) (dashed), local acceleration (dash-dotted) and \( \partial M_{xx}/\partial x \) (stars). (b) \( y \)-momentum equation: pressure gradient (solid), radiation stress gradient \( \partial S_{xy}/\partial x \) (dashed), local acceleration (dash-dotted) and \( \partial M_{xy}/\partial x \) (stars). (c) \( j \)-momentum equation: advective acceleration \( \frac{\partial}{\partial x} \left( Q_x \frac{Q_x}{h} \right) \) (solid), \( \partial S_{yy}/\partial y \) (dashed), \( -\frac{\partial}{\partial x} \left( h D_{xx} \frac{\partial \tilde{v}}{\partial x} \right) \) (dash-dotted) and bottom friction (stars). The stillwater shoreline is located at \( h_0/h_s = 0 \) and the breakpoint at \( h_0/h_s = 0.3 \).
The balance. In the inner surf zone, this term is found comparable to other terms, and is negative, which causes an increase in the pressure gradient and explains the difference between the envelopes of Fig. 2. In general, however, the dispersive mixing terms are of minor importance in the cross-shore momentum balance.

The dominating terms in the y-component of (16) are shown in Fig. 6 (b) and (c). Those terms are the local acceleration, the pressure gradient, the radiation shear stresses $\frac{\partial S_{yz}}{\partial x}$ and $\frac{\partial S_{zy}}{\partial y}$, the advection term $\frac{\partial}{\partial x} \left( \frac{Q_x Q_y}{h} \right)$, and the bottom friction. However, we also see that two Q3D terms, $\frac{\partial M_{yx}}{\partial x}$ and $\frac{\partial}{\partial x} \left( h D_{yx} \frac{\partial V}{\partial x} \right)$ are important. The first term is significant around the breakpoint for the same reason that the $\frac{\partial M_{yx}}{\partial x}$ was in the x momentum equation. The second term is of the same order of magnitude as the 2-DH terms inside the surf zone and is the same that was found to be in the dispersion of momentum in the case of a steady longshore current (Svendsen & Putrevu, 1994). In this case where the shear in the longshore current is also large, this term is again important.

CONCLUSIONS

A numerical study of the forcing of leaky infragravity waves by obliquely-incident wave groups is performed using the SHORECIRC model which incorporates all quasi 3-D terms. It is shown that some of these terms have a significant effect on the envelope of the infragravity waves. The magnitude of the quasi 3-D terms is analyzed and compared to the size of the terms which are retained in conventional nonlinear shallow water models. This shows that the quasi 3-D terms have a significant size around the break point and in the surf zone. The velocity profiles of the infragravity waves inside the surf zone exhibit a large curvature and time variation in the cross-shore direction, and a small - but essential - depth variation in the longshore direction. Outside the surfzone the velocities in the longshore direction are small, while in the cross-shore direction only the upper part of the profile is curved.

Numerical Modeling of Long Wave Ship Motions

John R. Headland, P.E.1, Ying-Keung Poon, P.E.2

Abstract

This paper presents a state-of-the-art numerical model for ship motion analyses along with an application of the model to a seiche problem in the Port of Long Beach, California. The practical uses of the model are emphasized along with a discussion of the efficacy of the modeling approach as a tool for decision-making.

Introduction

The tolerance for delays or inefficient cargo transfer at modern marine terminals due to environmental conditions (i.e., wind, waves or currents) is very low. Competition among shipping lines (and competition among the ports who desire to have the same shipping lines as tenants) demands marine terminals with uninterrupted service. Accordingly, the problem of excessive ship motions has been of particular concern in the development of new marine terminals. Additionally, recent trends in container ship design and terminal development has sparked renewed interest in ship motion problems. Specific developments include: (1) terminals located in areas exposed to harsher environmental conditions; (2) container ships that are larger but do not use commensurately stronger mooring/fender arrangements; and (3) a desire for higher loading/unloading rates which require little or no vessel movement.

The following paragraphs describe a methodology that can be used to simulate the motions of a moored vessel exposed to long waves. The hybrid approach combines the best features of physical and numerical modeling technology. This paper is one in a series on Los Angeles and Long Beach Harbor. The companion papers focus on other aspects of long wave behavior in the Ports (Lee et al, 1998, Poon et al, 1998, Raichlen et al 1998 and Walker et al 1998). Figure 1 shows the overall port complex. The specific application concerns ship motion experienced at the Pier J

terminal located in the Port of Long Beach. This terminal is presented in Figure 2 and shows protective breakwaters that were constructed to reduce ship motions.

**Modeling Approach**

Overall, the problem to be addressed is that of a moored vessel located in a geometrically complicated harbor exposed to long waves or seiche. From a practical point of view, the modeling approach is normally used to evaluate various design elements (for a new facility) or corrective actions (for an existing facility) that will reduce ship motions to an acceptable minimum.

Physical models have historically served as the most reliable means for assessing wave-induced ship motion problems. In recent years, however, numerical modeling technology has advanced to the point where reliable estimates can be made for relatively short waves (i.e. waves less than 25 seconds) in open water using time domain ship motion models. The predictive fidelity of these numerical models has generally been confirmed through comparisons with physical model tests. In most cases, these comparisons have been made for open water conditions or for conditions with a solid quaywall, i.e., the vessel is exposed directly to waves from the open sea.

In most harbor applications, vessels are moored within protected basins where they are exposed to waves, which have been diffracted through a harbor basin entrance or reflected from the walls of the basin, or both. The complications associated with diffracted/reflected waves make it difficult to apply typical mooring dynamics models without considerable approximation and this is why physical models are often used to confirm the results of mooring models for final design.

Physical models have been used successfully to examine both harbor disturbance and ship motion problems. Distorted physical models are generally required for large harbors and can be used to examine harbor resonance. Unfortunately, distorted physical models cannot be used to examine ship motion problems due to difficulties associated with achieving similitude.

Numerical models can be used to examine both harbor disturbance and ship motion problems. In practice, application of numerical models for short waves is problematic due to requirements for relatively small element sizes which can result in an unwieldy computational effort. Inasmuch as moored ships tend to respond at both short periods (< 25 seconds) and relatively long periods (> 1 minute) any modeling approach must be capable of simulating the full range of wave periods.
Figure 1. Ports of Los Angeles and Long Beach, California

Figure 2. Pier J in the Port of Long Beach
The hybrid approach presented in the present paper involves the combined use of physical and numerical models. A complete description of the physical model used to evaluate long wave problems in the Port of Los Angeles and Long Beach is described in Poon, et al (1998). It suffices to say here that the physical model encompasses the entire harbor complex and was used to evaluate wave amplification factors at various locations throughout the harbor including Pier J. Wave amplification factors derived from the physical model results were used to establish boundary conditions for a local numerical model in the vicinity of Pier J. Additionally, results from the physical model were also used to calibrate amplification factors at interior points in the numerical model mesh. While the physical model results were useful in calibrating the numerical model as regards harbor oscillations, the physical model was of no use in calibrating the mooring model. Reference to Poon, et al (1998) will show that the physical model was used to identify the preferred solution for the Pier J situation. Specifically, the preferred solution was to construct new breakwaters at the entrance to the Pier J basin, see Figure 3. The remainder of this paper focuses on the numerical model and model results regarding the ability of the proposed breakwaters to reduce ship motions.

Ship Motion Simulation Models

A moored ship responds to wave excitation in six degrees of freedom: three translational motions - surge, sway, and heave; and three rotational motions - roll, pitch, and yaw. An illustration of these motions is shown in Figure 3. The motion response of a container ship at berth is normally dominated by surge motion.

![Image of ship motion in six degrees of freedom](image)

Figure 3  Definition Sketch of Ship Motion in Six Degrees of Freedom

Ship motion analyses were calculated with two numerical models - HYDRO and TDBERTH. HYDRO applies the finite element method (FEM) to solve the wave-ship-berth interaction, treating the oscillating system of a berthed ship in a harbor as a fully three-dimensional system. Overall, the analysis consists of two successive steps. The HYDRO model calculates harbor basin response, the ship hydrodynamic coefficients (i.e. added mass and damping coefficients) and the first and second order wave forces in the time domain. HYDRO models the hydrodynamics of the ship and the harbor basin simultaneously. This feature of the HYDRO model is critical for long wave problems where interactions occur between the incident long waves, the harbor basin and the moored vessel. TDBERTH computes ship motions in the time domain using results from
the HYDRO model. Specifically, TDBERTH solves for ship motions, mooring line forces, and fender reactions.

**HYDRO Model**

The HYDRO model solves the wave/harbor/ship interaction problem in terms of potential flow theory. The six modes of ship motion are expressed as:

\[ x_j = x_{aj} e^{i\omega t}, \quad j=1,2,...,6 \]

where \( x_j \) is a displacement for \( j = 1,2,3 \) and a rotation for \( j=4,5,6 \) and \( x_{aj} \) is the corresponding complex amplitude, \( t \) is the time, and \( \omega \) is the radian wave frequency.

The total velocity potential describing the flow field is written as:

\[
\Phi = \phi_0 e^{-i\omega t} + \sum_{j=1}^{6} \phi_j x_{aj} e^{-i\omega t} + \phi_f e^{-i\omega t} + \phi_s e^{-i\omega t}
\]

where \( \phi_0 \) = potential of the incident wave

\( \phi_f \) = potential of the waves generated by the ship motion

\( \phi_s \) = potential of the scattered waves

Each of these velocity potentials also has to satisfy the Laplace Equation, i.e.

\[ \nabla^2 \phi_j = 0, \quad j = 0,1,...,7 \]

The HYDRO model employs the finite element method to solve the above equations together with the appropriate boundary conditions.

After the velocity potential has been determined, the wave loading on the ship and the hydrodynamic coefficients can be calculated by using the pressure equation. The fluid pressure at any point in the fluid domain can be obtained from the linearized Bernoulli equation:

\[ p = -\rho \frac{\partial \Phi}{\partial t} - \rho g z \]

where \( \rho \) is the fluid density, \( g \) the acceleration due to gravity and \( z \) the depth below water surface.

The total force, \( F_i \), acting on the ship can then be obtained by integrating the pressure over the surface of the ship. Applying Newton's second law of motion, the pressure
equation and the solution of the velocity potentials, the equations of motion of the ship in
matrix form can be written as:

\[ m_{ij} x_j + K_{ij} x_j = \zeta e^{-jwt} + f_{ij} x_j e^{-jwt} \]

where \( m_{ij} \) = six-by-six mass matrix of the ship
\( K_{ij} \) = hydrostatic restoring force (moment) matrix
\( x_j \) = motion vector
\( f_{ij} \) = wave exciting forces and moments per unit wave
\( f_i \) = forces and moments per unit ship motion
\( \zeta \) = wave amplitude

The added mass and damping coefficients can be found upon separation of the Real and
Imaginary parts of the above equation.

In addition to the first order wave forces, a ship is also subjected to second-order
mean and low frequency wave drift forces. These forces are partially attributable to
the velocity-square terms in the Bernoulli's equation, partially attributable to the
elevation variation of the water surface and partially attributable to first-order ship
motions. HYDRO computes these forces based on the perturbation method
developed by Pinkster and Van Oortmerssen (1977).

**TDBERTH Model**

Vessel motions and mooring line/fender forces were computed using a six-degree of
freedom numerical model TDBERTH. TDBERTH integrates the equations of motion in
the time domain by standard numerical methods. The model formulation is similar to that
developed by Van Oortmerssen (1975).

The governing equations of motion, which account for motion in six degrees of freedom,
are as follows:

\[ \sum_{j=1}^{6} [(M_{kj} + m_{kj}) \ddot{x}_j + \int_{-\infty}^{t} K_{kj}(t-\tau) \dot{x}_j(\tau) d\tau + b_{kj} \dot{x}_j + C_{kj} x_j] = F_{ew}(t) + \sum_{i=1}^{n} L_{ik}(t) + \sum_{i=1}^{n} N_{ik}(t) \]

\( k=1,2,\ldots6 \)

Where:
\( x_j, \dot{x}_j, \ddot{x}_j \) = displacement, velocity, and acceleration in the \( j \)-th mode
\( M_{kj} \) = inertia matrix
\( C_{kj} \) = hydrostatic restoring force matrix
\( K_{kj} \) = impulse response function matrix
\( m_{kj} \) = constant added mass matrix

\( F_{kw}(t) \) = wave exciting force in kth mode
\( L_{ik}(t) \) = mooring line force in kth mode from line i
\( N_{ik}(t) \) = fender force in kth mode from fender i

\( k \) = denotes mode of motion, (i.e. 1 (surge),
2 (sway), 3 (heave), 4 (roll), 5 (pitch), 6 (yaw))
\( n_i \) = number of mooring lines
\( n_f \) = number of fenders

The inertia matrix, \( M_{kj} \), and hydrostatic restoring force matrix, \( C_{kj} \), are computed using standard methods of naval architecture. The impulse-response function matrix, \( K_{kj} \), and the constant added mass coefficient, \( m_{kj} \), are computed as follows:

\[
K_{kj} = \frac{2}{\pi} \int_0^\infty b_{kj}(\omega) \cos \omega t d\omega
\]

\[
m_{kj} = a_{kj}(\omega^*) + \frac{1}{\omega} \int_0^\infty K_{kj}(t) \sin \omega^* t d\tau
\]

Where:

\( a_{kj} \) = frequency-dependent added mass
\( b_{kj} \) = frequency-dependent damping coefficient

The above frequency dependent hydrodynamic coefficients were computed using the HYDRO model.

The wave exciting force, \( F_{kw}(t) \), is computed as follows:

\[
F_{kw}(t) = \sum_{n=0}^N f_k^{(1)}(\omega_n) a_n \cos(\omega_n t + \varepsilon_n + \varepsilon_k)
\]

\[
+ \sum_{n=0}^N \sum_{m=0}^m f_k^{(2)}(\omega_n a_n a_m \cos((\omega_n t + \varepsilon_n) - (\omega_m t + \varepsilon_m))
\]
Where:

\[ f_k^{(1)}(\omega_n) = \text{first order wave transfer function in} \]
\[ k\text{-th mode for } n\text{-th wave component} \]
\[ f_k^{(2)}(\omega_n) = \text{second order wave transfer function in} \]
\[ k\text{-th mode for } n\text{-th wave component} \]
\[ \varepsilon_k = \text{phase of first order wave transfer function} \]
\[ \text{in } k\text{-th mode for } n\text{-th wave component} \]
\[ a_n = \text{wave amplitude of } n\text{-th wave component} \]
\[ \varepsilon_n = \text{phase of } n\text{-th wave component} \]
\[ \omega_n = \text{frequency of } n\text{-th wave component} \]

The first and second order wave transfer functions were computed using the HYDRO code. The above formula was used to simulate first and second order wave force time-histories resulting from an incident wave spectrum composed of \( n \)-waves having amplitudes \( a_n \) and frequencies \( \omega_n \).

**Simulation Conditions**

Several container ships were examined and the characteristics of each are shown in Table 1. The mooring configuration used for each simulation is shown in Figure 4 and consists of 10 lines and 17 fenders. Two mooring configurations were examined, namely: (1) conventional nylon lines and (2) mixture of nylon and steel lines. The lines were assumed to be 20 cm (8 inch) in circumference with a breaking strength of 832 kN (187 kips). The fender spacing was assumed to be 15.2 m (50 ft). Both the lines and fenders had non-linear load-deflection curves.

* Length-Between-Perpendiculars
Figure 4. Mooring Geometry

Figure 5. Finite Element Mesh
The container ship was moored at either the eastern or western berth of the nearly rectangular harbor (366 m by 975 m) with uniform water depth of 15.2 m (50 ft). The finite element grid used for numerical modeling is shown in Figure 5. The grid consisted mainly of a two-dimensional (2D) region with an embedded three-dimensional (3D) region (hatched area) to properly schematize the modeled ship. The 3D grid consisted of five layers, with the top three layers constructed to fit the ship, and two bottom layers representing the water between the ship and the basin floor.

The wave condition at the harbor basin entrance was chosen such that there were substantial surge motions under base conditions. The wave spectrum at the harbor entrance has the same spectral shape as the average spectrum measured by the US Army Corp of Engineers (1993) at Platform Edith, the latter is located about eight miles south of the Ports of Los Angeles and Long Beach.

**Simulation Results**

Ship motion response for each mooring/fender configuration was computed in the time domain with the TDBERTH model for a two-hour simulation period. Example time series of motions, line forces and fender forces are shown in Figures 6, 7 and 8. The above figures show the moored container ship response to be a mixture of 1st order and 2nd order wave responses at low frequency. Overall, the vessel response in surge is dominated by motions having periods near the natural period of the moored ship system (i.e., about 1.5-2 minutes). Results of the simulations are presented in Table 3 in terms of normalized peak-to-peak surge motions for a representative wave condition.

Figure 6. Motion Time Histories

Figure 7. Mooring Line Time Histories
Table 3 shows that the breakwater will substantially reduce surge motions for most of the simulations. For example, the existing surge motions are reduced to 51% of existing conditions with the breakwater for a vessel moored at the western end of the basin using all synthetic lines. Interestingly, the motions are not significantly reduced for a vessel moored by a combination of synthetic and steel lines at the western berth. The above results show that the proposed breakwaters would significantly reduce problematic vessel motions for conventional moorings at either berth. The results also show that it is important to consider both the mooring configuration and the location of the vessel within the harbor.

Summary

A methodology for examining ship motions excited by long waves has been presented. The hybrid approach combines the strengths of physical and numerical modeling. Physical model results are used to define boundary conditions for, and calibration of, the numerical model. The numerical model described in this paper provides a powerful and flexible means for examining complicated mooring problems. The model was recently used to examine the efficacy of constructing breakwaters to reduce ship motions at a berth in Long Beach Harbor, California. The model showed the proposed breakwaters would significantly reduce vessel
motions under most conditions. The breakwaters were constructed and preliminary experience indicates that the breakwaters have been successful.

The state-of-the-art in modeling of ship motions is mathematically advanced, however, additional model testing and field data collection efforts are necessary to gain as much confidence in ship/basin models as there presently exists in open sea models. A systematic series of physical model tests involving a vessel moored in simple basin geometries is recommended to advance the currently available modeling technologies.

RESPONSE OF MOORED VESSELS IN BUFFINGTON HARBOUR

E.P.D. Mansard¹, T. Faure¹ and K. MacIntosh²

ABSTRACT

In a temporary facility built within Buffington Harbour, it was proposed to operate two floating vessels as casinos. An extensive program of physical and numerical model investigations was undertaken to design a harbour and mooring layout that would ensure effective operation with minimal downtime for casino operations. Through a sophisticated model testing program, the motions of the floating vessels were established for different sea states. These motions were then used as inputs to a ship simulator where client representatives participated in the full scale simulations in order to select the sea states that would cause discomfort to clients.

INTRODUCTION

Lehigh Portland Cement Company is the owner of Buffington Harbour facilities in East Chicago. Barden Developments and Trump Indiana proposed to operate two floating casino vessels in a recently constructed temporary harbour facility built within the existing Buffington Harbour. The facility is now complete and the two vessels are in place. Figure 1 shows an overall view of the harbour and the casino ships.

The two vessels are moored on either side of a floating barge/passenger loading dock, which services both vessels. The vessels leave the harbour and enter Lake Michigan whenever weather conditions permit, otherwise operations continue while moored. Being a temporary facility intended for several years’ use only, it was important to keep costs down, while providing protection from waves to enable operation under most environmental conditions. This includes entry/exit to the harbour.

Baird & Associates was retained by Lehigh Portland Cement Company to develop preliminary and final designs for marine structures required to protect the vessels, and also to carry out tasks such as permitting, preparation of contract documentation,

¹ Canadian Hydraulics Centre, National Research Council of Canada, Ottawa, ON K1A 0R6 Canada
² W.F. Baird & Associates Ltd., 1145 Hunt Club Rd., Suite 1, Ottawa, ON K1V 0Y3 Canada
contractor negotiations and construction supervision. Analysis of environmental parameters (wave climate and water levels), physical and numerical model investigations of harbour wave agitation and response of the vessels, were parts of this study (Baird & Associates, 1996).

The Canadian Hydraulics Centre of the National Research Council of Canada was contracted by Baird & Associates to undertake physical model investigations to determine vessel motions and related mooring line loads for a variety of lake and harbour wave conditions. This information was required to establish downtime during which casino operations should be suspended due to excessive vessel motions.

PHYSICAL MODEL INVESTIGATIONS

Figure 2 shows a photograph of the two model casino vessels and the loading barge under study, while Figure 3 presents the layout of the harbour basin that was tested in the physical model. The model scale used for this study is 1:45.

This harbour layout, considered optimal, was established through a wave agitation study carried out earlier by Baird & Associates. Six different harbour concepts were studied under different combinations of wave heights and directions. This final harbour concept, with the proposed structures for casino operations, was tested as part of the ship mooring study, by measuring directly the response of the vessels induced by wave heights prevailing inside the test basin.

It should also be pointed out that physical model tests were carried out to assess the stability of the breakwater materials (armour, filter and core stone) on the north rubble mound structure. The potential impact of a storm during construction was also determined in a separate series of tests where the breakwater was constructed to varying degrees of completion and then subjected to a storm event. As a result of this work it was recommended that a 100 ft long revetment section, which extends along the west breakwall to the north of the north rubble-mound structure, be constructed (see Figure 3).

VESSEL CHARACTERISTICS

All three vessels, Trump Princess, Barden I and the barge were built at a 1:45 scale. Care was taken to reproduce as accurately as possible the salient characteristics of the vessels, including their hydrostatic conditions. Given below are some of the main characteristics of the vessels:

Figure 3: Proposed Layouts of the Harbour and the Breakwater

WAVE CLIMATE

A wave machine located outside the model harbour generated the waves in the harbour. The drive signals to this wave generator, were already available from the initial phase of this study when the optimization of the harbour was investigated. To create these driving signals, irregular wave time series, having a record length of 20 minutes prototype, were synthesized from a spectrum using the random phase spectrum method.

An array of three gauges was deployed near the offshore region to monitor the water surface elevations and to resolve the incident and reflected wave fields from them. The range of wave heights ($H_{m0}$) and peak period ($T_p$) used during the testing program is shown in Table 1.
Table 1: Incident Wave Characteristics during the Ship Mooring Tests

The waves were run from two different directions: 41 degrees East of North and 56 degrees East of North. The water level was varied from 4.7 ft to 6.4 ft (with reference to low water datum) in order to reflect the range in design water levels expected for this temporary harbour. Some additional tests were also carried out using sea states $H_{\text{m0}} = 8$ and 10 ft, with $T_p = 8s$.

MOORING

Mooring Line Simulation

Figures 4 and 5 show the layout of the mooring lines, with the locations of the bollards on the barge, the end piers and both ships. From these locations, a line length was derived for each mooring, to which 4 to 6 feet was added in order to include the distance between the fairlead and the bollards onboard the ship.

All lines were made of 2 5/8 inch diameter double braid polyester assumed to have a constant unit stiffness $EA = 2.353 \times 10^3$ kips per foot of elongation per unit length, over the expected range of tensions. The bow and stern moorings were made of three lines in parallel, whereas the spring lines were only single lines. The net stiffness of each mooring was $(n \times EA)/L$, where $n$ is the number of lines per mooring.

A thin steel cable attached to a set of springs simulated the elasticity of each mooring line. The springs were pre-calibrated to the desired load/elongation characteristics of the lines. Each line was also connected to a load cell to monitor the instantaneous loads. The hardware was designed in such a way that variable levels of pre-tension can easily be set in the mooring system (see Figure 6).

Static Verification of the Mooring Line Simulation

In order to verify that the mooring line simulation and the load cells gave the appropriate results, a simple static experiment was performed. A known force was applied horizontally at mid ship of the Trump Princess, pulling the ship away from the barge. At
Figure 4: Buffington Harbour Moorings – Plan View

Figure 5: Buffington Harbour Moorings – End View
the same time the two spring lines were disconnected to ensure that only the two port bow and stern lines were under tension. These line tensions were sampled and analyzed by the same software used during the project. Table 2 shows the theoretical tensions required to balance the system based on the geometry of the moorings, and the measured values.

Table 4. Mooring Tensions During Static Tests

The difference between the theoretical and the measured values shows the effect of the line friction when it goes around the fairleads. This test was a static test. It is expected that during dynamic simulations, these differences would be smaller since a dynamic friction coefficient is usually smaller than a static one.

Fenders
For the Trump Princess, three fenders were installed on the barge at the 7-ft elevation (above Low Water Datum). They consisted of a piston and a linear spring inside a cylinder bolted to the barge deck. The spring stiffness corresponded approximately to 130
kips/ft. The contact surface between the ship and the fender (the plastic head of the piston) was very small.

For the Barden I, two fenders were installed to simulate Yokohama fenders as proposed by naval architects. They consisted of a circular pipe simulating round fenders 8.8 ft in diameter and 11.8 ft long, floating on the water surface and free to move, but within limits. These pipes could be considered as having no elasticity in compression.

**INSTRUMENTATION**

Two different types of instrumentation were used to measure the six degrees of freedom of motion on the vessels: Qualisys and accelerometers.

**Qualisys**

During the harbour tests, one of the ship models was instrumented with the Qualisys position system. This optical tracking system was used to measure the vessel position in six degrees of freedom. Its principle of operation is as follows: A light beam is sent from two fixed cameras which reflect from an array of eight reflective markers mounted on the vessel. The reflected light is captured by the cameras and processed by a computer/video system, which calculates the exact position of each reflected light beam every millisecond. Software is then used to convert the light positions into x, y, and z positions for the vessel. This results in a very accurate measurement of surge, heave and sway of the vessel within ±0.5 mm (±1 inch prototype) and roll, pitch and yaw angles within ±0.1 degrees. Note that the low frequency motions of the vessels can be measured accurately by this system.

The marker array is surveyed to locate the relative position of each marker and the array position relative to the vessel. To provide synchronization with the mooring forces data, a vertical heave accelerometer was installed on each vessel. It also provides a cross-check with the heave motion measured by the Qualisys system. To obtain the motions of the second ship, each test was repeated with the Qualisys system installed on the other ship. Care was taken to ensure that the repeated tests provided similar estimates of mooring line loads.

**Accelerometers**

The six degrees of freedom motions of the vessels can also be measured by an array of seven accelerometers. These units are precision linear servo accelerometers that are specifically designed for high accuracy applications at frequencies from 0 to 100 Hz. The QA-900 servo electronics generates a current that maintains a seismic element in a position-captured mode. The current required to keep the sensor mass stationary is thus proportional to the applied acceleration. These sensors have a measurement range of ±1 g, a resolution of 5 μg and a maximum linearity error of 30 μg.

To obtain the displacements from the accelerations, an iterative analysis procedure was used to solve the full nonlinear differential equations that relate the various rigid body
displacement motions to the local accelerations measured at the seven discrete points. This iterative procedure employs a technique based on the Fast Fourier Transform (FFT).

The analysis method has been validated by comparing tests undertaken with a precision optical tracking system as described in Miles (1986). Within its valid frequency range, it can measure ship model motions with a typical accuracy of ± 1mm in surge, sway and heave and ±0.1 degree in roll, pitch and yaw. This instrumentation was used to measure the pitch and roll motions of the barge. Small plastic screws inside fixed aluminum brackets at the bow and stern restrained the barge. This provided freedom in heave, pitch and roll but prevented any significant surge, sway or yaw motion.

The barge was also equipped with a light vertical line running over a pulley to a small weight so that heave displacement at the midship point on the centerline could be measured directly. This was done by using a calibrated potentiometer that measured the angle of rotation of the pulley, which was linearly proportional to the heave displacement of the barge at the centre point.

TEST REPEATABILITY

Since the Qualisys system can measure the motions of only one vessel at a time, the tests were repeated in order to measure the motions of both the vessels (Trump Princess and Barden I) under each wave condition. Therefore it was essential that similar results were obtained when the tests were repeated. There were also two other issues: potential resonance build-up inside the harbour basin, and inadequacy of sampling rate. Additional sensitivity tests were therefore undertaken in order to address these two issues as well. These tests are described below.

Same Test

All tests were repeated at least once to be able to measure the motion of both ships with the same Qualisys system. In both instances, the mooring line tensions were measured, allowing a direct comparison. The cumulative distribution of the peak tensions calculated from these results indicated good repeatability. The small differences that were found could be attributed to the friction forces from the fenders against the ships and from the lines passing through the fairlead.

Wave Build-up in the Model

In order to ensure that there is no wave build-up in the model due to possible basin resonance, some tests were run for 40 minutes full scale instead of 20 minutes. The first 20 minutes and the next 20 minutes were analyzed separately. No differences in peak tension were found, implying that there is no wave build-up in the basin.

Effect of Data Sampling Rate

All channels were sampled by the data acquisition system at a rate of 20Hz. Additional tests were also undertaken at a higher sampling rate of 100 Hz to determine whether or not all peaks in the mooring tensions were measured properly or if there were other high
frequency phenomena. Once again the cumulative distribution of the peaks were examined. They were similar, implying that the 20 Hz sampling rate was sufficient.

**TEST RESULTS**

**Mooring Line and Fender Loads**
The mooring lines and fenders were modelled for all three vessels with each one requiring a unique setup to match the proposed prototype configuration. These tests included pretensioning the lines, modelling line elasticity, and fender stiffness. Mooring tensions were measured for each mooring line of both the Trump and Barden vessels (see an example of a graphical output of these measured tensions in Figure 7).

---

**Figure 7: Example Output of Barden I Mooring Line Tensions**
From the time series of the mooring line tensions, the peaks (defined as the maximum occurring between two average values) were identified and statistically analyzed. These time series and also some basic statistics of the line tensions associated with each mooring line (pretension, maximum, minimum, standard deviation, and 98 percentile loading level) were summarized for each test conducted as shown in Figure 7. Note that the maximum scale in the Y-axis corresponds to the estimated breaking strength of the lines.

**Motions**
The six degrees of freedom motions of the two vessels derived from the Qualisys system corresponded to the motions at the centre of gravity of each vessel. By additional calculations, the motions and accelerations corresponding to the gaming room locations could easily be estimated. The summary results were then presented in terms of the significant amplitude for each degree of freedom. It is equal to twice the standard deviation of the motion, and is analogous to the concept of significant wave height (which is equal to four times the standard deviation). Figure 8 shows the increase in significant amplitudes of the various motions with the wave height, for Barden I.

The passengers will board the vessels from gangways located on the barge. To obtain the motions of the gangways, the relative motions between the vessels and the barge were also calculated.

![Figure 8: Six Degrees of Freedom Motions of Barden I](image-url)
PASSENGER COMFORT

Determining the frequency of occurrence of ship motions, which exceed acceptable motions for client comfort, was a very important task in the design of the entire harbour facility. For this purpose, the motions and accelerations at various positions on both the gaming and loading barge vessels were computed in order to provide inputs to a full-scale ship simulator. The full scale simulator was utilized by representatives of both the Trump Princess and Barden as well as the naval architects, coastal engineers, and a human resources consultant, at the Marine Institute in St. John’s, Newfoundland. During these tests, a series of gradually increasing motion and acceleration data sets were used to drive the simulator. The participants were inside the simulator room, but were not provided with external visuals (equivalent to casino without windows). The majority of the simulations were conducted for the most aft outside gaming position on the third level of the Trump vessel as this represents the most active part of the vessel during a storm condition. Other areas tested included more central gaming areas such as the first deck towards the centre of the vessel. These areas were tested to determine whether or not it would be feasible to continue gaming in some areas of the vessel should motions become excessive in the most active areas.

These tests, in combination with the motion and mooring line tension data sets and naval architects’ input, resulted in a decision by the Trump and Barden representatives to limit gaming operations after wave exceed a significant wave height of 6 feet, and a peak wave period of 8 s or higher, offshore of Buffington harbour. Wave height levels of 6 feet (with peak periods less than 8s) or lower were considered acceptable for gaming at any position on the vessel. The surge motion was the most critical to passenger comfort.

FINAL RESULTS

The participation of the entire project team including naval architects, ship captains and representatives of Barden and Trump Princess during the test program facilitated the selection of the best possible design of the harbour facility. For example, the ship captains were able to maneuver the scaled ships through the model harbour entrance and the model harbour basin. They were able to observe vessel behaviour under a variety of wave conditions both while moored inside the basin and while offshore. Their comments were critical in choosing the optimal harbour layout. Similarly, the naval architects were able to observe the complex interactions that occur between the three floating vessels and to review the forces on each mooring line, which impacted the design of the mooring structures and the mooring arrangement. It also influenced the design of mooring points on the vessels themselves and the access points (gangways).

As a result of the mooring tension tests, the ship simulator tests, and design team meetings to discuss the related issues, three specific operating and related mooring conditions resulted. They are defined as follows:
Condition 1: Open Lake Cruising
Condition 1 mooring covers routine operations when the boat will be departing the harbour at regularly scheduled two-hour intervals, and then returning to the dock to exchange passengers. During this operation, one bowline, one stern line and one each forward and aft spring line will be deployed to moor the boats. This mooring arrangement will be adequate to permit safe loading and unloading of passengers, and will allow rapid deployment and release of mooring lines. The maximum permissible conditions of the wave and wind environment is expected to be limited by vessel maneuverability inside the gaming basin. At present this limiting environment is undefined and will be determined with experience. Environmental loading on the vessel is expected to be low.

Condition 2: Operating Alongside the Dock
When waves on the lake will produce vessel motions that are uncomfortable or unsafe to passengers, or winds are too high to permit safe maneuvering in or out of the harbour, gaming operations may be permitted with the vessels moored alongside the dock. In this case a heavy duty mooring system will be deployed which will secure the vessel to the dock, and will help limit vessel motions in surge and sway.

Condition 3: Survival
When wave conditions inside the harbour result in vessel motions that exceed limits determined for passenger comfort or safety, gaming operations will be shut down, and the passengers and unnecessary personnel will disembark. Additional storm mooring lines will be deployed to the breakwater dolphins, if they have not been rigged. The stern anchor line should also be connected. The gangways will then be pulled back from the vessels and the vessels will be moved off to the storm mooring position, approximately 40 feet off the dock. These conditions are expected to occur for 70 hours per year, on average. Five different storm-mooring configurations were tested in the physical model in order to find an optimal one.

CONCLUSIONS

The physical model provided results that were crucial for effective operation of the harbour with minimal downtime, and for determining an optimal design of the mooring layout and harbour structures.

By combining the frequency of occurrence of storms and the clients determination of acceptable level of motion, it was possible to make timely cost benefit decisions relating to harbour design and permissible wave agitation levels, while meeting the clients operational requirements and schedule objectives.

Statistical Wave Forecasting through Kalman Filtering Combined with Principal Component Analysis

Noriaki Hashimoto\textsuperscript{1}, Toshihiko Nagai\textsuperscript{2} and Masanobu Kudaka\textsuperscript{3}

Abstract

Statistical wave forecasting methods have been applied because of their convenience. Most of them, however, include some drawbacks from the statistical or numerical viewpoints. In this paper, these drawbacks are discussed and a new statistical wave forecasting method utilizing the Kalman filter technique combined with Principal Component Analysis (PCA) is proposed in order to mitigate the drawbacks. The applicability and reliability of the proposed method is examined for five wave observation stations around Japan through simulations based on 5-years of wave data and weather charts.

Introduction

Adequate wave forecasting is indispensable for the safe operations of cargo handling, optimum management of port construction projects, and navigating and/or mooring vessels. There are two kinds of wave forecasting methods. One is a numerical model describing the physical process between winds and waves. The other is an empirical model based on a statistical relationship between the weather and the wave data obtained in the past.

The former method has been widely used for wave hindcasting for estimating design wave conditions. The reliability of the method has been discussed in several papers so far. Practical computation with this method, however, requires special knowledge of both the atmospheric and wave systems. Also, a large investment in computations is sometimes required.

On the other hand, the latter method commonly utilizes simple statistical relationships among criterion variables and predictor variables using obtained data.

\textsuperscript{1} Chief, Hydrodynamics Laboratory, Marine Environment Division, Port and Harbour Research Institute, Ministry of Transport, 1-1 Nagase 3-chome, Yokosuka 239-0826, Japan
\textsuperscript{2} Chief, Marine Observation Laboratory, Hydraulic Engineering Division, ditto.
\textsuperscript{3} Chief, Wave Information Laboratory, ECOH Co., Ltd., 2-6-4 Kitaueno, Taito-ku, Tokyo 110-0014, Japan.
The statistical method has advantages in that it is easy to handle and does not require special knowledge in practical computations. Because of these advantages, several statistical models have been proposed so far. The most commonly used model is the multiple regression model in which the wave characteristics, such as significant wave height and period at a specific point, and the atmospheric pressure data and/or wind data at several points are interrelated. However, from numerical viewpoints, most of the existing models contain several drawbacks such as multicollinearity among predictor variables, over-fitting of the criterion variable to the data, and over adoption of predictor variables in the model.

For these reasons, it necessitates the development of a reasonable statistical model in which the dynamical behavior of each variable and the statistical relation among variables are properly taken into consideration to eliminate the above drawbacks. Before applying the model, it is necessary to examine the model in detail for the real data obtained in various sea conditions for practical applications.

In this paper, we propose a new statistical wave forecasting model utilizing the Kalman filter technique combined with Principal Component Analysis (PCA) in order to mitigate the above-mentioned drawbacks of the conventional statistical wave forecasting models.

**Drawbacks of the conventional statistical wave forecasting methods**

In the normal procedure of wave forecasting by using a numerical model, first, the wind field is calculated from the weather charts. Once the wind field is calculated, the generation, development and attenuation of the wave field can be calculated from the wind data. Usually, in numerical computations, a proper grid size is adopted to obtain accurate and reliable results. However, if the same grid size is applied to the statistical wave model, and the data for the predictor variables are given on the same grid points, such fine grid size sometimes cause inferior prediction. This is because of the high correlation among predictor variables themselves, which causes the multicollinearity in the correlation matrix of the predictor variables. In such situations, the data on such fine grids are no longer proper predictor variables. However, if a rough grid size is adopted for predictor variables to eliminate the above multicollinearity problem, important small scale atmospheric pressure patterns will be overlooked and the accuracy of the wave forecasting will be reduced. This is one of the problems for the conventional statistical wave forecasting method.

When analyzing the time series of atmospheric pressure data, the spectrum of the atmospheric pressure includes energies in a considerably wide range of frequencies including seasonal and yearly changes. If the atmospheric pressure data are directly applied for establishing the equations for short-term wave forecasting, unnecessary long-term components of the energy included in the data may cause biases in the relation between the criterion variable and the predictor variables. This leads to the deterioration of the prediction accuracy.

Over-fitting of the criterion variable to the data and over-adoption of predictor variables in the model are also common matters to be attended in the statistical model, which sometimes cause the prominent delay of the predicted values to the real values, and the predicted values tend to be more unstable.
In order to mitigate the above-mentioned drawbacks of the conventional statistical wave forecasting models, this new statistical wave forecasting model is developed which properly considers the dynamical behavior of each variable and the statistical relation among.

**Definition of the “wave forecast” used in this study**

First, to eliminate any possible confusion, the meaning of the word "forecast" used in this study should be clarified. The word "forecast" is generally used to estimate an unknown situation based on the information obtained at present or in the past. However, in this study, we assume that the accurate weather information at the time for wave forecasting has already been known, which is assumed to be predicted by some other methods. That is, when we try to forecast waves 24 hours ahead, the accurate weather chart 24 hours ahead has already been obtained and wave data observed at the time are also available. Though the accuracy of the wave forecast strongly depends on the accuracy of the weather information, we examine only the accuracy of waves forecasted by the proposed method under the condition that the accurate weather information is given. Though the forecasted weather chart may include some errors, it is beyond our research to examine the accuracy of the weather chart.

**Wave data and atmospheric pressure data used in this study**

The computation for wave forecasting is carried out using the atmospheric pressure data read every 12 hours at the grid points of 500km × 500km shown in Figure 1. Five years of atmospheric pressure data, from 1980 to 1984, are used in this study. The locations of the wave forecasting points are denoted by the upper case letters in Figure 1. At each location, wave observations have been obtained every 2 hours for many years. Though the grid size is very rough compared to the numerical model, the forecasted wave heights using this grid size is acceptable for practical applications as shown later.

![Figure 1: Wave observation stations and grid points of atmospheric pressure data](image-url)
Statistical wave forecasting model utilizing Kalman filter combined with Principal Component Analysis (PCA)

Figure 2 shows the flow chart of the procedure of wave forecasting by using the Kalman filter combined with Principal Component Analysis (PCA). The model employed here consists of three parts. The first is the real-time filtering by using the Kalman filter. The second step is the PCA. The final step is the wave forecasting by the time-dependent regression model utilizing the Kalman filter. By obtaining new wave information and atmospheric pressure data, these three steps are repeated to update the wave forecasting equation and improve the accuracy of the wave forecasting. The procedure of each step is introduced in detail in the following.

1) Real-time filtering of the atmospheric pressure data by the Kalman filter

The first step in Figure 2 is the real-time filtering by the Kalman filter. Using their technique, the time series of atmospheric pressure data on the grid points are separated into two components, i.e., a long-term component (longer than one-week period) and the remaining short-term component. The outline of the Kalman filter is as follows.

The equations of the state space representation are expressed by:

\[
x_n = F_n x_{n-1} + G_n v_n \quad \text{(System Equation)} \\
y_n = H_n x_n + w_n \quad \text{(Observation Equation)}
\]

where \( x_n \): state vector \((k \times 1)\), \( v_n \): system noise (Gaussian white noise with mean vector \(0\) and covariance matrix \(Q_n\) \((m \times 1)\)), \( y_n \): observation vector \((l \times 1)\), \( w_n \): observation noise (Gaussian white noise with mean vector \(0\) and covariance matrix \(R_n\) \((l \times 1)\)) and \( F_n, G_n, H_n \): respectively \((k \times k), (k \times m)\) and \((l \times k)\) matrix.

To estimate the state vector \( x_n \) in Equation (1) on the basis of the observation vector \( y_n \) in Equation (2), the following one-step prediction and filtering are recursively applied through Equations (3) - (7).
[One-step prediction]

\[ x_{n|n-1} = F_n x_{n-1|n-1} \]  
\[ V_{n|n-1} = F_n V_{n-1|n-1} F_n^T + G_n Q_n G_n^T \]

(3)  
(4)

[Filtering]

\[ K_n = V_{n|n-1} H_n^T (H_n V_{n|n-1} H_n^T + R_n)^{-1} : \text{Kalman gain} \]
\[ x_{n|n} = x_{n|n-1} + K_n (y_n - H_n x_{n|n-1}) \]
\[ V_{n|n} = (I - K_n H_n) V_{n|n-1} \]

(5)  
(6)  
(7)

where \( x_{n|j} = E(x_n | Y_j) \) and \( V_{n|j} = E(x_n - x_{n|j})(x_n - x_{n|j})^T \)

For separating long-term and short-term components of the atmospheric pressure, equation (8) is assumed as the observation equation of equation (2).

\[ y_n = t_n + w_n \quad \text{(Observation equation)} \]

where \( y_n \): the observed value, \( t_n \): the long-term component and \( w_n \): the short-term component.

Since the long-term component is a slowly varying value, Equation (9) is assumed as the system equation of equation (1).

\[ \Delta^k t_n = v_n \quad \text{(System equation)} \]

where \( \Delta^k \): k-th order difference operator, and the second order difference operator is applied in this study as \( t_n - 2t_{n-1} + t_{n-2} = v_n \).

Figure 3 shows the example of the spectra of the logarithm of the significant wave height measured at Mutsuogawara port and the atmospheric pressure data at a point. The spectra of the separated time series data of long-term component and short-term component are shown in the figure. As seen in the figure, appropriate separation

![Figure 3](image-url)

Figure 3  Spectra of the logarithm of the significant wave height at Mutsuogawara port and atmospheric pressure with the separated components
The purpose of separating the atmospheric pressure data into two components is to reduce negative effects from the long-term component to the short-term forecasting. This is necessary since we focus on the short-term wave forecasting and the long-term component may cause a bias in the relation between the criterion variable and the predictor variables.

2) Principal Component Analysis of atmospheric pressure data

The second step is the PCA by which the separated time series data on the grid points are projected onto the empirical eigen-vectors obtained from each component of the atmospheric pressure data on the grid points. Here, the empirical eigen-vectors are preliminarily computed by using the past three-years' atmospheric pressure data. The outline of the PCA is as follows.

Atmospheric pressure field $P_{z_t}$ can be approximately expressed by the
superposition of the eigen-vectors $e_{n,z}$ with weighting coefficients $c_{n,t}$:

$$ P_{z,t} = \sum c_{n,t} e_{n,z} $$

(10)

where atmospheric pressure field $P_{z,t}$ is normalized by the mean value and standard deviation of $P(x, y, t)$, and each eigen-vector $e_{n,z}$ is assumed to be orthogonal to each other as

$$ \sum e_{n,z} e_{m,z} = \delta_{n,m} $$

(11)

Then the eigen-vector $e_{n,z}$ can be estimated by solving the following equation.

$$ A = \lambda_n e_n $$

(12)

where $\lambda_n$: eigen-value, $a_{i,j}$ is the $(i, j)$ component of matrix $A$ and is expressed by

$$ a_{i,j} = \frac{1}{n_t} \sum_{t=1}^{n_t} P_{i,t} P_{j,t} $$

(13)

Using the orthogonal condition of the eigen-vector, the weighting coefficient $c_{n,t}$ can be obtained by

$$ c_{n,t} = \sum P_{z,t} e_{n,z} $$

(14)

Figure 5 shows examples of the eigen-vectors of the long-term component of the atmospheric pressure system. From the left to the right in Figure 5, each figure shows the 1-st, the 2-nd, the 3-rd, and the 4-th principal component, respectively.

As seen in the figure, the 1-st component is invariable with respect to time $t$. This component seems to be the average of the atmospheric pressure system. The 2-nd component seems to show the phenomenon in which the atmospheric pressure

![Figure 5](components_of_pca_for_target_time_and_12_24_hours_before_target_time.png)
system moves from the west to the east. The 3-rd component shows from the south to the north. The 4-th component from the south-west to the north-east with the developing pressure system. The behavior of the atmospheric pressure system is assumed to be approximated by the superposition of these orthogonal empirical eigen patterns in this study.

The weighting coefficient of each eigen-vector is stored to be used in the following 3-rd step computation. Through this procedure, the atmospheric pressure data on the grid points are transformed and condensed into fewer, yet more efficient and independent predictor variables. The purpose of introducing the PCA is to avoid the unfavorable effect of multicollinearity of the atmospheric pressure data on the space-time grid points, by which new predictor variables are generated through the PCA. Figure 6 is an example of the time series of the weighting coefficient $c_{n,t}$, which is used as the predictor variable in the next step.

3) Time dependent regression model for wave forecasting by Kalman Filter

The final step is the wave forecasting where the weighting coefficients previously obtained are used as the input data for the time-dependent regression model utilizing the Kalman filter.

The equation for the time-dependent regression model is assumed by
log_{10} H_{1/3} = a_0 + \sum_{i=1}^{N} a_i z_i + \varepsilon \quad (15)

This equation can be reduced to
\[ y_n = H_n x_n + w_n \quad \text{(Observation equation)} \quad (16) \]
where \[ y_n = \log_{10} H_{1/3}, \quad x_n = (a_0, a_1, \cdots, a_N)' \], \[ H_n = (1, z_1, z_2, \cdots, z_N) \], \[ w_n = \varepsilon \] and the weighting coefficient \( c_{n,t} \) is expressed as \( z_t \) for convenience.

If the coefficient \( a_n \) is a slowly varying value, then
\[ \Delta^k x_n = v_n \quad \text{(System equation)} \quad (17) \]
where \( \Delta^k \) is the k-th order difference operator, and the first order difference operator is applied in this study as \( a_n - a_{n-1} = v_n \).

The trade-off parameter defined by \( \sigma_v^2 / \sigma_w^2 \) is used to control the magnitude of the change of the model in each time step of the computations, where \( \sigma_v^2 \) and \( \sigma_w^2 \) are the variances of \( v_n \) and \( w_n \) in equations (17) and (16), respectively. Figure 7 shows examples of the variations of the time series of the state variables \( a_i \) \((i = 0, \cdots, N)\). Figure (a) shows the results calculated with \( \sigma_v^2 / \sigma_w^2 = 10^{-3} \), while figure (b) shows the results calculated with \( \sigma_v^2 / \sigma_w^2 = 10^{-10} \). When choosing a small trade-off parameter, the time variations of the state variables \( a_i \) \((i = 0, \cdots, N)\) can be suppressed so as to fluctuate around the mean values as seen in figure (b). The rapid change of the state variables \( a_i \) \((i = 0, \cdots, N)\) in figure (a) seems to reflect the over-fitting of the model to the data. In other words, the problem of the over-fitting can be reduced by choosing a proper value of the trade-off parameter \( \sigma_v^2 / \sigma_w^2 \) in the model.

Figure 7 Time series of the state variables \( a_i \) \((i = 0, \cdots, N)\) of the time-dependent regression model
The purpose of adopting a time-dependent regression model utilizing Kalman filtering is to detect a gradual change such as a seasonal variation in the atmospheric and wave systems, and to reflect it in the forecasting model to improve the accuracy of the wave forecasting.

These three steps are repeated for each time step. That is, by obtaining new wave data or atmospheric pressure data, the wave forecasting equation is updated to improve the accuracy of the wave forecasting.

**Numerical simulations of wave forecasting based on 5-years of data**

The applicability and reliability of the proposed method is examined for six wave observation stations around Japan, shown in Figure 1, through simulations based on 5-years of wave data and weather charts.

Figure 8 shows the accuracy of the proposed method applied for Mutsuogawara port. The horizontal axis is the lead time for wave forecasting. The vertical axis is the standard deviation of the prediction errors. It is seen that the predicted wave height by the proposed method shows different characteristics depending on the magnitude of the trade-off parameter, $\sigma_r^2/\sigma_w^2$, of the Kalman filter used in the 3-rd step. The trade-off parameter controls the magnitude of the change of the coefficients in each time step of the computations. If an appropriate trade-off parameter is chosen, the wave height errors, predicted several-steps-ahead, can be controlled within an allowable range, although the prediction error of one-step-ahead may not be the minimum. In other words, the problem of the over-fitting of the criterion variable to the data can be resolved by choosing an appropriate value of the trade-off parameter in the model.

![Figure 8](image)

**Figure 8** Accuracy of the proposed method (Error vs. lead time)
Consideration of the separation of long-term component and short-term component

| (a)  | ×    | $10^{-3}$ |
| (b)  | ×    | $10^{-10}$ |
| (c)  | 〇    | $10^{-3}$ |
| (d)  | 〇    | $10^{-10}$ |

**Table 1** Simulation conditions for wave forecasting

To examine the validity of the proposed method, we applied the proposed method for 4 different computation conditions. Table 1 shows the 4 cases. Figure 9 shows the scatter diagram between the observed wave height and the forecasted wave height for a lead time of 120 hours under the 4 different conditions for Mutsuogawara port.

The low correlation coefficient between the forecasted value and the observed value can be seen in the case (a) where the separation of the long-term component is not considered, and the trade-off parameter is also inappropriate. In the case (b), the trade-off parameter is properly chosen though the separation of the long-term component is not considered. In this case, the correlation coefficient is improved compared to the case (a). However, prominent bias between the forecasted value and observed value can be seen. In the case (c) where the separation of the long-term

![Figure 9](image-url) Scatter diagram between the observed wave height and the forecasted wave height for a lead time of 120 hours under the 4 different conditions
component is considered while the trade-off parameter is not appropriate, the correlation coefficient is not improved when compared to the case (b) although it does not show the prominent bias. In the case (d) where the separation of the long-term component is considered and the trade-off parameter is appropriate, this case shows the highest correlation coefficient in the 4 cases and does not show the prominent bias between forecasted and observed values.

From these comparative results obtained under the different conditions using the same data, it is demonstrated that each technique introduced in each step of the proposed method is effective. It is also demonstrated that the accuracy of the proposed method for short-term wave forecasting is better than the other methods (Kobune, et.al., 1988, 1990 and Suda and Yuzawa, 1983) when an appropriate trade-off parameter is properly chosen.

Figure 10 Comparison of the time series of the forecasted wave heights (●) for a lead time of 120 hours and the observed wave height (solid line)
Figure 11 Scatter diagram between the observed wave heights and the forecasted wave heights for a lead time of 120 hours.

The examinations of the wave forecasting for other observation stations were carried out using the atmospheric pressure data at 500km x 500km grid points around the wave observation stations shown in Figure 1. Figure 10 shows an example of the comparison of the time series of the forecasted wave heights for a lead time of 120 hours and the observed wave height, where • is the forecasted wave height and solid line is the observed wave height. As seen in the figure, the tendency of the time delay of the forecasted wave height to the real wave height is not recognized although most of the conventional statistical wave forecasting methods show such a drawback (Kobune, et.al., 1988, 1990 and Suda and Yuzawa, 1983).

Figure 11 shows the scatter diagram between the observed wave heights and the forecasted wave heights for a lead time of 120 hours. The examples for 6 wave observation stations around Japan are shown in the figure. All the data in one year are plotted in the figure. These examples demonstrate that the reliability of the proposed method for short-term wave forecasting can be acceptable for practical use if errors are allowed to a certain extent.
Conclusions

The overall conclusions of this study are summarized below.
1) The proposed method utilizing the Kalman filter combined with Principal Component Analysis can be a useful tool for a short-term wave forecast if errors are allowed to a certain extent.
2) If an appropriate trade-off parameter is chosen in the model, the wave height errors predicted several-steps-ahead can be controlled within an allowable range, although the prediction error one-step-ahead may not be the minimum.
3) The proposed method is easy to handle, which enables us to use the proposed method with a small personal computer.

Data Assimilation and Nested Hydrodynamic Modelling in Storm Surge Forecasting

Rafael Cañizares\textsuperscript{1} and Henrik Madsen\textsuperscript{1}

Abstract

A data assimilation method for state updating in a hydrodynamic model is presented. The method is based on the extended Kalman filter in which the error covariance matrix is approximated by a matrix of lower rank using a square-root factorisation (reduced rank square-root filter). Results from a test of the Kalman filter in a regional model of the North Sea and Baltic Sea are presented. In this respect, the influence of using nested hydrodynamic models together with data assimilation techniques is illustrated and discussed. The test reveals that assimilation of water level measurements from coastal stations significantly improves the model results.

Introduction

During the last decades, the interest of predicting water level rising as a consequence of storm surges has grown considerably. In countries that are affected by this phenomenon substantial efforts are made to predict storm surges so far ahead in time that appropriate actions can be taken.

The combination of numerical weather prediction models and hydrodynamic models forms the main frame of an operational storm surge forecast system (Bode and Hardy, 1997). The hydrodynamic model uses the predicted meteorological wind and pressure data to provide a prediction of the water level field. The storm surge prediction, however, is not always as accurate as desired which can mainly be ascribed to

1. Simplifications of the description of the physical processes in the numerical hydrodynamic model.
2. Bias in the meteorological forcing prediction.

1378
3. Inaccurate open boundary conditions.

The main errors in the hydrodynamic model are, respectively, simplifications of the physical processes in the numerical model equations and application of a too coarse spatial resolution to adequately resolve the dynamics of the system. To reduce the errors caused by the former problem more complex models should be considered, whereas for the latter problem the model has to be applied in a finer grid which can be defined locally by using nested hydrodynamic models (Vested et al, 1995). Nested models allow to have a finer resolution in areas where required while a coarser resolution can be maintained in the rest of the model domain.

The uncertainties of the meteorological forcing and the open boundary conditions as well as uncertainties of the physical model parameters can be accounted for by using data assimilation. In data assimilation, model and measurements of the system are combined in order to obtain a better estimate of the state of the system. Data assimilation algorithms, however, can become prohibitive when applied in large scale models due to the huge computational cost associated with this kind of applications. New algorithms, such as the reduced rank square-root (RRSQRT) Kalman filter (Verlaan and Heemink, 1995) have solved this problem. The RRSQRT filter is a suboptimal scheme of the extended Kalman filter that uses a square-root algorithm as well as a lower rank approximation of the error covariance matrix.

The RRSQRT filter has been integrated into an existing hydrodynamic modelling system that solves the vertically integrated equations of continuity and momentum in two horizontal directions (Cañizares et al, 1998). When measurements are available, the Kalman filter is adopted for updating the state of the system. In storm surge forecasting, the updated state is then used as initial conditions for the forecast simulation.

The paper is organised as follows. In the first section the applied numerical hydrodynamic model is described. In sections two and three the general Kalman filter updating scheme and the RRSQRT filter are presented and the implementation in the hydrodynamic model is described. Sections four and five outline the specific features of the nested version of the hydrodynamic model and the implementation of the filter in this type of model. Finally, a test case is presented where the Kalman filter is applied in a regional model of the North Sea and Baltic Sea.

The deterministic numerical model

In the present study, the data assimilation method has been implemented in the hydrodynamic module of the MIKE 21 modelling system which solves the vertically integrated equations of continuity and conservation of momentum (shallow water equations) in two horizontal directions (DHI, 1995). The equations that are solved are those of:
Continuity:

\[
\frac{\partial \xi}{\partial t} + \frac{\partial p}{\partial x} + \frac{\partial q}{\partial y} = S_0 - e
\]  

(1)

\[x\text{-momentum:}
\]

\[
\frac{\partial p}{\partial t} + \frac{\partial}{\partial x} \left( \frac{p^2}{h} \right) + \frac{\partial}{\partial y} \left( \frac{pq}{h} \right) + gh \frac{\partial \xi}{\partial x} + \frac{g p}{h} \left( \frac{p^2}{h^2} + \frac{q^2}{h^2} \right) - f \nu V_x - \frac{h}{\rho_w} \frac{\partial}{\partial x} (P_a) - \Omega q - E \left( \frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} \right) = S_{ix}
\]  

(2)

\[y\text{-momentum:}
\]

\[
\frac{\partial q}{\partial t} + \frac{\partial}{\partial y} \left( \frac{q^2}{h} \right) + \frac{\partial}{\partial x} \left( \frac{pq}{h} \right) + gh \frac{\partial \xi}{\partial y} + \frac{g q}{h} \left( \frac{p^2}{h^2} + \frac{q^2}{h^2} \right) - f \nu V_y - \frac{h}{\rho_w} \frac{\partial}{\partial y} (P_a) - \Omega p - E \left( \frac{\partial^2 q}{\partial x^2} + \frac{\partial^2 q}{\partial y^2} \right) = S_{iy}
\]  

(3)

where:

- \(x, y\): Horizontal coordinates [m].
- \(t\): Time [s].
- \(h\): Water depth [m].
- \(\xi\): Surface elevation [m].
- \(p, q\): Flux densities in \(x\) and \(y\) directions \([m^3/s/m]\), \((p, q) = (v_x h, v_y h)\) where \(v_x\) and \(v_y\) are the depth averaged \(x\) and \(y\) velocities \([m/s]\).
- \(S_0\): Source magnitude per unit horizontal area \([m/s]\). 
- \(S_{ix}, S_{iy}\): Source impulse in \(x\) and \(y\) directions \([m^2/s]\).
- \(e\): Evaporation rate \([m/s]\).
- \(E\): Eddy viscosity coefficient \([m^2/s]\).
- \(g\): Acceleration due to gravity \([m/s^2]\).
- \(C\): Chezy bed resistance coefficient \([m^\nu/s]\).
- \(\Omega\): Coriolis parameter \([s^{-1}]\).
- \(f\): Wind friction factor [-].
- \(V_x, V_y\): Wind speed and wind speed components in \(x\) and \(y\) directions \([m/s]\).
- \(P_a\): Atmospheric pressure \([kg/m/s^2]\).
- \(\rho_w\): Density of water \([kg/m^3]\).
At closed boundaries the flow perpendicular to the boundary is set to zero. At open boundaries the surface elevation is prescribed. With these boundary conditions and with prescribed initial values of surface elevations and flux densities, (1)-(3) form a well-posed boundary value problem.

MIKE 21 uses a finite difference approximation to solve the partial differential equations where the variables are defined on a space-staggered rectangular grid with surface elevations at grid points and fluxes midway between grid points (Leendertse, 1964). A time-centered alternating direction implicit (ADI) scheme is adopted. The equations are solved in one-dimensional sweeps, alternating between \( x \) and \( y \) directions. In the \( x \)-sweep, the continuity equation and the momentum equation in the \( x \) direction are solved with respect to \( \zeta \) at time step \( k+1/2 \) and \( p \) at time step \( k+1 \) using the known variables \( \xi_k, p_k, q_k+1/2, \) and \( q_k+1/2 \). In the \( y \)-sweep, the continuity equation and the momentum equation in the \( y \) direction are solved with respect to \( \xi_{k+1} \) and \( q_{k+3/2} \) using \( \xi_{k+1/2}, q_{k+1/2}, p_k, \) and \( p_{k+1} \).

**Implementation of the Kalman filter in MIKE 21**

For implementation of the Kalman filter in MIKE 21, the numerical model has to be formulated in a state-space form. The state variables to be considered are surface elevations and depth averaged \( x \) and \( y \) velocities in every point of the horizontal grid. The Kalman filter algorithm is based on a recursive two-time step formulation. The numerical scheme in MIKE 21, however, involves the \( y \) velocity at three time steps. To express this scheme using only two time steps, the \( y \) velocity at time steps \( k+1/2 \) and \( k-1/2 \) are included in the state vector. The numerical scheme based on (1)-(3) can then be written

\[
x_k = \Phi(x_{k-1}, u_k)
\]

where \( x_k = (\xi_k, v_x, v_y, v_y, v_y) \) is the state vector, and \( u_k \) is the forcing of the system in terms of the surface elevations at open boundaries and the meteorological forcing components in the momentum equations (wind stress and pressure gradient).

For modelling the uncertainty of the system, it is assumed that model errors are mainly related to errors in the forcing components. The error processes are assumed to be less spatially variable than the water flow process (Heemink, 1990), and the discrete error processes can thus be defined on a grid \( G_2 \) that is coarser than the model grid \( G_1 \). A stochastic representation of the system equation (4) can then be written

\[
x_k = \Phi(x_{k-1}, u_k + \Lambda \varepsilon_k)
\]

where \( \varepsilon_k \) contains the model error in every grid point of \( G_2 \), and \( \Lambda \) is a matrix that represents the sequence of linear interpolations between \( G_2 \) and \( G_1 \).
For the system, measurements $z_k$ of the state are assumed to be available at certain points in the model grid $G_1$. The stochastic representation of the measurement equation reads

$$z_k = C_k x_k + \eta_k$$  \hfill (6)

where $C_k$ is a matrix that describes the relation between measurements and state variables, and $\eta_k$ is a random measurement error with zero mean and known covariance matrix $R_k$.

When measurements are available, cf. (6), the model forecast and the measurements can be combined to obtain an updated estimate of the state of the system. The Kalman filter update of the state vector and the error covariance matrix $P_k$ is given by

$$x_k^a = x_k^f + K_k (z_k - C_k x_k^f)$$ \hfill (7)

$$P_k^a = P_k^f - K_k C_k P_k^f$$ \hfill (8)

where $K_k$ is the Kalman gain matrix

$$K_k = P_k^f C_k [C_k^T P_k^f C_k + R_k]^{-1}$$ \hfill (9)

which serves as a weighting function of model forecast and measurements and depends on the associated errors $P_k^f$ and $R_k$. In (7)-(9) superscripts $f$ and $a$ refer to, respectively, forecast and analysis (or update).

For large systems, the propagation of the error covariance matrix (determination of $P_k^f$) is the main bottleneck. This step requires $2n$ as much computing effort as is required to advance the deterministic model itself ($n$ being the dimension of the state vector). Applications to large systems are prohibitive under such conditions, and hence approximations of the Kalman filter, reducing the computational effort, have to be used. The technique described below, the reduced rank square-root filter, introduced in (Verlaan and Heemink, 1995) and (Verlaan, 1998), is based on an approximation of the error covariance matrix.

The Reduced Rank SQuare RooT (RRSORT) filter

For non-linear model dynamics an extended Kalman filter can be formulated in which the propagation of the error covariance matrix is based on a statistical linearisation of the model equation. Considering a white noise process for the model errors, the forecast step is given by
\[ x'_k = \Phi(x'_{k-1}, u_k) \]  

\[ P'_k = F_k P'_k F_k^T + G_k (\Lambda Q_k \Lambda^T) G_k^T \]  

\[ F_k = \frac{\partial \Phi}{\partial x} \bigg|_{x=x'_k}, G_k = \frac{\partial \Phi}{\partial u} \bigg|_{x=x'_k} \]  

where \( Q_k \) is the covariance matrix of the system noise, defined on grid \( G_2 \).

The RRSQRT approximation of the extended Kalman filter uses a square-root algorithm as well as a lower rank approximation of the error covariance matrix (Verlaan and Heemink, 1995). Denote by \( S \) the approximation of rank \( M \) of the square root of the error covariance matrix. The propagation of the error covariance matrix is then given by

\[ S'_k = \begin{bmatrix} F_k S'_{k-1} \mid G_k \Lambda Q^{1/2}_k \end{bmatrix} \]  

where \( Q^{1/2}_k \) is the square-root of \( Q_k \). The matrix \( S'_{k-1} \) has \( M \) columns where \( M \) is chosen much smaller than the dimension \( n \) of the state vector. To calculate the derivatives in \( F_k \) and \( G_k \), a finite difference approximation of \( \Phi(\bullet) \) is adopted. Thus, the propagation of the error covariance matrix requires \( M + p \) (the total number of noise points) model integrations, which is much smaller than the \( 2n \) integrations required in (11).

The propagation step in (12) increases the number of columns in the error covariance matrix from \( M \) to \( M + p \). To reduce the number of columns, and hence keep the rank of the matrix constant throughout the simulation, a lower rank approximation of \( S'_k \) in (12) is applied by keeping only the \( M \) leading eigenvectors of the error covariance matrix. The reduction can be achieved either by a singular value decomposition of \( S'_k \) or by an eigenvalue decomposition of the matrix \( (S'_k)^T S'_k \) (Canizares et al., 1998).

For uncorrelated measurement errors, a sequential updating scheme can be applied (Maybeck, 1979). This algorithm avoids the expensive calculation and storage of \( P'_k \) as well as the matrix inversion in (9) for the calculation of the Kalman gain. The procedure used in the present study follows (Potter, 1967), i.e.

\[ a_{k,i} = [S'_k]^T C'_i \]  

\[ \gamma_{k,i} = \frac{1}{a_{k,i}} \left( a_{k,i} + \sigma_{k,i}^2 \right) \]  

\[ K_{k,i} = S'_{k,i-1} a_{k,i} \gamma_{k,i} \]
\[ S_{k,j} = S_{k,j-1} - \frac{1}{1 + \sqrt{C_{k,j}}} \cdot \frac{1}{\sqrt{\sigma_{k,j}^2}}, \quad S_{k,0} = S_f \] 

(16)

\[ x_{k,j} = x_{k,j-1} + K_{k,j} \left[ z_{k,j} - C_{i} x_{k,j-1} \right], \quad x_{k,0} = x_f \] 

(17)

where \( C_i \) is the \( i^{th} \) column of matrix \( C \), \( z_{k,j} \) is the \( i^{th} \) measurement, and \( \sigma_i \) is the standard deviation of the measurement noise.

The filter can use time-coloured noise. In this case the state vector is augmented with variables that represent the estimated value of the noise. For the propagation of the state vector and the error covariance matrix new equations have to be defined for the RRSQRT filter (see Madsen and Cañizares, 1998). Moreover, the error covariance matrix has to be normalised prior to the eigenvalue decomposition. For further details on the RRSQRT algorithm see (Cañizares, 1998).

**Special features of the MIKE 21 nested model**

The nested version of the MIKE 21 model solves the hydrodynamic equations simultaneously in a number of dynamically nested grids. An important difference between nesting and boundary transfer from a coarse model to a finer one is that in nesting the information between grids travel in two directions, i.e. from the coarse to the fine grid and vice versa. On the other hand, in a boundary transfer model information travel only from the coarse to the fine grid. The two techniques are also denoted two-way and one-way nesting, respectively.

In order to ensure model stability and smooth transition between areas, certain constraints are imposed. The most important are:

- Open boundaries can only be defined in the coarsest grid.
- The spatial resolution from one level to another is reduced by a fixed factor (grid reduction factor), which is equal to 3.
- The water depths in common grid points along the internal boundaries must be equal in both the coarse and the fine grid. Between the common points along the internal boundary, the water depths in the fine grid are linearly interpolated using the values at the common points.
- The water depth in the coarse grid has to be identical in three points orthogonal to the internal boundary (at the border and one point at each side). Therefore the first four points orthogonal to the internal boundary in the fine grid have the same water depth. The intention of these corrections is to avoid instabilities in the internal boundaries.

Further details about the nested model can be found in (DHI, 1995).
Implementation of the RRSQRT filter in the nested model

The main features of the implementation of the RRSQRT filter in the nested model are:

- The model is propagated using the complete nested model.
- The error covariance matrix is represented in the coarsest grid (the main area). Hence, the number of variables considered in this matrix is the same as if only the coarsest grid is considered.
- The error covariance matrix is propagated using the complete nested model. The model error is interpolated from the main grid to the internal grids.
- If the measurement position is located in a grid point of an internal area, the value is extrapolated to the main area. Thus, vector $C$, represents the relation between the position of the measurement in the fine grid and the surrounding positions in the coarsest grid.
- The Kalman gains $K_t$ correspond to variables in the main area. The gains are interpolated from the main grid to the internal grids.

Under these assumptions, the associated cost of the data assimilation scheme in the nested model is comparable to application in the model defined in the coarse area. The main difference is that the time associated with a run of the nested model is larger than for the model defined in the coarse area. For further details on the application of the RRSQRT in the nested hydrodynamic model see (Canizares, 1998).

Application: a regional model of the North Sea and Baltic Sea

The Kalman filter has been applied to a regional model covering the North Sea and the Baltic Sea. Two open boundaries are defined in the North Sea between, respectively, Stavanger and Orkney Island (northern boundary) and Dover and Calais (southern boundary). A coarse model is defined with a grid size of 9 nautical miles (16670 m) in both directions. A nested area of the inner Danish waters has been defined in order to obtain a better and more detailed description of the water level and current fields in this area. The local model is defined in a grid with origin in (48,18) of the coarse grid and a grid size of 3 nautical miles (5667 m), i.e. one third of the grid size of the coarse model. The model setup and bathymetry are shown in Figure 1.

At the two open boundaries, the water level is specified. For the simulation period, wind velocity fields and pressure fields are available every three hours and they are linearly interpolated at every model time step (set equal to 10 min.). The flow resistance is defined with a Manning number equal to 32 m$^{1/3}$/s in the entire model domain. The model is initialised on 01/10/97 at 00:00 with water level and velocity fields obtained from a spin-up simulation of 48 hours.

The performance of the RRSQRT filter in both the standard hydrodynamic model (HD) and the nested hydrodynamic model (NHD) is tested. In the simulations, water level data from 14 coastal stations are assimilated and the results are validated.
against data from another 7 available coastal stations. The positions of the, in total, 21 stations are shown in Figure 1.

Figure 1. North Sea and Baltic Sea model setup and bathymetry (depth in meters). A nested area is defined for the inner Danish waters. Water level stations are represented with circles (measurement stations) and squares (validation stations).

A simulation period of three days from 01/10/97 00:00 to 03/10/97 00:00 was applied where continuous measurement of water levels were available at the 21 stations. Based on an initial sensitivity test the following parameters for the Kalman were used:

- The rank of the error covariance matrix is set equal to 100.
- The grid reduction factor between the noise grid and the coarse model grid is set equal to 8.
- Time-coloured noise is defined using a first order autoregressive model with a lag-one autocorrelation coefficient of 0.97.
- The noise in the meteorological forcing components of the momentum equation is defined using an exponential spatial correlation model with a correlation coefficient of 0.9 and a standard deviation that varies in space. The magnitude of the standard deviation varies from 0.0005 m²/s² in the North Sea to 0.0001 m²/s² in the Baltic Sea.
- At the northern boundary noise is defined using a spatial correlation coefficient of 0.95, standard deviation of 0.1 m, and a grid reduction factor of 3. At the southern boundary the same parameters are used except for the grid reduction factor, which is set to 1, i.e. it coincides with the model grid.
- The standard deviation of the measurement noise is set equal to 0.05 m.
Measurements were available every 20 minutes, and hence the updating step of the RRSQRT filter takes place every second time step.

In order to evaluate the performance of the filter the root mean square error (RMSE) between the observed and updated water levels are calculated and compared with the RMSE of the deterministic model simulation for both models. The RMSE has been calculated using the last 36 hours of simulation in order to reduce the influence from the initialisation of the filter. Figures 2 and 3 present the RMSE for the measurement and the validation stations, respectively, obtained from the deterministic and the updated HD and NHD models. Table 1 shows the global (spatial average) values of the RMSE for the different models.

**Figure 2.** RMSE for the deterministic (Det) and the updated (KF) hydrodynamic (HD) and nested hydrodynamic (NHD) models at measurement stations.

Figure 4. Water level and velocity field for the inner Danish waters at 02/10/97 19:00 calculated from the deterministic model (top) and the Kalman filter (bottom) using the hydrodynamic model (HD).
The HD and NHD deterministic models yield basically the same results. The use of a detailed description in the inner Danish waters improves the simulation only in some of the stations while providing worse results in others. This is a direct consequence of a poor schematisation of the area between Denmark and Sweden in the finer grid, resulting in worse results at the stations located at the southern part of the fine grid (Gedser and Klagshamn). The simulation at the other stations located in the nested area is improved using the finer resolution. No further efforts for calibrating the models have been done.

The Kalman filter for the HD as well as for the NHD model efficiently corrects the water levels in all parts of the regional model. At measurement points a global value of the RMSE equal to 0.072 m for the HD and 0.077 for the NHD have been obtained which is only slightly higher than the assumed standard deviation of the measurement noise (0.05 m). At validation points the corrections are not that significant but they still present a marked improvement (about 50% reduction of the RMSE) in all regions when compared with the deterministic models. In general, the results obtained in this case, in terms of reducing errors in water levels, are not improved by using a finer grid. Since the state vector is defined in the coarse grid, corrections in the fine area are obtained by interpolating the error estimated by the filter in the coarse area. The introduction of this new approximation causes a slightly worse performance of the filter in the finer grid. The use of a finer resolution is more important for corrections of the velocity field as illustrated below.

Figure 5. Water level and velocity field for the detailed area of the inner Danish waters at 02/10/97 19:00 calculated from the deterministic model (left) and the Kalman filter (right) using the nested hydrodynamic model (NHD).
Water level and velocity fields for the deterministic and updated models at 02/10/1997 19:00 are presented in Figures 4-5. Important differences in the velocity field can be observed in these figures. The flux entering the Danish waters from the North Sea is not well represented in the deterministic solution. The updated model provides higher water levels in the entrance to the Baltic Sea than in the deterministic model. In general, the updated model is able to reproduce the high water level elevation in the inner Danish waters and the northern coasts of Germany and Poland. When using a finer resolution, the velocity field is better represented. In this case, larger currents are obtained in the updated model, especially in areas with strong water level gradients. The type of global improvements presented in Figures 4-5 is maintained during the entire simulation.

Conclusions

A data assimilation method based on the RRSQRT filter has been implemented in a hydrodynamic model that solves the shallow water equations simultaneously in a number of dynamically nested areas with different resolutions. The use of a finer resolution grid in some areas of the model rapidly increases the number of computational points in the model. The state vector has been defined on the main (coarsest) grid in order to reduce the computational cost and the storage requirements of the Kalman filter. This implementation, however, did not improve the corrections of water levels in the detailed area as compared with the corrections obtained using only one area with a coarse resolution. Although this result may be partly caused by a poor schematisation of the nested model, more accurate results are expected if variables in all points of the nested grids are defined in the state vector, and hence avoiding the interpolation of the Kalman gain from the coarse to the fine grid.

The application example reveals that the use of data assimilation significantly improves the global model results. In storm surge forecasting, the improved estimate of the state of the system is then used as initial conditions for the forecast simulation. In the cases where the main interest is on water level predictions, as in the case in storm surge forecasting, the implementation using only one area of the regional model with a coarse resolution can provide sufficient accuracy. On the other hand, for prediction of currents more detailed information is required, and in this case nested modelling combined with data assimilation should be applied.

Part III: Coastal Structures

Groin at Fjaltring, Danish North Sea Coast

Coast Protection at Lønstrup, Danish North Sea Coast
Abstract

The difference in reshaping of a traditional berm breakwater constructed of two stone classes and a more stable armoured type of berm breakwater with the largest berm stones used as an armour layer has been studied through physical model tests at the Danish Hydraulic Institute. A total of eight series of model tests were carried out in a wave flume with the aim of studying the effect of different armouring of the berm. The test results are described in the form of profile development, recession of the berm, waves generated by overtopping and wave reflection.

Further, four series of flume tests were carried out for studying the influence of the width of the stone gradation for the berm material and the permeability of the berm material. Two stone gradations and three permeabilities of the berm material were tested.

Finally, four test series were carried out for studying the influence of scour protection on the scouring in front of the berm breakwater and the behaviour of the berm breakwater.

Introduction

The permeability of rubble mound breakwaters is known to have an effect on the armour layer stability. An armour layer placed on an impermeable core is less stable than an armour layer placed on a core of permeable stone material. This aspect is included in the stability formulae for rubble mound breakwaters established by van der Meer (1988).
In some cases, the stability of rubble mound breakwaters has been increased by going from two layers of stones in the armour layer to three or four layers. One of the features of berm breakwaters is the energy dissipation in the permeable berm, but this can be reduced if the permeability is reduced due to a high content of fines.

Research presented by Hall and Kao (1991) has shown that the reshaping of berm breakwaters is influenced by the stone gradation. They found, for $D_{n85}/D_{n15}<3$, that reducing the gradation width of the armour stones reduced the reshaping.

Experience from Iceland has shown that it is in most cases advantageous to construct berm breakwaters of more than two stone classes. The idea being that the largest stones are used where they will be most effective, i.e. as an armour layer protecting the berm. Armoured berm breakwaters made of several stone classes like a traditional breakwater require more sorting of stones, but at the same time the increased stability means that the overall dimensions can be reduced. Examples of the Icelandic experience with berm breakwaters are given by Sigurdarsson et al (1995) and Juhl and Jensen (1995).

Local scour can occur at a breakwater constructed on a sandy seabed and may endanger the overall stability due to sliding of the main armour layer if the toe and scour protection is failing. The scouring pattern is a function of the water depth, wave conditions, sediment characteristics, breakwater configuration, and reflection characteristics as described by Arneborg et al (1996). Further, a simultaneous current at the breakwater will influence the scouring.

Scouring in front of a berm breakwater constructed without a sufficient scour protection may result in berm stones sliding into the scour hole, which will lead to further reshaping of the protecting berm.

**Model Set-up and Test Programme**

**Model Set-up**

Physical model tests were carried out in a 23 m long and 0.60 m wide wave flume with the aim of studying profile reshaping and wave overtopping of berm breakwater profiles. A fixed bed foreshore with a slope of 1:80 was constructed in the flume.

The profiles used in the first 12 test series are shown in Figure 1. The water depth in front of the berm was 0.25 m for all tests. Profiles 1 to 8 were tested to compare the reshaping of a berm breakwater constructed of two stone classes with the reshaping of a more stable type of berm breakwater with the largest stones armouring the berm.
Figure 1  Tested berm breakwater profiles. Stone class characteristics are presented in
Profiles 1 to 4 were relatively high-crested breakwaters not allowing wave overtopping. Three alternative berm breakwaters of the armoured type (Profiles 1, 3 and 4) were tested and compared to tests with a traditional berm breakwater consisting of two stone classes (Profile 2). The subsequently tested four profiles were more low-crested breakwaters with the crest elevation and berm width adjusted to take into account different wave steepness \( S_{am} = 0.03 \) and 0.05.

The berm breakwaters were constructed of two or three stone classes, ie one for the core and scour protection and one or two for the berm, crest and rear side protection. The traditional berm breakwaters (Profiles 2, 5 and 7) were constructed of two stone classes, a relative wide stone gradation for the berm, \( D_{n50}/D_{n15} = 1.80 \), having a nominal diameter, \( D_{n50} \), of 0.022 m (stone class 2) and a core with a nominal stone diameter of 0.011 m (stone class 1). A summary of the stone classes used is presented in Table 1.

### Table 1 Summary of stone classes. The density of the stone material was measured to \( \rho_S = 2.68 \text{ t/m}^3 \).

In testing of the armoured type of berm breakwaters, the berm stones (class 2) were separated into two classes, the lower fraction to be used for the berm (stone class 4) and the higher fraction to be used as an armour layer (stone class 5). This means that the same stones were used for all tested profiles.

Profiles 9 and 10 were tested using berm material with a more narrow stone gradation, \( D_{n85}/D_{n15} = 1.40 \), having a nominal diameter, \( D_{n85} \), of 0.024 m (stone class 3). Profiles 11 and 12 were tested for studying the influence of the permeability of the berm material. The permeability was reduced by adding fine material (average weight of 0.24 g) to the narrow stone gradation, either to the surface zone of the berm or to the entire berm.

Four series of model tests were carried out for studying the scouring in front of a traditional berm breakwater having a high crest and a wide berm. In order to assess the scouring, the seabed below and 1.5 m in front of the breakwater was made of fine sand with \( d_{50} = 0.17 \text{ mm} \).
Test Programme

Each test series consisted of five to nine test runs each with a duration corresponding to 2,000 waves. Test runs were carried out with the following deepwater conditions: \( H_o = \frac{H_{mo}}{\Delta D_{n,50}} \) = 2.0, 2.5, 3.0, 3.5 and 4.0, where \( H_{mo} \) is the wave height, \( \Delta \) is the relative density and \( D_{n,50} \) is the nominal stone diameter. \( H_o \) is also called the stability number and is for the armoured berm breakwaters calculated using \( D_{n,50} \) for the entire berm material (0.022 m).

Further, the long-term development was studied with \( H_o = 4.0 \) for Profiles 1 to 3.

The deepwater wave steepness is given by the ratio between the wave height, \( H_{mo} \), and the deepwater wave length, \( L_{om} \), calculated on basis of the mean wave period, \( T_{om} \):

\[
S_{om} = \frac{H_{mo}}{L_{om}} = \frac{2\pi}{g} \frac{H_{mo}}{T_{om}^2}
\]

The tests were carried out in test series with fixed wave steepness in deep water, \( S_{om} = 0.03 \) respectively 0.05, i.e. the wave steepness in front of the berm breakwater varied due to differences in wave shoaling and wave breaking on the foreshore.

Two test series were carried out to study scouring in front of a berm constructed directly on a sandy seabed. The first test series consisted of nine test runs with a wave steepness of \( S_{om} = 0.05 \) and the second test series of six test runs with a wave steepness of \( S_{om} = 0.03 \) and two additional test runs with \( S_{om} = 0.02 \) (the last with the water depth reduced to 0.20 m).

A 0.05 m thick scour protection layer below the berm and extending 0.50 m in front of the berm was introduced in the third test series. In the fourth test series, the scour protection material was placed as a 0.10 m layer covering the front slope of the berm. The idea being that the first waves hitting the breakwater will reshape the scour protection material into a combined toe and scour protection. For both test series, four test runs were carried out with \( S_{om} = 0.03 \) and two additional test runs with \( S_{om} = 0.02 \) (the last with the water depth reduced to 0.20 m).

Measurements and Analysis

The waves were measured by a total of nine resistance type wave gauges, i.e. three in deep water, five in shallow water in front of the breakwater, and one behind the breakwater for measuring the overtopping generated waves (only Profiles 4 to 12).

A multigauge technique was used for separating the incoming and reflected waves, and subsequently determining the incoming significant wave height and the reflection coefficient both in deep water and in front of the breakwater. The waves reflected from the breakwater were absorbed by the wave generator applying DHI's AWACS system (Active Wave Absorption Control System).
The breakwater profiles were measured after each test for every 0.10 m across the flume (five profiles) before initiation of the tests and after each test run. The profiling was made by two lasers, one laser running on a beam placed across the breakwater for measuring the vertical distance to the breakwater and another laser for measuring the horizontal position of the other laser.

Analysis of the five profiles measured after each test run (for each 0.10 m across the flume) showed that the differences were very small, and thus the five profiles were averaged for the subsequent analysis. Analysis of the recorded profiles was made for determining the recession of the berm, i.e., erosion of the crest of the berm as shown in Figure 2. The waves behind the breakwater caused by wave overtopping were analysed with respect to the maximum wave height, $H_{\text{max}}$, and the spectral wave height, $H_{\text{m0}}$.

![Figure 2](pod12.96/dwg7130-3)  
**Figure 2** Definition of berm recession.

**Presentation of Results**

Profile developments, berm recessions, overtopping generated waves and reflection coefficients were analysed for the twelve tested profiles with the aim of studying the influence of berm armouring, berm free board, wave steepness, width of stone gradation of the berm material and permeability of the berm material. Finally, the results of the four series of tests carried out for studying the scouring were analysed.

**Influence of Armouring**

Three alternative berm breakwaters of the armoured type (Profiles 1, 3 and 4) were tested and compared to tests with a traditional berm breakwater consisting of two stone classes (Profile 2). Figure 3 shows the berm recession as function of the stability number calculated on basis of the wave height in front of the breakwater and $D_{n,50}=0.022$ m.
All three armoured type breakwaters showed significantly less erosion volume and berm recession compared to the traditional berm breakwater. The profile resulting in the smallest erosion volume and berm recession was Profile 3 (an armour layer at the top and at the front of the berm) followed by Profile 4 (armour layer placed as a hammer head), whereas Profile 1 (armour at the top of the berm) showed a little less effect, but has an advantage in construction.

Figure 4 shows the berm recession for the three armoured type berm breakwaters relative to the recession of the traditional berm breakwater as function of the near shore stability number. The increased stability of the armoured berm breakwaters implies that the overall dimensions can be reduced compared to a traditional berm breakwater, which will reduce the construction costs.

Comparisons of the test results for Profiles 7 and 8 (lower crest and berm elevation) also showed a significant reduction in the erosion volume and berm recession using the largest stones for armouring of the berm. The effect of the armouring was somewhat less pronounced for Profiles 5 and 6, run with a wave steepness of $S_{00}=0.03$. 

*Figure 3* Dimensionless recession ($\text{recession}/D_{n,50}$) as function of the nearshore stability number. Note: $D_{n,50}$ is for the entire berm.
Testing of Profiles 1 to 3 included long duration tests consisting of 10,000 waves with a stability number $H_o=4.0$. The results showed that an equilibrium profile was reached after about 8,000 waves, assuming no deterioration of the stones.

For the test series with a high crest elevation (Profiles 1 to 4), the overtopping generated waves were very small, whereas for the test series with a lower crest elevation (Profiles 5 to 8), the overtopping generated waves measured 1 m behind the centreline of the breakwater were analysed. For wave heights up to a stability number corresponding to about 3, the waves behind the breakwater were mainly due to transmission through the breakwater, whereas for larger incoming waves, overtopping became dominant.

Figure 5 shows the transmission coefficients (including overtopping generated waves) calculated on basis of the spectral wave height behind the breakwater as function of the nearshore stability number. The overtopping wave heights were found to be smaller for the armoured type of berm breakwater (Profiles 6 and 8) than for the traditional berm breakwater constructed of two stone classes (Profile 5 and 7). The effect on the wave overtopping is mainly due to the reduced berm reshaping for the armoured berm breakwater. The maximum wave height varied only a little for the different profiles.
Figure 5  Wave transmission coefficients based on the spectral wave height of the overtopping generated waves as function of the nearshore stability number.

The reflection coefficients for the tested berm breakwaters are a function of both wave conditions and breakwater profiles. This means that the reflection conditions are changing with the berm reshaping during the test runs, and thus the results are average values over the period of each test run. The reflection coefficients were found to be higher for the armoured type of berm breakwater compared to the traditional berm breakwater constructed of two stone classes due to the reduced profile reshaping.

Influence of Stone Gradation

Tests were carried out with two stone gradations, a wide stone gradation having $D_{n,85}/D_{n,15}=1.80$ (Profiles 5 and 7) and a more narrow having $D_{n,85}/D_{n,15}=1.40$ (Profiles 9 and 10).

It was found that the wider stone gradation resulted in larger erosion volume and berm recession. Therefore, also the rear side stability was reduced for the wider stone gradation. In a wide stone gradation, the smaller stones will partly fill the voids between the larger stones resulting in a reduced permeability, which for the considered stone gradations are expected to cause increased erosion volume and berm recession due to decreased energy dissipation in the berm.

Larger overtopping generated waves were found for the tests with the wide stone gradation (Profiles 5 and 7) than for the tests with the more narrow stone gradation (Profiles 9 and 10).
A significant increase in the reflection coefficients was found for the tests with the narrow stone gradation due to the reduced berm reshaping.

**Influence of Permeability**

Wave run-up and overtopping conditions are significantly influenced by the presence of fine material in the berm material reducing the permeability and thus the energy dissipation, which is one of the main features of berm breakwaters. The permeability of a berm breakwater may be reduced by the presence of finer materials, which could be either in the surface of the berm or in the entire berm. The first case could occur if e.g. a temporary construction road on the berm is not removed after completion of construction and the latter case as an outcome of deficient design or construction.

The influence of the permeability was studied by testing of two profiles with finer material added either to the top of the berm or to the entire berm constructed from stones with the narrow gradation, \( D_{n,85}/D_{n,15}=1.40 \). An increase in the erosion volume and berm recession was observed by adding finer material to the top of the berm (Profile 11). Adding finer material to the entire berm (Profile 12) led to a further increase in the erosion volume and berm recession. Further, a significant increase in overtopping was found, resulting in severe damage to both crest and rear side. Figure 6 shows the influence on the berm recession by reducing the permeability of the berm.

![Figure 6 Influence of permeability on berm recession.](image)
Scouring

A total of four test series were carried out for a qualitative study of the influence on the scour development in front of a berm breakwater and on the berm reshaping for two types of scour protection. The tests also included a study of the influence of the wave steepness.

The two profiles without a scour protection layer showed subsidence of berm stones into the sandy seabed, which resulted in larger berm recession. The tests showed the development of a larger scour hole in front of the breakwater for the tests with the smallest wave steepness.

Introduction of a scour protection layer moved the scour hole out in front of this. Further, no subsidence of berm stones into the sandy seabed was found and thus the reshaping of the berm was reduced.

Finally, a test series was carried out with the scour protection material placed as a 0.10 m layer covering the front slope of the berm, the idea being that the material under the exposure of the first waves will reshape into a toe and scour protection. During the reshaping process, some of this scour protection material was mixed into the berm material. The resulting reduced permeability led to increasing wave run-up and overtopping reducing the stability of the structure.

Conclusions

Model tests were carried out in a wave flume with the aim of studying the difference in reshaping of a traditional berm breakwater constructed of two stone classes and an armoured type berm breakwater with the largest berm stones used as an armour layer covering a part of or the berm. Further, the influence of the width of the stone gradation for the berm material and the permeability of the berm material was studied.

Finally, tests were carried out for studying the scouring in front of a breakwater without any scour protection followed by testing of two types of scour protection.

Wave conditions in front of and behind the breakwater were measured together with the profile development. All test series consisted of five test runs ($H_o$=2.0, 2.5, 3.0, 3.5 and 4.0, in deep water), each with a duration corresponding to 2,000 waves. However, for Profiles 1, 2 and 3, another 8,000 waves with $H_o$=4.0 were run for studying the long-term stability.
The main conclusions of this study can be summarised as follows:

- Comparisons between traditional berm breakwaters and berm breakwaters of the armoured type showed a reduction in the erosion volume and recession of the berm for the latter. An armour layer protecting both the top and the front of the berm (Profile 3) was found to be more effective than both the hammerhead solution (Profile 4) and a thicker layer at the top of the berm (Profile 1).
- A reduction in the berm width can be obtained by using the largest stones as an armour layer. However, the effects vary with a range of parameters, e.g. wave steepness, stone gradation, permeability, and breakwater geometry.
- A reduction in the wave overtopping was found for the armoured type of breakwater mainly due to the reduced berm reshaping.
- The reflection from a berm breakwater is dominated by the slope of the reshaping profile, and thus the wave reflection from the armoured type of breakwater was larger than for the traditional berm breakwater.
- An increase in the berm freeboard is associated with an increased berm volume and was found to reduce the reshaping of the berm.
- The berm reshaping was found to increase for decreasing wave steepness, i.e. increasing wave period.
- Tests made with two stone gradations showed larger erosion volume and berm recession for the wider stone gradation.
- Tests with fine material added to either the top of the berm or the entire berm (reducing the permeability) showed a significant increase in the berm recession and wave overtopping.
- Subsidence of berm stones into the sandy seabed was found for the profiles without a scour protection layer.
- Introduction of a scour protection layer extending 0.50 m (model) in front of the berm moved the scour hole out in front of this, and no subsidence of berm stones into the sandy seabed was found and thus the reshaping of the berm was reduced.
- During reshaping of the scour protection material placed as a 0.10 m layer covering the front slope of the berm, some of this finer material was mixed into the berm material. This reduced the permeability and led to increased wave run-up and overtopping.

Acknowledgements

The present study was carried out as a part of the research project on Berm Breakwater Structures co-sponsored by the European Commission under contract MAS2-CT94-0087 (1994-97).

The model tests were carried out at the Danish Hydraulic Institute, and the authors wish to thank Mr Per Vedel Brøndsted, Mr Erik Mathiesen, Ms Renata Archetti and Mr Nikolay Lissev for their assistance in carrying out the model tests and doing the initial analysis of the measurements.

Berm Breakwaters, Fifteen Years Experience

Sigurdur Sigurdarson¹, Gisli Viggosson¹, Sigtryggur Benediktsson¹, Sigurdur Einarsson¹ and Omar Bjarki Smarason²

Abstract

Berm breakwaters have been designed and constructed in Iceland since 1983. Over twenty rubble mound structures of the berm type have been constructed so far, fourteen were new structures, whereas the remaining six were improvements or repairs of existing breakwaters. During 1998 two berm breakwaters are being extended. Further two structures will be built every year for the next 2-3 years.

Although some of the berm structures in Iceland have already experienced the design or near to design wave conditions, only minor profile changes have been observed. Valuable experience has, however, been learned from the inspection of the reshaped profile of one structure.

The initial idea of berm breakwaters was that they should be wide voluminous structures, built of two stone classes with a wide size gradation. The Icelandic type of berm breakwaters has however been developed into a less voluminous, more stable structure, where large emphasis is put on maximising the outcome of the armour stone quarry and utilising this to the benefit to the design.

Introduction

At the Icelandic Maritime Administration (IMA) a variant of the original berm breakwater constructed of one or two stone classes has been developed. This variant can be described as “a tailor-made size graded berm” (Sigurdarson et al, 1996). The berm structure is build up of several size-graded layers. The largest stones are placed on top of the berm and some times also at its front, where they will be most effective in order to reinforce the structure, Figure 1. Smaller stones are used in the inner layers of the berm, even smaller than in the original berm breakwater, increasing the utilisation of the quarried material. The reinforcement of the berm has made it possible to reduce the berm width, which reduces the volume of the structure. The use of larger stones more narrowly graded on top and at the front of the berm has been

¹ Icelandic Maritime Administration, Vesturvor 2, 200 Kopavogur, Iceland
² Stapi Ltd. – Consulting Geologists, Armuli 19, 108 Reykjavik, Iceland
proved in model tests to decrease reshaping of the berm (Sigurdarson et al, 1998). This is due to a combination of larger permeability and the ability of the structure to swallow the wave more rapidly.

Development of design process
The design process for berm breakwaters in Iceland has been developed through the years in close co-operation with all partners involved, designers, geologists, supervisors, contractors and local governments. At the same time, the designers have been directly involved in the hydraulic model studies and supervision of the construction of the breakwaters. Instead of looking at the berm as a mass of stones, the design focuses more on each unit. It has become clear that “no construction unit is as far from being standardised as the armour rock in the primary cover layer with regard to form, strength and durability” as stated by Viggosson (1990).

Wave load and possible quarry yield
The design philosophy of berm breakwaters aims at optimising the structure with respect to wave load and possible yield from an armourstone quarry. The estimated yield from an armourstone quarry is used as an integrated part of the design process in an attempt to optimise the utilisation of the quarry.

Collaboration between designer and geologist
Close collaboration between the designer and geologist in the preparation of berm breakwater projects has been proven very effective over the years (Smarason et al, 1998). This has resulted in better designs and better use of the quarried material. This collaboration gives the designer the chance to fully utilise all rock classes from the quarry and has often resulted in 100% utilisation of the quarries. Close cooperation between the geologist, the project supervisor and the contractor is often

Figure 1. The Bolungarvik breakwater in 1995 two years after construction.
necessary to achieve maximum results in the quarry. Blasting and sorting of armourstone is by no means an easy task and slight alteration of spacing and tilt of drillholes may at times help to improve blasting results. It has to be realised that the contractor and the buyer should work as a team aiming for the same goal. Experienced contractors rely on the predicted quarry yield curves in their bidding.

**The origin of the Icelandic Berm Breakwater**

In the late seventies and early eighties many researchers and engineers were occupied with the idea of equilibrium slope and the importance of permeability (Bruun and Johannesson, 1976). Lessons were learned from 19th century breakwaters, like the breakwaters in Plymouth, England, and Cherbourg, France. These breakwaters were built by dumping all quarried material at the breakwater site. It was stated that when “maturing” the breakwaters might develop an S-shape.

In the early eighties the berm breakwater was introduced. For the protection of a runway extension in Unalaska, Alaska, Hall et al (1983) proposed a wide berm of one rock class, where the armour system was designed so that essentially 100% of the quarry was utilised. The stability of the armour layer was to develop during early stages of wave attack. Model tests showed that with greater thickness of the armour layer, the smaller the stones needed to be.

Gradually the ideas of berm breakwaters developed more and more to a dynamic or reshaping breakwaters. Van der Meer and Pilarczyk (1986) grouped berm breakwaters or S-shape profiles as having a stability parameter, $H_s/\Delta D_{n50}$, between 3 and 6. It became the general idea that berm breakwaters were only applicable where large stones were of limited supply. These structures were built up of a homogeneous berm of relatively small stones with wide size gradation.

**The natural dynamic structure**

What can we learn from nature about dynamic movements of stones? First we will look at gravel or shingle beaches and then move to larger units in rock slopes or boulder beaches.

Gravel or shingle beaches are in some places built up of stones, which are all of similar size as a result of sorting by the sea. The fines have been sorted from the shingle and are found in less exposed areas of the beach. These beaches can have a stability parameter, $H_s/\Delta D_{n50}$, in the range of 50 to 200. As a result of a uniform particle size the gravel beaches have a high permeability. They form a dynamic profile often with a rather steep slope. What happens when we try to scale up the experience from these gravel beaches?

In some places around Iceland rock slopes or boulder beaches exist. The boulder reef at Rif, Figure 2, is an example of this. The height of the reef, which is in an area of 4 m tidal difference at spring tide, is about 5 to 6 m above low water level, with front slope of about 1:4.5 to 1:8. Seen from distance this reef looks like the ideal dynamic berm breakwater. Rounded boulders of several hundreds of kilos up to 1 or 2 tonnes form the surface of the reef. The stability parameter, $H_s/\Delta D_{n50}$, is in the range 3 to 6. This natural dynamic structure looks quite permeable. But looking in-between
the boulders on the surface, smaller stones appear, some tens of kilos in weight. When they are picked up it can be seen that voids are plugged by gravel and sand. Less than 1 m from the surface of the reef all voids are filled up with small particles. The reef is a wide structure with a flat slope over low water level. The natural armouring, which can be looked at as two layers of stones, is in a dynamic action during storms. The waves are breaking on the slope causing high uprush and overtopping. But the reef is by no means a porous structure that swallows up the wave energy.

Figure 2. The boulder reef at Rif is a natural dynamic structure.

The dynamic berm breakwaters

Similar trends can be seen in the reshaped berm breakwater at Bakkafjordur in north-east Iceland (Sigurdarson et al, 1998). The berm breakwater at Bakkafjordur was built in 1983 and 1984 from stones of rather poor quality quarried at the breakwater site. Deterioration of the stones has accelerated a dynamic development of the profile. In the winter 1992/93 the breakwater is believed to have experienced waves close to the design load. The berm was eroded up to the crest and an unstable S-profile had developed. Repair took place in 1993 and in spite of the poor quality of the rock it was decided to use the local quarry again. In the autumn of 1995, the structure was exposed to the design storm. Video recordings from the storm show breaking waves in front of and on the structure, resulting in heavy overtopping. Inspection of the reshaped profile showed that deterioration of the stones had caused filling and plugging of voids and the structure did not function as a berm breakwater any longer, Figure 3. The main conclusion that can be drawn from the Bakkafjordur breakwater is that in a dynamic structure stones will break and the voids will gradually be filled up with smaller stones. This will decrease the ability of the structure to dissipate wave energy. Inspection at the site led to the conclusion that the poor quality (highly altered tholeiite basalt) of the stones in the Bakkafjordur breakwater only accelerated a development that would occur over a longer time period if it was built of better quality stones.
The rolling stones

The first concerns regarding rock quality came up at the same time as the berm breakwater was introduced in the early eighties (Poole et al, 1983). Those concerns were from the start a part of the development of the Icelandic berm breakwater. As stated before, no construction unit is as far from being standardised as the armour rock. Usually a large portion of natural stones used in breakwater construction has some fractures or other defects. When the stones start to move or roll up and down the slope and hit each other, high abrasion and splitting of stones will occur.

The presence of fines on the reshaped slope of a berm breakwater will result in plugging and filling up of voids, and an increase in the forces acting on each rock unit on the slope. This in turn will accelerate the dynamic movements of the stones and increase their breaking and splitting.

Rocking of stones in a berm breakwater can be accepted, but not rolling. The only rolling stones that last the rock 'n' roll are The Rolling Stones them selves.

Design Procedures

When designing the Icelandic type of berm breakwater the goal is that it shall be statically stable. Some deformation of the berm is allowed under design conditions, but reshaping into an S-shape is not allowed. It is recognised that the reshaping will increase during the lifetime of the structure, because of insufficient stone quality and repeated wave action. The design approach is not to fulfil certain prescribed stability parameters, Hs/ΔD50, but to look at the correlation between the armour stone quarry, size distribution and quality; the design wave, height, period and direction; water depth; function of the breakwater, for what purpose is it built, is wave overtopping a
problem or not. In many cases we have been able to design berms with a high stability of the armouring layer without any extra cost.

**Design parameters**

Various parameters have been proposed to describe the berm profile, like the horizontal width of the berm or the cross-sectional area of the berm from surface to bottom. These parameters are not good to compare different design. Differences in upper and lower slope can change the width parameter significantly although the structure is almost the same. Deep water / shallow water or if the berm does not extend to the sea bottom influences the area parameter very much, although the structure may function the same. The width parameter has on the other hand no information on the location of the core relative to the inner edge of the berm, which is important, as the berm can extend under the upper slope and still function to swallow up the wave energy.

In order to be able to compare different berm structures with regard to stability and overtopping two parameters have been defined that describe the thickness and the volume of the berm, Figure 4. The first parameter is the horizontal thickness of the berm from surface into the core, \( B \), measured at design water level. In the case that the core height is lower than the berm height, the parameter is measured to the extended core slope. The other parameter, \( A \), is the cross-sectional area of rock under and over the aforementioned line from surface into core, one wave height down and one up (1.5 wave height down could also be considered). The area is measured into the centreline of the crest structure. Both parameters are made dimensionless with wave height, \( B/H_s \) and \( A/H_s^2 \). Design guidelines for these parameters, dependent on the stability parameter, \( H_s/\Delta D_{h50} \), are under development.

![Figure 4. The parameters proposed for description of berm thickness.](image-url)
Construction

A berm breakwater can be constructed using readily available land based methods and less specialised construction equipment compared to the construction of a conventional breakwater. Usual equipment comprises of a drilling rig, two or three backhoe excavators, sometimes a front loader, and some trucks, Figure 5. When the first berm breakwaters were built, bulldozers were used to push stones to the berm. That resulted in breakage of stones and too many fines that plugged the voids. Backhoe excavators with open buckets or prong, up to 75 tonnes, are used to place stones. The number of trucks depends largely on the transport distance. Tolerance for the placement of stones is greater than for the conventional breakwater design. Usually no underwater placement is necessary, as the front slope is steep. Placement of stones in a slope of 1:1.3 has been achieved down to 8 -10 m water depth.

Figure 5. From the construction of the Dalvik breakwater during the winter 1994-95.

Experience from Iceland shows that small local contractors can quickly adopt the necessary technique to construct berm breakwaters successfully (Sigurdarson et al 1997). The risk during construction is much lower and repairs are also much easier than for the conventional breakwaters. Each breakwater project is tendered out and there is competitive bidding for the works from up to 10 contractors. The lowest bid is usually accepted.

Good interlocking of carefully placed stones is advantageous at the front and the edge of the berm. Experience from many breakwater projects has shown that working with several stone classes and placement of stones only increases the construction cost insignificantly. The construction period of larger projects often extends over two years and experience has shown that partially completed berm breakwaters function well through winter storms. Repairs are much easier than for the conventional breakwaters.
Construction cost has been cut considerably in some recent projects by using dredged material, usually coarse sand and gravel, as a part of the inner core of the structure. Although the berm breakwater is constructed of several layers the advantage of using simple construction methods are still achieved. The advantage of sorting the stone mass into several stone classes to strengthen the structure is far greater than the relatively low additional cost.

Recent developments in berm breakwater design have aimed at using extra large stones (16-25 tonnes) in the more exposed parts of the structures with high wave load. The reason is twofold. Firstly, many of the better quarries are found to produce 10 to 20% of armourstones exceeding 10 tonnes in size. And secondly, heavier machines with greater capacity, like large backhoe excavators, have recently become more readily available from contractors. A relatively low percentage (1-3%) of the largest stone class can be an advantage for most breakwaters. This is not only true for these extra large stone classes but also applies to lower wave load conditions and where quarries with lower size distribution are used.

**The Berm Breakwater Structure MAST Project**

The design philosophy of the tailor-made size graded structure has proven to reduce deformation of the berm and at the same time lead to a less expensive structure. JMA has recently participated in a European MAST project Berm Breakwater Structure (Sigurdarson et al, 1998) and (Juhl et al, 1998). A series of model tests were carried out in a wave flume at the Danish Hydraulic Institute. The difference in reshaping of a berm breakwater constructed of two stone classes was compared with armoured Icelandic type structure. One of the conclusions of the MAST project was that the Icelandic type structures showed a reduction in erosion volume and recession of the berm compared to the original berm breakwaters. The Icelandic design with armouring on top of and at the front of the berm, allows a significant reduction in the berm width, which varies with a range of parameters as for example wave steepness, stone gradation and breakwater geometry.

**Comparative Cost Analysis**

**Conventional rubble mound versus dynamic berm breakwater**

Several studies have been published comparing conventional rubble mound breakwater to dynamic stable berm breakwater. Ligteringen et al (1992) has published a comparative evaluation of various breakwater structures for a site between the islands of Lamma and Cheung Chau in Hong Kong. The water depth ranges between 10 and 18 m. The seabed consists of 15 to 25 m thick, soft marine deposits overlying alluvium. The site is exposed to typhoon generated waves with significant wave height of about 6.0 m. A comprehensive range of breakwater and geotechnical solution has been taken into consideration. In the second stage evaluation construction cost is given for a dynamic berm and a conventional rubble mound breakwater for three breakwater layouts. The cost for the berm type ranges between 67% and 86% of the cost for the conventional rubble mound.

Hauer et al (1995) has made a detailed comparison between a conventional statically stable breakwater and a dynamically stable berm breakwater. Two types of
quarry yield curves are used, a wide curve and a steep curve. According to this study the differences depend strongly on the way the quarry yield is subdivided into different stone classes for both types of breakwaters. Overproduction of the lighter stone classes is necessary to satisfy the demand for the heaviest armour stone classes. And it is stated that the extent of this overproduction has decisive influence in the comparison of the total cost. This is in very good agreement with experience from Iceland.

They conclude that for the specific harbour layout and the specific wave conditions considered in this study the construction of the berm breakwater instead of a conventional rubble mound breakwater resulted in considerable savings. Up to 64% savings of the total cost could be achieved for transport distances from quarry to construction site of 0 to 25 km. For extremely long transport distances, 250 km, 30% savings could still be achieved

Icelandic type berm breakwater versus conventional rubble mound breakwater

First a comparative cost analysis will be presented between the Icelandic berm breakwater and the conventional rubble mound breakwater. Then the difference between the Icelandic and the dynamic approach will be discussed.

The following cost comparison is influenced by a breakwater being designed in a moderate wave climate in Iceland. The structure stands on an 11 m water depth, where the mean spring tidal difference is about 4 m. The design wave height is Hs 3.0 m with mean period of Tz 9.2 s, the mean high water spring tide is +4.0 m and the design water level is +4.7 m. A conventional cross section is designed with a front

Figure 6. Cross-sections for the comparison between the conventional rubble mound breakwater and the Icelandic type berm breakwater.
slope of 1:1.5, a crest elevation of +8.75 and a toe structure at the front at -3.5 m, Figure 6. The required average mass of stone is determined according to the methods of van der Meer (1988 and 1993). Designing for damage factor $S = 2.1$, practically start of damage, storm duration of 3 hours, the mass density of the basaltic rock 2.85 tonne/m$^3$, the required average mass of stone, $M_{50}$, is 4.7 tonne. Armour stone classes are class I, 3 to 8 tonne. The harbour side is protected be class II, 1 to 3 tonne stones and class III, 0.3 to 1, tonne stones are used as filter layer on both sides. The available armour stone quarry is expected to give about 10% in class I, 13% in class II and 17% in class III.

To make the comparison not to favourable for the berm design, the same stone size is used on top of and at front of the berm as for the armour layer on the conventional breakwater, meaning an unusually high stability for a berm breakwater, Figure 6. The harbour side of the two cross-sections is completely the same, as is the toe structure on the front side, the only difference being the front of the structures from crest down to toe.

The cost estimate is very dependent upon the distance to the quarry. In general, quarries for production of armour stones and core material are within a distance of 10 to 15 km from the construction site. If the distance to a suitable armour stone quarry is more than that, another quarry closer to the structure is usually used for production of the core material. In the calculated example, the distance from the quarry to the breakwater site is about 10 km.

It is also common to use dredged material in the inner part of the core for economical reasons. The price difference of using dredged material instead of trucking the available quarried material in the case of the conventional breakwater is about 20% per m$^3$ in this case. Table 1 sums up key parameters in the cost comparison.

</table>

Table 1. Comparative cost analysis between the Icelandic type berm breakwater and the conventional rubble mound breakwater.
In total there is a 15% difference in cost in producing and transporting stones and core material, 10% difference in placing the material and 5 to 20% difference in limited competition. This adds up to 30 to 50% higher cost for the conventional breakwater. Even in a moderate wave climate, the difference is this high and with higher design wave height the difference will increase. Also, a poorer quarry yield will increase this difference. Although a better quarry yield lowers the difference, the difference in placing and limited competition will still remain. This should answer the question, why we retain the berm concept, even though the structure aims at static stability with a number of different rock gradings.

**Icelandic type berm breakwater versus dynamic berm breakwater**

In the example above, a dynamic structure would need to be of the order of 10% more voluminous than the Icelandic berm breakwater and the dynamic berm would need at least 25% more volume of stones than the Icelandic type berm. The cost of this far exceeds the cost for sorting and placing several stone classes. The largest waste in the two-stone class berm breakwaters is twofold. Firstly, large stones are used or are lost into places where they are not needed, at large water depth or inside the structure close to the core. And secondly, the contractor is not asked to produce close to the maximum yield from the quarry.

The cost comparisons with the Icelandic type berm breakwater are not comparable with the aforementioned studies, Ligteringen et al (1992) and Hauer et al (1995), since they may rely on different assumptions.

**Recent examples**

**The Dalvik breakwater**

The Dalvik breakwater, which was constructed in 1994 and 1995, is 320 m long and has a volume of 104,000 m³. The available quarry was of good quality with predicted quarry yield of 46 to 54% over 0.3 tonne. As the wave load was moderate, the design anticipated the use of dredged material in the inner part of the core, coarse sand or gravel, up to 30% of the total volume of the structure. The dredged mound experienced a winter storm before protected with material from land, but only minor

![Figure 7. Cross-section of the Dalvik breakwater](image-url)
deformation of the mound was measured. Figure 7 shows a cross-section of a trunk section. Class II rock, 1.5 to 4.0 tonne rock with stability parameter 1.6, covers the berm in two layers from low water level up to the crest and in one layer on the rear side. Class III rock is used between class II and the core material. The reason for class III extending down to sea bottom was that the design anticipated that all quarried material was placed with land based equipment. In order to increase the thickness of the berm around design water level a flat slope, 1:2.5, of the core is chosen. Class I rock, ≥ 4 tonne, is used on top of the berm at the breakwater head. The design fully utilises all stones over 0.3 tonne with an overproduction in both classes I and II. A 100% utilisation of all quarried material was achieved in spite of the use of dredged material.

The Husavik breakwater

The Husavik harbour located on the north east coast of Iceland is exposed to waves and swells from north-west to north-east. The outer breakwater, a concrete pier, was widened and protected from overtopping in 1989 to 1990 by a berm structure (Sigurdarson et al, 1995). Still the pier did not shelter the harbour sufficiently well and in the summer of 1997 a contractor was hired to construct a 100 m long breakwater, as an extension to the pier. Figure 8 shows a cross-section of an outer trunk section. One of the features of this design is that the front slope of the berm is more flat than usual, 1:1.5 over elevation -1.0. This is done to increase the stability of the berm. Another feature is the location of the core in relation to the crest or the inner edge of the berm. This location aims at minimising the total volume of the structure. On the breakwater head and outer most 20 m class I rock covers the front and top of the berm, but class II rock on the rest of the structure. The upper slope, crest and back slope are on the other hand covered by class III rock, as is the front slope under -1.0 m in elevation. The inner part of the structure is built up of class IV rock. The design aims at fully utilising all rocks from the quarry over 0.5 tonne, given that the contractor produces close to the maximum quarry yield, which is 35%.

In the autumn of 1997 sudden changes in the use of the harbour became evident. This development made an alteration in the location of the breakwater

necessary. The new location is in a more exposed area. Since funds were not available for a full construction the contract was renegotiated so that rocks were produced and stored near the new location.

**Conclusion**

Instead of a dynamic approach to berm breakwater the Icelandic type aims at a more stable structure. The use of larger stones more narrowly graded on top and at the front of the berm increases the permeability and the ability of the structure to swallow the wave more rapidly.

Although the Icelandic berm requires larger stones than the dynamic type it aims at maximising the utilisation of all quarried material. And often only a small fragment of the quarried material is used to reinforce the structure. It has been proven in many projects that the Icelandic berm lowers the construction cost significantly. Large, voluminous, dynamic structures may be attractive in some special cases. It is, however, believed that the narrower, stable Icelandic berm has a much wider usage. In the dynamic approach uncontrolled movements of stones will occur which can not be accepted, especially in the breakwater head.

Cost comparison between the Icelandic type berm breakwater versus conventional rubble mound breakwater show significant reduction in the construction cost. The Icelandic berm breakwaters have proved to withstand design or near to design wave condition with only minor profile changes, Figure 9.

References

An alternative berm type breakwater was proposed at the South Breakwater of the Typhoon Shelter at Hei Ling Chau, Hong Kong. The required berm width and the stone sizes were initially determined using a numerical model. The proposed berm breakwater was then tested using physical modelling approach. The testing programme made use of both two dimensional and three dimensional hydraulic model studies to assess the stability of the trunk and head sections respectively. Both tests confirmed that the proposed berm type breakwater would perform satisfactorily and the reshaped profiles would not encroach on the core material.

Introduction

To meet the forecast demand for typhoon shelter space in Hong Kong, it is recommended that a typhoon shelter at Hei Ling Chau be constructed to provide about 50 hectares of effective anchorage area. As the typhoon shelter would be located at the southwest of Hei Ling Chau, three breakwaters (see Figure 1) with a total length of about 2.6 km would be required in order to provide a safe and calm anchorage area. Among these three breakwaters, the South Breakwater will be exposed to the severe waves approaching from the southeast direction. Various types of breakwater have been considered for the design of the South Breakwater. However, if the South Breakwater was to be designed as a conventional rock armoured breakwater, it was estimated that an armour rock size of 17t was required. This is generally not commercially available in large quantity in Hong Kong. Precast concrete units could be used instead of amour rocks, but in this case 4t to 9t of cubes,
tetrapods or accropods would be required, which will require large works area for construction and thus increase the construction cost.

As an alternative option, the dynamically stable berm type breakwater was considered. With this type of breakwater, the size of armour rocks required would be smaller than that for a conventional breakwater. The construction cost would be lowered. The profile of the breakwater will, however, adjust to severe storm events. The dynamically stable berm type breakwater is thus considered as the preferred form of construction for the South Breakwater. In this paper, development of the berm type breakwater from the outline design to the verification using a physical model is presented.

Figure 1 Typhoon Shelter at Hei Ling Chau, Hong Kong

Berm Breakwater Concept

The berm breakwater design consists of a porous berm of armour stones which dissipates wave energy. The stones are expected to move under wave action leading to a stabilised and consolidated equilibrium profile. As a result, the shear strength of the stone mass and the resulting overall stability of the structure increases as the stones settle, nest and interlock. The geometry of the breakwater is a function of the prototype stone gradation and the design wave conditions.

The initial width of the berm determines the extent to which the profile reshapes. Berm breakwaters may be designed so that:

(i) full reshaping of the berm occurs (dynamic)
(ii) only a slight rounding of the outer edge of the berm occurs (static)
The dynamic design is a more common form of the berm breakwater and is the concept which has undergone the most extensive investigation. This type of structure is very cost effective and allows for maximum utilization of the quarry material. By knowing the quarry yield and the relative volumes of core to armour, the quarry yield can simply be split such that a production balance between core and armour is maintained for full utilization of the quarry. The dynamic berm concept has been implemented at a number of prototype locations in Australia, Canada, Iceland, the South Pacific and the USA with great success.

The static design approach requires approximately 70 - 80 % more material and is therefore more costly. However the factor of safety is increased. Static berms have been utilized in Australia, Iceland and the South Pacific.

Implementation of the berm concept at Hei Ling Chau also presents several advantages to the contractor involved with construction of the breakwater. The berm design is simple and thus an easier structure to build. With the berm alternative, it is only important to ensure that the full berm width is placed according to the design. Minimum underwater inspection is required due to the fact that the seaslope will change with time and thus may be built at the angle of repose of the stones. Furthermore, the armour layer is built up from the core until the required berm width is achieved. Feasibility of the berm breakwater applications in Hong Kong can be found in Chow and Sayao (1991).

Wave Climate and Design Storm

The extreme waves attack at the south of Hei Ling Chau are mainly generated by typhoons. There were no measured wave data available at the study site, the design wave conditions were derived using wave hindcasting techniques. The extreme offshore wave climate was hindcast using a parametric wind wave generation model developed by the Hong Kong Polytechnic University (Li et al 1992). For waves approaching from the south and southeast of Hei Ling Chau, various numerical models considering the effects of refraction, shoaling, bottom friction and wave breaking were applied to derive the nearshore wave climates. The derived design wave conditions can be found in Table 1. The Storm No. roughly represents the return period of the design storm.

Conceptual Design

Based on the above design storm, a quarry stone size of 17t was computed to be required for the conventional breakwater. However, this stone size is generally not locally available in large quantity commercially. Using the software BREAKWAT acquired from Delft Hydraulics, a conceptual design of the berm breakwater was carried out. The software showed that a width of berm of 12 m and a median rock size of 2 t and 4.5 t were found to be appropriate for the trunk and head sections respectively under the design storm conditions. Typical cross-section of the proposed berm breakwater profile can be found in Figure 2.

![Figure 2. Typical Trunk Section of the Berm Breakwater](image)

Physical Model Tests

To confirm the conceptual design, Scott Wilson was engaged by the Port Works Division of the Civil Engineering Department to undertake physical hydraulic model tests at the Hydraulics Laboratory of the National Research Council (NRC) in Canada. The testing programme made use of both two dimensional (2D) and three dimensional (3D) hydraulic model studies to assess the stability of the trunk and head sections respectively.
Testing Facilities and Model Set-up

The 2D berm breakwater stability tests and the 3D physical hydraulic model tests were carried out in the 14 m coastal wave flume and the multi-directional wave basin at NRC respectively.

Figure 3 illustrates the layout of the 2D model test structures in the 14 m flume (dimensions in model units), the irregular wave-generator and the location of the wave probes used to measure both the wave climate and reflection coefficients. Two model berm breakwater cross sections were tested (side by side) in the 2D model; one with a 12 m berm width and a second with a 18 m berm. As a consequence of this arrangement, both model structures were subjected to the identical wave climate.

Figure 4 illustrates the layout of the 3D model test structure in the Multidirectional Wave Basin, the location of the wave probes used to measure the wave climate and the location of the profile lines selected to record profile reshaping. The 3D model berm breakwater structure consisted of a 90 m trunk section, the full 75 m transition and the complete head. The wave basin is an indoor wave tank which is approximately 30 m by 20 m. The maximum depth of water is approximately 2.5 m. The segmented wave machine (60 individual paddle segments, total paddle length of 30 m) utilized in this basin is capable of producing model significant wave heights of 1 m, and can reproduce the interaction of irregular waves from different directions, i.e. truly three dimensional sea states. The basin is sufficiently large such that a 90° change in wave direction can occur at any point during the design storm without moving either the model structure or the wave machine. This means that many directions of wave attack may be modelled in this facility.

Because the bathymetry of the site at Hei Ling Chau is characterized by a very flat slope, the seabed topography for both 2D and 3D models was not modelled. That is, all tests were conducted with a fixed horizontal bottom located at elevation -7.0 mCD. The wave flume had a series of capacitance-type wave gauges located at strategic locations to measure the wave characteristics. The measured wave records were analyzed using zero crossing analysis and variance spectral density analysis to produce wave parameters and spectral plots respectively.

Both 2D and 3D physical model tests followed the Froude model law (U.S. Army, 1979). It consisted of an undistorted, two-dimensional, fixed bed model, with a geometric scale of 1:30. The model was sufficiently large to avoid Reynold's effects (U.S. Army, 1984).
Required Stone Sizes

Armouring requirements for the trunk section of the model structure was specified in the Project Brief as Type 13 with the following parameters:

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

The Type 13 stone used in the 2D tests was also used for the trunk section in the 3D tests. Model armour stone was sorted in the laboratory to yield a gradation which closely represents the above specified values for the Type 13 and Type 14 materials.

Waves, Water Levels and Wave Measurements

Irregular waves were synthesized by specifying a JONSWAP wave energy density spectrum with $\gamma$ of 3.3 for both models. Wave measurement probes were positioned at various locations to measure water level fluctuations. These probes are representative of wave conditions generated by the wave machine, and the wave condition in front of the test structures. The specified wave climates and water levels for the 2D and 3D tests can be found in Tables 2 and 3 respectively.

Prior to testing the stability of the model structures, the waves were calibrated to the specified conditions. That is, for each Run, the (initially) synthesized wave train was generated in the model basin for a limited period of time. Data samples were recorded and analyzed. As a consequence, adjustments of the synthesized wave trains were required to "tweak" the waves to match those specified wave climate (see Tables 2 and 3). However, when the generated wave heights (at the wave machine) were increased for both 2D and 3D tests, more waves broke offshore of the berm structure resulting in a reduced wave climate and a significantly transformed spectral shape. By studying the spectral plots collected at the laboratory, it is believed that the longer period waves underwent transformation to another spectral form due to finite depth conditions.

Berm Breakwater Profiling Device

An automated berm breakwater profiling device was installed and used in the basin to record profile development. The device is an extremely simple mechanism used to measure any 2D (X,Z) surface profile be it a berm breakwater profile or a beach profile. The device operates on the concept of rolling a wheel over a surface and tracking the X,Z location of that wheel with a real time recording system. To accomplish this, a post and beam assembly was installed over the berm breakwater as shown in Figure 5. On the top surface of the beam, a mouse is moved from one end of the beam to the other by means of a hand crank, which pulls the mouse by a cable in tension. The horizontal location of the mouse is measured by a linear potentiometer at a frequency of 20 Hz. This measurement is the mouse location X₁ (see Figure 5) relative to some fixed reference point.
Two Dimensional Wave Flume Tests

A series of 2D berm breakwater stability tests were carried out in the 14 m coastal wave flume. Under the synthesized wave climate, both the 12 m and 18 m model berm breakwaters performed well. The reshaped profiles did not encroach on the core material, and the crest and backslope model armour material were stable under all wave conditions specified. The toe protection armour stone was also determined to be statically stable under the tested conditions.

Van der Meer (1987) has developed the parameter “S” which relates to the “damage” measure of a conventional breakwater structure. In the context of berm breakwater, the parameter “S” does not relate to damage, but rather to the degree of reshaping of the profile. Van der Meer defines “S” as

$$ S = \frac{A}{(D_{n50})^2} $$

where A is the eroded area and $D_{n50}$ is the nominal diameter of the armour stone associated with the 50% value of the mass distribution curve.

The actual value of S is not important, but rather the rate of change of S with respect to the number of waves. Since S really represents the degree of reshaping (in the context of berm breakwaters), one is interested in determining at what locations in the storm profile the rate of change of S is large, i.e. the profile is reshaping significantly, and subsequently, when the rate of change of S becomes small, i.e. reshaping has stabilized.

Figure 6 shows the values of S as a function of cumulative waves for each berm structure. It is apparent from these curves, that the rate of change of S is greatest in Run 3, which indicates that the greatest reshaping of the berm profiles occurred during this storm segment.

On a previous project, it was shown that a 9 m berm in 2D tests reshaped in a dynamically similar manner as an 11 m berm in 3D (all other parameters held constant) (Fournier et al, 1990). Therefore, the 3D tests will be more conservative estimates of breakwater stability than the 2D counterparts. To confirm the stability of the test section, 3D model tests were conducted for the 12 m berm breakwater design.

Three Dimensional Wave Basin Tests

Under the synthesized wave climate, the model berm breakwater performed well. The reshaped profiles did not encroach on the core material, and the crest and backslope model armour material were stable under all wave conditions specified. The toe protection armour stone was also determined to be statically stable under the tested conditions.
During Runs 4 to 8, longshore transport of the armour material occurred due to the 60° oblique angle of wave attack. The material was transported along the trunk towards the transition. Because of this longshore transport, the trunk profiles in close proximity to the transition actually built up due to deposition of Type 13 stone. The source of the transported material was the trunk section closest to the wave machine. As a result, a scour hole was developed in Run 5. To maintain integrity of the test and to simulate the supply of armour stone from a structure much longer than that which was modelled, "artificial feeding" of Type 13 armour stone was performed at the scour hole location. The rate of stone feeding was roughly in accordance with the rate of scouring.

Conclusions

With the aid of the software BREAKWAT, a berm breakwater with 12 m berm width was adopted for the South Breakwater of the Hei Ling Chau Typhoon Shelter. The proposed berm breakwater was tested in a 2D wave flume and a 3D wave basin. In the 2D and 3D physical modelling tests, the proposed structure would reshape, but without excessive damage, under the design storm conditions. Both 2D and 3D tests confirmed that the proposed 12 m berm breakwater performed satisfactorily and the reshaped profiles did not encroach on the core material.

Abstract.

The paper describes laboratory tests on berm breakwaters in shallow water, e.g. in water depths where waves might break before they break on the breakwater. Analysis have been made of test results for breakwaters in shallow and deep waters and a unified design equation is presented for the berm recession of berm breakwaters in shallow and deep water.

Introduction.

Rubble mound berm breakwaters are increasingly used throughout the world. The main advantage of the berm breakwater is that lower stone weights are required on a berm breakwater than on a conventional rubble mound breakwater of quarried rock.

During the EU MAST II Berm Breakwater Structures project model tests were carried out for a berm breakwater, including a breakwater head, in deep water at the Danish Hydraulic Institute, DHI (1995), Juhl et al (1996), while tests in shallow water on a trunk section and including a head were carried out at SINTEF, Tørum (1997), as supplementary tests to the more extensive tests at DHI. In addition 2D tests were carried out at DHI, DHI (1996), Juhl and Sloth (1998). "Deep water" means in this context that the waves will not break until they break on the breakwater, while "shallow water" means that some of the larger waves will break before they arrive at the breakwater due to depth limitation. In the present paper we describe the shallow water tests carried out at SINTEF and give some brief results from them. We further include results from other tests series, notably from Andersen and Fleming (1991), DHI(1995), Lissev (1993), Tørum (1988) and Tørum (1997, 1997A) to arrive at an equation for the recession of the berm as a function of the stone diameter, the wave height and wave period. This equation can be considered as a design equation for the berm recession.

Model Test Set-up.

The SINTEF "shallow" water model test set-up is shown in Figure 1. The waves were generated in 0.70 m water depth. After travelling for approximately 15 m, the waves climbed a slope of 1:30 to a horizontal plateau where the water depth was 0.25 m and where the breakwater model was placed.

Figure 1. Test set-up.

Three different cross-sections were tested, A, B and C, Figure 2. Section A is almost a copy of the section tested at DHI, except that the water is shallower and except that the initial slope of the outer slope of the berm was 1:1.5 while this slope was 1:1.1 for the DHI tests. The gradation of the berm stones was such that $D_{15} = 0.018 \text{ m}$, $D_{50} = 0.022 \text{ m}$ and $D_{85} = 0.030 \text{ m}$.

Figure 2. Tested cross-sections, A, B and C.

Wave measurements.

Wave measurements were carried out without the breakwater model being present in the flume. The wave measurements were carried out at the location of the centreline of the breakwater head with water depth 0.25 m, and in the deepest part of the flume, where the water depth was 0.70 m. The target spectra in "deep" water were JONSWAP spectra with an enhancement factor $\gamma = 3.0$. 
Figures 3 and 4 show the relation between the measured significant wave heights, $H_s = H_{mo}$, and the measured zero-upcrossing periods, $T_z$, at water depths 0.70 m and 0.25 m respectively. The measured peak period, $T_p$, is also shown. However, the peak periods are not as "robust" as the zero-upcrossing periods as it may be somewhat arbitrary for which frequency the peak in the calculated spectrum will occur.

In shallow water the highest waves will break. Thus the ratio between the maximum wave height, $H_{max}$, and the significant wave height, $H_{mo}$, is expected to be lower in shallow water than in deep water. $H_{mo} = 4 (m_o)^{0.5}$, where $m_o$ = area under the spectrum. Figure 5 shows this ratio for different significant wave heights for $T_p = 1.77s$.

Figure 3. Measured zero-upcrossing periods $T_z$, peak periods, $T_p$, and significant wave heights, $H_s = H_{mo}$. Water depth $d = 0.70$ m.

Figure 4. Measured zero-upcrossing periods, $T_z$, peak periods, $T_p$, and significant wave heights, $H_s = H_{mo}$. Water depth $d = 0.25$ m.
Figure 5  Ratio $H_{\text{max}}/H_s$ ($H_s = H_{\text{mo}}$) for wave period $T_p = 1.77$ s and for water depth $d = 0.70$ and 0.25 m.

Test program.

The test program we used was approximately the same as for the DHI tests, DHI (1995), Juhl et al (1996) with respect to the number of waves for each wave step, except that we included a very long test run at the end of each test series. All tests were carried out with a target steepness of the waves of $s = 2\pi H/s g T^2 = 0.05$, where $g=\text{acceleration of gravity. This is the same steepness as used for most of the DHI tests.}$

After discussions with other partners in the EU MAST II Berm Breakwater Structures project we decided to use, as has been common practise, the zero up-crossing period in deep water ($d = 0.70$ m) and $H_{\text{mo}}$ from shallow water (local wave height at $d = 0.25$ m) when calculating the steepness $s$. The test program is shown in Table 1. Here $D_0 (T/0.333$ and $\Delta = (\rho_s / \rho_w)^{-1}, W_{50} = \text{fifty percent of the stones are larger (and smaller) than } W_{50}, \rho_s = \text{specific mass of the stones and } \rho_w = \text{specific mass of the water.}$

As mentioned it was the wave steepness based on the "deep" water wave periods that was the governing factor for establishing the test program waves. However, it is the steepness based on the shallow water wave period that the breakwater "feels". Hence this steepness should have been used rather than the steepness based on the "deep" water wave period. In the unified analysis (see later) we have used the wave periods for shallow water.

The tests were run in the following way:

After building the breakwater model the wave/breakwater parameter \(Ho\), the stability number, was increased in steps according to Table 1. 2000 waves were run for each step. Profiles were taken with a laser distance measurement system, generally after each step. The distance between each profile was 0.10 m and the distance between each measurement point in a profile was 0.02 m.

After this reshaping process with five \(Ho\) steps, \(Ho\) up to 3.85, the steps were repeated again, but now with 1000 waves in each step. Since no "damaging" effects occurred on Breakwaters A and C at the end of this sequence of runs, we continued to run 10,000 waves with \(Ho = 3.85\).

For Breakwater B the planned test program was the same as for Breakwaters A and C. However, when running the tests a slight damage on the rear side due to wave overtopping occurred for \(Ho = 3.40\) in the first wave step sequence (the sequence with 2000 waves for each step). For \(Ho = 3.85\) the damage on the rear side was so large that we decided to terminate this step after approximately 1600 waves.

**Test results for the 3D tests in shallow water at SINTEF.**

We will present only some few of the results from this particular study and later include the results in an analysis of the reshaping of berm breakwaters were we also include results from other test series.

Figures 6 and 7 show an oblique "view" of Breakwater A before and after the testing, while Figure 8 shows one of the profiles before the test started and after completion of the test program for Breakwater A.
Figure 6. Oblique view of Breakwater A before testing.

Figure 7. Oblique view of Breakwater A after testing.

Figure 8. Breakwater A. Cross-sections at 1200 mm before and after testing.
Both Breakwater A and C were considered to be dynamically stable in the sense that no core material was visible after the testing had been completed and no damage had occurred on the rear side. Also it was noted that not much of the berm stones on the breakwater head had been thrown into the area behind the breakwater.

We took stone samples of the surface stone material at the still water line and at the toe of the berm after completing the test program for Breakwater C. It was interesting to note that the stones at the toe are significantly larger, \(D_{n50}\), than at the still water line. At first instance this observation may seem unexpected because the smaller stones are easiest to move. Western and Tørum (1997) measured the wave forces on a single armour unit placed at different positions along the slope of a reshaped berm breakwater. They found that the highest forces occurred above the still water line, and that to some extent as "impact" forces. This fact together with the observation of the smallest stones at the still water line support the concept that the stones are "knocked" loose above and around the still water and roll down the slope. The larger stones have a larger momentum and rolls more easy than the smaller stones. Hence the larger stones tend to move a longer distance than the smaller stones. The effect is probably the same as we see in a rock slide, where the largest stones are located at the toe of the slide.

Figure 8 reveals that only a part of the berm of Breakwater A was reshaped during the SINTEF "shallow" water tests. The DHI "deep" water test results, DHI (1995), Juhl et al (1996), show that for the same test program that almost the whole width of the berm was reshaped. When analysing the results with respect to an understanding of the differences, we saw that tests carried out under apparently similar conditions in different laboratories have given what we at first instance will consider as significant result differences. We will therefore review some of these test and include the results in a unified analysis.

Analysis of berm breakwater test results from different tests series.

The following analysis is mainly considering the two-dimensional case with waves normal to the breakwater axis.

The geometry of a berm breakwater is defined by notations as shown in Figure 9, while Figure 10 show notations for the reshaped berm breakwater. \(f_b\) = berm width, \(f_v\) = berm height, \(w\) = crest width, \(R_c\) = crest height, \(d\) = water depth, \(m\) and \(n\) defines the "inner" and "outer" slopes, \(R_{ec}\) = recession of the reshaped berm, \(l_s\) = step length, \(h_s\) = step height, \(A_1\) = eroded area and \(A_2\) = deposited area.

Occasionally we will also see from berm breakwater test results that some of the berm stones will move above the original berm elevation. This phenomenon could be very pronounced for finer material than normally found in berm breakwater berms, e.g. van der Meer (1988), but is not very pronounced for berm breakwaters.

The most relevant non-dimensional parameters used for the analysis of berm breakwater test results are the following:

\[Ho = \frac{H_2}{\Delta D_{n50}}\] (1)
\[ HoTo = \frac{H_o}{\Delta D_{50}} \left( \frac{g}{D_{50}} \right)^{1/2} \]  

(2)

Ho was introduced by Hudson (1958) (as the stability number \( N_s \)) and HoTo was introduced by van der Meer (1988) as a dimensionless wave period parameter. Typical values for berm breakwaters are \( Ho < 3 \) and \( HoTo < 100 \).

![Figure 9. Geometry definitions of a berm breakwater.](image1)

![Figure 10. Reshaping parameters of a berm breakwater.](image2)

Figure 10 shows that from a continuity point of view the areas \( A_1 \) and \( A_2 \) must be equal for the two-dimensional case. van der Meer emphasised on the step length \( l_s \) and step height \( h_s \) (among other geometrical parameters) as a kind of "universal" parameters as they were found to be to a large extent independent of the original profile slope etc observed in his tests, at least for large values of \( HoTo (HoTo > 1000) \). van der Meer (1988) obtained values for \( h_s \) and \( l_s \) as well as the shape of the profile from tests on straight slopes with \( HoTo = 100 - 50,000 \). Based on some limited number of tests van der Meer gave also an indication of how \( h_s \) and \( l_s \) was dependent on the waterdepth. When the values of \( h_s \) and \( l_s \) and the profile shape are known it is a matter of trial and error procedure to find the recession such that \( A_1 = A_2 \). However, van der Meer (1988) did not cover so well the lower range of \( HoTo (HoTo < 100) \) as found for berm breakwaters.

We have tried to measure values of \( h_s \) and \( l_s \) from different profiles from different berm breakwater test series. Our conclusion is that it not so easy to obtain values of \( h_s \) and \( l_s \) with any good accuracy. Hence it is not so easy to predict the
recession, \(\text{Rec}\), with any accuracy either. We will therefore consider the direct measurement of the recession, \(\text{Rec}\). This is a length parameter that can be measured with a reasonable good precision and it is a vital parameter for berm breakwater design.

Based on test results from different berm breakwater test series in "deep" water we have in the diagram of Figure 11 plotted the dimensionless parameter \(\text{Rec}/D_{n50}\) vs. \(H_0\). The results are from Andersen and Fleming (1991), DHI (1995) (DHI 3D tests), Lissev (1993), Tørum (1988), Tørum (1997, 1997A).

The main characteristics of the test series are the following:

Andersen and Fleming (1991):
Water depth \(d = 0.67 - 0.90\) m, berm height \(f_v = 0.10\) and \(0.20\) m, berm width \(f_h = 0.65\) m, outer slope \(1:1.1\), stone diameter \(D_{n50} = 0.034\) m, wave steepness \(s = 0.05\)

DHI (1995)
Water depth \(d = 0.55\) m, berm height \(f_v = 0.10\) m, berm width \(f_h = 0.65\) m, outer slope \(1:1.1\), stone diameter \(D_{n50} = 0.022\) m, wave steepness \(s = 0.03\) and \(0.05\)

Lissev (1993)
Water depth \(d = 0.79\) m, berm height \(f_v = 0.08\) m, berm width \(f_h = 0.65\) m, outer slope \(1:1.25\), stone diameter \(D_{n50} = 0.034\) m, wave steepness \(s = 0.045\)

Tørum (1988)
Water depth \(d = 0.50\) m, berm height \(f_v = 0.10\) m, berm width \(f_h = 0.45\) m, outer slope \(1:1.5\), stone diameter \(D_{n50} = 0.029\) m, wave steepness \(s = \text{varying } 0.018 - 0.075\)

Tørum (1997A)
Water depth \(d = 0.40\) m, berm height \(f_v = 0\) m, berm width \(f_h = 0.59\) and \(1.09\) m outer slope \(1:1.3\), stone diameter \(D = 4 - 60\) mm, \(D_{50} = 15\) mm (gradation curve values), wave steepness \(s = 0.05\)

To some of the data points in Figure 11 a second degree polynomial fit has been provided, based on the "least square" principle. There are some minor differences in these test series with respect to test set-up and test programs. But they are not that different and we will consider the test series to be reasonable homogenous.

Based of van der Meer's concept we see that the recession, \(\text{Rec}\), of a homogenous berm for a given wave condition could be dependent of the berm height, \(f_h\), and the water depth \(h\). We see however from Figure 11 that there is not much of a difference in results of the tests with \(f_v = 0.10\) m and \(f_v = 0.20\) m.

For "shallow" water there are fewer results than for "deep" water. We have in Figure 12 plotted data from tests at DHI (1996) and SINTEF, Tørum (1997A). We have for \(H_0\) used the wave height and wave periods as measured at the shallow water location. For the SINTEF tests the \(T_z\) values were measured, while for the DHI tests the wave spectrum was measured and \(T_z\) has been taken as \(T_z = T_{02}\).
+ Experiments $f_v = 0.10$ m from Andersen and Poulsen (1991).
\[ \circ \] Experiments $f_v = 0.20$ m from Andersen and Poulsen (1991).

Figure 11. Recession of the berm of berm breakwaters from different test series. "Deep" water.

If we compare the results of Figures 11 and 12 we see that the results are comparable when the local wave parameters are used to calculate $H_o/T_o$.

There is a considerable scatter in the test results shown in Figure 11. The scatter is between different tests in the same series of tests at a specific laboratory and between test series in different laboratories. But the scatter is probably not more than we normally find for breakwater testing.

We have not been able to resolve why there are differences and scatter in the results. We will thus presently consider the scatter of the data as "natural" scatter and consider all results of equal value. Based on this consideration we have in Figure 13 plotted the results from Figure 11 and Figure 12 in the same diagram. We have in Figure 13 omitted the data from Tørum (1997A) since those data were from tests on aberm of quarry run material not typical for berm breakwaters.

We have provided a second degree polynomial fit to the data. We also tested out a third and a fourth degree polynomial fit, but these fits did not appear to be more accurate than the second degree polynomial fit.

The equation for the second degree polynomial fit is given by:

\[
\frac{Rec}{D_{950}} = 0.00073908(HoTo)^2 + 0.0498855(HoTo) + 0.604 \tag{3}
\]

This equation may be considered as a design equation for the recession of the berm.
Figure 12. Recession of the berm of berm breakwaters from different test series. "Shallow" water. Note that HoTo is based on wave parameters measured at the "shallow" water location of the breakwater.

Figure 13. Recession of the berm of a berm breakwater in "shallow" and "deep" water as function of "local" HoTo-values. 2nd degree polynomial fit ±σ

The scatter of the data has been analysed in the following way:

\[
\frac{f - f_k}{f_k} = f(\text{HoTo})
\]

where 
- \( f = \) datapoint for a given HoTo-value
- \( f_k = \) value after 2nd degree polynomial fit
- \( f(\text{HoTo}) = \) function of HoTo
The result of this analysis is shown in Figure 14 where we have also indicated the standard deviation $\sigma = 0.337$. We have also included the "2nd degree polynomial fit" $\pm \sigma$ in Figure 13.

We have further in Figure 15 shown the data compared to a normal distribution function. The design equation, Eq. (3) and the scatter information may be used in a probabilistic analysis of berm breakwaters.

DHI (1996), Juhl and Sloth (1998), carried out tests on "islandic" type berm breakwaters. The idea is to place the largests blocks from the quarry on top of the berm as a composite breakwater. We have analysed the results of these tests in a similar way as we analysed the results from the tests with homogenous berms. For $D_{50}$ we used the $D_{50}$ for the largest stones on top of the berm. The results are shown in Figure 16 where we also have plotted the design equation, Eq. (3). The design equation works also reasonably well for the composite berm breakwater.

**Figure 14.** $(f-f_k)/f_k$ as function of $HoTo$ (local values). The standard deviation $\sigma = 0.337$.

**Figure 15.** Standardised distribution of $(f - f_k)/f_k$ compared to a theoretical normal distribution.
Figure 16. Recession vs. HoTo for composite berm breakwaters. "Local" wave parameters. \( D_{50} \) of largest stone class. Profile 2 is a homogenous profile. Design eq. is Eq (3).

Discussion and conclusion.

We have analysed two-dimensional test results and arrived at a simple design equation for the recession of the berm of a berm breakwater without major overtopping. This equation may be used, at least in the conceptual design phase, for berm breakwaters in water depths and for storm duration that are normally encountered for berm breakwaters.

If the waves are oblique to the breakwater, the lateral transport of the stones have to be considered, e.g. Alikhani et al (1996).

There is no well establish criteria for which stability number Ho or wave period parameter HoTo the design should be accepted. Such criteria should apparently be linked to the mechanical strength of the stones.

Acknowledgement.

This study was funded by the European Communities Research Program MAST II under contract MAST-Contract MAS2-CT94-0087 Berm Breakwater Structures and by the Norwegian Coast Directorate. We appreciate very much this financial support. We also appreciate the many discussions with the other partners of the project.

Abstract

This paper presents the design and economic analysis for two alternatives (soft-versus-hard) for shore protection of facilities at the US Navy's Fleet Combat Training Center, Dam Neck, Virginia, USA. Three key factors are discussed that resulted in the selection of the soft alternative (dune construction and beach nourishment) which also included a buried seawall/revetment structure beneath the dune to provide a unique solution for shore protection. Construction was completed in the fall of 1996 and the results of the first year’s monitoring effort are presented. The advantages of the soft alternative are many (environmental, recreational, etc.) and may even include the economic advantage as demonstrated in this paper for one site on the Atlantic Ocean.

Introduction

The perception exists that renourished beaches (i.e., the “soft” alternative) for shore protection costs more than seawalls and revetments (“hard” alternative) over the design life of the project (Smyth, 1996). Beach nourishment is perceived as an endless expense whereas massive concrete seawalls and stone revetments require little maintenance. Economic analysis of the total, life-cycle costs of “soft” versus “hard” shore protection alternatives are needed to provide some real evidence in this debate.

The design and economic analysis for two alternatives (soft-vs-hard) for shore protection of facilities at the US Navy's Fleet Combat Training Center, Dam Neck, Virginia on the Atlantic Ocean below Virginia Beach, Virginia USA (Fig. 1) are described below. Approximately $95 million of structures including the gunnery range were threatened by historic erosion averaging 0.7 m/yr and recent years of severe storm activity that damaged the existing dune-beach system. Fig. 2 shows the Bachelor Officers

Quarters (BOQ) protected by the dune-beach system (top, aerial photo\(^2\)) and by an artificial, stone armour layer revetment (bottom, graphic artist schematic\(^3\)).

The soft alternative (Fig. 2, top) also included a rebuilt dune system with buried seawall/revetment structure that together provided a unique solution for shore protection in the US. The retreat alternative was far too expensive and unacceptable because the gunnery range must be located adjacent to the coastline for effectiveness and safety reasons.

Design Criteria

The design criteria was for storm damage mitigation against the one percent chance, annual storm surge event (2.65 m, NGVD, 1972 adj.) and related wave conditions (\(H_{mo} = 4.82\) m, \(T_p = 13.7\) s) in a nearshore water depth of about 9 m. Design life selected was 25 years with an interest rate of 9.5 percent that was two points above the prime lending rate (1994) for the economic study of life cycle costs. The beach was to be restored whenever conditions returned to 1995 beach widths which were less than 12 m (MHW) at some locations.

Composite average, median grain size was 0.29mm for the native beach.

Key Factors in Design Alternatives

Hard Revetment

Fig. 3 displays a plan view of the BOQ, the Enlisted Man's (EM) Club and the gunnery range to be protected by over 1100 meters of revetment including tapered ends. Offshore contours are relatively straight and parallel to the shoreline to permit the use of one nearshore profile (August, 1994 at the EM Club) as representative for all sections.

The design wave height for the stability analysis of the stone armour layer was obtained by considering all the factors that influenced the design water depth at the structure toe. The (1) beach profile is at its lowest expected position at the end of the 25 year design life; (2) the flattened, winter condition profile is employed and; (3) toe scour during storms must also be included. These conditions produced a below sea level elevation (-1.8m) for the hard structure that greatly increased the initial costs for the revetment.

Two numerical models were employed to calculate the design wave height at the structure toe for varying berm elevations with results shown in Fig. 4. The SBEACH model (Larsen and Kraus, 1989) and the SZED model (Baumer, 1991 based on Thornton and Guza, 1983) both produced similar results and a design wave height of 2.5m. A 4.3 ton (US) natural stone or a 2.3 ton (US) artificial armour block unit (CORE-LOC) was required for stability. In short, the design was based on beach conditions expected during a major storm at the end of the design life (with no beach remaining, Fig. 2) and not on today's condition of the beach.

Fig. 5 is a cross-section of the armoured revetment design with crest elevation at +6.71m (+22.0) to minimize overtopping.

Soft System

The soft system alternative consisted of three components:

(1) a buried rock seawall/revetment with crest elevation at +5.49m and toe elevation of +2.7m;

(2) a rebuilt dune with crest elevation at +6.71m and crest width of 15.2m, and;

(3) a renourishment beach with design width of 23m at +2.13m berm elevation, as depicted in Fig. 6. The buried structure was placed well back in the dune and 1.2m beneath the dune crest so that dune volume during storms was still available to feed the beach. This combination "soft" system is believed to be unique for shore protection in the US. The buried rock structure was first proposed by Headland, (1991) for Dam Neck. The buried seawall design concept has been constructed at other locations around the world (e.g. van der Graff, 1998, personal communication).

A key factor in the cost analysis for the dune design was the development of "damage" curves as shown in Fig. 7 (Basco and Shin, 1997). Again, the beach profile numerical model SBEACH (Larsen and Kraus, 1989) was utilized over a wide range of storm surge elevations, S relative to the design storm surge level, \( S_d = 2.77\)m (MSL) to estimate the volume change in dune cross-section, i.e. damage to the dune. Classical, probabilistic methods for estimating future dune damage and subsequent costs analogous to maintenance costs for rubble mound structures were then employed (Basco and Shin,
Figure 3  Plan view of armoured structure to protect Bachelor Officer's quarters (left), Enlisted Man's club (center) and gunnery range (right)

Figure 4  Spectral significant wave height -vs- elevation of beach profile at toe of structure - modeled results
1997). Dune damage curves were estimated at the end of a beach renourishment cycle (8 - 9 yrs) when the beach profile approximates before nourishment conditions. As a safety margin, the secondary, buried structures traps some sand (Fig. 7, with seawall) but serves as shore protection in case two severe storms should be encountered in one hurricane season.

Another key factor in the economics of the soft alternative was identification (Kimball and Dame, 1989) and utilization of a suitable, long term borrow site for sand required for periodic beach nourishment. The offshore borrow area is in Federal government water (beyond the 3 mile limit) about 5 km from Dam Neck. Over 30 million cubic meters of excellent beach material ($d_{50} = 0.34$ mm) is available for the design life so that the unit costs estimated at $6.67/m^3$ ($5/cy$) will be reasonable.

Finally, the relatively low annual erosion rate at the site (0.7 m/yr) also contributed to an 8 - 9 year estimate for the renourishment cycle and the relatively lower costs for the soft alternative.

Comparison of Alternatives

Costs

Table 1 summarizes the cost comparison for the hard and soft alternative designs. The new CORE-LOC, artificial, armour unit (Melby and Turk, 1997) was slightly less expensive than natural stone and resulted in a unit cost of slightly over $7200/m for a 1103m revetment.

</tr>
</tbody>
</table>

The soft alternative costs per unit meter were also based upon this length for shore protection (Fig. 3) but the design beach was longer (1600 m) to increase its life. As shown in Table 1, the life-cycle costs favor the soft alternative, in this example. The life-cycle unit costs were $6016 per meter and included almost $3 million in maintenance costs for two nourishment events. These are "present worth" maintenance expenses.

Decision Criteria

Costs are only one criteria in the decision matrix for choosing the soft or hard alternative. Table 2 summarizes all the criteria used to evaluate the alternatives. The sole advantage of the armoured revetment is lower annual maintenance costs. All others favored the dune-beach buried seawall system.

The soft alternative provides a recreational and environmentally useful (turtle nesting habitat) beach at the end of the design life. The permitting agencies, public perceptions, and public relations (image) of the US Navy also favored the soft alternative. Both alternatives provide the same level of shore protection.

The dune/beach/buried seawall, i.e. "soft" alternative was selected for final design and construction.

Final Design, Construction, Monitoring

Final Design

At the Navy’s request, the final design was to extend the useful life of the initial beach fill to 12-13 years so that only one renourishment event was expected over the 25 year design life. This required an increase in the beach length (2804 m) including 150 m tapers at both ends for an average length of 2679 m. The design width was also increased to about 38 m to give an average section design fill of 34.4 m$^3$/m (85.9 cy/ft). The Corps of Engineers’ Technical Note, CETNII-32 (CETN, 1994 revised) was employed to estimate the dry beach design width for intersecting profiles since the borrow material was coarser than the native beach material.

End losses for a finite beach fill were estimated using the analytical solution for a one line model of beach fill following Dean, (1992) as discussed further below.

Construction

The major portion of the dune with buried seawall/revetment was constructed in the fall of 1995. Fig. 8 is a photo showing dune/seawall construction and Fig. 9 pictures the final dune before beach nourishment which began in the summer of 1996. The initial placement volume as measured by nearshore sled survey in November, 1996 was about 520,000 m$^3$ or about 9.4 percent less than the design placement volume. The difference was due to (1) the lack of a true, pre-placement survey (June 1995 survey employed); (2) early erosion occurring between the end of beach fill construction and the initial survey in November 1996; and (3) the dredging contractor not filling the design template. All three factors combined probably contributed to the difference.

Monitoring

A three year monitoring effort is underway to determine volume change of the dune and renourished beach. Sled surveys of beach profiles at 17 locations out to closure depth are being made over a 4875 m reach that extends beyond the beach nourishment project on both ends. The initial year of monitoring (completed October 1997) accounted for all the initial fill volume. The percentage of beach fill volume remaining after year one of the monitoring effort was 84.8 percent over the project length of 2679 m.

Fig. 10 displays the percent volume remaining (crosses) of the nourished beach including intermediate surveys (Mar 1997, June 1997) over the initial year. The dashed line with sediment diffusion coefficient G equal to 0.065 miles$^2$/year was employed for design. End losses are estimated from the diffusion equation

$$\frac{\partial y}{\partial t} = G \frac{\partial^2 y}{\partial x^2}$$

where $y (x, t)$ is the shoreline position in the one-line model for shoreline change (Dean, 1992). The G coefficient depends upon many factors, but mainly the annual wave energy climate striking the beach. A nearshore wave gauge (VA001) is available nearby to measure the waves and is being employed in the monitoring effort. Wave year 1997 (October 96 - September 97) had higher than normal wave energy, yet the sand loss measured followed the theoretical design curves for lower wave energy. Monitored results after three full wave years will (hopefully) be presented at the ICCE ‘2000
Figure 8  Photograph of dune with buried seawall/revetment under construction

Figure 9  Photograph of completed dune structure before beach renourishment
The actual life of the beach is a key factor in the economics of the "soft" alternative.

Conclusions

On eroding shorelines, hard structures pin the shoreline location, flatten and deepen the profile. Design of hard structures must be for conditions at the end of the design life, when no beach may exist, not for today's beach conditions. The economics of the soft alternative depend upon many factors including (1) historic erosion rate; (2) relative grain size of borrow material, location and long-term volume in borrow area; (3) cross-sectional volume and length of beach fill. The soft alternative maintains a flexible shoreline location and natural beach conditions even at the end of the design life. The advantages of the soft alternative are many (environmental, recreational, etc.) and may even include an economic advantage as demonstrated in this paper for one site on the Atlantic Ocean at Dam Neck, Virginia, USA.

Abstract
The nature of uncertainty in coastal engineering is discussed with reference to an empirical study of practising coastal engineers in the UK. This study provided evidence which indicates that a complex multi-disciplinary set of issues are taken into account in decision making only some of which are explicitly articulated. It is argued that current approaches to handling uncertainty based on reliability theory provide an important but incomplete perspective on a rich and complex topic. An approach to uncertainty modelling based on Interval Probability Theory is proposed. Process modelling is used to track the sources of uncertainty in analysis, design and decision making and to integrate different types of evidence. This approach to uncertainty analysis, which involves exploring and accounting for the sources and nature of uncertainty in decision making, is illustrated with reference to sea defence projects on the East Coast of the UK.

Introduction
The coastal engineer is confronted with uncertainty in the random nature of hydraulic loads, in the complexity of structural, morphological and environmental responses, in the diversity of decision objectives and in the fallibility of the human systems which implement coastal defences. The engineer is, nonetheless, expected to make dependable, timely and transparent decisions. To do so requires an understanding of the nature of uncertainty and appropriate techniques for managing it.

The research described in this paper is a merger of three streams of enquiry:

1. a programme of interviews with UK experts and practitioners in coastal engineering to elicit contemporary knowledge on the sources and management of uncertainty;
2. investigation of theoretical approaches to representing uncertainty in hydraulic engineering including probability theory (both frequentist and Bayesian), fuzzy sets, the Dempster-Shafer theory of evidence and interval probability theory;

3. contemporary developments in generic modelling of human and physical processes.

The research is based on a systems approach which takes account of the richness of sensitivities and interactions which characterise both the natural and human aspects of the coastal zone. This research, which lies on the socio-technical interface, is intended to provide a link between the scientific and largely reductionist theoretical approach to engineering practice and the difficulties of actual practice itself. The research has resulted in development of new methods for assessment and management of uncertainty in coastal engineering projects.

This paper begins with a description of an empirical study of the nature and sources of uncertainty in coastal engineering. Some of the limitations of a purely probabilistic approach to representing uncertainty are discussed before introducing an new approach based on process modelling and interval probabilities. An implementation of this approach for decision support is discussed with reference to example projects.

**Descriptive study of practising coastal engineers**

Worthwhile decision support tools must be founded on an understanding of the problem domain to which they are to be applied. Decision support systems have failed in the past because they are culturally incompatible with the organisation in which they are applied (Platt, 1994). These problems can be minimised by careful descriptive analysis of the problem domain before proceeding towards decision support.

Descriptive analysis of complex processes on the socio-technical interface is not straightforward. Many of the issues taken into account in decision-making are unquantifiable and may not even be made explicit. To make sense of these issues an investigative technique called Grounded Theory developed by Glaser and Strauss (1967) for field work in the social sciences was used to analyse the problems which coastal engineers encounter in practice. Grounded Theory is a general methodology that aims to develop theory from qualitative data. Theory is in the form of conceptual models of the phenomenon under consideration. The word ‘grounded’ derives from the concept that the theory generated is ‘grounded’ in data. Grounded Theory is therefore believed to provide more reliable and more complete understanding than is achievable by conducting an informal consultation exercise or questionnaire surveys. Details of the Grounded Theory study and analysis are reported in Hall et al. (1998a). A series of semi-structured interviews were held with eight practising flood and coastal defence engineers from a variety of backgrounds in the UK. The interview data was analysed in detail with a view to identifying

- characteristics of the decision making process in coastal engineering;
- sources of uncertainty in decision making;
- current approaches to coping with uncertainty.

The interview data demonstrated that

- A complex set of socio-technical issues are taken into account during decision-making only some of which are explicitly stated. Technical issues play an important part but interact with other issues and are not necessarily paramount.
• Individual decisions are integrated in an ongoing infrastructure management process.
• In the UK intuitive and implicit methods of taking uncertainty into account in decision-making are currently much more prevalent than explicit methods. This is despite increasing emphasis on risk-based methods from government and researchers.
• Sources of uncertainty in decision-making are diverse but can be categorised as being ‘modelling issues’, ‘values issues’, ‘communication’, and ‘environmental constraints’. The term ‘modelling’ is being used in the most general sense. The term ‘environmental’ is used here to refer to surrounding institutional, political and cultural issues outside the immediate control of the decision-maker.

The findings of the empirical study have guided the subsequent research which aims to satisfy identified needs
• to provide a systematic overview of the coastal management process;
• to address the issue of model uncertainty;
• to support the process of obtaining and manipulating data and then making decisions;
• to provide a measure of the dependability of the processes which lead up to a decision;
• to keep track of the sources and sensitivities to uncertainty in a decision.

Methods of representing uncertainty
Uncertainty is a rich and diverse topic which has been addressed in quantitative, linguistic and symbolic terms. Of all the methods for handling uncertainty, probability theory has by far the longest tradition and it is the best understood. That of course does not imply that it should be beyond criticism as a method of handling uncertainty. It does, however, mean that it is relatively well tested and well developed and can act as a standard against which other more recent approaches may be measured (Krause and Clark, 1993).

Blockley et al. (1983) argued that the additivity axiom or law of excluded middle in probability theory is an assumption which can be difficult to justify under circumstances involving sparse data and incomplete and possibly inconsistent knowledge. This and other re-evaluations of the axioms of probability theory since the 1970s have lead to the development of various alternative and generalised calculi for quantitative handling of uncertainty, including fuzzy set theory, the Dempster-Shafer theory of evidence, mass assignment theory and interval probability theory which is discussed later in this paper. Hall et al. (1998b) proposed a pragmatic approach to uncertainty where the axioms of the probability calculus are matched to the characteristics of the situation in hand. The fundamental problem with quantitative uncertainty methods is one of mapping messy real world situations onto precise mathematical syntax. Several different approaches can provide useful evidence on which to base a decision.

In coastal engineering, as in other fields, probability theory has been developed into a sophisticated and useful tool. Reliability theory and probabilistic risk assessment are now well established methods for coping with the uncertainty inherent in many of the parameters which coastal engineers input into their models. However it is inevitable
that some of the response functions used in probabilistic models will be more dependable than others. For example quantitative models of breaching the low clay embankments which act as flood defences in many areas of the UK are still of limited dependable. Doubtless quantitative understanding of more challenging failure mechanisms will increase in future. More effective and less intrusive methods of obtaining information about the strength of coastal defence structures will be developed, though for the time being methods of obtaining detailed information about the internal constitution of flood defence embankments are very costly. Nonetheless, there will always be a limit to the level of risk analysis that it is practical and economic to undertake. Some failure mechanisms will always be better understood than others. Decision processes need to reflect that fundamental disequilibrium of information. Without some understanding of the dependability of input distributions and of response functions, the data generated by probabilistic methods can be difficult to interpret and in the wrong hands quite misleading.

It is important to recognise that the numbers generated by reliability calculations are hardly scientific (in the Popperian sense) as they cannot normally be falsified. They are better viewed as deductions from a set of premises. Some of those premises will be better supported by evidence than others. Yet unless a procedure is adopted for recording and auditing the premises used in a reliability calculation the ultimate deduction will be of limited value.

Some attempt has been made to address the issue of modelling or systems uncertainties in the theoretical representations of the physical behaviour of structures by use of one or more extra basic variables in the constitutive reliability equation. The value assigned to this variable may for example depend on whether physical model studies have been conducted or not. The empirical evidence supporting this approach is questionable and, as Blockley (1998) argues, its use is inadequate because the level of sophistication of handling such a difficult and important part of the total uncertainty is very much less than for the relatively straightforward issue of parameter uncertainty.

Structural reliability calculations are therefore now widely recognised as only one part of the assessment of structural safety. The results of such calculations are not ‘true’ probabilities of failure, rather they are ‘notional’ probabilities of failure. Even in the relatively constrained context of the process industries, calculations of failure probabilities conducted by independent expert teams around Europe have been shown to typically differ by up to three orders of magnitude and in some cases differences were as large a five orders of magnitude (Lemkowitz et al., 1995). It is not unreasonable therefore to have misgivings about the numbers which are generated in reliability calculations in coastal engineering. These calculations do not generally include the behaviour of individuals and almost never include organisational factors such as organisational culture.

It is clear from the analysis conducted in the UK that engineers have difficulty in communicating even quite basic probabilistic concepts of flood risk, not to mention the distinction between notional and statistical probabilities, to the populations at risk. Reliability calculations are seldom transparent to stakeholders who have an interest in the outcome of those calculations. The consequence of adopting authoritarian technocratic approaches which are not transparent is that the co-operation from politicians and the public, which is necessary to implement flood defence works, will not be forthcoming (Beck, 1992). If therefore engineers are not to undermine their own best endeavours on society’s behalf for safety, efficiency and sustainability they need to recognise the social construction of risk and acknowledge that their reliability calculations provide but one rather incomplete perspective on a complex phenomenon.
The normative theory of decision making under risk and uncertainty provides a rational theoretical framework for decision making in coastal engineering. By linking risks with costs, it, in theory, provides a mechanism for optimising investment in coastal engineering. However, besides the problems associated with computing probabilities described above, there are profound difficulties in eliciting the value (or utility) functions required to compare the attributes of different options. It may be extremely difficult to project some fuzzy values onto a numerical scales. For example it may be hard to state precisely whether a particular coastal defence is sustainable or not. In order to make a decision experts will usually resort to linguistic descriptions of the sustainability, which cannot be manipulated within normative decision theory.

Moreover, all of the possible outcomes of a decision must be predetermined in precise terms for a probabilistic decision analysis. This limits the applicability of probability theory for coping with fuzzy events or incomplete situations. These problems are becoming more apparent when we address more complex multi-disciplinary problems. For example, there is currently much interest in making the coast more resilient. To do so involves restoring natural systems and enhancing flexibility and diversity. Much of the value of a resilient coastline is its capacity to cope with the unforeseen and unpredictable, in particular climate change. These benefits cannot be fully evaluated in probabilistic terms. Moreover, a resilient coastline will be highly dependent on human systems of monitoring and management. Predicting the reliability of these systems represents a particular challenge in complex, dynamic situations because some behaviour is truly unforeseen and so by definition is not included in the reliability model. Unfortunately many engineering failures are the unforeseen consequences of human actions (Blockley, 1980). Collingridge (1980) suggests that unforeseen outcomes in socio-technical systems can be controlled by:

- monitoring,
- reducing the cost of error,
- reducing the corrective response time,
- reducing the cost of remedy,
- keeping one's options open (adopting flexible solutions, enhancing variety).

The intention of these strategies is to improve the robustness of a plan or design in the face of events which are not predictable by the models available to the planner or designer at the moment of decision making. It may be necessary to weigh the apparent loss of expected value involved in adopting a robust decision, against the apparent loss of flexibility in adopting the "optimal" decision. The balance will tend to favour robustness in conditions of high uncertainty (Rosenhead et al., 1972).

The foregoing arguments should not lead to the rejection of reliability calculations and probabilistic decision theory. These approaches provide important evidence on which to base decisions. However, engineers should recognise the need to broaden their perspective and explore ways of enriching current methods in order to merge qualitative and quantitative perspectives. A systems approach recognises that an infrastructure can be described at a number of different levels of resolution and from a number of different perspectives. Reliability theory can be fitted within this more general framework.
Process Modelling

The issues raised in the proceeding discussion have been addressed by broadening attention from specific data (which are the focus of probability theory) to include the process of obtaining and manipulating data and then making decisions. The quality of a design will inevitably reflect the process by which it was produced (Platt and Blockley, 1994). Modelling both human and physical processes in generic terms is now an important research theme at the University of Bristol. One of the main theoretical and practical challenges is establishing an appropriate model structure. The structure represents the flow of information and control during a project, and in particular the flow of information towards important design and management decisions. Both hierarchical and cyclic models have been explored. In hierarchical terms, process can be modelled using a series of sub-processes. Figure 1 illustrates some of the processes in one of the case studies examined in this research. The hierarchy represents and integrates processes which manipulate evidence of different pedigree, from numerical model studies to more qualitative geomorphological analysis. Note that the process model is a descriptive commentary of how the processes were conducted, not a normative model of how the process should have been conducted.

![Figure 1 A section of the process hierarchy relating to the Orplands project](image)

Engineers should be concerned with the dependability of a process to deliver an appropriate level of function - its quality, or fitness for purpose. An understanding of the dependability of a process can be gained by scrutinising the activities which are
involved in that process and considering evidence of their dependability and the interactions between them. Evidence will range from the size of data sets to testimony of the experts involved.

Looking upwards through the process hierarchy, processes become increasingly general in definition. Thus statements of national policy which represent the top level in a hierarchy of concepts are necessarily expressed in fuzzy linguistic terms such as "sound" and "sustainable". In the UK, Shoreline Management Plans are the next stage below national policy in the hierarchy of concepts, defining policy for a given stretch of coastline. Precise statements, often expressed in numerical rather than linguistic terms, are necessary at project and operational levels. Process modelling enables coherent integration of the hierarchical decision making which characterises modern coastal management. The interface between human and organisational processes and physical processes is handled using the same language which should enable clearer and smoother flow of information.

Interval Probability Theory

Having established a logical hierarchy of processes the next stage is to find a means of expressing uncertainty in each process. The approach adopted here has been to express the dependability of each sub-process using an interval number and calculate how the various uncertainties affect the processes above them using Interval Probability Theory (Cui and Blockley, 1990). An interval number, on the range $[0,1]$, is used to represent the belief in the dependability of a concept.

$$P(E) = [S_n(E), S_p(E)]$$

where

- $P(E)$ is the measure of belief in the dependability of a concept $E$,
- $S_n(E)$ represents the extent to which it is certainly believed that $E$ is dependable,
- $1 - S_n(E) = S_p(\overline{E})$ represents the extent to which it is certainly believed that $E$ is not dependable, and
- $S_p(E) - S_n(E)$ represents the extent of uncertainty of belief in the dependability of $E$.

Evidence or belief is mapped onto interval numbers using membership functions similar to those used in fuzzy set theory. Three extreme cases illustrate the meaning of this interval measure of belief:

- $P(E) = [0,0]$ represents a belief that $E$ is certainly not dependable,
- $P(E) = [1,1]$ represents a belief that $E$ is certainly dependable, and
- $P(E) = [0,1]$ represents a belief that $E$ is unknown.

The interval $S_n(E) = S_p(E)$ implies that there is no uncertainty in the evidence and corresponds to the theory of classical probability. Thus, whilst Interval Probability Theory is founded on the axioms of probability theory, it allows support for a conjecture to be separated from the support for the negation of the conjecture. It can therefore handle situations where incompleteness is an important issue, because the problem domain need not be completely specified in order to obtain meaningful inferences.

The idea of interval representation has attracted numerous researchers (Dempster, 1969, Shafer, 1976 and Baldwin, 1986). Cui and Blockley (1990) developed previous
work by introducing the parameter $p$ which represents the degree of dependence between evidence. Inference rules based on the assumptions of dependence (notably fuzzy set theory (Bier, 1992)) or independence are therefore special cases of IPT.

If $p$ is expressed as an interval number $[p_i, p_u]$ the intersection is

$$S_n(E_1 \cap E_2) = p_n(S_n(E_1) \cap S_n(E_2))$$

$$S_p(E_1 \cap E_2) = p_p(S_p(E_1) \cap S_p(E_2)).$$

The inference mechanism is the total probability theorem

$$P(H) = P(H|E)P(E) + P(H|\overline{E})P(\overline{E})$$

which can be rewritten as

$$P(H) = P(H|E)P(E) + P(H|\overline{E})(1 - P(E)).$$

Dubois and Prade (1990) showed that when all the terms are expressed as interval numbers the bounds on $P(H)$ are

$$S_n(H) = S_n(H|E)S_n(E) + S_n(H|\overline{E})(1 - S_n(E)); \quad S_n(H|E) \geq S_n(H|\overline{E})$$

and

$$S_p(H) = S_p(H|E)S_p(E) + S_p(H|\overline{E})(1 - S_p(E)); \quad S_p(H|E) \geq S_p(H|\overline{E})$$

Dubois and Prade only dealt with one item of evidence $E$. Recently Hall et al. (1998c) have developed a generalised approach to finding the least conservative bounds on the inference for any number of items of evidence. In multi-dimensional problems the simplex algorithm is used to find the least conservative bounds.

An interval approach is attractive because of the much increased flexibility it provides for representing uncertainty knowledge when compared with conventional probability theory. On the other hand it significantly increases the dimensionality of the inference problem. Analysis of any inference problem is therefore a compromise between, on the one hand, having degrees of freedom constrained in a way which does not do justice to the complexities of the situation and, on the other, having to input large amounts of instance-specific information or generating large amounts of uncertainty. The method used will depend on the nature of the problem under consideration. Interval Probability Theory is suitable in situations involving sparse or conflicting data, whilst more precisely defined situations can be effectively tackled with more conventional quantitative approaches.

**Implementation of IPT for process modelling**

A software tool has been developed which combines visual representation of hierarchical processes with uncertainty propagation using Interval Probability Theory. By combining Interval Probability Theory with process modelling an overall measure of the dependability of the process leading up to a decision can be obtained.

Figure 2 shows a typical working screen. The processes are arranged in a logical
Figure 2 A process model showing the evidence relating to the decision to implement depolderization at Orplands
hierarchy. Each process is analysed to identify sub-processes which contribute to the success of the process. The process is decomposed in this way down to a level of resolution appropriate for the problem in hand.

Figure 3 is a detail from the screen shown in Figure 2. The processes are titled and the probability intervals shown as pairs of numbers under the title and graphically as coloured bars at the bottom of each process box. The left bar is coloured green and the right bar red, representing the evidence for or against the success of the process respectively. Between the two bars is a white area representing the uncertainty.

Interval values are input by the user for all of the 'leaf' processes in the hierarchy. At every node in the hierarchy values of the dependency parameter \( p \) and of the conditional probabilities which express the structure of the inference problem are input by the user. Using this information the software calculates the interval probability which represents the evidence for success of the top process in the hierarchy, which is a logical consequence of all of the interval probabilities input elsewhere in the hierarchy. It is therefore possible to explore the influence of low level processes on the uncertainty in the overall design, modelling or decision making process. Knowledge of the overall dependability, which is provided by the top level interval number can be used to inform and enhance decision making. In this way the process model and interval numbers provide commentary on the process of obtaining and manipulating evidence. The decision maker thereby obtains a means of comparing different predictions (which may be expressed in probabilistic or deterministic terms) which have been obtained from different models. Hall et al. (1998c) also proposed an approach whereby the interval probabilities generated from modelling the dependability of an analysis process can be combined with the probabilistic information generated by that process, for example in the form of a probability of failure, to generate bounds on probability of failure.
Case Studies

Uncertainty analysis which combines process modelling with interval probability theory has been applied to two contrasting flood defence projects on the East Coast of England.

Orplands seawall managed retreat project

One of the projects is a depolderization (managed retreat) project on an estuary in Essex. The dykes which protected a few square kilometres of low grade agricultural land were in need of major repair. To avoid the high cost of repair it was decided to abandon the dykes and retreat the defence line inland. This has had the added benefit of reinstating an area of saltmarsh habitat and reducing stress on the eroding estuary. The scheme was planned based on the experience of the experts involved, supported with some quantitative analysis which was carried out by consultants. The uncertainty analysis was carried out to assess the dependability of the process of choosing to implement the depolderization rather than any of the other options.

![Figure 4 High level processes in the Orplands model](image)

Figure 4 shows the high level process in the process model. The hierarchy shown in Figure 1, 2 and 3 are lower level parts of the same process model. The model was constructed using documented evidence in the form of reports and correspondence relating to the project, together with testimony of the engineers involved. On the basis of this evidence the support for the top process of “choosing an appropriate flood defence” was calculated to be [0.05, 0.75] which represents rather low dependability with low confidence in that assessment. The uncertainty model therefore demonstrated that there was substantial uncertainty in the overall process of choosing an appropriate defence option when this was not necessarily made clear in the documentation relating to the project.

The interval probabilities relating to the sub-processes shown in Figure 4 are listed in Table 1. The main reason why the dependability of the top process was calculated to be low was because of the low support for the economic appraisal process which in the UK has a great influence on the overall dependability of the decision making process. The economic appraisal was found to have dependability [0.03, 0.60]. The lower bound on this interval is a dominant influence on the lower bound of the top process. The economic appraisal was found to be of low dependability because of the complexity of the failure mechanisms at the site, upon which the economic assessment of flood risk depended. Failure probabilities (which are necessary aspects of the economic benefit assessment) were assigned using expert judgement and were not
particularly dependable. To reduce uncertainty in the decision making process would require investment in an improved assessment of flood risk.

The findings of the uncertainty model should not be used in isolation but should complement the information relating to the options which was generated during the economic appraisal, hydraulic and environmental assessment and consultation exercise. These indicated that depolderization was a favourable option which was robust to changes in key parameters in the decision making process. Testing of the uncertainty model suggested that for a project of this size (the estimated cost of the project was only £87k) it would on balance be appropriate to proceed cautiously without further analysis, especially in view of the high cost associated with reducing the uncertainty of key processes.

Construction and use of the uncertainty model forced reflection on how the different activities and studies which had been undertaken contributed to the strategic decision to implement the depolderization project. The final model structure was confirmed by the Environment Agency's project manager to be a good representation of the processes leading up to the strategic decision.

The Lincshore beach nourishment project

The second project used as a case study was a £71 million beach nourishment scheme which is being implemented over a number of years. The scheme has been the subject of detailed numerical model studies and is being intensively monitored. There was therefore much more evidence on which to base the design of the scheme than at the Orplands site.

The first phase of the uncertainty analysis for this project proceeded in the same way as the Orplands project described above, examining the strategic decision to implement beach nourishment rather than any of the other options evaluated during the feasibility study. This demonstrated once again that the risk assessment and economic appraisal process were the main sources of uncertainty in the overall decision. The analysis then proceeded to model the current decision making process relating to the renourishment strategy for the coming five years. This demonstrated how probabilistic modelling to optimise the beach nourishment programme could be combined with hierarchical modelling of the decision making process using Interval Probability Theory.

Conclusions
A descriptive study, using methods developed in the social sciences, has identified principal sources of uncertainty in decision making. Descriptive studies of this type are an important precursor to the design and development of decision support systems.

It has been argued that reliability theory provides an important but incomplete picture of uncertainty in coastal engineering. It cannot be assumed that traditional methods of dealing with uncertainty are as efficient as they could be or that they will continue to be effective in increasingly complex coastal management systems in which more interactions and sensitivities are taken into account. Engineers need to be prepared to explore new methods to give efficiency, safety and sustainability in the defences for which they are responsible. A range of techniques are available for managing uncertainty so engineers should be prepared to draw upon appropriate techniques, remembering that all measures of uncertainty are not absolute measures but are aids in the process of managing uncertainty (Blockley, 1985).

Interval Probability Theory has been found to be a useful approach which accounts for the incompleteness and dependency between items of evidence in an evidential reasoning framework. Interval Probability Theory is an appropriate way of modelling uncertainty in complex situations involving sparse or conflicting information.

Process models of coastal engineering projects have been constructed with Interval Probability Theory. These supplement and enhance existing approaches to uncertainty including reliability methods. These models have been used to support the management of coastal engineering projects on the East Coast of the UK. Two case studies have demonstrated the extent of uncertainty in key decisions during project planning and design. They have highlighted that the a key source of uncertainty and indicated where investment would have to be directed to reduce uncertainty. Moreover, the analysis forced reflection on how the different activities and studies contributed to strategic decisions.

Uncertainty analysis involves giving an overview of where uncertainty lies in a decision. By identifying the most significant sensitivities and sources of uncertainty and by making the most of available information it helps to enable better decision making for coastal engineering projects.

PREVENTING NATURAL BREACHING OF THE MAJOR SAND SPIT
PROTECTING THE PORT OF WALVIS BAY

J S Schoonees¹, L Lenhoff² and A J Raw³

Abstract

During seasonal storms, waves wash over the major peninsular sand spit protecting the Port of Walvis Bay. The possibility of breaching of the spit was assessed and conceptual measures were proposed to prevent breaching. Aeolian, longshore and cross-shore sand transport rates were computed. Modelling was done of beach profile changes during storms. It was found that the spit would probably not be breached during a single storm. Sand nourishment, methods to prevent erosion, and methods to induce accretion in vulnerable areas were considered to prevent breaching. A contingency plan was recommended involving the use of low-cost shore protection.

1. Introduction

Major coastal sand spits are common features along the Namibian and Angolan coasts of Africa. Examples of these can be found at Walvis Bay (central Namibia; Figure 1), Sandwich harbour (50 km south of Walvis Bay), Baia dos Tigres (southern Angola, about 70 km north of the mouth of the Kunene River) and Lobito (central Angola).

Walvis Bay, which is the biggest deep-water port in Namibia (Figure 1), is protected against wave action by the Walvis Peninsula. This long (about 10 km) but low-lying (about +1 m to mean sea level, MSL) sand spit is growing northwards because of the net northbound longshore transport. However, during storms at high tide, the waves wash over a section of the sand spit (at Donkie Bay; Figure 1), causing concern that natural breaching may occur. This can be a real threat. At

1475
Baia dos Tigres natural breaching of the 41 km long spit occurred, leaving an 11 km wide gap in the spit and destroying safe anchorage. At Sandwich harbour extremely dynamic sand banks and channels occur. If breaching does occur at Walvis Bay, the port would have to contend with significant wave action hindering navigation and quay operations. Furthermore, shifting sand banks which are hazardous to shipping, may form in the shipping channel and result in increased maintenance dredging. Because of the seriousness of the consequences and the cost of closing a gap in the spit, a study was undertaken to assess the possibility of breaching of the Walvis Peninsula and propose conceptual measures to prevent it (CSIR, 1996).

The aims of the study were: an initial assessment of the possibility of breaching, the gathering of essential data required for this task, and the proposal of conceptual measures (e.g. shore protection) to prevent breaching. For the study, beach and hydrographic surveys were conducted of the low-lying area (Donkie Bay) and of Pelican Point (the tip of the Walvis Peninsula). It was essential to obtain accurate information on sand spit levels in order to determine the extent of the problem and the most suitable solution. A survey of the Pelican Point area was conducted to assist in estimating the longshore sand transport rate along the Walvis Peninsula.

2. Environmental data

2.1 Historical data

Although charts of the study area date back to 1796, the first reliable map was compiled in 1885 by the British Navy. Subsequently a number of charts and aerial photographs became available which illustrate the development of the spit over the past 100 years. From these data an average annual growth rate could be determined, which has a direct bearing on the longshore sediment transport rate in the area - an aspect which will be discussed in more detail in Section 3.2 below.

2.2 Bathymetry and topography

To assess the present configuration of the Walvis Peninsula, detailed bathymetric and topographical surveys of Pelican Point and its surrounds as well as the area around Donkie Bay were conducted. Echo-sounding and conventional land surveying techniques were used to obtain detailed elevation contours at 1 m intervals. The data show that the Walvis Peninsula is a low-lying spit with an average height of about +1.0 m to MSL, sloping steeply towards deeper water, especially at Pelican Point.

A cross-section at Donkie Bay (Profile 2) is shown in Figure 2. The profiles at Donkie Bay are very similar; however, the crest of the dune is the lowest in Profile 2.

2.3 Waves

The dominant deep-sea waves, obtained from voluntary observing ships
COASTAL ENGINEERING 1998

2.4 Sediment grain size

Sand samples taken from the wetted beach and the sea bottom at Donkie Bay and Pelican Point show that the average median grain size ($D_{50}$) is about 0.35 mm, that is, medium sand.

3. Sediment transport analysis

3.1 Aeolian transport

About 6 years of wind data collected near the Walvis Lagoon (Figure 1) were used to compute seasonal and annual wind-blown sand transport rates on the Walvis Peninsula, using the method proposed by Swart (1986). The average of the median grain sizes (0.33 mm) of the samples taken on land across the Walvis Peninsula was applied.

It was found that the dominant transport is towards the north-eastern and north-western sectors with distinct seasonal variations. The net northward movement of sand is equal to the difference between the northbound and southbound transports, which is about 38 m$^3$/year per m. By using the average width of the Walvis Peninsula (605 m), it was calculated that the potential net northbound aeolian transport is approximately 23 000 m$^3$/year.

3.2 Longshore transport

Longshore sediment transport usually takes place from south to north along the western shore of the Walvis Peninsula. The tip of the Walvis Peninsula acts as a total trap for sand moving alongshore with the result that the spit is growing over time. By determining the volume of sand deposited over a period of time, the net longshore transport rate can be calculated. An analysis of the historic data (old maps and aerial photographs) showed that Pelican Point grew at an average rate of about 17.4 m/year between 1885 and 1980. Between 1980 and 1996 Pelican Point has prograded over a total distance of 340 m (determined accurately from the surveys), that is 22.6 m/year on average. In contrast to growth at the tip the eastern coastline configuration of the spit did not change between 1980 and 1996. Along the western flank, however, a significant shift took place around Donkie Bay, resulting in a decreased width in this area, which gave rise to the present concerns regarding breaching.

Based on all the available statistical information, a prediction was made with respect to the expected location of Pelican Point in the year 2006, that is, in 10 years' time. Using geographical information system (GIS) techniques, it was found that a total of 8.83 million m$^3$ of sediment will be required to enable the growth of
Pelican Point to achieve its predicted shape in 2006. This implies an average annual addition of 883,000 m$^3$ of sediment. If the Walvis Peninsula is considered a total sediment trap, the figure of 883,000 m$^3$/year represents the net northward sediment transport rate along this coastline.

One should subtract the net northbound aeolian transport (23,000 m$^3$/year) from the calculated volumetric rate of 883,000 m$^3$/year. Thus the net northbound longshore transport rate along the western shore of the Walvis Peninsula is considered to be 860,000 m$^3$/year.

3.3 Cross-shore transport

Erosion by offshore sand transport (during storms) can potentially cause breaching of the Walvis Peninsula. Modelling of cross-shore transport and the associated beach profile changes was therefore carried out.

The Sbeach cross-shore transport/morphological model (Larson and Kraus, 1989) was chosen for predicting beach profile variations due to storms. In a comprehensive review, Schoonees and Theron (1995) found that this is one of the best models currently available. The theoretical basis is acceptable and the model has been extensively verified (Schoonees and Theron, 1995). In addition, it can simulate dune overwash which can be important in the Donkie Bay case. No calibration data are available for the Donkie Bay case and the results should therefore be regarded as first estimates only. However, since Sbeach is a well-verified model against prototype data, the results are considered to be realistic.

Profile 2 was selected because the crest of the dune is the lowest in this profile (Figure 2), thus representing the most critical scenario. A median grain size of 0.35 mm was used for the profile. Two storms were modelled, namely, storms having significant wave heights ($H_s$) of 3 m and 4 m respectively. These wave heights correspond roughly to the 1-in-1 year (3.6 m) and the 1-in-10 year (4.4 m) conditions. More extreme wave heights were not chosen because it has previously been found that medium-sized waves occurring over longer periods cause more erosion than short-lived, high-wave events. The peak wave periods ($T_p$) associated with these wave heights are 11.7 s and 12.5 s respectively. The durations of these two storms were 68 h and 41 h respectively. The water-level variation was obtained from the most extreme tides predicted for 1996: from -0.94 m to +0.89 m to MSL (the latter value approaches the highest astronomical tide of +1.02 m to MSL).

Figure 2 shows the progressive erosion of the beach profile for the 3 m storm. An offshore bar formed at a depth of about -5 m to MSL. The predicted maximum horizontal erosion of 23.5 m (and 18.8 m for the 4 m storm) occurred at 0 m to MSL. Because of its longer duration, the 3 m storm caused slightly more erosion than the 4 m storm. Based on experience, these values appear realistic. As indicated by Figure 2, it is unlikely that the dune crest will be flattened, although the model does predict overwash as has been observed on site. Smaller waves will therefore not be able to erode the beach continually. However, it should be borne in mind that the model could not be calibrated for Walvis Bay due to a lack of data.
The results are therefore preliminary only. In addition, only two storms were modelled.

4. Possible breaching of the Walvis Peninsula

The possible breaching of the Walvis Peninsula was approached in two ways: firstly, by analysing measured beach profile variations (in a horizontal plane) from other sites and secondly, by modelling storm erosion as explained above.

Beach profile variations have been recorded on exposed beaches along the Southern African coastline. Typically the maximum, natural, horizontal storm erosion for exposed beaches is between 30 m and 95 m over the long term.

The predicted maximum horizontal erosion of 23.5 m compares well with the range of measured erosion. The beach profile modelling showed that overwash will most probably not flatten the dune (Figure 2). However, caution is necessary because it was not possible to calibrate the model (Sbeach) for Walvis Bay.

When considering the width of the Walvis Peninsula, which is at least 500 m wide, it is clear that it is highly unlikely that the peninsula could be breached by a single storm. Erosion of no more than 50 m can be expected during one storm. However, a potential danger exists for wave action to flatten the frontal dune (although this was not predicted in the beach profile modelling). This could possibly cause smaller, more commonly occurring waves to flatten the peninsula with breaching occurring eventually.

It is therefore recommended that the Donkie Bay area be inspected weekly and also immediately after heavy seas to ensure that flattening of the dune is noticed timeously. In the event of flattening, emergency protection can be installed (see Chapter 5) to prevent breaching. It is further recommended that bi-monthly beach surveys be conducted of the Donkie Bay area.

5. Conceptual measures to prevent breaching

5.1 General

A number of generic measures can be employed to prevent breaching of the Walvis Peninsula. These measures are: sand nourishment, methods to prevent erosion, and methods that induced accretion in the vulnerable areas.

A number of factors should be considered when evaluating the suitability of these measures. These factors include availability of construction materials and equipment, cost of construction, accessibility of the construction site and whether a temporary or permanent solution is required.

5.2 Sand nourishment

Sand can be brought in artificially to widen the vulnerable section of the peninsula (Donkie Bay). Possible methods for bringing in sand from nearby areas where there is abundant sand are: by means of trucks, pumping, or bulldozing sand into the sea just south of the Donkie Bay area. Especially in the case of bulldozing, the sea can be used to transport the sand towards the Donkie Bay area.
The extra sand can serve as an emergency measure by filling up or feeding an eroded section, or by acting as a buffer against future erosion. It is most likely that sand nourishment will be only a temporary solution. If applied correctly, it can, however, be an effective and low-cost solution.

5.3 Methods to prevent erosion

There are a number of different methods for preventing erosion. These include low-cost shore protection, a rock berm (armour), a gabion structure, and a sheetpile wall.

The CSIR has done extensive research into low-cost shore protection. Initially, a literature survey was done and new concepts were developed which were tested in the laboratory. Thereafter, a one-day field exercise was conducted. This was followed by a full-scale test at Hermanus (an exposed site) in November 1992. A 3 m high dune (sand wall) of 110 m length was constructed, which was protected by four different configurations of low-cost protection structures. The detailed results of this test are discussed in Theron et al. (1994). Based on these results, the three most promising protection methods were found to be sandbags, sand sausages (Figure 3) or a combination of both. In two subsequent cases sandbag groynes were also used successfully in False Bay near Cape Town.

Low-cost protection and breakwaters are in use around the world. In Mexico several major coastal structures have been built (Porraz, 1976, 1987) which have withstood a number of hurricanes. Dette and Raudkivi (1994) devised a shore protection system (Figure 4) very similar to the CSIR design shown in Figure 3. They tested it in the Large Wave Flume in Hannover, Germany before a successful prototype application on the island of Sylt in the North Sea. The defence has withstood storms from 1991 up to at least the date of the publication (1994). Dette and Raudkivi (1994) also mentioned a similar successful deployment in Fiji for hurricane protection.

The main advantages of low-cost shore protection are that it is relatively easy and fast to build and remove and that the building material (usually sand) is locally available. The disadvantages are that the protection is mostly temporary (that is, withstanding a 2 to 6 month period of wave attack) and that degradation of the geotextile material will eventually occur due to ultra-violet radiation from the sun.

Profile 2 (Figure 2) is the most vulnerable section of the Walvis Peninsula. If the top of the dune is flattened during a storm, it is possible to protect the peninsula with a double row of tightly stacked (1 m$^3$) sandbags placed as shown in Figures 5 and 6 around the eroded area. These emergency measures are, however, only essential if significant erosion has already occurred.

For protecting the Walvis Peninsula permanently, a dynamically stable rock berm, consisting of smaller rock, will most probably be cheaper (also in the long term) than a statically stable rock protection. Allowance will have to be made for scour in front of the structure. By placing enough rock, a sacrificial toe can be
constructed which will partially fall into the expected scour hole in front of the rock protection. Figure 7 shows a conceptual rock berm (median rock mass \(w_{so} = 1150\) kg) for protecting the vulnerable Donkie Bay area. This type of design has proved its adequacy in prototype in a similar situation at Saldanha near Cape Town (CSIR, 1994). Such a rock berm can be placed in the same position as the low-cost shore protection (Figure 5). Three-dimensional effects need to be considered. For example, wave overtopping can cause the formation of pools of water behind the rock berm which will rush back to sea at the lowest point of the berm, causing a dangerous and erosive return current.

Other possible methods of preventing erosion at the Walvis Peninsula are gabions and a sheetpile wall. Gabions are susceptible to failure if they are continually exposed to wave action. This is mainly due to abrasion and corrosion of the wire of the gabions. A sheetpile wall will probably be very expensive. Allowance also has to be made for the extra scour in front of such a wall because of wave reflection. Therefore, these two methods do not appear to be appropriate for the Walvis Peninsula.

5.4 Methods that induce accretion

There are different methods that can be employed to induce accretion of sand in the Donkie Bay area. These include: one or more groynes to trap the longshore transport of sediment, the construction of a headland to trigger the formation of a half-heart bay, and the trapping of wind-blown sand.

One-line theory (Larson et al., 1987) was chosen to predict the shoreline evolution caused by the construction of different groynes. The theory predicts the position of a single contour line over time (taken to be the shoreline or 0 m to MSL contour). Despite simplifying assumptions such as the theory being only applicable for small wave approach angles and that no net cross-shore sediment transport takes place, one-line theory has been proved to give good results in Japan (Hanson and Kraus, 1986), the United Kingdom (Brampton and Goldberg, 1991), the USA (Hanson et al., 1989) and Southern Africa (Coppoolse et al., 1994).

Three different groynes extending to -1.5 m, -3 m and -5 m to MSL were simulated in the model. These groynes are 61 m, 86 m and 116 m long if measured from the +2 m to MSL contour. The simulation runs were for a groyne just north of the vulnerable Donkie Bay section at alongshore distance (or Chainage) 4 000 m (Figure 5). At Chainage 3 800 m (the corner of Donkie Bay), the shoreline turns sharply westwards forming Donkie Bay. In addition, two groynes of 61 m length each, one at the above-mentioned position at Chainage 4 000 m and one at 350 m further northward along the Walvis Peninsula at Chainage 4 350 m, were also simulated. This was done because it is considerably cheaper to build two 61 m groynes than one long groyne. In addition, the 61 m groynes will only extend to -1.5 m to MSL, which means that they can be constructed from land using sandbags (Theron, et al., 1994).

As input parameters, the net longshore transport obtained in Section 3.2, a
representative wave incidence angle at the breaker line (4°), a total height (above and below the water) over which nearshore profile changes take place (12 m), and beach slopes and water depths at the groynes obtained from the surveys were used.

Figure 8 represents the shoreline evolution caused by the 116 m groyne. Note that the original coastline is at a cross-shore distance of 200 m. Accretion of about 69 m takes place reasonably rapidly next to the groyne. Equilibrium is reached after about two years with little significant accretion occurring after a year. This means that significant bypassing will take place almost immediately after the groyne has been constructed, thus limiting downdrift erosion. At 200 m south of the groyne (in the corner of Donkie Bay) eventual accretion of approximately 63 m (12 m after 1 month) can be expected. The sand will form an appreciable extra buffer against storm erosion.

Two 61 m groynes were also modelled to evaluate the effects on the beach (Figure 9). It can be seen from this figure that, initially, some erosion is evident north (to the right) of the first groyne (at Chainage 4 000 m), after which significant bypassing takes place and accretion occurs (in the order of 19 m). Because of the relatively high longshore transport rate and the short groynes, the coast will be close to equilibrium after about 6 months.

Downdrift erosion of about the same magnitude as the accretion can be expected to the north of the groyne (or the northernmost groyne in the case of two groynes). However, if erosion occurs when the peninsula is wide (more than 500 m) and not vulnerable, it is considered acceptable.

Half-heart bays can be used to stabilise a coast. However, in the case of the Walvis Peninsula, this will mean that at least one major headland will have to be constructed because the peninsula is an exposed coastline with high longshore transport. Because of the high cost, this option is not considered viable.

Aeolian sand can be trapped by erecting geotextile fences across the Walvis Peninsula. Because of the low aeolian transport rate of about 23 000 m³/year, it will take a long time to achieve appreciable accretion at Donkie Bay. To be conservative, only the width of dry sand on the peninsula should be considered and not the total width of the peninsula at Donkie Bay because moisture limits sand transport by wind. If this is done, the net northbound aeolian transport is only about 3 040 m³/year. The accretion against the fences will therefore be small and it will take a long time to achieve significant results. The additional protection offered against storm erosion will therefore be small in the short to medium term, which is the required time span.

Although the solution is initially cheap, considerable maintenance is envisaged. Access to Pelican Point for lighthouse personnel, anglers, etc. will be hindered because of the fences. The fences are also prone to damage by vandalism. Trapping wind-blown sand is therefore not regarded as a suitable option.

6. Conclusions and recommendations

It is highly unlikely that the Walvis Peninsula would be breached during a
single storm. There is, however, the potential danger that wave action could flatten the frontal dune (although this is not predicted in the beach profile modelling). Flattening of the frontal dune could possibly cause smaller more commonly occurring waves to flatten the peninsula with breaching occurring eventually. It is therefore recommended that the Donkie Bay area be inspected weekly and also immediately after heavy seas to ensure that flattening of the dune is noticed timeously. In the event of flattening, emergency protection can be installed to prevent breaching. Bi-annual beach surveys of the area are recommended.

Because it is unlikely that the peninsula would be breached during a single storm, it is not deemed necessary to opt for the best permanent solution, namely a rock berm. Such a permanent solution will obviously be more expensive than a temporary solution. However, it is strongly recommended that a contingency plan be drawn up in order to facilitate a timeous response in case of an emergency. It is recommended that 1 m$^3$ bulk bags be bought and kept in storage at Walvis Bay for such an emergency. These can be used either as low-cost shore protection (Figures 5 and 6) or to construct one or two short groynes (Figure 9). Arrangements should also be made for obtaining a large excavator (on metal tracks; 20 tonnes) at short notice to fill and transport the bulk bags. The low-cost shore protection and groyne(s) should be designed in detail because experience has shown that the method of construction and deployment can have a profound effect on the overall success of the protection (Theron et al., 1994).

It is also advisable to have a bulldozer available at short notice. Bulldozing sand into the surf zone upstream of the damaged (eroded) area can help to delay erosion, thus buying time for placing the bulk sandbags. It is also advisable, though not essential, to build one short (61 m) groyne. The advantages are that an additional buffer of sand will be formed thereby reducing the possibility of a breach and that the construction will serve as a training exercise for deployment of low-cost protection during an emergency. In addition, by monitoring the beach accretion, calibration data for modelling shoreline evolution resulting from the groyne will be obtained to confirm the predictions presented above. The disadvantage of the construction of the groyne is that unnecessary cost will be incurred. On the other hand, such a groyne will most probably cost less than the more extensive remedial protection required in an emergency.

The paper deals with experimental and theoretical investigations of dynamics of a plate-fluid system. In experiments, a horizontal plate was suspended elastically in a wave flume and loaded with impact pressure forces resulting from growing water waves. The data obtained in experiments has revealed the essential role of the elasticity of the plate and its supports as well as the fluid compressibility in estimating the structure-fluid interactions. Therefore, in order to get a better insight into the problem considered, harmonic vibrations of an elastic band plate submerged in an infinite domain of compressible fluid have also been examined. The solution obtained and formulae derived enable to calculate the fluid pressure induced by the plate vibrations.

1. Introduction.

In offshore engineering we have a wide variety of problems associated with water wave forces acting on offshore structures. Among them, there are also cases of horizontal plates (or plate like elements of a structure) loaded with abrupt pressure forces resulting from growing sea waves. Examples are sea piers and suspended breakwaters under the action of water forces of short duration. A theoretical description of the mentioned problem is very difficult because of a complicated structure of the equations of the fluid motion together with the relevant boundary conditions, especially at moving boundaries of the fluid domain. Therefore, in describing the structure - fluid interaction, we are forced to resort to approximate methods, which, in principle, should be verified by experimental investigations. For this purpose and, to learn more about the phenomena, experimental investigations of dynamics of a horizontal plate in contact with water have been performed in the wave flume of the Institute of Hydro-Engineering of PAS in Gdańsk. The performed experiments allowed for collecting information important in creating approximate computational models which describe the structure-fluid interaction with an acceptable accuracy.

2. Laboratory experiments.

The experimental set-up is shown schematically in Fig. 1. It consists of the following main components: the model of a horizontal plate constructed in the form of a box with frame skeleton and casing made of aluminium alloy, the system of springs and strings, the piston type wavemaker and the system of pressure, wave and acceleration gauges together with a recording unit. The horizontal plate was suspended elastically in the wave flume over the still water level by means of a system of prestressed elastic springs at a chosen distance from the wavemaker. In order to obtain reliable results, we looked for a wave problem that could be controlled. Therefore, at a first step, we have chosen the case of standing water waves growing with time. In order to obtain these waves, additional rigid vertical plate was installed in the flume, just in the neighbourhood of the horizontal plate. In this way, the wavemaker together with the vertical plate formed a rectangular basin of water with its own set of eigenfrequencies.

During experiments the wavemaker frequency was chosen to be equal to the first and the second lowest natural frequencies of the water test section and thus, the lengths of the generated waves were equal to the distance between the wavemaker and the vertical plate and, twice the distance, respectively. Due to the resonance, the harmonic motion of the wavemaker, starting from rest and moving with a relatively small amplitude, led to the standing surface wave with amplitude growing in time. The growing wave crest could reach the horizontal plate level at a certain moment of time and thus, the impact pressure phenomenon occurred. The generated waves were measured by means of two or three wave gauges, the vibrations of the plate - by four acceleration gauges and, the distribution of the impact pressure – by eight pressure gauges, respectively. The latter gauges were installed in two rows on the lower surface of the plate.

The data recorded in experiments has the form of a sequence of numbers corresponding to the assumed sampling frequency. The electronic devices used in
Fig. 2. The measured acceleration and pressures for standing waves.
experiments allowed to register the data numbers with the maximum sampling frequency equal to 20,833 Hz. These records were then processed with the help of the Kalman filter which enabled us to decompose the vibrations into components corresponding to dominant frequencies of the system mentioned.

The experiments started with the identification of the considered dynamical system in air. By applying an initial displacement of the plate, which was then released, the free vibrations of the plate were obtained. The spectral density of the acceleration record of the vibrations showed three eigenfrequencies: 24 Hz, 38 Hz and 416 Hz corresponding to the vertical, rotational and flexural displacements of the plate,

Sampling frequency = 20833 Hz

Fig. 3. The analysis of measured acceleration.
respectively. The two lowest frequencies detected correspond to the plane rigid body motion of the plate, while the third one is associated with a deformation of it. The plate as a box structure has many eigenfrequencies and the highest frequency detected is the lowest one of the plate.

The basic experiments of the plate loaded with water wave forces were performed for a relatively large number of particular cases corresponding to the chosen rigidity of the springs, the chosen gap width between the lower surface of the plate and the still water surface and, the assumed amplitude and length of the generated wave (the distance between the vertical plate and the wavemaker was a parameter in the experiments mentioned). With respect to the amount of data obtained, we attached here only few illustrative examples. Typical results of an experiment performed are shown in Fig.2 and in Fig.3, where the plots of the water wave, acceleration of the plate and the pressure acting on the plate surface are depicted. This experiment can be divided into a number of stages. The first one lasts from the outset of the generator motion to the moment of the maximum height of the surface wave, just before water

Fig. 4. The impact pressure of a standing wave.
strike at the plate. Then, we have a very short second stage during which the plate receives a finite impulse of the pressure forces. The registered measurements pointed the existence of acoustic waves propagating with sound velocity. With the end of this short stage the third – transitive stage begins during which the free damped vibrations of the plate take place. This third stage may be assumed to last till the next water strike at the plate. Since the water flow is not fully periodic in time, we cannot speak about periodic behaviour of the system at hand and thus, the second wave impact on the plate is assumed to be the beginning of the fourth stage and so on. From the plots in Fig.2, it may be seen that in addition to the range of frequency mentioned above we have now also the frequency of order 1 Hz relevant to the gravitational wave. Besides, the zoom sections shown in Fig.3, reveal the important feature of the impact pressure phenomenon, namely, a wide range of frequencies associated with the system as a whole. The frequencies vary from 1 Hz of the generation of water waves, through 10-30 Hz relevant to rigid body motion of the plate and approx. 200-400 Hz of the lowest eigenfrequency of the box structure. In addition to these frequencies, we have also higher frequencies corresponding to higher modes of vibrations of the box structure and dilatational waves propagating within the fluid. The higher frequencies of the system considered and thus, the influence of the dilatational waves on the system behaviour are of primary importance, especially in proper estimation of the impact pressure forces. This can also be seen in Fig.4, where the distribution of pressure recorded by pressure gauges installed on the plate is given. From the plot it follows, that the time range of the impulse pressure is very narrow and thus, in describing the impact pressure phenomenon, the small compressibility of the fluid as well as the elasticity of a structure must be taken into account. At the same time, because of the small interval of the impulse action on the plate, the higher modes of the system motion can be investigated independently from the lowest modes associated with the surface gravitational waves.

Therefore, the basic experiments mentioned so far were supplemented with experiments concerning vibrations of the plate initially resting on the surface of calm water (floating plate). The vibrations were induced by initial displacements of the plate or, by a hammer strike on it. In order to identify the lowest eigenmodes of the plate vibrations, the theoretical model of the plate shown in Fig. 5. was constructed. The experiments started with vibrations of the plate in air. Some of the results obtained are illustrated in Fig. 6, where the acceleration record is presented. The experimental results were confirmed in theoretical calculations based on a simplified

model of the dynamical system shown in Fig. 5. A similar test was performed for the plate having a contact with water. Like in the previous case, the vibrations of the plate were induced by an initial displacement of it. The results obtained in the experiments are shown in Fig. 7. The spectral density of the plate vibrations in contact with water is shifted to the left (in the direction of lower values) as compared to the case of vibrations in air. The changes of eigenfrequencies are due to covibrating masses of fluid. The vibrations of the plate induced by a hammer strike are illustrated in Fig. 8, where an acceleration record is shown. When compared to the afore-going cases we have here almost exclusively one component corresponding to flexural vibrations of the plate. This is a result of the method used to induce the vibrations of the system mentioned. From the acceleration plots it is seen, that the vibrations of the system are damped. In the case of vibrations in air we have the so called structural damping resulting from energy dissipation within the material (the mechanical energy is transformed into heat and dissipated in cyclic deformations). In the case of vibrations of the plate – fluid system, the damping is a result of the dissipation of energy mentioned above and the transmission of energy outside the structure by dilatational waves. It is worth to add, that during reflections of the propagating waves from the flume boundaries, some energy is transmitted outside the fluid.

3. Fluid compressibility and a structure-fluid interaction.

From the experiments performed it follows, that in analysis of a structure loaded with impact pressure forces of fluid and, or vibrating in contact with fluid, the elastic deformation of the structure and the small compressibility of the fluid must be taken into account. Accordingly, for higher frequencies of the vibrations, the dilatational waves generated play an important role in proper estimation of the structure – fluid dynamical interactions. In order to get a better insight into the phenomena considered, the problem of harmonic vibrations of a structure submerged in an infinite domain of compressible fluid has been investigated. In particular, we have confined our attention to the plane problem of harmonic vibrations of an infinite elliptical cylinder immersed in the compressible fluid domain. The solution derived corresponds to the vibrations of the cylinder in the direction of the smaller axis of the ellipse. In the limit, the smaller axis of the ellipse was assumed to decrease to zero and, the solution for the ellipse approached the solution for an elastic infinite plate vibrating in the fluid. In this way, the solution for the ellipse was converted into the solution for the plate. For comparison, a similar problem for an infinite circular cylinder was also considered. The solutions obtained enable us to calculate the resultant force $R$ of the fluid pressure acting on the cylinder or thin plates vibrating in fluid:

$$R = \dot{\omega}(t) \cdot \rho \cdot \pi \cdot b_x^2 \cdot F_m(h) + \dot{\omega}(t) \cdot \rho \cdot \pi \cdot b_x^2 \cdot F_T(h), \quad h = \frac{\omega \cdot a}{c},$$

where: $\rho$ is the fluid density, $\omega$ is the angular frequency of vibrations, $a$ is the radius of the cylinder, $c$ is the velocity of sound in fluid, $\dot{\omega}$ and $\ddot{\omega}$ are the velocity and the acceleration of the cylinder (or the plate). In the case of the cylinder $b_x = a$ and, in the case of the plate $2b_x = 2a$ is the plate width. The resultant force has two components: the first one corresponding to the covibrating mass of fluid, and the second – describing the damping of vibrations. The plots of the resultant components for the rigid body vertical motion of the circular cylinder and a band plate are shown in Fig. 9. Similar plots of the resultant components for the flexural and rotational vibrations of the plate are presented in Fig. 10. From the plots it is seen, that with
Fig. 9. The influence of compressibility. The coefficients $F_u(h)$ and $F_T(h)$ for vertical vibrations of a circular cylinder (a) and a band plate (b).

neglecting the fluid compressibility in description of the problem considered, no information about damping of structure vibrations can be obtained. In other words, the fluid compressibility is important in proper estimation of the covibrating mass of fluid and is essential in calculating damping of vibrations.

The phenomenon of impact pressure forces induced by water waves has been examined experimentally by means of a horizontal plate supported elastically in a hydraulic flume. The pressure, wave and acceleration gauges allowed for recording the relevant parameters in the time domain. With respect to the results of the experiments, a theoretical solution to the problem of harmonic vibrations of an elastic band plate submerged in an infinite domain of compressible fluid has also been
derived. From the results of experimental and theoretical investigations performed, the following conclusions may be withdrawn:

a) The value of the impulse strongly depends upon the elasticity of the supports of the plate. Thus, the problem has to be studied as a problem in hydro-elasticity.

b) In the first stage, due to the impact, progressive dilatational waves appear in water and a lot of eigenfrequencies of the structure are initiated. This stage is difficult to be described by a theoretical model.

c) In the next stage damped vibrations appear. In our experiments we observed not only damped rigid body motions, but also damped vibrations due to bending of the plate.
d) For higher eigenfrequencies, the compressibility of the fluid and the propagation of dilatational waves have to be taken into account. To get reliable results we had to measure and register the data with 20,000 Hz frequency for each gauge.

e) The experiments with vibrations of the structure placed on the surface of the water due to initial displacement or impulse show that the calculated covibrating mass is in good agreement with experimental values and, the theoretical dissipation of energy due to the propagation of dilatational waves is a reasonable estimate for damping for high frequencies.

f) In our experiments the impact was repeated, but the consecutive pressure impulses were random.

Two and three-dimensional pressure-impulse models of wave impact on structures.

Deborah J. Wood † and D. Howell Peregrine †

Abstract

For violent wave impacts against sea walls and breakwaters Cooker and Peregrine (1990, 1992) suggest the use of a pressure-impulse model. Here the model is used for three-dimensional examples.

1. Introduction

When a wave is breaking or near breaking when it hits a wall then very high, short lived, pressures can occur. Though this peak in pressure occurs for only a short period of time the magnitude is often many times larger than any other pressures associated with the impact, and maybe enough to cause damage to a structure such as a sea wall or breakwater. This peak in pressure is quite difficult to predict because, as Bagnold noted (Bagnold, 1939), pressures for similar waves vary considerably, whereas pressure impulse (the integral of pressure with respect to time, over the duration of the impact) has less variation.

Pressure impulse, as given in Lamb (1932) and Batchelor (1967), has been used to provide a theoretical model for wave impact by Cooker and Peregrine (1990, 1992, 1995). Chan (1994) and Losada, Martin and Medina (1995) have shown that this theory compares well with experiment. Pressure impulse theory has been further used for impacts in containers (Topliss, 1994) and impacts under a deck (Wood and Peregrine, 1996). A useful property of pressure-impulse theory is the relative insensitivity to the geometry of the problem.

†Research assistant, School of Mathematics, University of Bristol, University Walk, Bristol, BS8 1TW, UK, (Deb.Wood@bristol.ac.uk)

‡Professor of Applied Mathematics, School of Mathematics, University of Bristol, (D.H.Peregrine@bristol.ac.uk)
Many theoretical and experimental studies of wave impact on a vertical wall are two-dimensional. However, it is clear that for a wave impacting on a structure, such as a breakwater, the impact is rarely two-dimensional. Nevertheless, if the wave crest is sufficiently wide at impact then the impact can be considered to be two-dimensional towards the centre of the wave. This is where the highest pressures are expected to occur. Here we present three-dimensional examples which can be used directly, or to judge when the two-dimensional result is adequate.

2. Pressure impulse

Let $p$ be the excess pressure over atmospheric. The pressure impulse $P$ is defined by

$$ P = \int_{t_1}^{t_2} p\, dt, $$

where $t_1$ and $t_2$ are the times just before and after impact respectively.

Choosing units made dimensionless with the water density, $\rho$, a typical impact velocity, $U$, and length scale, $H$, the total depth of water at impact, we follow Cooker and Peregrine (1990, 1992, 1995) and simplify the equation of motion to

$$ \frac{\partial u}{\partial t} = -\nabla p, $$

for the short time interval, $\Delta t$, of the impulse, when for almost all the velocity field the rate of change of velocity, $u$, is the dominant term. Integration with respect to time over the duration of the impact gives:

$$ u_2 - u_1 = -\nabla P, $$

where $u_2$ and $u_1$ are the velocities after and before impact respectively. Now we assume the water is incompressible before and after impact, and so we have $\nabla.u_2 = \nabla.u_1 = 0$. Therefore we need to solve

$$ \nabla^2 P = 0 $$

in the fluid domain, subject to appropriate boundary conditions.

The boundary conditions can be grouped into three different types:
1) At the free surface the $p = 0$, so

$$ P = 0. $$

2) At points on a rigid boundary where impact occurs the velocity component perpendicular to the boundary is taken to be zero after impact, and some function of position, $V$, before impact. Using the normal component of equation (3) we find:

$$ \frac{\partial P}{\partial n} = V, $$

where $n$ is in the normal direction to the surface pointing into the fluid. We often choose $V$ to be uniform in space, for want of better information, as a reasonable
simplifying assumption. Then, choosing $V$ to be the velocity scale $U$, and to be in the direction towards the wall, equation (6) simplifies to give:

$$\frac{\partial P}{\partial n} = -1. \quad (7)$$

3) At points on a fixed rigid boundary where no impact occurs the velocity normal to the boundary is zero both before and after impact, and thus

$$\frac{\partial P}{\partial n} = 0. \quad (8)$$

The far-field condition is that $P > 0$.

Hence, to find a pressure-impulse model for an impact problem we must solve Laplace’s equation subject to these boundary conditions. In this paper $P$ is non-dimensional, to get back to dimensional quantities simply multiply $P$ by $\rho U H$. Note that since accelerations are assumed much greater than gravity, see equation (2), this approach only applies to violent impacts.

3. Impact on a wall.

Chan (1994), figure 19, examines the model from Cooker and Peregrine (1990, 1992) and looks at plots of pressure impulse down the wall, varying the depth of water but keeping the impact region size constant. As the water depth becomes the large, there is a ‘tail’ to the pressure impulse distribution down the wall. Cooker and Peregrine (1995) gives the infinite depth solution, which when integrated gives logarithmic divergence giving a total impulse that is infinite. This shows that for deep water cases this model is inadequate. This emphasises the importance of examining three-dimensional effects.

3.1. Three-dimensional impact on a wall.

Consider the impact of a body of water on a patch of a wall. Cooker and Peregrine (1995) noted that unless the width of the impacting water is quite small the actual shape of the wave away from the impact region is relatively unimportant. So we simplify the free surface to be horizontal and let $A$ denote the area of the patch. We use the boundary conditions described in section 2. On the free surface the usual condition of $P = 0$ is required. The patch is where impact takes place so we need $\frac{\partial P}{\partial y} = V(x, z)$, with $y$ in the direction normal to the patch and into the water, with $x$ and $z$ as shown in figure 1. On the rest of the wall no impact occurs so we require $\frac{\partial P}{\partial y} = 0$. Along the bottom of the region of the fluid, on $z = -1$, we have a solid boundary so $\frac{\partial P}{\partial z} = 0$. We also need $P \to 0$ as we move far away from the impact patch. So a solution to Laplace’s equation subject to the boundary conditions shown in figure 1 is required.

We can solve this problem in terms of a Fourier series expansion and a Fourier integral. The boundary conditions on the planes $z = 0$ and $z = -1$ enable the separation of the $z$ dependence giving an expression for $P$:

$$P(x, y, z) = \sum_n P_n(x, y) \sin(\lambda_n z), \quad (9)$$
where $\lambda_n = (n + 1/2)\pi$. A Fourier transform of the problem is taken in the $x$ direction. We assume that the patch is symmetric about $x = 0$ for simplicity. Hence the Fourier cosine transform is defined as:

$$\mathcal{F}_n(x, y) = \int_{-\infty}^{\infty} P_n(x, y) \cos(kx) dx.$$  \hspace{1cm} (10)

The boundary condition on the impact patch becomes:

$$\sum_n \frac{\partial P_n(x, 0)}{\partial y} \sin(\lambda_n z) = V(x, z).$$  \hspace{1cm} (11)

Multiply by $\sin(\lambda_r z)$ and integrate with respect to $z$:

$$\frac{\partial P_r(x, 0)}{\partial y} = 2 \int V(x, z) \sin(\lambda_r z) dz,$$  \hspace{1cm} (12)

where the integration in $z$ is, for a given $x$, over values of $z$ on the patch. Finally we transform this equation in $x$ to give:

$$\frac{\partial \mathcal{F}_n(k, 0)}{\partial y} = 2 \int_A V(x, z) \sin(\lambda_n z) \cos(kx) dz dx,$$  \hspace{1cm} (13)

where the integration is over the patch area $A$. 

Figure 1: Impact on a patch of a wall. View facing wall.
The transform in $x$ of Laplace’s equation leads to:

$$\frac{\partial^2 P_n}{\partial y^2} - (k^2 + \lambda_n^2)P_n = 0. \quad (14)$$

To simplify the notation we use $m^2 = (k^2 + \lambda_n^2)$. In future expressions it must be remembered that $m$ is dependent on $k$ and $n$. We require $P(x, y, z) \to 0$ as $y \to \infty$, which means that solving equation (14) gives:

$$P_n(k, y) = A_n(k)e^{-my}, \quad (15)$$

where $A_n(k)$ are functions of $k$, to be found using the boundary condition at the wall. Then equations (13) and (15) give:

$$A_n(k) = \frac{2}{m} \int \int_A V(x, z) \sin(\lambda_n z) \cos(kx) dx dz. \quad (16)$$

The final step is to take the inverse transform of equation (15) and substitute into equation (9) to obtain the Fourier sum for $P$:

$$P(x, y, z) = \sum_n \frac{1}{\pi} \int_0^\infty A_n(k)e^{-my} \sin(\lambda_n z) \cos(kx) dk, \quad (17)$$

with $A_n(k)$ given by equation (16).

Next consider the specific case of a rectangular patch of depth $d$ and width $2a$ (symmetric about $x = 0$). $V(x, z) = -1$ on the patch. Now we can carry out the integration in equation (16) directly to obtain

$$A_n(k) = -\frac{4}{k\lambda_n m} \sin(ka) [1 - \cos(\lambda_n d)]. \quad (18)$$

Using (17), for this specific case, we obtain the Fourier sum for $P$:

$$P(x, y, z) = -\sum_n \frac{4}{\pi \lambda_n} [1 - \cos(\lambda_n d)] I(n, x, y) \sin(\lambda_n z), \quad (19)$$

where

$$I(n, x, y) = \int_0^\infty \frac{\sin(ka) \cos(kx)e^{-(k^2 + \lambda_n^2)^{1/2}y} dk}{k(k^2 + \lambda_n^2)^{1/2}}. \quad (20)$$

To evaluate pressure impulse for this problem the Fourier series must be truncated. For a patch of height 0.1 the difference between taking 20 and 50 terms is only 4% and for a patch of height 1, the difference is substantially less. The integration is carried out using NAG routine D01ASF, which treats the integral as a Fourier cosine transform. This enables us to evaluate pressure impulse for this problem. Of particular interest are the contours of pressure impulse on the wall itself, as shown in figure 2 for a patch of height 0.2 and width 2.

The total impulse is 1.085 and 0.085 for patches of width 2 and depths 1 and 0.2 respectively. If integration is only taken over the central width $2a$ then
the corresponding values are 0.878 and 0.074. As expected the larger the area of impact the larger the total impulse. Figure 3 shows a plot of total impulse against depth of water (the total impulse has been temporarily been scaled to have depth of impact 1 as our length scale $H$, to compare with Chan (1994)), where the integration is over the central width of $2a$, and the impact region is the top distance 1. We note that the total impulse seems to tend to a finite value instead of increasing with depth of water below the impact region, as predicted by the two-dimensional solution. It is more realistic that as the depth of water at the wall becomes very deep that the total impulse tends to a finite value.

Figure 4 shows a comparison of the pressure impulse on the wall for the two-dimensional impact model and down the centre line of the three-dimensional 'patch' model. For the comparison impact on the top 20% of the depth of water is used. Even when the patch width is twice the water depth at the wall the 'patch' model shows a lower pressure impulse down the centre line than is found using the two-dimensional model. For narrower patches the difference is more significant. The difference between the pressure impulse down the centre line for the three-dimensional 'patch' and two-dimensional models is much larger if we move away from the centre line.

Figure 5 is a plot of pressure impulse at the base of the wall under the centre of the patch for varying values of $d$ (the depth of the impact patch). As expected increasing the depth of impact increases the pressure impulse at the base of the wall. Figure 6 shows a plot of $P/P_m$ offshore on the bed along the line of symmetry for a comparison of the Cooker and Peregrine two-dimensional model, and the 'patch' model with a patch of length 0.5, 1 and 2 all for $d = 0.5$ and depth of water 1. $P_m$ is the value of $P$ at the middle bottom of the wall. This shows that once the pressure impulse has been scaled by the value at the wall all the curves are similar in nature. However, as expected once the patch length is 1 or smaller there is a significant difference between the values predicted by the two-dimensional model and the 'patch' model.
Figure 3: Total impulse against depth of water at the wall, for three-dimensional impact on a patch of a wall, where the integration is over the central width of 2a (a = 1), and the impact region is the top portion of depth 1. The total impulse has been temporarily rescaled (for this diagram only) to have the unit length scale as the depth of impact, and $D$ as the depth of water at the wall.

Figure 4: Pressure impulse along the centre line for the for patches of width 0.5, 1, 2, and two dimensional model ($\infty$) of impact on a wall, with impact on the top 20%.
Figure 5: Pressure impulse at the base of the wall in line with the centre of the patch for patches of width 0.5, 1, 2, and two-dimensional model (∞), varying the depth of the impact region.

Figure 6: Plot of $P/P_m$ offshore on the bed along the centre of the line of symmetry for a comparison of the Cooker and Peregrine two-dimensional model, and the 'patch' model with a patch of length 0.5, 1 and 2. $d = 0.5$, depth of water 1. $P_m$ is the value of $P$ at the middle bottom of the wall.

We need to have a clearer way of comparing the 'patch' model and the two-dimensional case. If the patch is sufficiently long, at or towards the centre of the patch the solution is the same as for the two-dimensional case. Hence, for a given length of patch, we need to estimate how far into the patch it is reasonable to assume that the solution has become two-dimensional. For a finite patch, this is difficult to assess as both ends of the patch have an effect on the solution. So we next consider a semi-infinite patch.

Figure 7 shows the problem we need to solve for impact on a semi-infinite region of the wall. We again take our length scale $H$ as the depth of water at the wall, and work in dimensionless quantities. As we need to impose the forcing condition on the patch over a semi-infinite region we solve using a slightly different method to that used for the finite patch. We split the problem up into the two regions $x < 0$ and $x > 0$, the solutions to which we will denote as $P_l$ and $P_r$ respectively. We then use continuity of $P$ and $\partial P/\partial x$ along the line $x = y = 0$, to find the solution. We consider first the solution in the left hand region. As $x \to -\infty$ the solution will tend to the two-dimensional solution for impact on a wall (denoted now by $P_{2D}$). If we subtract the solution, $P_{2D}$, for the two-dimensional problem off $P_l$ then the remaining problem whose solution is $P_{re}$ is the same as in left hand region of figure 7 except that the condition over the patch is now $\partial P/\partial y = 0$. So $P_{re} = P_l - P_{2D}$, we solve this problem for $P_{re}$ and then $P_l = P_{re} + P_{2D}$. In a similar manner to the solution of the finite
patch model we take a Fourier transform of the problem, for \( P_{re} \), but this time the Fourier transform is a Fourier-cosine transform in the \( y \) direction (since we'll need to match with the right hand side along \( x = 0 \)).

\[
\mathcal{F}(P_{re}(x, k, z)) = 2 \int_0^\infty P_{re}(x, y, z) \cos(ky) \, dy.
\]  

(21)

The solution is given by:

\[
P_{re} = 2 \int_0^\infty \sum_n A_n(k) e^{m x} \sin(\lambda_n z) \cos(ky) \, dk,
\]  

(22)

where \( \lambda_n = (n + \frac{1}{2})\pi \), \( m^2 = k^2 + \lambda_n^2 \), and the \( A_n \) are obtained by the continuity conditions given at \( x = 0 \).

The solution to the two-dimensional problem (Cooker and Peregrine 1990, 1992, rescaled to have the length scale as the depth of water at the wall) is given by

\[
P_{2D} = -2 \int_0^\infty \sum_n \frac{2}{\lambda_n^2} \left[ 1 - \cos(\lambda_n d) \right] \sin(\lambda_n z) e^{-\lambda_n y},
\]  

(23)

hence

\[
P_1 = 2 \int_0^\infty \sum_n A_n(k) e^{m x} \sin(\lambda_n z) \cos(ky) \, dk
\]

\[= -2 \sum_n \frac{2}{\lambda_n^2} \left[ 1 - \cos(\lambda_n d) \right] \sin(\lambda_n z) e^{-\lambda_n y}.
\]  

(24)

Solution in the right hand region is similar to \( P_{re} \). The conditions at \( z = 0 \), \( z = -1 \) and on the wall are the same. However we require \( P_r \) to be positive, and to decrease to zero as \( x \to \infty \) instead of being negative and increasing to zero as \( x \to -\infty \) (as \( P_{re} \)). The change in sign in front of the \( x \) is to satisfy the conditions at \( x = \pm \infty \), and the negative in front of the whole expression is to ensure continuity of pressure-impulse gradient at \( x = 0 \). Hence \( P_r \) is given by

\[
P_r = -P_{re}(-x, y, z):
\]

\[
P_r = -2 \int_0^\infty \sum_n A_n(k) e^{-m x} \sin(\lambda_n z) \cos(ky) \, dk,
\]  

(25)

From continuity of \( P \) at \( x = 0 \) we find that:

\[A_n(k) = \frac{1}{\pi \lambda_n^2} \left[ 1 - \cos(\lambda_n d) \right] \frac{\lambda_n}{k^2 + \lambda_n^2} \quad k \neq 0
\]

\[A_n(0) = \frac{1}{2\pi \lambda_n^3} \left[ 1 - \cos(\lambda_n d) \right] \quad k = 0.
\]  

(26)

Integration is carried out in a similar manner to that used in the evaluation of the pressure impulse for the finite patch impact. Hence \( P \) is given by equation (24) for \( x < 0 \) and equation (25) for \( x > 0 \), with \( A_n \) given in equation (26).
Figure 8: (a) Pressure-impulse contours, for the semi-infinite patch, on the wall for a patch of depth 0.3. (b) Pressure-impulse contours, for the semi-infinite patch, on the bed in front of the wall for a patch of depth 0.3.
Figures 8 (a) and (b) show pressure impulse contours, for the semi-infinite patch, on the wall and base respectively for a patch of depth 0.3.

When the patch is of depth 0.3 the values calculated by the two-dimensional model only approximate the three-dimensional values well at a distance into the patch of two times the depth of the water i.e. the width of influence of the boundary conditions outside of the patch is twice the depth of the water. Figure 9 is a plot of $P$ along the bottom of the wall for different depths of patch (scaled by the two-dimensional model value). If we examine this then we can see that the depth of impact has little effect on the influence distance of the three-dimensional boundary into the patch. If we look at a distance of 0.5 into the patch (along the bottom of the wall), we can see that the pressure impulse is only approximately 0.775 and 0.850 of the two-dimensional value for patches of depth 0.2 and 1.0 respectively.

![Figure 9: P/(2D value) for the semi-infinite patch as a function of position along the base of the wall, for $d = 0.2, 0.4, 0.6, 0.8, 1.0$ (from left to right in the top half of the graph).](image)

This semi-infinite solution can be used to give an alternative derivation of the rectangular patch case, namely:

\[
x > \frac{a}{2}, \quad P_t(x - \frac{a}{2}, y, z) - P_t(x + \frac{a}{2}, y, z)
\]

\[
-\frac{a}{2} < x < \frac{a}{2}, \quad P_t(x - \frac{a}{2}, y, z) - P_t(x + \frac{a}{2}, y, z)
\]

\[
x < -\frac{a}{2}, \quad P_t(x - \frac{a}{2}, y, z) - P_t(x + \frac{a}{2}, y, z)
\]
5. Conclusions

The Cooker and Peregrine (1990,1992) pressure-impulse model for impact on a plane vertical wall has been used for three-dimensional examples. The extension of this work to the impact on a semi-infinite patch of wall allowed conclusions to be drawn as to what distance into the patch we could assume two-dimensionality. The length of influence was found to be about twice that of the height of the wall. Interestingly, this distance of influence is little affected by the percentage of the water depth involved in impact. We conclude that if the wave impact width is greater than four times the height of the wall, then a two-dimensional model can be used to predict peak pressure impulse. However for waves with crest width less than twice the water depth three-dimensional effects play a significant role and should be included.

It is thought that comparison with experiment would lead to greater understanding of three-dimensional effects. However, the difficulties associated with estimating the width of the wave crest at impact from experiment means that as yet this has not been possible.

Thyborøn Barriers – A Mastercase of Coastal Engineering
Per Roed Jakobsen1, Ida Brøker2, Jesper Holt Jensen3, Ann Skou4, Sanne Poulin4

Abstract

Thyborøn, Denmark is placed at the entrance to a fjord system, which connects the North Sea with Kattegat. The inlet acts as a trap for the littoral transport from both sides. The adjacent barrier beaches suffer from severe erosion, which is alleviated by large structures and nourishment. The entrance was formed only 135 years ago and is still undergoing morphological changes. During its lifetime engineers have investigated various schemes for stabilising the shoreline – the most radical suggestion has been to close the entrance to avoid the ongoing loss of beach material. The present paper presents the major findings of a comprehensive study of the hydrographic and geological conditions, the coastal processes and the morphological evolution.

Background

In 1862 the North Sea breached a since then permanent gap in the 22 km long Thyborøn Barriers and created a coastal scenario which over the years has occupied and challenged Danish coastal engineers. Shortly after the breach the construction of a large groyne system was initiated. Today the barrier beaches are managed by maintenance of the structures, controlled withdrawal, and major nourishment with about 750,000 m$^3$/year of coarse sand.

There are three major reasons for taking a conclusive review of the behaviour of the system:
1. A law of 1970 was prepared on the final assumption, that it was acceptable to leave the Channel open. Danish Coastal Authority is conditioned to monitor the development. Does the assumption hold at the 25-year anniversary?
2. Despite 135 years of dynamic evolution, the system has not yet achieved a full equilibrium since profile steepening is ongoing as well as long-term changes in channel configuration.
3. Modern model tools enable a more detailed and integrated description of processes allowing for improved verification of project assumption such as littoral transport in original and now steep profiles.

**Historical Review**

The generation of the present barriers started around year zero as a part of smoothening of the coastline. From the Icelandic sagas is known that there has been a connection between the fjord and the North Sea since there are narratives of the vikings' passing on to the North Sea through the Limfjord in the 11th century. The barrier system at the earliest closed about year 1100.

There have been multiple breaches in the barriers during the period from 1600 until 1800, but none serious until 1825 where the Agger channel was formed and it lasted until 1868. The most severe breach came in 1862 and formed the Thyborøn Channel. Immediately after this the retreat of the coastline started.

Since the construction of the groyne system, the initial flattening of the coast profiles, caused by the excessive recession of the shoreline, was replaced by a gradual steepening of the seabed seaward of the groynes, which is ongoing but declining. In the 1930s, this steepening gave rise to deep concern among the responsible engineers who felt that disaster was looming ahead. They feared that the coast profiles were becoming so steep that even a short serie of severe storms could generate such effects that control of the development would be lost. This was called "The Theory of Disaster".
On this basis an act was passed by Parliament in 1946 whereby the Thyborøn Channel would be closed such that the loss of sand from the seacoasts to the Limfjord would be stopped and the seacoasts thereby stabilised. The project included the construction of 16 km of “safety” embankments placed approximately 2 km behind the coastline as well as the building of two major breakwaters and two sluices for vessels and salt water inflow, respectively.

Before the works to close the Channel were commenced, Per Bruun (1954) in his doctoral thesis, Coast Stability, raised serious doubts as to the “disaster theory” which was the basis for the project and proposed new investigations of the problems. Along similar lines, Helge Lundgren in 1954 and 1956 made specific proposals for new investigations, including scale model tests with movable bed to be carried out in Holland, particularly with a view to keeping the channel open and to saving a major part of the project costs.

The government followed these recommendations and a range of studies of various aspects of the problem were initiated, the most important ones of which were carried out at the Technical University of Denmark headed by Helge Lundgren and Torben Sørensen, Lundgren (1968).

The crucial question of whether the steepening of the coast profiles indicated a risk of disastrous development was resolved by an analysis demonstrating that the steepening was simply a question of the coast profiles adjusting to the reduced shoreline recession achieved by the construction of the groyne system, Sørensen (1961). This realisation in fact eliminated the basis for the very expensive and in many ways controversial project. The soundings of coast profiles over 125 years have confirmed the validity of this analysis.

However, the project had a number of other aspects, which also required analysis and considerations. Among those were the statistics of storm flood levels in the North Sea at Thyborøn.

In consequence of these investigations, the 1946-law was repealed in 1970 under the condition that the Danish Coastal Authority should follow the situation for at least 50 years. This was done the first time in 1975. The major conclusion in this work was that the steepening almost had stopped and that the system to some extent was stable.

Today the system configuration is the following. The length of the barrier islands is 22 km and the number of groynes, about 400 m long, in the system is 78. The maximum retreat of coastline since 1862 is 1.5 km, see figure 1. Coastline retreat rate was previously 1-2 m/year but is now mitigated by yearly nourishment. Net erosion in the system is 1.1 Mio m$^3$/year, channel shoals deposition is about 500 – 700,000 m$^3$/year and longshore transport from each side is 2 – 500,000 m$^3$/year. Coastal protection scheme today consists of maintenance of hard structures and yearly nourishment at about 775,000 m$^3$/year. (485,000 at beach and dike and 290,000 on shore face).

Total value today of the whole system has been estimated to about 1000 Mio DKK (170 Mio US$). Costs of nourishment and withdrawal of groynes and buffer dikes in line with coastline retreat on 1 – 2 m/year are equal, which leaves full flexibility for the detailed policy for coastal maintenance.

**Hydrographic conditions**

The astronomical tide on this coast is very small, max. 0.3 m, whereas extreme high water levels caused by wind set-up with westerly winds may reach 3.
To give an impression on the weather conditions at the West Coast of Jutland, wind, wave and extreme water level conditions for Thyborøn are shown in figure 2.

Directional wave measurements have been undertaken since 1991. These detailed measurements supplement 15 years of wave height recordings and have formed the basis for the statistical analysis of the wave conditions.

**Geology**

The upper layers of the barriers consist of sand and gravel while below −6 m, marine clay can be found to a great extent, eg. about 30 m at Thyborøn. Underneath this are glacial deposits.

The clay layer has been found until 75 km further to the west of the present coastline out on 'Jutland Reef', which consists mainly of deposits of eroded glacial material. This indicates that the glacial formations in the early Holocene period extended further to the west protecting a calm basin where the clay layer could be deposited.

The start of the barriers buildup as a part of the formation of the present glacial coastline is dating back to the start of our era, and the barriers properly closed early in the 12th century, as explained in the historical review.
Sediment transport processes

The sediment transport processes around the inlet have been studied and quantified through a comprehensive set-up of numerical models, see Brøker et al (1996) for details. The various modules comprise a depth-integrated hydrodynamic model MIKE 21 HD, a spectral wind wave model MIKE 21 NSW, which is used to transfer waves from the measurement station to the entrance, a mild slope wave model MIKE 21 PMS for the more detailed calculation of wave fields in the entrance area, and a deterministic intra-wave period model for transport of non-cohesive sediment, MIKE 21 ST, see Deigaard et al (1986). The areas covered by the numerical models and the measurement stations, required to drive the modelling complex, are shown in figure 3.

Figure 3. Areas covered by hydrodynamic, wave and sediment transport models, and location of measurement stations.

The meteorology is dominated by low-pressure systems travelling from West towards East. The westerly winds and waves are responsible for the morphological development of the coast. Typically, in the beginning of a westerly storm, the water level rise off Thyborøn, and, due to the connection across the peninsula of Jutland, strong in-going currents may last for the entire storm period, 3 - 5 days. Strong outgoing currents seldom occur in combination with severe wave action. Waves from southwesterly directions cause northward littoral drift along the barrier beaches.
Figure 4. Sediment transport and corresponding initial morphological change, top: southwesterly storm, middle: northwesterly storm, bottom: northwesterly storm. $H_{rms}$ lies in the interval 1-2 m in all 3 cases.
The entrance is too wide to allow for any significant natural bypass and most material is deposited in the entrance area. During northwesterly storms, the littoral drift is southgoing, and for these wave directions the layout of the entrance allows for significant wave penetration into the channel. Therefore, during northwesterly storms, the sediment is kept in suspension further into the channel, and it may be transported all the way through the channel before it deposits on the shoals on the inside of the channel. The net effect of these processes are that littoral drifts for both barriers are directed towards the central channel.

Transport patterns and the corresponding initial morphological changes for cases with southwesterly and northwesterly waves combined with in-going current and northwesterly waves combined with out-going current are depicted in figure 4. It is seen how the channel tends to migrate to the East during in-going flow and towards west during out-going flow. These calculations correspond to a distribution of sediment properties described from about 240 bed samples in the area.

Figure 5. Average sediment transport pattern for the years 1991–1997, net transport across 7 cross-sections for the mildest and the roughest year during the period.
The yearly transport and morphological development are functions of the yearly climate, and at the present location even small variations in the dominant wave conditions change the sediment balances significantly. The modelling complex has been used to quantify this variability. Both the water level and the currents in the channel are strongly correlated to the instantaneous wave conditions. The frequency of occurrence of combinations of wave height and direction, water levels and currents in the channel have been analysed based upon 6 years of simultaneous measurements of water levels and waves, and 1 year of simulations of the currents through the ‘fjord’ which crosses the peninsula of Jutland, see figure 3 and Brøker et al. (1996).

The waves, currents and sediment transport have been modelled in detail for a number of historical events in total 25 days. 448 different combinations of waves, water level off the channel and current through the channel have been picked from the simulations. These sediment transport patterns are subsequently weighted to reflect the yearly transport pattern for different periods of time. Figure 5 shows the weighted sediment transport pattern for the years 1991–1997 and the integrated transport capacity through certain sections for the mildest and the roughest years of the period.

It appears that the transport capacity off the southern barrier-island increases slightly towards the entrance giving rise to the erosion which today is compensated by nourishment. Inside the channel the calculations indicate ongoing redistribution of material and a loss of material to the internal shoals. The sediment transport capacities inside the channel area have been adjusted to account for the presence of the non-erodible clay surface.

Profile Steepening

Foresighted engineers started profile surveys only 12 years after the final breach in 1862. With few interruptions, such as during the Second World War, the profiles have been surveyed every second year ever since and the database now forms a unique basis for evaluating the long-term trends of profile development, notably steepening of the profiles. The volume of eroded sand along the coast and profile development have been calculated based on these surveys.

From the geological study, the position of the clay surface is known, which means that it has been possible to calculate erosion along the coast for the sand layers only. The sediment balance has been calculated for 4 periods, 1874–1900, 1900–1936, and 1936–1978 and at last 1978–1992. For the first two periods the calculations are carried seaward to a depth of −8 meter DNN. In 1930s, DCA started measuring seaward to a depth of −16 m DNN. The calculations for the last two periods are therefore carried out to this depth. The results are shown in figure 6.

The results clearly show the large erosions immediately after the breach in the barriers. This continued in the following years also after the construction of the groynes. As the steepening began the erosion decreased.

On the basis of the long series of profile sounding the retreat of the coastline, the cliff and the 7, 8, 10 an 16 meter depth contours have been calculated. The results just off the town of Thyborøn are shown in figure 7.
Figure 6. Calculated eroded and nourished volumes for four periods

Figure 7. Profile development off Thyborøn town
Figure 7 clearly shows the importance of long-term surveying, the yearly and in periods large fluctuations are so large that say even 25 years of monitoring could have been misleading. Now with 125 years of data at hand it is possible to extract reliable long-term trends from the otherwise confusing data. From figure 7 it is seen that the retreat of all elements was larger in the beginning of the period compared with the retreat today. For the coastline, the four, and 6-meter depth contours, the retreat has stopped. The depth contours off the groynes are still retreating. This leads to the conclusion that the steepening of the profiles has not yet stopped along all sections of the coast as earlier concluded in the 1975. This is especially true close to the inlet. It should however be noted that the wind and wave conditions were extremely severe for almost 20 years after 1975. Examples of historical and more recent profiles are shown in figure 8.

![Figure 8. Profile steepening for selected stretches along the barriers.](image)

The effects of the profile steepening on the sediment transport capacity have been quantified by modelling of waves, currents and sediment transport for a historical storm using a recent bathymetry and a bathymetry constructed from the old profile measurements. Figure 9 shows the comparison of simulated sediment transport fields and integrated transport along the barrier islands at one time step during the simulation at which the waves come from southwest, $H_{rms} = 1.5$ m. It is clearly seen that the transport zone has become very narrow in 1994 and the total littoral drift as well as the gradient of the littoral drift have declined. The groynes have been moved backward in pace with the ongoing erosion, however leaving submerged parts still active on the seabed. The erosion rates are significantly reduced compared to a hundred years ago due to the steepening of the coastal profiles. These simulations
illustrate the sediment transport processes which are reflected in the measurements of the morphological evolution of the area.

Figure 9. Examples of sediment transport rates, historical and recent bathymetries, \( H_{\text{rms}} = 1.5 \) m, dir. 255°, mean current in the channel 1.25 m/s. Comparison of integrated littoral drift.

Sediment budget

Both south and north of the barriers there exists a nodal point for the littoral transport from which the net transport is directed towards the central channel. Based on the data which lead to figure 6, the total volume of eroded sand between the northern and southern nodal point has been calculated. Depending on the distance from the coastline taken into account, which is from the top of dunes until 12 to 16 meters depth, the volume range is 450,000–600,000 m³/year for the stretch from the southern nodal point up to the channel and 150,000–200,000 m³/year from the northern point down to the channel. This gives of total of 600,000–800,000 m³/year between the two nodal points.

Calculations of shoal deposit behind the barriers has been carried out based on soundings of the shoals in 1972 and in 1991. The calculations leads to the conclusion that 500,000–700,000 m³ is deposited on the shoals every year.

The numerical model gives some ranges for the transport capacity through 7 sections along the sea shore and through the channel, see figure 5. The transport capacity through the central part of the channel is 5–750,000 m³/year for the mildest and roughest year, respectively, du-
ring the period 1991-1997. The transport capacity along the coastline varies between 0-100,000 m$^3$/year for the northern barrier and 150,000-400,000 m$^3$/year for the southern barrier.

Combining these information's ranges for the overall longshore sediment budget can be obtained. The northgoing transport is in the range 3-500,000 m$^3$/year and the south-going is up to 200,000 m$^3$/year. The transport rate through the channel is 500,000-700,000 m$^3$/year. This is illustrated in figure 10.

Figure 10. Overall sediment budget for the barriers
The safety level for Thyborøn

The extreme water levels at Thyborøn have been reassessed based on data from the past 20 years. Figure 11 shows a comparison of extreme analysis results based on the data for the periods 1931 to 1975, from 1975 to 1995 and the full data set. The period just after 1975 covers a number of very extreme events, and therefore the analysis, based on the latest period only, shows a somewhat higher level than the analysis from the first period and the full series. The dikes have been reinforced, the beach better maintained and the total system will therefore be able to provide flood protection in a 1000 event even accounting for the new analysis of extreme water levels.

Further, it has been investigated if there should be a certain limit to extreme water levels at Thyborøn due to the nearness of more open and deeper waters to the north. Simulations in a numerical model of the North Sea were performed for a recorded storm scaled to predicted extreme conditions. The simulations showed that the extreme water levels are functions of the barometric conditions mainly, and that a limit could not be identified.

Overall Conclusion

- Although the outer part of the profiles close to the inlet is still getting steeper, the rates of steepening are significantly decreased and the nearshore zone can be kept stable by comprehensive nourishment.
- The safety level at Thyborøn is still 500-1000 years.
- Numerical modelling has greatly supported the understanding of the coastal processes around and in the Thyborøn Channel. Comparison between modelled sediment transport
for a historical and a recent bathymetry has illustrated that relevant processes are sufficiently well represented in the models to reflect the major morphological changes. Inside the channel the modelling has illustrated how different hydrographic conditions lead to different morphological developments such as migration of the channel and very varying depositions in the entrance area.

- Calculations of erosion on the coast, calculations of deposit material on inlet shoals and numerical calculations of the littoral transport capacity have helped gaining a more narrow range for the littoral sediment budget along the barriers.

APPLICATION OF SHORE PROTECTION SCHEMES IN HORBÆK

Mads Peder Jørgensen 1
Peer Skaarup 2
Karsten Mangor 3
Jørgen Juhl 4

ABSTRACT

Horbæk Harbour was built more than a hundred years ago on a sandy coast with predominant eastward longshore sediment transport. After construction of the harbour the littoral transport was disrupted leading to a large accretion of sand upstream of the harbour whereas lee-side erosion occurred downstream of the harbour. Soon problems were experienced due to sedimentation in the harbour entrance and in the beginning of the century a breakwater was constructed for blocking the sand transport. This breakwater was later extended and finally a lee-side breakwater was constructed.

Horbæk harbour represents a classical case of the problems encountered when constructing a harbour on a coast with littoral drift. Only in recent years focus has been put on environmental issues and the present project shows a good example of remedial measures by involving a number of shore protection schemes.

The applied shore protection schemes consist of beach nourishment, beach de-watering and maintenance of shingle beaches along with extension and repair of existing slope protection. On completion of the project a monitoring programme has been started in order to track the development of the coastline in response to the beach nourishment scheme.

1. HORNBÆK HARBOUR - HISTORICAL ASPECTS

Horbæk is situated in Denmark in the northern part of Zealand as seen in Figure 1. The harbour is largely sheltered from waves from all directions except from the northwest.

Horbæk harbour represents the classical case of harbour construction on a uniform coast with pronounced longshore sediment transport. Before construction of any transverse structures the coastline was near-stable even though there is a significant eastward longshore transport of sediment.

Subsequent construction of the harbour has had the effect of blocking this longshore transport resulting in accretion upstream of the harbour (west) and lee-side erosion downstream of the harbour (east).

The harbour originated as a shore-connected single breakwater creating a sheltered area for mooring fishing vessels.

As shown in Figure 2 the breakwater west of the original basin has been extended gradually from 1878 to 1924 in response to continuous upstream accretion and sedimentation in the protected area east of the breakwater.

Due to the continuous sedimentation and increased cost of dredging, a new secondary breakwater was constructed in 1990. Sand dredged from the harbour basin was placed as sand fill east of the harbour forming a small beach area. The construction of the eastern breakwater reduced the sedimentation in the fore harbour from several thousand cubic metres to a few thousand cubic metres a year. In recent years the western breakwater has been renovated, which also involved a more smooth plan shape mirroring the eastern breakwater and this has even further reduced sedimentation of the fore harbour. There is, however, still a requirement for annual maintenance dredging of the access channel.

The continuous extension of the breakwater has had a dramatic effect on the town of Hornbæk. Due to the pronounced accumulation of sand upstream of the harbour the main activities of the town has moved from fishing operations towards recreation and tourism. The beach west of the harbour is today one of the most popular beaches on Zealand and through the fifties and sixties the town hosted a reputed health resort which emerged into a beach hotel and has in later years become a hospital.

2. COASTAL PROCESSES

The construction of the harbour has significantly influenced the morphology in the area. The coastline west of the harbour has accreted continuously necessitating the extension of the western breakwater. The retreat of the coastline east of the harbour has occurred more slowly due to self-armouring of the seabed with gravel and stones originating from erosion in moraine tills. This implies that the erosion in the considered area is mainly caused by storms in conjunction with high water.
The development of lee-side erosion east of the harbour and accretion west of the harbour is seen in Figure 3. From 1880 to 1997 the lee-side erosion has been of the order-of-magnitude of 50 m whereas the advance of the coastline to the west has been in the order of 100 m.

Throughout the years approximately 7,000 m$^3$ of sand has been mined from the accretion area each year in order to minimise sedimentation problems in the harbour entrance. The sand was used by local contractors and has thus been missing in the sediment budget east of the harbour.

Before the construction of the eastern breakwater the yearly maintenance dredging was approximately 15,000 m$^3$, most of which was dumped in deep waters. After construction of the eastern breakwater, approximately 4,000 m$^3$ of sand has been dredged yearly in the harbour entrance and in the access channel and deposited in the shallow water area east of the harbour.

The coastal areas adjacent to Hornbæk Harbour are dominated by waves coming from the northwest originating from the large fetch areas in Kattegat. Waves coming from west and from the direction range north to east are limited due to sheltering effects from Zealand and Sweden (Figure 1).
Based on a study of the wave climate and storm surges a numerical study of the littoral drift budget was carried out using the LITPACK modelling system. Findings from this study was used for assessing the amount of sand needed for beach nourishment east of the harbour. Figure 4 shows a detail of the sediment budget for the harbour area in 1995. The cumulated transports show a net accumulation of sediment in the region just east of the harbour of around 2,000 m$^3$/yr.

Sediment trapped in the harbour mouth (4,000 m$^3$/yr) is dumped near-shore along the beach east of the harbour resulting in a total transport of 6,000 m$^3$/yr further east along the coast.

The sediment is clearly deposited in the formation of a large shoal (Figure 5) which is expected to connect with the beach area further east of the harbour closing off a shallow water area. At this point in time there will probably be a decision about whether to fill in the shallow water area creating a wide beach or about relocating the sediment in the shoal to the coastline proper.
3. SURVEYS AND DETAILED DESIGN

Consulting services covered the following main topics:

- Assessment and modelling of the coastal processes
- Preparation of alternative schemes for shore protection
- Surveys
- Detailed design and preparation of tender documents
- Construction supervision
- Monitoring of the beach development

A series of surveys was made including bathymetric and topographic measurements and borings at sea for determining the soil conditions. A detailed design was produced for the selected protection schemes and was followed by preparation of tender documents divided into beach nourishment and slope protection, respectively. The design detailed:

- Beach Nourishment, 7-14,000 m³/yr for five years in succession.
- Maintenance of shingle beaches
- Repair of existing slope protection
- Extension of the slope protection at the most exposed location (100 m berm and an additional 10 m protection of the slope)

Upon receipt of the tenders for the beach nourishment, it was decided to have the sand by-passed by dredging and pumping instead of using trucks as the pumping solution was preferable from an environmental point of view.

4. SHORE PROTECTION SCHEMES

The present project is part of a larger plan for the area financed by the County of Frederiksborg (lead partner) together with the Municipality of Helsingør and the State Forest District of Kronborg. Other parts include the following:

- About 1.5 km west of the harbour another project including the beach face dewatering concept has been completed. The purpose is to stabilise and widen the beach in this area which is considered one of the best bathing resorts in the northern part of Zealand.
- The outer breakwaters of the harbour have been modified within the last 10 years with the purpose: to increase the capacity of the harbour, to minimise the sedimentation and to increase the natural bypass of sand.

The final project focused on rehabilitation of a 2.5 km stretch of coastline east of the harbour where protection was needed against further erosion. The project included general repair of existing slope protection and extension of the slope protection in the form of a berm at the most exposed location. Furthermore the shingle beaches were replenished in order to slow down erosion and finally, beach nourishment was carried out along 300 m of the coastline just east of the harbour. The beach nourishment was
carried out through bypassing of sand from the accretion area west of the harbour, which has also reduced sedimentation in the harbour entrance. Figure 6 shows the repair works and extension of the existing slope protection. A 100 m long berm is placed along the toe of the slope protection. In front of the berm a 1 m thick layer of shingle is placed acting as a kind of nourishment.

Figure 6 - Placing of geotextile and armour.

Figure 7 shows the berm shortly after completion. The waves have washed some of the shingle ashore which conceals the larger part of the berm structure and allows for safe passage along the beach.

Figure 7 - Berm Structure on completion
Beach nourishment was carried out east of the harbour in order to improve the quality of the beach in this partly self-armoured area. A total of about 12,000 m$^3$ of sand was bypassed by dredging in the accretion area west of the harbour and pumping in a pipeline to the nourishment zone east of the harbour. This was performed in April 1997 and April 1998. It is planned to repeat the beach nourishment each year for the next three years and probably more years after. Figure 8 shows the nourishment zone just after nourishment has taken place. The size of the nourishment area is approximately 300 m by 40 m.

Figure 8 - Aerial View of Beach Nourishment upon Completion of Works

Figure 9 shows the estimated sediment budget for the harbour area while nourishment is taking place (compare with Figure 4). For the given example 12,000 m$^3$/yr of sediment is mined west of the harbour and used as nourishment east of the harbour. The western breakwater has been rounded and sedimentation in the access channel has decreased to 2,000 m$^3$/yr. The corresponding maintenance dredging of 2000 m$^3$/yr is dumped nearshore east of the harbour.

Figure 9 Sediment budget including artificial nourishment
The littoral transport west of the harbour remains the same, resulting in a natural bypass of 1,000 m$^3$/yr to the shoal. The shoal is also receiving 3,000 m$^3$/yr from the east coast and loses 5,000 m$^3$/yr towards east, resulting in an annual loss of sand from the shoal of 1,000 m$^3$/yr. The shore east of the harbour now receives 2,000 m$^3$/yr from the shoal and 14,000 by artificial nourishment resulting in a supply to the downdrift shore of 16,000 m$^3$/yr.

In total the beach nourishment scheme has the effect of maintaining the stable beach west of the harbour, reducing sedimentation in the access channel, improved beach quality east of the harbour (compared to sedimentation on the shoal) and increased littoral transport further east along the coast for the benefit of the downdrift shore.

5. MONITORING

The beach east of the harbour was surveyed prior to initiation of the beach nourishment and again after finalization. Monitoring will take place twice a year throughout the next four years in order to assess erosion and changes in beach profiles. Thereby the quantity of future requirements for beach nourishment will be assessed.

At this point in time measurements of the location of the shoreline and bathymetric surveys of the nourishment zone have been conducted in March 1997, November 1997 and March 1998. The bathymetric surveys of the nourishment zone show relocation of submerged shoals and other sand formations as well as the presence of dunes on the shore. Apart from this the preliminary monitoring results show the coastline being practically stable during the last year. This is mainly because the surveys of March 1997 and March 1998 were conducted just prior to nourishing. The survey from October 1997 shows no evidence of the nourished sand, which indicates that the majority of the material has been transported eastward along the beach as planned. This is in agreement with the philosophy of the nourishment project, which is a gradual rehabilitation of the beach east of the harbour by nourishing locally along a 300 m long section in close vicinity of the harbour. Surveys conducted in coming years are expected to reveal trends in the interaction between the native and the nourished material as well as the effectiveness of the nourishment programme.

6. CONCLUSIONS

Accretion has been taking place west of Hornbaek Harbour over decades, however, the accretion area has stabilised many years ago. The extension of the western breakwater has caused a large offset of the littoral transport in comparison with the original coastline. Historically, most of the normally bypassed sand was trapped in lee of the single western breakwater from where it was dredged and dumped in deep waters, which means that it was lost for the downdrift coastline.
Since 1990 where the eastern breakwater was constructed, sedimentation and maintenance dredging has decreased from 15,000 m$^3$ to 2,000 m$^3$ per year. The remaining bypassed sand has accumulated in the shallow area east of the harbour but separated from the coastline. The conclusion with respect to the impact of the harbour on the downdrift coast is that the harbour has caused lee-side erosion in the entire period of its existence.

The selected shore protection scheme for 2.5 km of coastline east of the harbour consisted of beach nourishment with 12,000 m$^3$ of sand mined west of the harbour and 2,000 m$^3$ dredged in the harbour entrance, maintenance work on shingle beaches along with extension and strengthening of exposed parts of the slope protection.

The new wide and sandy beach east of the harbour attracted many guests during the first summer but as expected a significant part of the sand was transported eastwards during the winter season. Additional beach nourishment will be carried out the next four years during spring time. Twice a year the development of the new beach will be monitored. The monitoring results will form the basis for assessing the amount of sand to be pumped from the accretion area to the new beach in the coming years.

This project is carried out respecting the natural processes of the sand transport along the coast and thus represents an example of the Consultant's planning with nature instead of against it, so-called shore protection in lieu of coastal protection.

7. ACKNOWLEDGEMENTS

The authors wish to thank Architect Dan Hasløv from Hasløv and Kjærsgaard for assisting with aesthetic view points in the studies of the various protection schemes and O. Juul Jensen, COWI for advice on the coastal structures.
Design and Construction of Seawater Exchange Breakwaters

Sadamitsu AKEDA¹, Yasushi YAMAMOTO², Katsutoshi KIMURA³ and Kenji YANO⁴

Abstract

The establishment of breakwaters in Japanese ports has progressed in recent years and has greatly improved the calmness in the ports. However, the seawater exchange within and outside of the port has greatly decreased. In ports near urban areas, in particular, the inflow of domestic and industrial wastewater, and the accumulation of sludge are causing a variety of environmental problems. Therefore, it is necessary to solve two contradictory technical problems: improving seawater exchange while at the same time improving calmness in the port.

An armored caisson breakwater with intake holes has been developed to conduct external seawater into the port using wave energy. In this paper, the hydraulic characteristics and the practical design of this structure will be presented.

Introduction

In ports near urban areas located in inner bay, the various water environmental problems have occurred due to the inflow of domestic and industrial wastewater, and the accumulation of sludge. It is necessary to urgently improve the water environment in these ports. Therefore, it is required that port structures promote the seawater exchange, which is contradictory to original functions such as structural resistiveness against wave action and the maintenance of the calmness in the port.

An armored caisson breakwater is one of the most popular breakwater structure in Japan. It excels in decreasing reflected and transmitted waves, and in being stable in stormy wave conditions. By 2-D & 3-D hydraulic model tests and field tests, the Civil

4) Hokkaido Tohkai University; Minamisawa 5-1-1, Minami, Sapporo, 005-0825 JAPAN
Engineering Research Institute has researched and developed an armored caisson breakwater with intake holes, which enabled the seawater exchange within and outside of the port, while making the most of its excellent hydraulic characteristics (C.E.R.I. et al., 1991-1995, 1997). Fig.1 shows the conceptual drawing of the armored caisson breakwater with intake holes.

![Fig.1 Conceptual Drawing of an Armored Caisson Breakwater with Intake Holes](image)

**Experimental Set-up**

In the armored caisson breakwater, wave-dissipating blocks installed in front of the breakwater bodies dissipate incident wave energy, and raise the mean water level by wave-setup. The principle of seawater exchange of the armored caisson breakwater with intake holes is the generation of one-way flow into the port through intake holes, using the increase in the mean water level within wave-dissipating blocks (Sarukawa et al., 1993).

Although the seawater exchange is promoted by the increase in the size of intake holes, the wave transmission into the port through intake holes is also increased, and the calmness in the port is decreased. There are also unsolved problems regarding the procedure of design calculation on wave force. Therefore, to confirm the hydraulic functions of the armored caisson breakwater with small or large intake holes, and to establish the structurally resistive design against wave action, 2-D hydraulic model tests were conducted on the following research items.

1) the wave transmission through intake hole  
2) the increase in the mean water level within wave-dissipating blocks  
3) the intake flow  
4) the wave pressure distribution for the structurally resistive design against wave action  
5) the influence of the opening ratio $\varepsilon$ of intake holes on the wave transmission and the intake flow  

Fig.2 shows the experimental models for 2-D hydraulic model tests. The definition of opening ratio $\varepsilon$ of intake hole was as follows. The opening ratio $\varepsilon$ of intake hole was changed to 16.8, 10.5 and 5.0%.
\[ \epsilon = \frac{\text{an area of cross section of intake holes}}{\text{an area of underwater cross section of breakwater including rubble mound foundation}} \times 100 \% \]

An understanding of the wave transmission through intake holes is very important, when considering the size and the arrangement of intake holes, and their influence on the utilization of the port in stormy wave conditions. Fig. 3 shows the relationship between the wave steepness \( H_{1/3}/L_{1/3} \) and the wave transmission coefficient \( K_t \) with the opening ratio \( \epsilon \) as a parameter. As the wave steepness \( H_{1/3}/L_{1/3} \) decreased, and as the opening ratio \( \epsilon \) increased, the wave transmission coefficient \( K_t \) of the armored caisson breakwater with intake holes increased, on condition that 2-D hydraulic model tests were conducted under condition without the wave transmission by wave overtopping.

**Fig. 2 Experimental Models for 2-D Hydraulic Model Tests**

**Fig. 3 Wave Transmission Coefficient**
(2) The increase in the mean water level within wave-dissipating blocks

Fig. 4 shows the relationship between the wave height $H_{1/3}$ and the increase in the mean water level $\eta_{\text{mean}}$ within wave dissipating blocks, with the opening ratio $\varepsilon$ and the wave period $T_{1/3}$ as parameters. The increase in the mean water level $\eta_{\text{mean}}$ within wave-dissipating blocks was not related to the opening ratio $\varepsilon$ and the wave period $T_{1/3}$, but was in proportion to the square of the wave height $H_{1/3}$, which was equivalent to the wave energy-loss dissipated within wave-dissipating blocks.

(3) Intake flow

Fig. 5 shows the relationship between the increase in the mean water level $\eta_{\text{mean}}$ within wave-dissipating blocks and the mean velocity $U_{\text{mean}}$ through intake hole. The mean velocity $U_{\text{mean}}$ was in proportion to the dimensionless velocity $(2g \eta_{\text{mean}})^{0.5}$. "g" is the acceleration of gravity. If the increase in the mean water level $\eta_{\text{mean}}$ within wave dissipating blocks exceeding a certain level does not occur, the portward one-way flow through intake hole does not occur. Similar results were obtained through field tests in
Urakawa port (Akeda et al., 1996). As shown in Fig. 5, it means that the seawater exchange cannot be expected from the armored caisson breakwater with intake holes, unless there is an increase in the mean water level exceeding a certain level, in other words, the wave height exceeding a certain level.

(4) Outflow into inner port from intake hole

When using the inside of an armored caisson breakwater with intake holes as a quaywall, it is necessary to understand the influence of the outflow into the inner port from intake hole. Fig. 6 shows the damping characteristics of the outflow from intake hole. The damping factor $U/U_0$ was defined as shown in Fig. 6. The outflow from intake hole decreased as the distance from intake hole increased, and almost leveled off when $x/h=1.5-2.5$. When the opening ratio $\varepsilon$ was 16.8%, the damping factor $U/U_0$ was 0.3-0.4 when $x/h=1.5-2.0$.

![Fig.6 Damping Characteristics of the Outflow](image)

![Fig.7 Wave Pressure Distribution (T_o=1.96s, H_o=21.3cm)](image)

**Design wave pressure**

(1) Wave pressure distribution

When the intake hole is put on relatively shallow position, the impact wave pressure
acts on the inside of intake hole. Fig. 7 shows an example of the wave pressure distribution on the top and the bottom of intake hole. The horizontal axis is the distance from the front-end of intake hole. The vertical axis is the dimensionless wave pressure $P_{\text{max}}/w_0H_{\text{max}}$. The left figure is the case when the intake hole is put on relatively deep position. The wave pressure distribution was largest at the front-end of intake hole, then decreased linearly toward the rear-end of intake hole. The upward and downward wave pressure distribution in intake hole were almost symmetrical. The right figure is the case when the intake hole is put on relatively shallow position. The wave pressure distribution was not attenuated toward the rear-end of intake hole.

Fig. 8 shows the influence of the crown depth of intake hole on the dimensionless wave pressure $P_{\text{max}}/w_0H_{\text{max}}$. The horizontal axis is the dimensionless crown depth of intake hole $d_1/H_{1/3}$. The vertical axis is $P_{\text{max}}/w_0H_{\text{max}}$. $d_1$ was the crown depth of intake hole. When the wave-dissipating blocks were installed in front of the breakwater bodies, $P_{\text{max}}/w_0H_{\text{max}}$ was almost constant at 0.2-0.4 when $d_1/H_{1/3}$ was larger than 0.2. When $d_1/H_{1/3}$ was smaller than 0.2, the impact wave pressure did not occur even though $P_{\text{max}}/w_0H_{\text{max}}$ increased. When the wave-dissipating blocks were not installed in front of the breakwater bodies, $P_{\text{max}}/w_0H_{\text{max}}$ was almost constant at 0.3-0.4 when $d_1/H_{1/3}$ was larger than 0.4. It was observed that $P_{\text{max}}/w_0H_{\text{max}}$ increased with the decrease in $d_1/H_{1/3}$, and the impact wave pressure occurred when $d_1/H_{1/3}$ was smaller than 0.3.

![Fig. 8 Influence of the Crown Depth of Intake Hole on the Dimensionless Wave Pressure in Intake Hole](image)

(2) Wave pressure formula

Fig. 9 shows the wave pressure distribution used for the structurally resistive design against wave action. The horizontal wave pressure and the uplift pressure acting on the front and the bottom of the breakwater body can be determined on the basis of the modified Goda's formula (Yamamoto et al., 1997). In consideration of the influence of intake hole, the horizontal wave pressure is not acted on the vertical surface of "opening part". The uplift pressure is acted on the top of intake hole, and triangularly
distributed toward the rear-end of intake hole, with an intensity of wave pressure at the front-end of intake hole of $p_{w2}$. The difference between the horizontal intensity of wave pressure acting on the top and the bottom of intake hole is defined as $p_{w2}$.

![Design Wave Pressure Distribution](image)

The details of the wave pressure formula are as follows:

$$\eta^* = 1.5\lambda H_D$$

$$P_1 = \lambda \alpha_1 \omega_H D$$

$$P_2 = \frac{P_1}{\cosh(2\eta / L)}$$

$$P_3 = \alpha_2 P_1$$

$$P_u = \lambda \alpha_1 \alpha_2 \omega_H D$$

$$P_{u2} = P_3 - P_6 = \frac{d_2 - d_1}{h} (P_1 - P_3)$$

Where,

- $\eta^*$: the wave height where the intensity of wave pressure becomes 0 (m)
- $P_1$: the intensity of wave pressure on the still water level (tf/m$^2$)
- $P_2$: the intensity of wave pressure on the sea bottom (tf/m$^2$)
- $P_3$: the intensity of wave pressure at the bottom of the intake hole (tf/m$^2$)
- $P_u$: the intensity of wave pressure on the top of the intake hole (tf/m$^2$)
- $P_{u2}$: the intensity of uplift pressure at the front leg of the bottom of the upright wall

$$\alpha_1 = 0.6 + \frac{1}{2} \left[ \frac{4\pi H / L}{\sinh(4\pi H / L)} \right]^2$$

$$\alpha_2 = \min \left[ \frac{h - d \left( \frac{H_D}{d} \right)^2}{3h} \left( \frac{H_D}{h} \right)^2 \right]$$

$$\alpha_3 = 1 - \frac{h'}{h} \left[ 1 - \frac{1}{\cosh(2\eta / L)} \right]$$

$h_b$: the water depth at the top of the upright wall (m)

$h_t$: the water depth at a distance 5 times longer than the significant wave height from the front of the upright wall to the offshore side (m)

$d_1$: the water depth at the top of the intake hole (m)

$d_2$: the water depth at the bottom of the intake hole (m)

$\omega$: the unit volume weight of sea water (tf/m$^3$)

$H_D$: the wave height used for design calculation (m)

$L$: the wave length used for design calculation at the water depth of $h$ (m)

$\lambda$: the wave pressure reduction rate by covering with wave-dissipating blocks ($\lambda = 0.8$)
Fig. 10 shows the relationship between the sliding distance and the critical sliding wave height. The horizontal axis is $H_{\text{max}}/H_c$. $H_{\text{max}}$ is the maximum wave height. $H_c$ is the critical sliding wave height calculated by the wave pressure formula. The vertical axis is the dimensionless sliding distance $S/H_c$. $S$ is the sliding distance. Because $S/H_c$ increased dramatically over $H_{\text{max}}/H_c=1$ regardless of the opening ratio $\varepsilon$, the above-mentioned wave pressure formula was thought to be reasonable.

Field Test in Urakawa Port

(1) Measuring conditions

In Urakawa port on the Pacific coast of Hokkaido, the armored caisson breakwater with an intake hole with the opening ratio of 5.0% was constructed to conserve the water quality and promote the seawater exchange. A field test on the hydraulic functions of this structure was conducted from October 26 to November 16, in 1995. The following items were observed:

1) the wave condition (wave height, wave period) in front of the breakwater (at 150m offshore, the depth of 8m)
2) the water pressure (at the front-end and the rear-end of intake hole)
3) the intake flow

Fig. 11 shows the layout of measuring instruments. Fig. 12 shows the time histories of the wave conditions in front of the breakwater of $H_m$, $T_\alpha$, the difference in the mean water level in front-end and rear-end of intake hole of $\Delta \eta$, and the mean velocity through intake hole of $U_{\text{mean}}$. The difference in the mean water level were calculated on the basis of the difference in the water pressure in front-end and rear-end of intake.
hole. At 8 a.m. on November 8, when the maximum wave \( H_{1/3} = 4.40 \text{m}, T_{1/3} = 8.6 \text{s} \) occurred, the difference in the mean water level in front-end and rear-end of intake hole was \( \Delta \eta = 6.9 \text{cm} \), and the mean velocity through intake hole was \( U_{\text{mean}} = 46.1 \text{cm/s} \). The observed value was equivalent to the inflow of seawater of about 10,000 tons per hour.

![Wave Height, Wave Period, Difference in Mean Water Level, Mean Velocity](image)

**Fig. 12 Time Histories of Observation Data**

(2) Flow velocity through intake hole

Fig. 13 shows the relationship between the wave height in front of the breakwater \( H_{1/3} \) and the difference in the mean water level in front-end and rear-end of intake hole \( \Delta \eta \). It was found from 2-D hydraulic model tests that the increase in the mean water level within wave-dissipating blocks was not related to the opening ratio \( \varepsilon \) or the wave period, but was in proportion to the square of the wave height. In field test, the difference in the mean water level in front-end and rear-end of intake hole \( \Delta \eta \) was in proportion to the square of the wave height in front of the breakwater \( H_{1/3} \), in case of the long-period waves with the wave period \( T_{1/3} \) of 8 sec or longer. In case of the short-period waves with the wave period \( T_{1/3} \) of shorter than 8 sec, there was hardly any difference in the mean water level in front-end and rear-end of intake hole due to the small incident wave height.

Fig. 14 shows the relationship between the difference in the mean water level in front-end and rear-end of intake hole \( \Delta \eta \) and the mean velocity in intake hole \( U_{\text{mean}} \).
In the same way as in 2-D hydraulic model tests, the mean velocity in intake hole $U_{\text{mean}}$ was in proportion to the a half power of the difference in the mean water level in front-end and rear-end of intake hole $\Delta \eta$. From the relationship shown in Figs. 13 and Fig. 14, it was found that the mean velocity in intake hole was in proportion to the wave height in front of the breakwater.

(3) Effect of the long-period oscillation

Fig. 15 shows an example of the fluctuation of the mean water level in the port $\Delta \eta$ and the mean velocity in intake hole $U_{\text{mean}}$ observed at 8 a.m. of Nov. 13. The wave condition were the wave height of $H_{1/3}=0.44$ m, and the wave period of $T_{1/3}=8.4$ sec. Under relatively calm wave conditions, when the wave period $T_{1/3}$ is 6 to 7 seconds or shorter and the wave height $H_{1/3}$ is 1.5 m or smaller, the external force which causes the seawater exchange is thought to be the long-period oscillation in the port with a period
of over 10 minutes and an amplitude of several centimeters. As shown in Fig.15, an oscillatory flow with a flow velocity amplitude of 20 to 40 cm/s was observed, and it was equivalent to a seawater exchange of several hundred tons per hour. From the above results, it was found that long-period oscillation in the port would contribute to seawater exchange within and outside the port under relatively calm wave conditions.

![Fig.15 Long-period Oscillation in the Port and Mean Velocity through Intake Hole](image)

**Case study on Kudoh Fishing Port**

In Kudoh Fishing Port on the Sea of Japan coast of Hokkaido, the construction of an armored caisson breakwater with intake holes with a large opening ratio was planned to improve the calmness in the port. 2-D & 3-D hydraulic model tests and numerical analysis were conducted to determine the inflow condition of external seawater and the calmness in the port, to examine the effectiveness of the construction of the armored caisson breakwater with intake holes in Kudoh Fishing Port (Akeda et al., 1998). Fig.16 shows a plan view of the Kudoh Fishing Port. The opening ratio $\varepsilon$ was about 16 to 22%, based on the installation depth of the north inner breakwater.

(1) Seawater exchange by tides

If the north inner breakwater is an impermeable structure, the seawater exchange by tides cannot be expected, the seawater exchange rate will be decreased to 1/100 to 1/50 of the present (without the north inner breakwater). Although the seawater exchange rate will be decreased to 1/6 to 1/5 of the present if the north inner
breakwater is the armored caisson breakwater with intake holes, there will be no problem concerning water quality in the port.

Fig. 17 Results of Visualization Experiment on the Inflow (T_{10}=12.0 s, H_{10}=5.3 m)

NO. 1 is after 8 min. NO. 2 is after 26 min. NO. 3 is after 38 min. NO. 4 is after 77 min. NO. 5 is after 100 min. NO. 6 is after 124 min.

Fig. 18 Results of Numerical Analysis on the Inflow (T_{10}=12.0 s, H_{10}=5.3 m)

(2) Seawater exchanges by waves

Fig. 17 shows an example of the results of a visualization experiment of the inflow by waves, when the north inner breakwater is the armored caisson breakwater with intake holes. Numbers in the Fig. 17 are the field-converted hours after external seawater flowed into the port. Under all experiment conditions, the dye tracer injected into the intake hole flowed into the port without spreading outside the port at all. It was found that the armored caisson breakwater with intake holes were effective in
inducing seawater even with oblique incident waves. The numerical analysis of seawater exchange using a 3-D multi-stratified flow model (Fujihara et al., 1997) was conducted under the same condition as that of the visualization experiment of the inflow of external seawater. Fig. 18 shows the numerical analysis result with the same condition as Fig. 17. As shown in Fig. 18, the tracer distribution and the velocity vector of the inflow external seawater obtained by the numerical analysis almost corresponded with the results of the 2-D hydraulic model tests.

If the north inner breakwater was the armored caisson breakwater with intake holes, it is expected that, in addition to the seawater exchange of 0.5 times/day by tides, the seawater exchange of 3.4 times/day would occur when $T_{10}=12.0\text{s}$ and $H_{10}=5.3\text{m}$, which were equivalent to wave heights generated several times a year. The seawater exchange of 0.6 times/day would occur when $T_{10}=8.0\text{s}$ and $H_{10}=1.9\text{m}$, which is equivalent to wave heights generated once or twice a month.

(3) Calmness in the port

Present wave heights (without a north inner breakwater) and future wave heights (with an armored caisson breakwater with intake holes as the north inner breakwater) in the basin for small fishing boat inside of the north inner breakwater were compared. Here, the wave height ratio was defined as the ratio of mean wave height in the basin for small fishing boat to transiting wave height at the position of the north inner breakwater. The wave height ratio was large (0.3 to 0.4) in the basin for small fishing boat as the direct invasion of waves from the base of the north inner breakwater in the west side of the port. The wave height ratio was particularly high (0.50 to 0.65) in front of the slipway. It was found that, in the future, the wave height ratio would decrease to 0.1 to 0.2 in the basin for small fishing boat and the effect of construction of the north inner breakwater on the calmness in the port would be significant. The rate of effective working days of the quaywall and slipway would also be improved to the required level.

Conclusions

The main results of this research were as follows.

(1) As the wave steepness $H_{10}/L_{10}$ decreased, and as the opening ratio $\varepsilon$ increased, the wave transmission coefficient $K_t$ of the armored caisson breakwater with intake holes increased.

(2) The increase in the mean water level $\eta_{\text{mean}}$ within wave-dissipating blocks was not related to the opening ratio $\varepsilon$ and the wave period $T_{10}$, but was in proportion to the square of the wave height $H_{10}$. The mean velocity $U_{\text{mean}}$ through intake hole was in proportion to the dimensionless velocity $(2g \eta_{\text{mean}})^{0.5}$. The results of field test in Urakawa port were similar to one of 2-D hydraulic model tests.

(3) The horizontal wave pressure and the uplift pressure acting on the front and the bottom of the breakwater body can be determined on the basis of the modified Goda's formula, in consideration of the influence of intake hole.

(4) The amount of seawater exchange could be determined by numerical analysis using

The armored caisson breakwater with intake holes is excellent in high stability against waves, and can be designed in the same way as a conventional method. Also, it does not require special construction methods and large machinery. The dissemination and the popularization of this technology is expected in the future.

Application of Overtopping Models
to Vertical Walls against Storm Surges

Holger Schüttrumpf\textsuperscript{1)}, Andreas Kortenhaus\textsuperscript{2)}, Hocine Oumeraci\textsuperscript{3)}

Abstract

The use of different wave overtopping models has been analysed. These overtopping models were applied to vertical walls with different geometries built for the protection against storm surges in the harbour of Hamburg (Germany). A comparison of existing overtopping test data and results from specific hydraulic model tests for existing geometries in Hamburg was also performed. A simple design diagram to predict both the overtopping rate $q$ and the required freeboard $R_c$ is presented. Furthermore, a simple engineering approach is proposed for the reduction of the horizontal wave load of the harbour walls due to wave overtopping. Finally, conclusions are drawn to come up with a "general overtopping formula" and further research work is outlined.

1. Introduction

The harbour of Hamburg is located on both sides of the river Elbe about 100 km upstream of the river mound (German Bight). The harbour area is divided in many harbour basins with bordering stock areas (Fig. 1). The river Elbe at this location is influenced by the tide resulting in a tidal range of about 2 m in Hamburg. During storm surges the water is pushed upstream the river Elbe from the German Bight and during high floods parts of the harbour are submerged. The cargo areas ("polders") are protected against storm surges by harbour walls with a total length of about 100 km. In Hamburg different geometries are used. Fig. 2 shows a classification of the typical harbour walls.

The local wave conditions during storm surges are as follows: the freeboard is higher than 0.2 m, the significant wave heights vary between 0.1 m and 0.7 m, the
mean wave periods between 1.0 s and 4.0 s and the wave directions between 0° and 90°. The water depth $h_s$ is about 15.0 m for design conditions and the average design wind velocity is about 20 m/s. Short crested wave conditions can be expected during high floods.

From above it can be seen that the design conditions in Hamburg for wave overtopping are very complex and an easy-to-use guideline is wanted to calculate wave overtopping. Within a case study the available reports, published and unpublished data have been collected and adapted for the Hamburg harbours walls. The main objectives of this study were:

(1) to identify the most reliable model to predict wave overtopping of vertical walls,
(2) to present an easy-to-use design diagram for the selected model and several applications to different geometries and wave conditions incl. comparisons to other models,
(3) to develop an engineering approach for the reduction of horizontal forces due to overtopping and

Figure 1. Port of Hamburg

Figure 2. Typical harbour wall geometries
(4) to outline the problems which have to be solved in order to come up with a "general overtopping formula".

2. Influencing Parameters

Wave overtopping is influenced by several parameters which can be identified and classified in the following way (Fig. 2 and 3):

- **Structural Parameters:**
  Structure Type, crest height and width, berm width, height and slope (Fig. 2)

- **Wave parameters and water depth:**
  Wave height, period and direction, spectral quantities, water depth in front of the structure

- **Wind parameters:** Wind velocity and direction

- **Scale and model effects**

- **Measured quantities:** average overtopping rate, individual overtopping rate, number of overtopping waves

3. Available Overtopping Models

Various overtopping models have been established over the last decades considering more or less of the aforementioned parameters. The most relevant investigations will be summarized in the following with respect to the geometric conditions in Hamburg.
GODA (1985) presents nondimensional diagrams for vertical harbour walls (Type b in Fig. 2) with different foreshore slopes based on small-scale model tests (wave flume) with irregular waves with and without rubble foundation.

DOUGLASS (1984) compares the GODA method with the SPM method (WEGGEL, 1976) and concludes that the two methods show reasonable good agreement for relative water depths $h_s/H_s = 0.4$ and $h_s/H_s = 0.75$. For higher ratios of $h_s/H_s$ the SPM overpredicts GODA. AHRENS and HEIMBAUGH (1989) performed model tests with wave spectra for seven test setups, considering a large variety of structure types. DAEMRICH (1991) performed model tests with wave spectra including wave direction (longcrested waves) for the Hamburg harbour wall type a in Fig. 2 (Fig. 4). MÜHLESTEIN (1992, a,b) tested the Hamburg harbour wall type without berm and foreshore (Type c in Fig. 2) in a wave flume and a wave basin using wave spectra and wind (Fig. 5).

FRANCO et al. (1995) compiled model data (2D and 3D) from several European laboratories within the MAST II MCS-project (MAS2-CT 92-0047) and added own data (Type c in Fig. 2) from multidirectional wave tests. He proposed the following exponential relationship to calculate the average overtopping rate (in the following referred to as MCS-formula):

$$\frac{q}{\sqrt{g H_s^3}} = a \exp \left( -b \frac{R_C}{H_s} \frac{1}{\gamma_i} \right)$$

with: $q =$ average overtopping rate [m$^3$/(s·m)]
$H_s =$ significant wave height [m]
$R_C =$ freeboard [m] (measured with respect to SWL)
$\gamma_i =$ non dimensional reduction coefficient [-]
$a, b =$ nondimensional coefficients (recommended: $a=0.082$; $b=3.0$ for normal wave attack and no directional spreading)

For oblique wave attack FRANCO recommends $\gamma_0=\cos \theta$ (for $\theta<37^\circ$) and $\gamma_0=0.79$ (for $\theta>37^\circ$) for longcrested waves and $\gamma_0=0.83$ (for $\theta<20^\circ$) and
\( \gamma_b = \cos(\theta - 20^\circ) \) (for \( \theta > 20^\circ \)) for shortcrested waves.

The influence of wind on wave overtopping is considered by HAYAMI et al. (1966), IWAGAKI et al. (1966) and DE WAAL (1996) for vertical walls. They found that firstly wind has an influence on wave overtopping by affecting the wave profile which again influences the breaker type (breaking occurs earlier, breaker number becomes smaller) and the breaking point moves seaward. Secondly basic spray is transported landward from the sea and thirdly the so called "green water" overtopping increases. Model tests are available for "green water" overtopping resulting in the following findings:

- For most experimental conditions wave overtopping increases due to wind except for very small relative water depths (\( h_s/L_0 < 0 \)).
- A quantitative description of the wind influence is still not available due to the scaling problems of wind (drops, drop transport capacity, shear stress between wind and water).

Therefore, further investigations are necessary to check the influence of wind on wave overtopping by large-scale model tests and field measurements.

None of the investigations has yet considered the width of the berm (Type a and Type d in Fig. 2). It is questionable whether the approach by VAN DER MEER et al. (1998) for smooth slopes can be used in the same way or has to be adapted for vertical walls. VAN DER MEER et al. (1998) considered the influence of a berm by introducing a reduction factor \( \gamma_b \) which is defined as:

\[
\gamma_b = 1 - \frac{B_b}{L_{berm}} \left( 1 - 0.5 \left( \frac{d}{H_S} \right)^2 \right)
\]  

with:
- \( d \) = distance between the middle of the berm and still water level (SWL)
- \( B_b \) = width of berm [m]
- \( L_{berm} \) = horizontal distance between the two points which are 1.0 \( H_S \) below and above the middle of the berm on the structure [m]
- \( H_S \) = significant wave height [m]

Table 1 shows a comparison of the geometric wall configurations in Hamburg with the model setups of the main investigations used in this paper.

4. Comparison of Model Data to Overtopping Models

Chapter 3 has shown that only the approach by FRANCO considers short- and longcrested waves. Therefore, this approach is compared to the model test results from MÜHLESTEIN (1992a, b) and DAEMRICH (1991) with longcrested waves. These studies were performed to test the geometrical conditions in Hamburg so that comparisons between model data and MCS-formula will show the applicability of the formula for different conditions. Subsequently, the model tests by DE WAAL (1996) for shallow water are introduced in the analysis (s. Table 1).

A comparison to the MCS-formula is shown in Fig. 6 for tests by MÜHLESTEIN (1992a,b). From Fig. 6 a very good agreement between MCS-formula and model tests can be observed for overtopping rates higher than $q = 0.1 \text{l/(s-m)}$. For lower overtopping rates there is a considerable scatter in the results which is common in many model tests. A similar scatter can be found in model tests by OWEN (1980) and VAN DER MEER et al. (1998).

The same conclusions can be drawn when the MCS-formula is plotted against data from DAEMRICH (1991) (Fig. 7). The difference between calculated and measured overtopping rates increases with a decrease in the overtopping rate (below 5 l/(s-m)). It can be concluded that the MCS-formula results in fairly smaller overtopping rates for small overtopping rates especially for oblique wave attack ($\theta = 40^\circ$). For high overtopping rates ($q>100 \text{l/(s-m)}$) the MCS-formula overestimates the overtopping rate. This fact probably results from missing overtopping tests for $R_c=0$ by FRANCO. Using the model results by DAEMRICH the range of applicability of the MCS-formula is extended for low relative freeboards, higher wave steepnesses and a small steep berm. In Fig. 8 a comparison between the MCS-formula and the overtopping tests by DE WAAL (1993) is shown. In this case the range of applicability of the MCS-formula is extended for high freeboards (small overtopping rates). The scatter of the data is considerable.
Figure 6. MÜHLESTEIN data versus MCS-formula

Figure 7. DAEMRICH data versus MCS-formula
5. Design Diagram for Wave Overtopping

The comparison between different model data sets and the MCS-formula shows that FRANCOs formula is a reasonable good approach to predict wave overtopping for many different vertical wall geometries. Therefore, this equation has been plotted in a diagram which has been first presented by MÜHLESTEIN (1992) and which is represented in a modified version in Fig. 9 by using Eq. (1).

The overtopping rate can be calculated by entering the diagram with the significant wave height $H_s$ and the freeboard $R_c$. On the other hand, the requested freeboard can be calculated by using the significant wave height $H_s$ and a critical average overtopping rate $q$.

The diagram is valid for longcrested waves. For shortcrested waves the freeboard $R_c$ must be divided by $y_9=0.83$ (for $\theta \leq 20^\circ$) or $y_9=\cos(\theta-20^\circ)$ (for $\theta > 20^\circ$) and only the line for $\theta=0^\circ$ in the left diagram can be used.

From Table 1 and chapter 4 the range of validity of this diagram is obvious. It can be used for relative freeboard heights $R_c/H_s=0-5$, wave steepnesses $H_s/L_0=0.007-0.057$ and relative water depths between $h_s/H_s=4.7$-deepwater. Furthermore reasonable scatter has to be expected for overtopping ratios lower than 5.0 $l/(s\cdot m)$. Oblique wave attack has to be treated very carefully, because of higher possible overtopping rates.

6. Influence of Wave Overtopping on Wave Forces

The influence of the wave overtopping rate on the wave loading of the wall has not yet been investigated. Many investigations have been performed concerning
wave pressures at the front of vertical walls due to waves (e.g. GODA, 1985; KORTENHAUS et al., 1996) but to the authors knowledge the reduction of pressures due to wave overtopping still remains an unsolved problem. Two main aspects can be distinguished which are dependent on the quantity of wave overtopping:

- indirect reduction of wave forces due to reduction in wave reflection,
- direct reduction of wave forces due to wave overtopping

![Figure 9. Easy-to-use design diagram for long-crested waves](image)

### 6.1. Indirect Reduction of Wave Forces due to Reduction of Wave Reflection

DAEMRICH (1991) published data on the reflection coefficient influenced by wave overtopping. The reflection coefficient is defined as:

$$ C_r = \frac{H_{S,r}}{H_{S,i}} \quad (3) $$

A reanalysis of DAEMRICH’s data (1991) shows a decreasing trend of the reflection coefficient with increasing overtopping rate. This trend is obvious but the scatter of the data is considerable. Unfortunately, model tests on the influence of wave overtopping on wave reflection are still lacking, so that further comparison is not possible.

### 6.2. Direct Reduction of Wave Forces by Wave Overtopping

Overtopping will lead to a reduction of the horizontal load on the wall. To date this phenomenon has given very little attention in literature and to the authors...
knowledge only very few hydraulic model tests have been conducted with a relatively low crest height where considerable amount of overtopping occurred.

The present working assumption for design is to cut the pressure figure at the top of the wall if any overtopping occurs. A typical example for a comparison of cases with and without overtopping is given in Fig. 10. Fig. 10b shows how the pressure distribution is cut at the top of the wall. The pressure ordinate at the top of the wall can be calculated from an interpolation between the ordinate at the height of the design water level (DWL) and the point above the water level where the pressure would be zero if the wall was high enough.

However, this method does not result in a significant decrease of the load. Therefore, an additional approach is proposed. Two boundary conditions are defined: in Fig. 10a the calculated pressure distribution just reach the top of the wall (Case I) whereas in Fig. 10c the design water level (DWL) has reached the top of the wall (Case II). In the latter case wave induced hydrodynamic pressures cannot exist any more. So this case can be designed by using simple hydrostatic approach. Between cases I and II further reduction of wave pressures and forces should be considered (Fig. 10b).

In Case II the wave-induced loading has to be zero at the top of the wall. Especially for impact breakers this is not the case when the pressure figure is simply cut off at the top of the wall (a pressure head of $p_t$ in the height of the DWL is still calculated by any design formulae). Therefore, this procedure will result in a too high pressure at the top of the wall.

A factor $k_{Fh}$ is introduced that significantly reduces the loading. This factor accounts for the fact that the pressure distribution and the force in Fig. 10c (Case II) has to be zero and has its maximum at an infinite high wall (Fig. 10a). A reduction of horizontal forces $F_h$ can then be obtained by:

$$F_{h,ov} = k_{F,h} \cdot F_h$$  \hspace{1cm} (4)

and for the moment $M_h$ the reduction is given by:

$$M_{ov} = k_{F,h} \cdot M_h$$  \hspace{1cm} (5)

In Eq.(4) $F_{h,ov}$ is the reduced force, $F_h$ is the horizontal force according to the design method used and $k_{F,h}$ is the reduction factor for overtopping as given by Eq.(6).

$$k_{F,h} = 1 \quad \text{für } \eta_* \leq R_c$$

$$k_{F,h} = \sqrt[3]{\frac{R_c}{\eta_*}} \quad \text{für } \eta_* > R_c$$  \hspace{1cm} (6)
Figure 10. Comparison of Pressure Distributions With and Without Overtopping
In Eq. (6) $\eta$ is the distance of the highest point of the pressure distribution to the design water level and $R_c$ is the freeboard of the wall (see Fig. 10). Cutting the pressure distribution at the top of the wall is independent from this approach and will be taken into account in all cases. The $k_{Fh}$ factor results in the lower curves shown in Fig. 11 for three different loading cases (1: standing waves; 2: impact waves; 3: broken waves).

These curves are assumed to be closer to reality than the common method of cutting the pressure distribution. However, for more accurate methods hydraulic model tests should be performed where the reduction of horizontal forces due to overtopping can be measured.

7. Summary and Recommendations for Future Research Work

Many research work has been performed for wave overtopping on vertical walls during the last years. Available papers and data have been reviewed with respect to the various geometric conditions in Hamburg. The most universal overtopping model has been selected and presented in a diagram for practical engineering use. Problems and restrictions of this model have been outlined. Finally an engineering approach for the reduction of wave forces by wave overtopping was shown. The results presented in this paper are in use for the design of about 100km vertical wall length in Hamburg.
From this study the following problems using available model tests and overtopping data have been encountered:

- A variety of overtopping models are available. It is however important to consider both reliability and simplicity when recommend any overtopping model for design.
- The influence of the different berm widths on wave overtopping is insecure. Therefore, more research work conducting model tests is necessary, especially for long berms.
- The influence of wave overtopping on the structure load has not yet been investigated. Consequently, new research work has to concentrate on the direct and indirect influence of wave overtopping. As a first working assumption it is proposed to use the approach presented in this paper.
- The influence of wind on wave overtopping is still under discussion and further research work is needed here.

Acknowledgements

This study has been initiated and supported by the Hamburg harbour authority "Strom- und Hafenbau", Germany. This collaboration is gratefully acknowledged. However, without the basic research project OU 1/2-1 on "Hydrodynamic loading of the inner slope of sea dikes by wave overtopping" supported by the German Research Council (DFG), the practical results presented in this paper would not have been achieved. The very useful comments by Dr. Daemrich (Franzius-Institut, Hannover, Germany) in the preparation of this paper are also gratefully acknowledged.

Advanced assessing of the stability of existing placed block revetments

Adam Bezuijen and Gerard A.M. Kruse

Abstract

Quality assessment of dikes is being set up in the Netherlands. The existing placed block revetments are a part of this assessment. In cases where a routine assessment is insufficient to come to a definitive conclusion, legislation prescribes a more advanced assessment. In this paper, the possibilities of such an advanced assessment are investigated. Three locations were selected for this assessment. The paper describes the experiments, field tests and calculations performed and concludes with the results of the assessment. Permeability of filter layer and cover layer appears much lower than expected, which influences the possible failure mechanism. The residual strength of a clay layer of 0.8 m underneath the blocks appears to be limited.

Introduction

In the Netherlands, where 60% of the land is below sea level, the quality of the water retaining structures is of extreme importance. Now legislation is in progress to come to a regular assessment of the strength of all the water retaining structures.

The first placed block revetments were evaluated in 1996 according to a provisional version of the legislation to come. In principle this is a routine assessment, with three possible results: 1. the structure is safe, 2. it needs further testing, 3. it is unsafe. This routine assessment used general rules on stability, based on model tests and experience, but always on the safe side. This routine assessment will be described in a paper of Stoutjesdijk et al. (1998). The first results of this routine assessment showed that there are quite a number of revetments with scored 2 or 3, further testing or unsafe.

1 Consultants, Strategic Research Departement, Delft Geotechnics, P.O. Box 69, 2600 AB Delft, The Netherlands.
Advanced assessment

To check the results of the routine assessment a more detailed assessment is performed for the revetments at selected locations. This, what is called, advanced assessment, has also been performed to investigate the possibilities of such a specific assessment and if it is worthwhile to make this a standard procedure for revetments, that did not pass the routine assessment.

The test results of the selected locations were 2 or 3 after the routine assessment mentioned before. In the assessment, described in this paper, samples were taken from the filter layer, the material between the blocks of the revetment and the subsoil. The permeability of the various layers has been determined in situ and is used to calculate the loading on the revetment, using wave conditions specially determined for the location in study. In cases where blocks had been placed directly on a clay substratum, the quality of the substratum has been evaluated. Furthermore, the clamping forces between the blocks were measured.

After selection of the locations (based on the routine assessment), it appeared that the revetments of these locations were to be improved in 1997. This offers the opportunity to see much more of the filter layers and clay layers than would have been possible without this improvement.

Locations

Three locations were selected. All these locations were along the Western Scheldt. One is on the northern side of the estuary, near the village Borssele. Two are located close together at the southern side near the hamlet Griete.

The location at the northern side would not experience extreme loading during highest storm surges. The highest water levels in the Western Scheldt are expected during spring tide and violent storm from the Northwest, during these conditions this revetment is on the high shore.

The two other locations are at the lee shore during extreme storm conditions. These two locations had the same revetment. At one of the locations, the revetment is placed on a dike of sand covered with a clay layer of approximately 0.8 m thickness. At the other location, the new dike is an enlargement of an old dike of clay material. The old clay dike can present a residual strength to the dike if the revetment is damaged.

The type of revetment is shown in Fig. 1. Concrete blocks are placed on a filter layer below the high water level. Above the high water level the blocks are placed directly on a clay layer. The photo is taken near Borssele, where the entire cover layer is constructed with square concrete blocks. Near Griete the lower part of the revetment was constructed with basalt blocks as a cover layer. Cross-sections of the dike and revetment near Borssele and near Griete at the location where the old clay dike is incorporated in the dike, are shown in Fig. 2 and Fig. 3. The cross-section of the dike near Griete without the old dike is the same except that the old clay dike is missing.
Results field tests

General

No damage was found where the revetment was placed on a filter layer. Some settlement was found where blocks were placed directly on clay at both locations.

Clamping forces

Pull out tests showed that most of the blocks are well clamped between their neighbours and that a loose block is an exception. There was not much difference between the concrete and basalt blocks. This result confirms earlier measurements (Stoutjesdijk et al. 1992).

The results of the tests on these locations are summarised in Table 1. In this table, the column 'height' is the height with respect of NAP, approximately equal to the mean sea level. At each height, 10 blocks were tested. These blocks were selected blocks. Blocks were chosen from which it was assumed that they could be pulled out of the revetment more easily than the average block. This assumption was based on wider joints between the blocks or some settlement of the block. The maximum possible pull out force was 9 kN. When non-of the 10 blocks in a row were removed with this force, the maximum deformation at this force is given in Table 1. It appears that only in the lower rows at the location Griete some basalt blocks could be removed (in each row 2 of the 10 blocks were removed). Removing was only possible at relatively
high forces of more than 10 times the block weight. The concrete blocks could not be removed with the maximum 9 kN pull out force. The maximum movement that was measured when pulled with 9 kN was less than 0.01 m in all cases.

**Permeability of cover layer and filter**

It appeared from the samples taken that all layers have a very low permeability. Values less than $10^{-6}$ m/s were found in the laboratory, less than the permeability of sand. Field tests, as described by Stoutjesdijk et al (1992), performed by the Dutch Public Work Department resulted also in low permeability values although on average higher values than found in the laboratory. Values ranged between $10^{-6}$ up to $10^{-4}$ m/s. Sieve analysis showed that the joints between the blocks are filled with sand and fines as well as the filter layer underneath the blocks. The difference in grain size and permeability was small between the 3 locations.

Most likely, the migration of fines, and the presence of organic slimes have led to the low permeabilities measured. When a block revetment is placed on a filter layer, the normal way of construction is to place the blocks on a thin layer of gravel. Underneath the gravel is a layer of mine stone (coarse mudstone gravel) that is placed on the subsoil of the dike (sand or clay). Just after construction, the permeability of the gravel is higher than that of the mine stone. However, it appears from the field tests that fines that are transported by water in the estuary can migrate in the gravel, but not in the mine stone (due to the smaller grains in the mine stone). This resulted in a gravel layer with a lower permeability than the mine stone layer underneath.

During the research, it was questioned whether the fines will be washed out from the joints and the gravel during extreme storm events, but no evidences what will happen could be obtained. On what is found in the field tests, it is assumed that fines can be washed out from the joints of the cover layer. However, it is unlikely that fines are washed out of the filter layer because of the small joints between the blocks and the limited duration of an extreme storm event.

**Clay**

To investigate the subsoil below the revetment, a trench was made at all locations. The various layers in the subsoil could be distinguished from the sidewalls from this trench. An example is shown in Fig. 4.

![Figure 4: Cross-section through revetment under layers and subsoil.](image-url)
At 2 locations a clay liner of 0.8 m thickness on a sand core was encountered. The other the substratum of the block revetment consisted of material supplemented to an existing dike body of clay material (as shown in Fig. 3).

As is common for the upper 1 m of clay in the unsaturated zone of dikes, it has experienced soil formation, and has a soil structure. This structure disrupts the integrity of the clay liners on sand completely. Based on pedological characteristics, it was found that the clay had not been properly densified during construction at the 2 locations with clay liners on sand, and appeared to exist of lumps of clayey material with sand partings. At one location wide, 2 – 5 mm, vertical cracks ran through a thinner section of the clay, and were connected to mine stone below the liner (see Fig. 2). These cracks lead to further erosion of the clay as can be seen from Fig. 5.

At the third location the substratum of the block revetment consisted of clay and rubble applied to an already existing dike. The outline of the former dike could be traced by indications of the former grass sods and dike pavement (see Fig. 4). The old dike body had a soil structure entirely comparable to present day soil structure under grassland, but at much denser packing, making it more stiff and less permeable.

The residual strength, expressed in the time it would take to remove the clay substratum of the dike, is very little for clay liners with soil structure on sand, and contributes less than 0.5 to 1 hour for extreme storm and wave conditions. The much denser and stiffer clay body of the older dike at the third location, and its sheer thickness, will make it withstand design loads during a storm surge period.

CPT's were used to assist in determining the overall build up of the dike, and to determine characteristics of clay liners. For the latter purpose the features discerned in the CPT graphs have to be correlated to information derived from sampling pits, however.

**Failure mechanism**

The failure mechanisms for placed block revetments on a filter layer are described by Burger et al. (1990) and Bezuijen et al. (1987). However, these failure mechanisms were derived from model tests. In these model tests no fines were present between the blocks and in the filter layer, resulting in a much higher permeability for both of these layers in the model, compared with these field locations. Lifting of the
blocks appears to be caused by the pressures on the slope and wave induced flow in the filter layer. During wave rundown, there is a water flow from the filter layer through the cover layer. This water flow can push a block out of the revetment (Bezuijen et al. 1990). Calculation methods have been derived to calculate the stability of the blocks. In these calculation methods, the flow in the filter layer is calculated as a function of the measured or schemed wave pressure distribution on the slope (Bezuijen and Klein Breteler, 1996).

For the revetments studied here, it is unlikely that flow in the filter layer can really contribute to lifting of the blocks. Due to the low permeability the discharge will only be limited leading to minor block movements. From what is seen in the field, it is more likely that flow underneath the blocks results from a small joint between the blocks and the filter layer. Whether this flow can lead to failure of the blocks in the revetment will be described in the next section.

**Numerical calculations**

The numerical calculations were focussed on the influence of joints between the blocks and the filter layer on the stability. The flow through such a joint can be described with the same equations as the flow through a permeable filter layer. However, in this case the 'filter layer' in the numerical model, represents the joint and has a finite length. In such a situation, largest uplift pressures over the blocks can occur when the waves causes steep pressure gradients on the slope.

Wave pressures were available from a series of small-scale model tests. In these tests, the pressure was measured with 25 pressure gauges. Tests were run with
irregular waves on a slope with a berm, as was present at these locations. From the tests the moments with steepest wave pressure gradients between two adjacent pressure gauges were selected. An example of such a selection is shown in Fig. 6. From this figure it appears that high wave pressure are present during wave impact, when there is a peak in the wave pressure, but also at some moments of low wave pressure. These moments occur just after the wave impact and then wave pressures lower than the atmospheric pressure can be measured. After this selection was made calculations where run with the STEENZET program to find what moments are most critical for the stability. These are the moments with the largest uplift pressure. These calculations were run for a joint of 3 or 4 block lengths. The waves were scaled up to the expected wave height at the various locations. For the wave pressures shown in Fig. 6 a scaling factor of 12.72 is used, which means that the actual wave height that is simulated in the calculations is 1.31 m with a wave period of 6.6 s. This is the maximum wave height to be expected at the toe of the revetment near Borssele. The extreme wave height for the revetment near Griete can be up to 2.5 m for a water level of 6 m + NAP.

Some results are shown in Figures 7 and 8. In these figures the blocks on the slope where the assumed joint below the blocks is present, are indicated. The black area is the measured wave pressure distribution (in m water). The part from the still water line until the lowest block is shown. Only the wave pressure distribution above the blocks has a consequence for the calculated pressure in the joint. The STEENZET program was designed for this extreme wave impact events and therefore the wave pressure is drawn through the results.

The calculated pressure in the joint below the blocks is indicated with the grey area (again in m water). The maximum uplift pressure is indicated, if this pressure is higher than the under water weight of the blocks, the revetment is potentially unstable because a block can be lifted. At the two locations described in this paper, the under
The water weight of the concrete blocks was 2.7 kN/m². For the basalt, this was 3.4 kN/m². The figures show that the low wave pressure that can occur directly below the wave impact can result in the largest uplift pressures. In this situation, the uplift pressure of 5 kN/m² is well above the pressure corresponding to the underwater weight of the blocks.

Further calculations with the STEENZET program have shown that for this situation the loading during impact is far more severe than the loading during maximum wave run down. The maximum loading depends largely on the length of the joint underneath the blocks. A larger joint leads to a much larger loading.

These results show that a block can become unstable when there is a small joint underneath the blocks. However, it is still difficult to determine an objective failure criterion based on these results. Since the wave pressures used, were measured during wave impact, the large gradients in the wave pressure measured will exist only for a short period. In such a short period, it is not possible that a block is lifted completely out of the revetment. If however some movement of the blocks occurs during this period, then the following waves can cause damage. Comparing the maximum uplift pressures with the pull out forces that were found, no damage has to be expected, but the pull out tests were performed on one single block. During wave attack, an uplift pressure can be present over a row of blocks and wave impacts can result in minor adjustments of the blocks leading to different clamping forces. It is therefore assumed that an uplift pressure of nearly two times the weight of the concrete blocks can result in instability. To get quantitative information it is necessary to perform large-scale model tests on revetments with comparable low permeable cover layers and filter layers and to analyse the measured pressures.

The situation for the basalt is less critical than for the concrete blocks, because of the larger joints between the basalt. In cases where there is a joint between the ba-
salt blocks and the filter layer there is also the possibility for pressure relief through the joints between the blocks. Furthermore the basalt is only placed at the lower parts of the revetment, up to a water level of 3.45 m + NAP, while the design wave attack is expected at a higher water level of approximately 5.5 m + NAP.

Conclusions

- The permeability of cover layer and filter layer in an existing revetment with sand and fines between the blocks and in the filter layer is much lower than of a newly build revetment. This will lead to other failure mechanisms than normally tested on in model tests or calculation models. Quality of workmanship preventing space between blocks and filter layer (due to settlement or erosion) will become more important to evaluate stability. The clamping forces between the blocks increase stability, but also can conceal open space underneath the blocks.

- Due to the low permeability the failure mechanism differ from the failure mechanism that are normally seen in model tests, with more permeable cover layer and filter layers. This means that model tests for existing revetments should be performed modelling the actual situation and not the as built situation.

- Since it not to be expected that about 0.8 m of clay in the unsaturated zone of dikes can withstand erosion for a significant amount of time, it is relevant to find out where such conditions occur. The erosion resistance of clay cores of dikes requires further research.

- Assessment of the quality of revetments still needs ‘engineering judgement’. Further research is needed to come to an objective assessment.

Abstract

The basic and detailed design of revetments and breakwaters in the Öresund Link were carried out by the Consultant, Carl Bro a/s\textsuperscript{4} for the Contractor, Öresund Marine Joint Venture, ÖMJV\textsuperscript{5}, based on design requirements and additional background information given by the Owner, Öresundskonsortiet, ÖSK. Final design was to be approved by the Owner, but with the liability of the Consultant/Contractor and with due consideration to the contractors method of construction. As part of the design process and in order to fulfil given geometrical restrictions the design requirements where further elaborated based on results of physical model tests and desk studies of critical assumptions. Some of the aspects and considerations in that process are discussed below.

Introduction

The Öresund Link creates a fixed link from Denmark to Sweden. As part of the Link, a 4 km long artificial island, named Peberholm, south of the island Saltholm and a Peninsula east of Amager have been constructed, see the overall layout in Fig. 1. The Link carries both rail and road traffic, from the Peninsula to the new island in a 3.5 km immersed tunnel, and from the island to Sweden on a 7.8 km double deck bridge with cable-stayed central spans. The Peninsula includes approx. 3.5 km permanent revetments. The artificial island includes approx. 8.5 km of permanent revetments and 1 km of semi-submerged breakwaters at the eastern and western ends. Further, approximately 2 km of temporary revetments and breakwaters were designed and constructed along with 3 temporary, sheltered and 3 unprotected work harbours.

Ballast Needam Dredging, the Netherlands
A total of approximately 8,000,000 m$^3$ of dredged material has been placed in the reclaimed areas behind permanent revetments and breakwaters consisting of approximately 650,000 m$^3$ coarse pebbles, 130,000 m$^3$ filter stones and 250,000 m$^3$ armour stones.

A brief description of the design requirements and calculations for design of typical cross sections of the revetments in the 14 km coastal structures is given below. The discussion is mainly on wave heights and the correlation with high water level used in the design of armour layer and in calculations of overtopping. Also the formal proof of the stability of the toe and scour protection is discussed in further detail.

**Figure 1. Layout of the Öresund Link - Reclamation Works**

As Consultant for design Carl Bro a/s carried out the tender, basic and detailed design of revetments and breakwaters for the Contractor Öresund Marine Joint Venture, (ÖMJV) based on design requirements given by the Owner, Öresundskonsortiet, (ÖSK). Desk studies and physical model tests revealed that the design requirements had to be re-evaluated to make the final structure fulfil geometrical requirements also given by the Owner.

**Design Requirements**

Significant wave heights and water levels with a 10, 100 and 10,000 year return period where given for specific locations in the Öresund area as design requirements. The wave data were given for two positions on the alignment of the Link (one in the Drogden Channel and one in Flinterenden). Also a set of data for Drogden lighthouse situated approx. 8 km south of the link was given. The requirements were based on field data and numerical wave and water level modelling (MIKE 21 NSW and MIKE 21 HD) performed by Danish Hydraulic Institute, DHI. The numerical modelling was carried out with no island or peninsula present.

Further results from the study done by DHI were available as Background Information, and wave climate data reduced due to friction and wave breaking over the shallow areas was given along the entire length of the Link alignment as well as for 6 points south of the future artificial island. From this a wave climate depending on water depth was developed and used in the Tender Design, see Table 1 below.
The above described approach for determining the design wave heights was not accepted by the Owner and for the basic and detailed design of the armour layer more conservative wave heights were specified in order to reduce the risk of damages. Data from "deep" water were to be applied unreduced on the revetments and breakwaters according to the criteria given below. The results from the numerical modelling were only accepted by the Owner for design of the northern perimeter of the reclaimed island. Also the criteria $H_s < 0.6h$, where $H_s$ is the significant wave height and $h$ is the local water depth at design water level, was given by the Owner, but due to large water depth not applied.

The basis for design requirements for wave heights applied in the final design can be summarised by the following:

- Peninsula (P1-P3): Wave data from Drogden Channel
- Western part of the Island (I1): Wave data from Drogden Channel
- Southern perimeter (I2-I4): Interpolation between Drogden and Flinterenden
- Eastern part of the Island (I5): Wave data from Flinterenden
- Northern perimeter (I6-I9): Results from numerical model increased by 1.15

The positions at the island, I1-I9 and peninsula, P1-P3 are indicated in Figure 1 and the wave heights used for designing armour stones etc. are listed in Table 1.

Table 1. Wave heights and High Water Levels (100 year return period). Water levels include expected level increase of 0.15 m over 100 years.

The water level in the Öresund region is governed by wind and barometric pressure, and tide is only limited. The Öresund link is constructed on a sill, that creates a dividing line between the salty waters in Kattegat to the north and the brackish water of the Baltic Sea to the south and east. A large difference in water level can occur across the sill, and the exact water level at the Link is difficult to determine.
The design requirements stated that if no other studies were performed the conservative wave heights should be used fully correlated with maximum high water level in the design and especially for calculations of overtopping. The correlated high water levels used in the Tender Design were based on data as presented in Background Information. Figure 2 below indicates a correlation between high water levels and waves from northerly directions, while this does not seem to be the case for waves from southerly directions. Due consideration was also given to the high risk sections around the tunnel portals and the abutment area (point P2, I1 and I5 in Figure 1) by using full correlation between maximum wave heights and water levels.

![Figure 2. Wave heights and correlated water levels. Data from 1962-1984 (Waves from Northerly (360) and southerly (180) directions)](image)

This however resulted in an unacceptable large volume of predicted overtopping that theoretically would endanger the overall stability of the structure. Hence a detailed statistical investigation was carried out for data on observed water levels and wave heights at Drogden Lighthouse 1962-1984 in order to establish a more accurate description of the correlation. The data was sorted according to wave height and high water level and curves of correlation could be determined, cf. Figure 3 and 4 which include selected results. The limited period of observation meant that a full set of design curves could not be evaluated, and an engineering approach in determining the curves for large wave heights was accepted by the Owner. The less conservative wave heights found in the numerical modelling were specified by the Owner to be used for the calculation of the overtopping, and with a given wave height the correlated high water level was determined. This resulted in the design wave heights and water levels also listed in Table 1. It must be noted that the high water levels listed in Table 1 includes a general increase of 0.15 m of the water levels in the Öresund region over 100 years.
Figure 3. Correlation between water level and wave height
(Waves from southerly directions, based on data from 1962-1984)

Figure 4. Correlation between water level and wave height
(Waves from northerly directions)
Typical cross sections

In Figure 5 and Figure 6 two typical cross sections of revetments in the Öresund Link are given. Figure 5 shows a normal cross section with the filter stone layer extended behind the crest as a protection against overtopping. Figure 6 illustrates the design adopted at the tunnel portal and abutment area. The vertical wall was part of the geometrical requirements given by the Owner as part of the design basis.

The core of the revetment consists of coarse pebbles ($W_{50\%}=1.0-3.5$ kg) which were specified in the design requirements. The filter stones ($W_{50\%}=16-80$ kg) follow the filter criteria towards core and armour layer. As already noted above the Owner had specified the interface between backfill and core to be multiple layers of sand, which are difficult and costly to place. In order to greatly simplify and reduce the number of operations the Owner agreed to substitute the layers of sand with a geotextile, which could be proven to have the same effect.

As an important part of the design basis for armour layer, crest, toe and scour protection a series of physical model test were performed for the revetments and breakwaters. From the results simple design criteria could be found.
Armour stones

The formulae given in (Meer, 1987) were approved by the Owner in the design requirements for calculating the armour stone size. Further the damage level was defined as the damaged cross sectional area relative to the total cross sectional area of armour stones. This gives a non-logical dependency between armour stone size and water depth / crest level. Theoretically a higher crest or deeper water required smaller armour stones for identical wave climates. In stead the results of the physical model tests were used to establish design criteria for the stability number, N. Δ is the relative density and $D_{n,50\%}$ is the nominal diameter of the armour stone.

\[
N = \frac{H_s}{\Delta D_{n,50\%}} = 1.45 \text{ for damage level of } 2\% \\
N = \frac{H_s}{\Delta D_{n,50\%}} = 1.85 \text{ for damage level of } 5\% \\n\]

The design requirements specified that the armour stone size for the sections at the tunnel portal and at the abutment were designed for 2% damage in a wave climate with 100 year return period and for 5% damage in a 10,000 year return period. The remaining permanent revetments and breakwaters are designed for 5% damage for a 100 year return period.

The armour stones were grouped in a limited number of stone classes in agreement with the Contractor, but due to repeated changes in design requirements throughout the construction phase this number had to be increased. A list of the armour stones used is given in Table 2, where the locations refer to Figure 1.

Table 2. Armour stone size with corresponding 100 year wave height.

The armour stones on the northern perimeter have been designed to withstand a temporary situation (5% damage for a 10 year return period) without the low crested breakwaters, the Whiskers, at the eastern and western tip of the island. Further it can be noted that the temporary revetments and breakwaters protecting the compounds used as a construction site have been constructed from materials that can be reused in the construction of the whiskers ($W_{50\%} = 1,800$ kg armour stones).
Toe and scour protection

Initially the toe and scour protection was designed based on experience and a large redundancy was built into the structure. The toe structure was questioned by the Owner, and a detailed investigation was carried out based on the results of the physical model tests. Design curves are shown in Figure 7, where $H_s$ is the significant wave height, $N$ is the stability number and $h_t$ is the water depth over the toe or scour protection.

The physical model tests showed a general smoothing of the edge of the coarse pebbles and minor damage (less than 5%) to the layer of filter stones. Both layers were at least dynamically stable and the overall stability was not endangered in any of the tests. It was accepted by the Owner, that the curve obtained for the filter stones could be used as a design curve for both toe and scour protection. Based on results presented in (CIRIA/CUR, 1991) and other previous studies the design curve was then extended to be valid for $h_t/H_s > 0.6$. Also $H_s$ could be limited by $H_s = 0.5h$ in stead of the criteria $H_s = 0.6h$ used for the design of the armour layer.

![Figure 7. Design curves for toe and scour protection](image-url)
As can be seen from Figure 7 a toe with 0.6 m layers of filter stones on coarse pebbles including a large redundancy could not be proven theoretically stable due to the shallow water over the toe. By including a smoothing, where the layer thickness was allowed reduced (0.6 m to 0.4 m for filter stones in the toe and 0.6 m to 0.3 m for the coarse pebbles in the scour protection), the structure could be proven theoretically stable for the following water depths, h:

- 0.4 m Filter stones in toe stable for $h > 1.45$ m
- 0.3 m Coarse pebbles in scour protection stable for $h > 0.45$ m

The Owner then accepted a smoothing of the toe in general to a slope of 1:6, and by using (Meer, 1987) the toe and scour protection could be proven theoretically static stable for the following water depths, h:

- Filter stones in toe stable with slope 1:6 for $h < 1.20$ m
- Coarse pebbles in scour protection stable with slope 1:6 for $h < 0.35$ m

No formal proof of the static stability of the toe and scour protection could be obtained for the intermediate water depths, but the Owner agreed that there is no reason why the structure should be especially unstable for these water depths.

A study of the sediments in the seabed in the area showed mainly coarse materials with limited chances of extensive scour in spite the increase in current speed due to concentration around the island and peninsula. On sections with a large ratio of sand in the seabed the toe and scour protection was extended by 1 m to a total of 3.0 m width of the toe.

Hence the initial design of the toe and scour protection was finally accepted with only minor increase of the toe width on exposed sections, but as a part of the accept, the Owner specified a monitoring programme commencing after handover.

Overtopping

The initial theoretical calculations of overtopping in the Tender Design showed an unacceptable amount that would endanger the overall stability of most sections of the revetments. Based on the physical model tests a formula for calculating the mean volume rate of overtopping, $Q_m$, without correction for the influence of wind was derived by using the structure of a formula by Bradbury et. al. as given in (CIRIA/CUR, 1991).

$$Q_m = gH_s T_z \cdot 2.8\cdot10^{-5} \cdot (\Delta h/H_s)^7$$

(3)

Using this formula the overtopping volumes were recalculated using maximum wave heights correlated with maximum water levels. This also showed an unacceptable amount of overtopping, and the crest levels were recommended raised. The physical model tests indicated a recommended freeboard of not less than $\Delta h = 1.35H_s$ for an overall stable structure. The crest levels were fixed by the Owner, and hence the Owner initiated discussions on the correlation between waves and high water levels. Finally agreement was reached on design criteria with less conservative wave heights.
and correlated water levels as given in Table 1. This reduced the overtopping significantly but additional protection of the crest was still necessary. Especially on the southern perimeter of the island, where the crest is down to +3.0 m, a layer of filter stones behind the crest of armour stones is placed.

The Owner further granted that the Contractor would not be responsible for overtopping causing flooding of building sites or erosion of the unbound service road / backslope of clay till bunds.

As an indication of the theoretically calculated amounts of overtopping for different sections of the revetments a list is given in Table 3 for a wave climate and high water level situation with a 100 return period. The volume is measured behind the crest of armour stones.

Figure 3. Calculated overtopping for situation with 100 year return period

The permanent structures should also withstand a situation with a 10,000 year return period, where the volumes of overtopping are 10-50 times as large. Again the overall stability could be endangered if the backfill is eroded, but the Owner accepted liability for this failure mode and for erosion of the service road behind the revetment.

Conclusion

The revetments and breakwaters in the Öresund Link were described in design requirements given by the Owner, ÖSK, including certain requirements for loads, layout, geometrical dimensions and levels as well as specifications for materials used. The method of construction used by the Contractor, ÖMJV also gave rise to certain requirements for the detailed design carried out by the Consultant, Carl Bro a/s.

Mainly the design is based on general design criteria for armour stone size, design of toe and scour protection as well as a critical crest level, all evaluated from a series of physical model tests. The design of some elements in the revetments and breakwaters were more or less given through requirements in the contract, but it is
noted that multiple layers of sand as a filter towards the back fill were substituted by a geotextile.

The input data as regards wave characteristics and water levels were specified by the Owner based on a conservative evaluation of the numerical modelling of the Øresund region for design of armour stones. Hence an additional factor of safety was included in the design of the armour layer.

Full correlation between waves and high water levels combined with requirements to geometry, lay out etc. given by the Owner, theoretically resulted in an unacceptable large volume of predicted overtopping endangering the overall stability of the structure. Correlation curves were derived based on a detailed statistical investigation of observed wave heights and correlated water levels. The Owner then specified less conservative wave heights for the evaluation of overtopping, but still additional protection of the crest was found necessary. The Owner then agreed that the Contractor would not be responsible for damages to areas behind the revetments due to overtopping.

The initial design of the toe and scour protection was questioned by the Owner, but formal proof of static stability based on physical model tests, could be made for most water depths by including a smoothing of the large redundancy built into the structure. Interestingly the large redundancy theoretically made the toe and scour protection less stable due to a reduced distance to the surface. An engineering approach was accepted for intermediate water depths but a monitoring programme was required by the Owner.

DESIGN OF ALTERNATIVE REVETMENTS

M. Klein Breteler\textsuperscript{1}, K. W. Pilarczyk\textsuperscript{2}, T. Stoutjesdijk\textsuperscript{3}

Abstract

Within the scope of the research on the stability of open slope revetments, much knowledge has been developed about the stability of placed (pitched) stone revetments under wave load (CUR/TAW 1995) and stability of rock under wave and current load (CUR/CIRIA 1991).

Until recently, no or unsatisfactory design tools were available for a number of other (open) types of revetment and for other stability aspects. This is why the design methodology for placed block revetments has recently been extended in applicability by means of a number of desk-studies for other (open) revetments:

- interlock systems and block mats;
- gabions;
- concrete mattresses;
- geosystems, such as sandbags and sand sausages;

and other stability aspects, such as: flow-load stability, soil-mechanical stability and residual strength.

This paper aims at giving a summary of the increased knowledge, especially that concerning the design tools that have been made available. The details behind it can be found in (Pilarczyk et al 1998).

1 THEORETICAL BACKGROUND OF WAVE LOADING

Wave attack on revetments will lead to a complex flow over and through the revetment structure (filter and cover layer). During wave run-up the resulting forces by the waves will be directed opposite to the gravity forces. Therefore the run-up is less hazardous then the wave run-down. Wave run-down will lead to two important mechanisms:

- The downward flowing water will exert a drag force on the cover layer and the decreasing freatic level will coincide with a downward flow gradient in the filter (or in a gabion). The first mechanism can be schematised by a free flow in the filter or gabion with a typical gradient equalling the slope angle. It may result in sliding.
- During maximum wave run-down there will be an incoming wave that a moment later will cause a wave impact. Just before impact there is a 'wall' of water giving a high pressure under the point of maximum run-down. Above the run-down point the surface of the revetment is almost dry and therefore there is a low pressure on the structure. The high pressure front will lead to an upward flow in the filter or a gabion. This flow will meet the downward flow in the run-down region. The result is an outward flow and uplift pressure near the point of maximum wave run-down (Figure 1).

The schematised situation can be quantified on the basis of the Laplace equation for linear flow:

\[
\frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} = 0
\]

with:
- \( \phi = \phi_0 \) potential head in the filter or a gabion (m)
- \( y = \) coordinate along the slope (m)
- \( z = \) coordinate perpendicular to the slope (m)

After complicated calculations the uplift pressure in the filter or a gabions can be derived. The uplift pressure is dependent on the steepness and height of the pressure front on the cover layer (which is dependent on the wave height, period and slope angle, see Figure 2), the thickness of the cover layer and the level of the freatic line in the filter or a gabion. In case of gabions, it is not dependent on the permeability of the gabions, if the permeability is larger then the subsoil. The equilibrium of uplift forces and gravity forces leads to the following (approximate) design formula (Pilarczyk et al 1998):

\[
\frac{H_{scr}}{\Delta D} = f \left( \frac{D}{\Lambda \xi_{op}} \right)^{0.67}
\]

\[
\Lambda = \sqrt{\frac{bDk}{k'}}
\]

or

\[
\frac{H_{scr}}{\Delta D} = f \left( \frac{D k'}{b k} \right)^{0.33} \xi_{op}^{0.67}
\]
or \[ \frac{H_{scr}}{\Delta D} = F \xi_{op}^{0.67} \] (2c)

where \( H_{scr} \) = significant wave height at which blocks will be lifted out [m]; \( \xi_{op} = \tan \alpha / \sqrt{H_s/(1.56 T_p^2)} \) = breaker parameter [-]; \( T_p \) = wave period at the peak of the spectrum [s]; \( \Lambda \) = leakage length [m]; \( \Delta = (\rho_s - \rho)/\rho \) = relative volumetric mass of cover layer [-]; \( b \) = thickness of a sublayer [m], \( D \) = thickness of a top layer [m], \( k \) = permeability of a sublayer [m/s], \( k' \) = permeability of a top layer [m/s], \( f \) = stability coefficient, mainly dependent on structure type, \( \tan \alpha \) and friction [-]; \( F \) = total (black-box) stability factor [-].

The leakage length (\( \Lambda \)) and stability coefficient are explained in detail in the next section.

2 STRUCTURAL RESPONSE

2.1 Wave-load approach

There are two practical design methods available: the black-box model and the analytical model. In both cases, the final form of the design method can be presented as a critical relation of the load compared to strength, depending on the type of wave attack:

\[ \left( \frac{H_s}{\Delta D} \right)_{cr} = \text{function of } \xi_{op} \] (3a)

For revetments, the basic form of this relation is:

\[ \left( \frac{H_s}{\Delta D} \right)_{cr} = \frac{F}{\xi_{op}^{2/3}} \text{ with maximum } \left( \frac{H_s}{\Delta D} \right)_{cr} = 8.0 \] (3b)

In which: \( F = \) revetment (stability) constant (-), \( H_s = \) (local) significant wave height (m), \( \Delta = \) relative density (-), \( D = \) thickness of the top layer (m), and \( \xi_{op} = \) breaker parameter (-).

The relative density is defined as follows:

\[ \Delta = \frac{\rho_s - \rho_w}{\rho_w} \] (4a)

with: \( \rho_s = \) density of the protection material and \( \rho_w = \) density of water (kg/m³). For porous top layers, such as sand mattresses and gabions, the relative density of the top layer must be determined, including the water-filled pores:

\[ \Delta_t = (1 - n) \cdot \Delta \] (4b)

In which: \( \Delta_t \) = relative density including pores (-) and \( n = \) porosity of the top layer material (-).

The breaker parameter is defined as follows:

\[ \xi_{op} = \frac{\tan \alpha}{\sqrt{H_s / L_{op}}} \] (5)

The wave steepness \( S_{op} \) is defined as:

\[ S_{op} = \frac{H_s}{L_{op}} = \frac{2 \pi H_s}{g T^2} \] (6)

In which: \( L_{op} = \frac{g}{2 \pi} T_p^2 \) (7)

with: \( \alpha = \) slope angle (°), \( L_{op} = \) deep-water wavelength at the peak period (m), and \( T_p = \) wave period at the peak of the spectrum (s).
The advantage of this black-box design formula is its simplicity. The disadvantage, however, is that the value of $F$ is known only very roughly for many types of structures. The analytical model is based on the theory for placed stone revetments on a granular filter (pitched blocks). In this calculation model, a large number of physical aspects are taken into account. In short, in the analytical model nearly all physical parameters that are relevant to the stability have been incorporated in the "leakage length": $\Lambda = \sqrt{(bDk/k')}$. The final result of the analytical model may, for that matter, again be presented as a relation such as Eq. 3 where $F = f(\Lambda)$.

With a system without a filter layer (directly on sand or clay, without gullies being formed under the top layer) not the permeability of the filter layer, but the permeability of the subsoil (eventually with gullies/surface channels) is filled in.

To be able to apply the design method for placed stone revetments under wave load to other systems, the following items may be adapted:

- the revetment parameter $F$;
- the (representative) strength parameters $\Delta$ and $D$;
- the design wave height $H_s$;
- the (representative) leakage length $\Lambda$;
- the increase factor $\Gamma$ on the strength.

Only suchlike adaptations are presented in this summarising review. The basic formulas of the analytical model are not repeated here. For these, reader is referred to (CUR/TAW 1995).

### 2.2 Flow-load stability

There are two possible approaches for determining the stability of revetment material under flow attack. The most suitable approach depends on the type of load:

- flow velocity: 'horizontal' flow, flow parallel to dike;
- discharge: downward flow at slopes steeper than 1:10, overflow without waves; stable inner slope.

When the flow velocity is known, or can be calculated reasonably accurately, Pilarczyk's relation (Pilarczyk et al 1998) is applicable:

$$\Delta D = 0.035 \frac{\Phi}{\Psi} \frac{K_T}{K_s} \frac{u^{2}_{cr}}{2g}$$  \hspace{1cm} (8)

in which: $\Delta =$ relative density (-), $D =$ characteristic thickness (m), $g =$ acceleration of gravity ($g=9.81 \text{ m/s}^2$), $u^{2}_{cr} =$ critical vertically-averaged flow velocity (m/s), $\Phi =$ stability parameter (-), $\Psi =$ critical Shields parameter (-), $K_T =$ turbulence factor (-), $K_h =$ depth parameter (-), and $K_s =$ slope parameter (-).

These parameters are explained below.

**Stability parameter $\Phi$:**

The stability parameter $\Phi$ depends on the application. Some guide values are:

<table>
<thead>
<tr>
<th>Revetment type</th>
<th>Continuous toplayer</th>
<th>Edges and transitions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Riprap and placed blocks</td>
<td>1.0</td>
<td>1.5</td>
</tr>
<tr>
<td>Blockmats, gabions, washed-in blocks, geobags, and geomattresses</td>
<td>0.5</td>
<td>0.75</td>
</tr>
</tbody>
</table>
**Shields parameter** $\Psi$:
With the critical Shields parameter $\Psi$ the type of material can be taken into account:
- riprap, small bags $\Psi \approx 0.035$
- placed blocks, geobags $\Psi \approx 0.05$
- blockmats $\Psi \approx 0.07$
- gabions $\Psi \approx 0.07$ (to 0.10)
- geomattresses $\Psi \approx 0.07$

**Turbulence factor** $K_T$:
The degree of turbulence can be taken into account with the turbulence factor $K_T$. Some guide values for $K_T$ are:
- Normal turbulence: abutment walls of rivers $K_T \approx 1.0$
- Increased turbulence: river bends downstream of stilling basins $K_T \approx 1.5$
- Heavy turbulence: hydraulic jumps sharp bends strong local disturbances $K_T \approx 2.0$
- Load due to water (screw) jet: $K_T \approx 3.0$ (to 4.0)

**Depth parameter** $K_h$:
With the depth parameter $K_h$, the water depth is taken into account, which is necessary to translate the depth-averaged flow velocity into the flow velocity just above the revetment. The depth parameter also depends on the development of the flow profile and the roughness of the revetment.
The following formulas are recommended:

- fully developed velocity profile: $K_h = \frac{2}{\log\left(\frac{12h}{k_s}\right)^2}$ (9a)
- non-developed profile: $K_h = \left(\frac{h}{k_s}\right)^{0.2}$ (9b)
- very rough flow ($h/k_s < 5$): $K_h = 1.0$ (9c)

In which: $h =$ water depth (m) and $k_s =$ equivalent roughness according to Nikuradse (m).
In the case of dimensioning the revetment on a slope, the water level at the toe of the slope must be used for $h$.
The equivalent roughness according to Nikuradse depends on the type of revetment/geosystem. For riprap, $k_s$ is equal usually to twice the nominal diameter of the stones, for bags it is approximately equal to the thickness (d), for mattresses it depends of the type of mattress: $k_s$ of about 0.05 m for smooth types and about the height of the rib for articulating mats.

**Slope parameter** $K_s$:
The stability of revetment elements also depends on the slope gradient under which the revetment is applied, in relation to the angle of internal friction of the revetment. This effect on the stability is taken into account with the slope parameter $K_s$, which is defined as follows:
$K_s = \sqrt{1 - \left(\frac{\sin \alpha}{\sin \theta}\right)^2} = \cos \alpha \sqrt{1 - \left(\frac{\tan \alpha}{\tan \theta}\right)^2}$ \hspace{1cm} (10a)

or

$K_s = \cos \alpha_b$ \hspace{1cm} (10b)

with: $\theta =$ angle of internal friction of the revetment material, $\alpha =$ transversal slope of the bank (°), and $\alpha_b =$ slope angle of river bottom (parallel along flow direction) (°).

The following values of $\theta$ can be assumed as a first approximation: 40° for riprap, 30° to 40° for sand-filled systems, and 90° for stiff and anchored mortar-filled mattresses and (cabled) blockmats ($K_s = \cos \alpha$). However, for flexible non-anchored mattresses and blockmats (units without contact with the neighbouring units) this value is much lower, usually about 3/4 of the friction angle of the sublayer. In case of geotextile mattress and blockmats connected to geotextile lying on a geotextile filter, $\theta$ is about 15° to 20°.

The advantage of this general design formula of Pilarczyk is that it can be applied in numerous situations. The disadvantage is that the scatter in results, as a result of the large margin in parameters, can be rather wide.

With a downward flow along a steep slope it is difficult to determine or predict the flow velocity, because the flow is very irregular. In such case formulas based on the discharge are developed (Pilarczyk et al 1998).

2.3 Soil-mechanical stability

The water motion on a revetment structure can also affect the subsoil, especially when this consists of sand.

Geotechnical stability is dependent on the permeability and stiffness of the grain skeleton and the compressibility of the pore water (the mixture of water and air in the pores of the grain skeleton). Wave pressures on the top layer are passed on delayed and damped to the subsoil under the revetment structure and to deeper layers (as seen perpendicular to the slope) of the subsoil. This phenomenon takes place over a larger distance or depth as the grain skeleton and the pore water are stiffer. If the subsoil is soft or the pore water more compressible (because of the presence of small air bubbles) the compressibility of the system increases and large damping of the water pressures over a short distance may occur. Because of this, alternately water undertension and overtension may develop in the subsoil and corresponding to this an increasing and decreasing grain pressure. It can lead to sliding or slip circle failure, see Figure 3.

![Figure 3](image_url) Schematised development of S-profile and possible local sliding in the base (sand)

The design method with regard to geotechnical instability is presented in the form of design diagrams. An example is given in Figure 4 (more diagrams and details: see Pilarczyk et al, 1998). The maximum wave height is a function of the sum of the cover layer weight ($\Delta D$) and filter thickness ($b_f$).
3 STABILITY CRITERIA FOR BLOCKMATS

3.1 System description

A (concrete) blockmat is a slope revetment made of (concrete) blocks that are joined together to form a "mat", see Figure 5. The interconnection may consist of cables from block to block, of hooks connecting the blocks, or of a geotextile on which the blocks are attached with pins, glue or other means. The spaces between the blocks are usually filled with rubble, gravel or slag.

The major advantage of blockmats is that they can be laid quickly and efficiently and partly under water. Blockmats are more stable than a setting of loose blocks, because a single stone cannot be moved in the direction perpendicular to the slope without moving other nearby stones. It is essential to demand that already with a small movement of an individual stone a significant interactive force with the surrounding stones is mobilised. Large movements of individual blocks are not acceptable, because transport of filter material may occur. After some time, this leads to a serious deformation of the surface of the slope.

The blockmats are vulnerable at edges and corners. If two adjacent mats are not joined...
together, then the stability is hardly larger than that of pitched loose stones.

### 3.2 Design rules with regard to wave load

Table 1 gives an overview of useable values for the revetment constant $F$ in the black-box model for linked blocks (blockmats).

<table>
<thead>
<tr>
<th>Type of revetment</th>
<th>$F$ (-)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Linked blocks on sand</td>
<td>5 to 6</td>
</tr>
<tr>
<td>Linked blocks on clay</td>

</tr>
<tr>
<td>good clay</td>
<td>5 to 6</td>
</tr>
<tr>
<td>mediocre clay</td>
<td>4.5 to 5</td>
</tr>
<tr>
<td>Linked blocks on a granular filter</td>
<td></td>
</tr>
<tr>
<td>favourable construction</td>
<td>5 to 6</td>
</tr>
<tr>
<td>normal construction</td>
<td>4 to 5</td>
</tr>
<tr>
<td>unfavourable construction</td>
<td>3 to 4</td>
</tr>
</tbody>
</table>

Table 1 Recommended values for the revetment parameter $F$ for blockmats (the lower values refer to blocks connected to geotextile while the higher ones refer to cabled blocks).

The terms "favourable", "normal" and "unfavourable" refer to the composition of the granular filter and the permeability-ratio of the top layer and the filter layer (see CUR/CIRIA, 1991). In a case of fine granular filter and relatively permeable top layer the total composition can be defined as "favourable". In a case of very coarse granular layer and less permeable top layer the composition can be defined as "unfavourable". In a case of blocks connected to a geotextile and concrete-filled mattresses on a filter layer the construction can be usually defined as between "unfavourable" and "normal", and the stability factor $F = 3.0$ to $3.5$ (max. $4.0$) can be applied. For blockmats and permeable mattresses on sand $F = 5$ (max. $6.0$) can be applied. The higher values can also be used in cases that the extreme design loading is not very frequent or when the system is (repeatedly) washed in by coarse material providing additional interlocking.

This wide range of recommended values for $F$ only gives a first indication of a suitable choice.

Furthermore it is essential to check the geotechnical stability with the design diagrams (see for example Figure 4 and for a full set of diagrams see Pilarczyk et al 1998).

### 4 STABILITY CRITERIA FOR CONCRETE-FILLED MATTRESSES

#### 4.1 Concrete Mattresses

Characteristic of concrete mattresses are the two geotextiles with concrete or cement between them. The geotextiles can be connected to each other in many patterns, which results in a variety of mattress systems, each having its own appearance and properties. Some examples are given in Figure 6.
The permeability of the mattress is one of the factors that determine the stability. It is found that the permeability given by the suppliers is often the permeability of the geotextile, or of the so-called Filter Points. In both cases, the permeability of the whole mattress is much smaller. A high permeability of the mattress ensures that any possible pressure build-up under the mattress can flow away, as a result of which the uplift pressures across the mattress remain smaller.

In general, with a subsoil of clay and silty sand the permeability of the mattress will be higher than the permeability of the subsoil. Therefore the water under the mattress can usually be discharged without excessive lifting pressures on the mattress.

The permeability of the mattress will be lower than the permeability of the subsoil or sub layers if a granular filter is applied, or with a sand or clay subsoil having an irregular surface (gullies/cavities between the soil and the mattress). This will result in excessive lifting pressures on the mattress during wave attack.

Figure 6 Examples of concrete-filled mattresses

Figure 7, Principles of permeability of Filter Point Mattress
4.2 Design rules with regard to wave load

The failure mechanism of the concrete mattress is probably as follows:

- First, cavities under the mattress will form as a result of uneven subsidence of the subsoil. The mattress is rigid and spans the cavities.

- With large spans, wave impacts may cause the concrete to crack and the spans to collapse. This results in a mattress consisting of concrete slabs which are coupled by means of the geotextile.

- With sufficiently high waves, an upward pressure difference over the mattress will occur during wave run-down, which lifts the mattress (Figure 1).

- The pumping action of these movements will cause the subsoil to migrate, as a result of which an S-profile will form and the revetment will collapse completely.

It is assumed that local settlement of the subsoil will lead to free spans of the concrete mattress. Then, the wave impact can cause the breaking of these spans, if the ratio of $H_w/D$ is too large for a certain span length. A calculation method is derived on the basis of an empirical formula for the maximum wave impact pressure and the theory of simply supported beams. The collapsing of small spans (less then 1 or 2 m) is not acceptable, since these will lead to too many cracks.

The empirical formula for the wave impact is (Klein Breteler et al. 1998):

$$\frac{F_{\text{impact}}}{\rho g} = 7.2 \ H_w^2 \ tan \ \alpha$$  \hspace{1cm} (11)

With: $F_{\text{impact}} = \text{impact force per m revetment (N)}$.

Calculation has resulted in an average distance between cracks of only 10 to 20 cm for a 10 cm thick mattress and wave height of 2 m. This means that at such a ratio of $H_w/D$ the wave impacts will chop the mattress to pieces. For a mattress of 15 cm thick and a wave height of 1.5 m the crack distance will be in the order of 1 m.

Apart from the cracks due to wave impacts, the mattress should also withstand the uplift pressures due to wave attack. These uplift pressures are calculated in the same way as for block revetments. For this damage mechanism the leakage length is important.

In most cases the damage mechanism by uplift pressures is more important then the damage mechanism by impact.

The representative/characteristic values of the leakage length for various mattresses can be assumed as follow:

<table>
<thead>
<tr>
<th>Mattress</th>
<th>Leakage length $\Lambda$ (m)</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>on sand $^\text{on}$</td>
</tr>
<tr>
<td>Standard - FP</td>
<td>1.5</td>
</tr>
<tr>
<td>FPM</td>
<td>1.0</td>
</tr>
<tr>
<td>Slab</td>
<td>3.0</td>
</tr>
<tr>
<td>Articulated (Crib)</td>
<td>0.5</td>
</tr>
</tbody>
</table>

$^\text{on}$ good contact of mattress with sublayer (no gullies/cavities underneath)

$^\text{on}$ pessimistic assumption: poor compaction of subsoil and presence of cavities under the mattress
Taking into consideration the above failure mechanisms, the following design (stability) formula has been derived for the mattresses (Eq. 3b):

\[
\frac{H_s}{\Delta D} = \frac{F}{\zeta_{op}^{2/3}} \quad \text{with:} \quad \frac{H_s}{\Delta D}_{\text{max}} = 4
\]

with:

\[
D = \frac{\text{mass per m}^2}{\rho_s}
\]

(which can be called \(D_{\text{effective}}\) or \(D_{\text{average}}\))

\[
\Delta = \text{relative volumetric mass of the mattress (}) = (\rho_s - \rho)/\rho
\]

\[
\rho_s = \text{volumetric mass of concrete (kg/m}^3\)
\]

\[
F = \text{stability factor, see table (-)}
\]

For an exact determination of the leakage length, one is referred to the analytical model (Klein Breteler et al 1998). However, besides the mattresses of a type as, for example, the tube mat (Crib) with relative large permeable areas, the other types are not very sensitive to the exact value of the leakage length. It can be recommended to use the following values of \(F\) in design calculations:

- \(F = 2.5\) or \((\leq 3)\) - for low-permeable mattresses on (fine) granular filter,
- \(F = 3.5\) or \((\leq 4)\) - for low-permeable mattress on compacted sand,
- \(F = 4.0\) or \((\leq 5)\) - for permeable mattress on sand or fine filter \((D_{\text{eff}} < 2 \text{ mm})\).

The higher values can be applied for temporary applications or when the soil is more resistant to erosion (i.e. clay), and the mattresses are properly anchored.
5 STABILITY OF GABIONS

5.1 Introduction

Gabions are made of rectangular baskets of wire mesh, which are filled with stones. The idea of the protection system is to hold the rather small stones together with the wire mesh. Waves and currents would have easily washed away the small stones, but the wire mesh prevents this. A typical length of gabions is 3 to 4 m, a width of 1 to 3 m and a thickness of 0.3 to 1 m. The gabions with small thickness (less than 0.5 m) and large length and width are usually called Reno-mattresses.

An important problem of this protection system is the durability. Frequent wave or current attack can lead to a failure of the wire mesh because of the continuously moving grains along the wires, finally cutting through. Another problem is the corrosion of the mesh. Therefore meshes with plastic coating or corrosion resistant steel are used. On the other hand the system is less suitable where waves and currents frequently lead to grain motion.

5.2 Hydraulic loading and damage mechanisms

Wave attack on gabions will lead to a complex flow over the gabions and through the gabions. During wave run-up the resulting forces by the waves will be directed opposite to the gravity forces. Therefore the run-up is less hazardous than the wave run-down.

Wave run-down, as it was already mentioned in Section 2, will lead to two important mechanisms:

• The downward flowing water will exert a drag force on top of the gabions and the decreasing freatic level will coincide with a downward flow gradient in the gabions.

• During maximum wave run-down there will be an incoming wave that a moment later will cause a wave impact. Just before impact there is a ‘wall’ of water giving a high pressure under the point of maximum run-down. Above the run-down point the surface of the gabions is almost dry and therefore there is a low pressure on the gabions. The interaction of high pressure and low pressure is shown in Figure 1.

A simple equilibrium of forces leads to the conclusion that the section from the run-down point to the freatic line in the filter will slide down if:

• if there is insufficient support from gabions below this section

• if the downward forces exceed the friction forces: (roughly) \( f < 2 \tan \alpha \)

with: \( f \) = friction of gabion on subsoil; \( \alpha \) = slope angle.

From this criterion we see that a steep slope will easily lead to the exceeding of the friction forces, and furthermore a steep slope is shorter than a gentle slope and will give less support to the section that tends to slide down.

Hydrodynamic forces, such as wave attack and current, can lead to various damage mechanisms. The damage mechanisms fall into three categories:

1. Instability of the gabions
   a) The gabions can slide downwards, compressing the down slope mattresses
   b) The gabions can slide downwards, leading to upward buckling of the down slope mattresses
   c) All gabions can slide downwards
   d) Individual gabions can be lifted out due to uplift pressures

2. Instability of the subsoil
   a) A local slip circle can occur, resulting in a S-profile
   b) The subsoil can wash away through the gabions

3. Durability problems
   a) Moving stones can cut through the mesh
   b) Corrosion of the mesh
   c) Rupture of the mesh by mechanical forces (vandalism, stranding of ship, etc.).
5.3 Stability of gabions under wave attack

An analytical approach of the development of the uplift pressure in the gabions can be obtained by applying the formulas for the uplift pressure under an ordinary pitched block revetment, with as leakage length: $\Lambda = 0.77 D$.

With this relation the stability relations according to the analytical model are also applicable to gabions. Substitution of values, which are reasonable for gabions, in the stability relations according to (CUR/CIRIA 1991) provides stability relations which indeed match the a line through the measured points.

After complicated calculations the uplift pressure in the gabions can be derived (Klein Breteler et al, 1998). The uplift pressure is dependent on the steepness and height of the pressure front on the gabions (which is dependent on the wave height, period and slope angle), the thickness of the gabions and the level of the freatic line in the gabions. It is not dependent on the permeability of the gabions, if the permeability is larger then the subsoil.

The equilibrium of uplift forces and gravity forces leads to the following (approximate) design formula (Eq. 3b):

$$\frac{H_s}{\Delta D} = F \cdot \xi_{op}^{2/3}$$

with $6 < F < 9$ and slope of 1:3 ($\tan \alpha = 0.33$)

with: $H_s$ = significant wave height of incoming waves at the toe of the structure (m)
$\Delta$ = relative density of the gabions (usually: $\Delta \approx 1$)
$D$ = thickness of the gabion (m)
$F$ = stability factor (-)
$\xi_{op}$ = breaker parameter (-) = $\tan \alpha / \sqrt{(H_s/(1.56T_p^2))}$
$T_p$ = wave period at the peak of the spectrum (s)

It is not expected that instability will occur at once if the uplift pressure exceeds the gravity forces. On the other hand, the above result turns out to be in good agreement with the experimental results.

Figure 9: Summary of test results ((Ashe 1975) and (Brown 1979)) and design curves
The experimental verification of stability of gabions is rather limited. Small scale model tests have been performed by Brown (1979) and Ashe (1975), see Figure 9.

5.4 Motion of filling material

It is important to know if the filling material will start to move during frequent environmental conditions, because it can lead to rupture of the wire mesh. Furthermore the integrity of the system will be effected if large quantities of filling material is moved.

During wave attack the motion of the filling material usually only occurs if $\xi_{op} < 3$ (plunging waves). Based on the Van der Meer's formula for the stability of loose rock (CUR/CIRIA, 1991) and the assumption that the filling of the gabion will be more stable then loose rock, the following criterion is derived (Van der Meer formula with permeability factor: $0.1 < P < 0.2$; number of waves: $2000 < N < 5000$; and damage level: $3 < S < 6$):

$$\frac{H_s}{\Delta_f D_f} = \frac{F}{\sqrt{\xi_{op}}} \quad \text{with} \quad 2 < F < 3 \quad (14)$$

with: $H_s =$ significant wave height of incoming waves at the toe of the structure (m)

$\Delta_f =$ relative density of the grains in the gabions (usually: $\Delta \approx 1.65$)

$D_f =$ diameter of grains in the gabion (m)

$F =$ stability factor (-)

$\xi_{op} =$ breaker parameter (-) = $\tan\alpha/\sqrt{(H_s/(1.56 T_p^2))}$

$T_p =$ wave period at the peak of the spectrum (s)

6 CONCLUSIONS

Alternative systems can be a good and mostly cheaper alternative for more traditional materials/systems. These new systems deserve to be applied on a larger scale.

The newly derived design methods and stability criteria will be of help in preparing the preliminary alternative designs with these systems. However, there are still many uncertainties in these design methods. Therefore, experimental verification and further improvement of design methods is necessary. Also more practical experience at various loading conditions is still needed.

Abstract

This paper describes the results of a nationwide inventory of the stability of existing placed block revetments in the Netherlands. The inventory is now complete at a basic level: the revetments have been tested using simple stability criteria. These criteria are described in this paper and the main results of the inventory are presented and discussed.

Introduction

In coastal engineering much emphasis is placed on designing coastal structures and description of the physical behaviour of these structures. It is less common to evaluate the actual performance of existing coastal structures in view of today's safety standards and today's knowledge.

In the Netherlands a nationwide inventory of the stability of the existing 8 million square metres of placed block revetments has been performed. This paper is about the reasons why, the methods used and the results.

The paper will start with a short historic overview. This historic overview will eventually lead to the current legal framework, which prescribes a periodical testing of the safety of water-retaining structures. The testing of placed block revetments is only a small part of this procedure. Four failure mechanisms have been tested: migration of sublayers, geotechnical stability, stability of the top layer and residual strength of the sub-layers. A short description of the failure mechanisms and the testing method for each failure mechanism is included.

After that the results of the inventory are presented and discussed. As it will appear, remedial actions are necessary. The actions which are currently being undertaken will be described.
**Historic overview**

Since approximately the 13th century the Dutch have been building dikes to protect the hinterland from flooding. With increasing water levels and subsidence of the land nowadays huge bodies of sand and clay are necessary to provide protection against storm surges and high water levels.

The outer slope of the dikes along the coast, the estuaries, inner lakes and tidal rivers is subject to wave attack. In history several methods, including wooden piles and rip-rap, have been used to stop erosion of the outer slope of the dike. Due to a limited availability of sufficient quantities of rip-rap within transportation distance, a system in which the stones were placed by hand in a closed pattern came into use. In recent years, natural stone is more and more replaced by concrete elements, which can be placed by machines, but the principle remains the same. This type of slope protection is called a placed block revetment. Among other types of slope protection, placed block revetments are now commonly found in the Netherlands.

In 1953 a major storm (a once per 200 years storm) occurred, and large areas in the South Western part of the Netherlands were flooded. Although many dikes were breached or suffered severe damage, almost all stone revetments in the tidal zone survived this event. After 1953 it was understood that one of the main reasons of the storm disaster was the fact that the dikes were not high enough to withstand extreme storm surges. A new philosophy, based on statistic evaluation of water levels, prescribed that the dikes should be high enough and strong enough to withstand water levels and storm conditions with a recurrence period of 1,250, 2,000, 4,000 or even 10,000 years, depending on the economical value of the protected area. As a result of this new safety standard most dikes had to be improved, which meant that the crest height had to be raised considerably and that the dike slopes had to be flattened. Most of these reinforcement works have taken place in the sixties and seventies. An example of a cross-section of a dike before and after reinforcement is given in Figure 1.

![Figure 1 Cross-section of a dike before and after reinforcement](image)
In Figure 1 it is shown that in 1953 in the tidal zone natural stones placed on a filter layer were present. In many cases this part of the revetment survived the storm and can still be present. During the reinforcement works new slope protection, often consisting of blocks on placed directly on clay, was used to protect the higher part of the slope up to the storm surge level. In the example given in Figure 1, the old dike has been damaged severely by overflow of water and subsequent erosion. However, there are also large stretches in which the original clay dike is still present today. The meaning of this fact will become apparent later in this paper.

It is fair to say that most placed block revetments have been constructed based mainly on experience, without the present day knowledge. Without design rules, only the local experience could be taken into account. If a certain location proved to be damaged frequently during seasonal storms, this revetment would be replaced by another type of revetment or by thicker stones of the same type. However, experience normally does not exceed a period of for instance 30 to 50 years.

Since approximately 1980 fundamental research into the stability of placed block revetments is being performed. New design methods are based on the results of this fundamental research. The new design criteria are such that a once per for instance 2000 years or 4000 years storm has to be withstood. That there is a gap between experience (i.e. a period of 30 to 50 years) and the scientific approach (thousands of years) seems obvious. In the following the consequences will become clear.

**Legal framework**

In 1993 and 1995 the Netherlands experienced high and sometimes critical river water levels. It appeared that there was sometimes a lack in maintenance, especially regarding dike height. This has lead to a speed up of new legislation that has two purposes:

1. existing structures have to be tested for their ability to perform their task of retaining water during extreme conditions. If necessary, the structures have to be improved to meet today's safety standards.
2. the required level of safety has to be maintained by a periodical testing of these structures.

The testing procedure is such that all known failure mechanisms have to be taken into account. Examples are overflow and overtopping due to insufficient dike height, dike failure due to a large scale slip circle failure of the soil body and so on. The failure mechanism of inundation due to failure of the slope protection is another example.
Among technicians, the general feeling was that extrapolation from experience (i.e. conditions that occur in a period of maximum 100 years) to conditions that occur only once every 4000 years would lead to the conclusion that in many cases the stability of existing placed block revetments would be insufficient. Some case studies confirmed this expectation. That was the reason why the Dutch Ministry of Transport and Public Works commissioned Delft Geotechnics to carry out an inventory of the stability of existing placed block revetments in the Netherlands.

**General testing procedure**

There are several levels at which the stability of revetments can be tested (see also Figure 2):

- the basic level, using for instance results of large scale model tests or rules of thumb as a reference to recognize evidently safe and evidently insufficiently safe revetments and exclude them from further testing. Note that in this black box approach there is a large range of uncertainty.
- for the 'doubtful' revetments the possibility of detailed testing is open. Detailed testing consists in large lines of two components: one has to know more about the construction and an analytical method instead of the black box model is used to test the stability.
- if there remains doubt an advanced testing procedure is started: the most sophisticated means and expertise can be used and a numerical model can be used to evaluate the stability. Bezuijen (Bezuijen, 1998) describes the results of the experience with case studies.

The inventory of existing revetments has at this moment only been completed at the basic level.

![Figure 2 Different levels of testing](image-url)
Elements of the testing procedure for placed block revetments

The placed block revetments are tested on four different failure mechanisms. These mechanisms are described in the following four paragraphs. In Figure 3 a scheme showing the procedure is given.

In the first step experience plays an important role in the procedure. A 'safe' result of the testing procedure can only be obtained if all criteria regarding the geotechnical stability, the migration of sublayers and the stability of the top layer are met. If the stability of the top layer is insufficient, but there is sufficient residual strength, the result is 'sufficiently safe'. This is not an ideal situation, because during extreme conditions the top layer will be damaged, and will have to be replaced.

Figure 3  Scheme of testing placed block revetments
Geotechnical stability

One failure mechanism is geotechnical instability. As shown in Figure 4, water pressures on the outside of the construction differ from the internal water pressures inside the core of sand. Close beneath the surface these differences can be so extreme that locally the soil stability is lost and a shallow slide failure takes place. Figure 5 shows a schematic presentation of a slide failure of the subsoil.

Figure 4 Components of loads and structure

Figure 5 Slide failure of the subsoil
This type of failure is less likely to occur if the slope angle is less steep or the weight of the top layers, including filter layer and clay layer, increases. Therefore, if one of the two following conditions is true, there is no risk of a slide failure due to pressure differences:

- if the slope is less steep than 1 : 4 and there are no indications from practice that indicate possible problems, or:
- if the slope is less steep than 1 : 3 and the thickness of the top layers (blocks, filter and/or clay) is larger than 1.2 m.

If these conditions are not met, the simple testing method provides graphs in which the pressure differences in the subsoil are compared to the weight of the top layers which is required to prevent the subsoil from sliding. The outcome is dependent on wave height, wave steepness, slope angle and sand grain size. If there still remains doubt, a more sophisticated analysis is required, see for instance (Bezuijen, 1991).

Migration of sublayers

The second failure mechanism is migration of sublayers. Sub-layers can be either the filter material, sand from the core or clay beneath the blocks. Migration of sublayers can be described as the washing out of filter material, sand or clay from beneath the blocks, thus causing settlement of the blocks and a decrease in stability. The basic level of testing is therefore to see whether or not settlement of blocks has taken place. If this is not the case, and the revetment has been placed more than 5 years ago, apparently migration of sublayers is not a big problem. When in doubt, the normal rules regarding filter layer stability or sand and clay tightness of geotextiles can be applied for blocks placed on a filter layer and sand.

Experience shows that for blocks placed on clay, migration of the clay from beneath the blocks is always a problem. In a period of five to ten years holes and channels with dimensions of centimetres or even decimetres have been discovered beneath the blocks. As these holes and channels increase, the stability of the top layer decreases. This is one of the reasons why blocks placed directly on clay, which has been used frequently in the Netherlands in the sixties and seventies, nowadays proves to be an unfavourable construction. If this construction is to be used at all, a geotextile should be applied to prevent erosion of the clay.

Stability of the top layer

The stability of the top layer is governed by the wave conditions on one side, and the weight of the blocks and the permeabilities of top layer and sublayers on the other hand. There are several publications describing these relationships, for instance (Bezuijen, 1996) and (Pilarczyk, 1998). These relationships have been extensively investigated and are well understood. Large scale model tests have been
used to verify the modelling and the design criteria. At the basic level of testing only the results of these large scale model tests are used to evaluate the stability of existing revetments. Figure 6 shows an example of a testing graph, that can be used to determine which revetments are evidently safe and revetments which are evidently not safe. On the x-axis the wave breaking parameter $\xi$ is given. On the y-axis the ratio between wave height and weight of the top layer is set out. This is a simple black box approach. Between safe and not safe there is a large range of doubtfull stability. Revetments which end up in this doubtfull range require further investigation to reach a final score.

![Testing Graph for Top Layer Stability](image)

Figure 6 Example of testing graph for top layer stability

In (Stoutjesdijk, 1992) and (Stoutjesdijk, 1996) it is stated that physical properties of constructions 'in the field' can differ quite dramatically from those of newly build constructions of large scale model tests, due to aging effects. Such an aging effect is for instance the fact that in the tidal zone both the filter layer and the top layer have been washed in with sand, silt, shells and other material. As also discussed in (Bezuijen, 1998) it is difficult to test these aged constructions. The
testing graphs are based on model tests and can not be used for aged revetments. However, in 1998 large scale model tests have been performed on constructions which have been deliberately filled with a clayey material to simulate aged constructions in the tidal zone. These tests indicate that the stability of these revetments is not less than that of a new revetment. On the other hand it is at this moment not possible to prove that aged revetments are more stable than new revetments. However, as long as the stability of revetments does not decrease with age, it is possible to test aged constructions the same way as new constructions.

**Residual strength and safety**

Once the top layer has failed there may be a residual strength, because clay may be able to some extent to resist wave attack. As far as we know right now, clay layers of small thickness (less than 0.8 m) dry out and crack. This is a process that progresses in time. Therefore the resistance to wave attack of clay on existing revetments is small. If however a large body of clay, for instance the remains of an old clay dike form part of the existing dike, the residual strength may be sufficient to resist the design storm.

The best reference for the erosion resistance of clay are large scale model tests, performed in the Delta Flume of Delft Hydraulics in 1993. The clay for these tests has been cut out of existing dike slopes. Because of drying out and cracking of the clay, the residual strength proved to be limited: a layer of 0.8 m clay showed progressive damage within a matter of hours with a significant wave height of 1.5 m.

The testing method compares the period that the clay layer is exposed to wave attack, with the residual strength of clay, which is expressed in terms of 'the period during which a clay layer of certain thickness can resist wave attack'. It appears that the thickness of the clay layer is an important quantity. As the thickness increases, the drying out and cracking of the clay is less pronounced and therefore the erosion resistance increases. This thought has already lead to the idea of using very thick clay layers or clay layers under flat slopes as a revetment type instead of a hard defence such as a placed block revetment.

A validated model for the erosion process of clay under wave attack is not yet available, and therefore detailed testing of this aspect is not possible.

**Results of the inventory**

A total of 8 million square metres of placed block revetments has been tested at the basic level. Figure 7 gives a bar chart with the main result. Almost a quarter of these revetments proved to be evidently unsafe. About one third was evidently safe. The rest, almost half of the surface will have to be further investigated to come to a final conclusion.

This further investigation will take place in the coming years. If we
speculate on the final outcome of this further investigation it may well be the case that approximately half of all existing revetments proves to be insufficiently safe and will have to be improved.

![Graph showing the results of the inventory](image)

**Figure 7 Main result of the inventory**

Based on these results an estimation of the expected cost of remedial actions has been made. A total amount of about half a billion US dollars should be spent to improve the existing revetments.

**Discussion of results**

These results at first sight seem startling. However, on second sight the result is much as should be expected in view of the historic facts. Most existing revetments have been constructed based on experience only, without the design aids available today. Today's safety standards have been raised much higher than in the past, because of new ways of thinking about safety and increasing economical activities behind the dikes. Only about the last two decades the fundamental knowledge regarding the stability of revetments has been developed. If we add up all these factors it seems no more than logical that existing revetments may well be insufficient regarding today's standards.

Another point to consider is that the inventory at this point in time has only taken place at the basic level. Further investigation at a detailed and advanced level may lead to somewhat different views. Furthermore we have to be conscious of the fact that today's knowledge is not perfect either. For instance, there is a large activity in the area of calculating the correct wave conditions for testing of revetments, we do not know enough about interaction between blocks and we can until today not specify the influence of aging
on the stability of revetments.

Despite all these considerations it is demonstrated clearly by this inventory that the testing of existing coastal structures against today's safety standards can be a useful action. In the Netherlands this testing is now prescribed by law, probably as the first country in the world. It can be stated that this idea represents a rational approach towards safety, and it is necessary to accept the consequences of the transition to this new philosophy. It is fair to say that, after spending a lot of money, the safety against flooding in the Netherlands will have been increased to a significantly higher level. This would never have been reached without this action.

**Remedial actions**

At the moment several actions are being taken by Rijkswaterstaat, the Dutch Ministry of Public Works:

- clearly insufficient revetments are being improved. The entire operation will take 10 to 15 years to be completed
- detailed and advanced testing of doubtful revetments will take place in the coming years. This means that the exact parameters in the field will have to be determined to allow a more sophisticated evaluation of the stability of these revetments
- fundamental research is being performed to provide as much of a contribution as possible on sharper testing procedures and ways to facilitate detailed and advanced testing.
- large scale model tests at the Delta flume of Delft Hydraulics are being performed (see Figure 8). Most of these tests concern possible remedial alternative revetment types (Klein Breteler, 1998), but also for instance aged constructions are part of the investigation.

![Figure 8](image.png) Large scale model test on aged placed block revetment
Conclusion

As it appears today, we are faced with a substantial problem. The challenge is to contribute as much as possible to the solution. The final statement is that, although the inventory of existing structures has brought to light significant problems regarding the stability of placed block revetments, the outcome of this action will be that safety has been brought in accordance with today's demands. It is better to know of a problem and be able to solve it, than not to know there is a problem until it's too late. Therefore the concept of evaluating existing coastal structures with the present day knowledge and testing them against current safety standards should be whole-heartedly supported.

SECOND ORDER WAVE INTERACTION
WITH A LARGE STRUCTURE
Bjarne Büchmann *, Jesper Skourup ^ and David L. Kriebel

Abstract
Wave diffraction around a large vertical circular bottom mounted cylinder is considered. Results from a 3D second-order numerical time domain Boundary Element Model, a 3D second-order semi-analytical frequency domain model and experiments are compared and show good agreement over a wide range of wave frequencies and wave steepnesses. In general the agreement between the calculated and experimental results is satisfactory even in some cases where second-order Stokes' wave theory is not a priori expected to provide accurate results. The two numerical models have thus been validated against each other and validated against experiments. It is noted that the inclusion of second-order effects is important for the accurate estimation of run-up on a structure.

1 INTRODUCTION
Wave interaction with a large cylindrical structure is considered. The Keulegan-Carpenter number is small and thus inertial effects are dominant. Hence, potential theory can be applied. Conventional methods for estimating the influence on the wave field due to the presence of a large structure are often based on linear wave theory. However, second-order effects may be important and can lead to a significant increase of e.g. the run-up on a structure when compared to run-up calculated using linear theory. In the present paper a 3D time domain Boundary Element Model (BEM) correct to second order (see Büchmann et al., 1998) is used for simulating the three dimensional interaction between waves and a structure. Comparisons are made with the run-up envelope results from the second-order semi-analytical frequency domain model by Kriebel (1990) as well as with experimental results by Kriebel (1992) for all the test cases considered by Kriebel (1992). Comparisons are also made to the well known first-order solution by MacCamy and Fuchs (1954) (see Skourup and Bingham, 1996, for further first order comparisons.)

2 Numerical models

The BEM is formulated and implemented up to second order with the wave steepness as perturbation parameter. The kinematic and dynamic free surface conditions are Taylor expanded about the mean free surface position and perturbation expansions are applied to the free surface elevation and to the velocity potential there. Hence, the boundary value problem is formulated at each order in a time-invariant geometry. The velocity potential and the free surface elevation are separated into incoming (known) and scattered components, and the boundary value problem at each order is then solved for the scattered parts alone. The scattered waves are all outgoing (of the domain) and the lateral boundary conditions can thus be formulated as radiation conditions. In the present work the lateral boundaries are modeled as active wave absorbers (as known from physical wave tank facilities). These may be used in combination with a sponge layer on the free surface in order to ensure an efficient absorption over a wide range of wave frequencies. Further details about the model can be found in Skourup (1996) and in Büchmann et al. (1998).

A closed-form frequency domain solution correct to second order for the diffraction of Stokes waves around a large vertical circular bottom mounted cylinder is given by Kriebel (1990). At first order the solution corresponds to the usual linear diffraction theory. At second order, however, the solution consists of a combination of forced waves due to the non-linear wave–wave interaction of the first order incident and scattered waves, and free waves due to the interactions of the forced waves with the cylinder. Further details about this semi-analytical frequency domain model can be found in Kriebel (1990, 1992).

3 Study parameters

Since both the numerical time domain model and the semi-analytical frequency domain model employ a Stokes’ expansion method on the non-linear free surface conditions, it is expected that both models are limited to waves of small to medium wave steepness. Thus, it is appropriate to compare the wave steepness used in the experiments to the maximal wave steepness for the given frequency and water depth. Fenton (1990) gives a rational-function approximation for this maximum wave height by fitting to numerical results for progressive waves of maximum steepness.

\[
\frac{H_{\text{max}}}{h} = \frac{0.141063 \frac{L}{h} + 0.0095721 \left( \frac{L}{h} \right)^2 + 0.0077829 \left( \frac{L}{h} \right)^3}{1 + 0.078340 \frac{L}{h} + 0.0317567 \left( \frac{L}{h} \right)^2 + 0.0093407 \left( \frac{L}{h} \right)^3}
\]

Here \( H \) is the wave height, \( L \) is the wave length and \( h \) is the water depth. As a measure of the non-linearity of the wave the relative wave steepness, \( S \), i.e. the wave steepness relative to the maximum steepness, can be introduced as

\[
S(k, H) = \frac{kH}{(kH)_{\text{max}}} = \frac{H}{H_{\text{max}}}
\]

where \( k = 2\pi/L \) is the wave number.

It is well known that a secondary crest appears in the trough of the primary wave when Stokes’ second-order theory is used for very steep waves. This is often used as an upper
limit to this theory by imposing a "no secondary crest" condition. For progressive waves
of permanent form the condition can be written as

\[
\left( \frac{H}{L} \right)_{\text{max}} = \frac{1}{4f_\eta(kh)} , \quad f_\eta(kh) = \frac{\pi}{4} (3 \coth^3 k h - \coth k h)
\]  

(3)

see e.g. Svendsen and Jonsson (1980) for details. Equivalently the ratio, \( a^{21} \), between the
second-order wave amplitude and the linear wave amplitude can be used to limit the theory.
The "no secondary crest" condition then corresponds to \( a^{21} < 0.25 \). For progressive Stokes
waves of permanent form \( a^{21} \) is

\[
a^{21} = \frac{1}{8} k H (3 \coth^3 k h - \coth k h)
\]  

(4)

It should be noted that the second-order Stokes' progressive wave theory may show consid-
erable error when compared to e.g. the stream function wave theory even without violating
the limit \( a^{21} < 0.25 \).

For a blunt body in waves a partially standing wave system is located in front of the struc-
ture. Thus it may be more appropriate to use the "no secondary crest" condition for Stokes'
second-order standing waves as an upper limit. The criterion for plane standing waves is
somewhat more restrictive than for progressive waves, especially in deeper waters, and can
be expressed as e.g.

\[
\left( \frac{H^{(s)}}{L} \right)_{\text{max}} = \frac{1}{4f_\eta^{(s)}(kh)} , \quad f_\eta^{(s)}(kh) = \frac{\pi}{4} (3 \coth^3 k h - \coth k h + 2 \coth 2 k h)
\]  

(5)

where \( H^{(s)} \) is the height of the incident wave.

It is evident that numerical models based on Stokes’ theory should not be employed to
model waves in the cnoidal wave regime. The Ursell parameter \( U = HL^2 / h^3 \) can be
used as an indication of the wave regime. Thus, for \( H/h \) larger than, say, 10% an Ursell
parameter \( U = 40 \) can be used to divide the Stokes’ waves regime from the cnoidal waves
regime.

The Keulegan-Carpenter number, \( KC \), is an important parameter for indication of the rela-
tive importance of viscous effects. A value of \( KC \) less than about two to three indicates that
viscous effects are not of importance for wave–structure interaction. Using linear Stokes
theory at the mean water level to predict the maximum horizontal velocity, \( u_{\text{max}} \), \( KC \) can
be written on the form

\[
KC = \frac{u_{\text{max}} T}{2a} = \frac{\pi}{2} \frac{k H}{k a \tanh k h}
\]  

(6)

where \( T \) is the wave period and \( a \) is the radius of the cylinder.

4 Experiments

Kriebel (1992) conducted a series of experiments to find the run-up around the circumfer-
ence of a vertical circular bottom mounted cylinder in various regular wave conditions. A
A definition sketch showing the geometry and main variables is given in Figure 1. The test conditions ranged from fairly low wave steepness to very steep waves where wave breaking around the cylinder was observed. In some cases super-critical run-up occurred in the form of a vertical jet on the cylinder. Since the potential theory models considered in this work are limited to non-breaking waves, these test cases are not considered in detail here. Also in the cases where breaking was observed in the experiments the agreement between the two second-order numerical models is good, but the results deviate significantly from the results found in the experiments.

In Table 1 the parameters for the test cases considered are given. In addition to parameters mentioned previously, the ratio of the cylinder diameter, $D$, to the wave length is also given:

$$D/L = ka/\pi$$  \hspace{1cm} (7)

It is noted from Table 1 that the Keulegan-Carpenter number $KC$ is small in all the test cases considered. Thus, it is expected that inertial effects are predominant and potential theory can be applied.

To give an overview of the range of wave conditions used, a scatter diagram of the wave height relative to the water depth against the wave length relative to the water depth is

Figure 1: Definition sketch.
depicted in Figure 2. It is noted that the waves are very close to breaking in a few of the cases. In the cases used in this work (shown with squares) the relative wave steepness, $S$, varies from 15% to 72% (see also Table 1). It is noted that the “no secondary crest” condition for progressive second-order Stokes waves (3) is violated in three of the test cases used, while in many of the cases this limit is exceeded using the standing wave criterion (5). Thus it is clear that in many of the test cases it would be appropriate to use a model based on a Stokes theory of order larger than two, or even a model based on a fully non-linear wave theory. Therefore, the present study also gives indications of the validity range of the two numerical models.

5 RESULTS

Using the time domain BEM the influence on the wave field due to the presence of a fixed structure is computed as mean values over some wave periods. The parts of the time series where initial conditions or reflections from the lateral boundaries can be seen are not used. The run-up on a bottom mounted vertical circular cylinder is calculated in this paper, but this specific shape of the structure is not a restriction to the BEM. The wave run-up is

Table 1: Parameters for the test cases used in this work, and thus also the experiments conducted by Kriebel (1992). The figure numbers correspond to the figures in this work. An asterisk denotes an experiment where wave breaking or vertical jetting was observed.
computed correct to second order by first solving the linear problem and then using this result as input to the second-order problem. The linear results are compared with the well known linear diffraction theory solution by MacCamy and Fuchs (1954), while the second-order results are compared with the semi-analytical solution and with experimental results – both by Kriebel (1992). All the test cases from Kriebel (1992) have been reproduced in the present work and good agreement is found between the results of the two numerical models for all cases considered here. (see Figures 3 to 8). In the figures the BEM results for the linear run-up are shown with dashed lines and the second-order run-up with solid lines. The analytical linear run-up (i.e. the MacCamy and Fuchs solution) is shown with crosses and the second-order semi-analytical solution with diamonds. Experimental results are shown with squares. Due to symmetry only the run-up around half the circumference of the cylinder is depicted.

The agreement between the two linear solutions is excellent for all cases considered. For the maximum run-up on the cylinder the difference between the results of the present linear time domain BEM and the ditto analytical solution is less than 0.5%.

The agreement between the BEM and the semi-analytical second-order run-up by Kriebel (1992) is also good. It can be seen for all cases that the second-order wave run-up is sig-

![Figure 2: Scatter diagram of the experiments by Kriebel (1992) used in this work (○) and experiments with observed wave breaking or vertical jetting (•). Also shown is the highest wave (Fenton, 1990) (—), the limit for Stokes' second-order progressive waves (---), the limit for Stokes' second-order standing waves (···), and the Ursell number \( U = 40 \) (---).](image)
significantly larger than the linear wave run-up. For assessment of wave overtopping or deck
slamming on gravity-based bottom mounted structures this is of significant importance.

The experimental results by Kriebel (1992) show larger run-up both on the front and on the
lee side of the cylinder than predicted by linear theory. Thus significant non-linear diffrac-
tion effects are represented in the experimental data. The second-order results compare
reasonably well with the experiments in all but the most severe cases (see Figs. 4d-e, 5d-e
and 7b). It should be noted that in all these latter cases the “no secondary crest condition”
for second-order standing waves (5) has been violated.

A vertical cross-section of a wave envelope in the direction of the main wave propagation
direction is shown in Figure 9 as an example of the good agreement between the 3D BEM
and the semi-analytical second-order solution in the fluid domain away from the cylinder.
The cross-section is taken along the x-axis, i.e. with y = 0 (see Fig. 1.) It is noted from
the figure that the agreement is good even though a fairly small computational domain has
been used for the time domain BEM.

6 CONCLUSIONS

A comparison has been made between the 3D second-order time domain Boundary Element
Model by Bührmann et al. (1998) and the second-order semi-analytical frequency domain
solution by Kriebel (1990) for calculation of run-up on a large vertical circular bottom
mounted cylinder. Good agreement has been found between results from the two models.

Comparison between the second-order results and the experimental results by Kriebel
(1992) show reasonably good agreement except in cases with strongly non-linear waves.
By comparing with solutions of the linear wave diffraction problem, it is demonstrated
that second-order effects are important for assessment of e.g. wave overtopping or deck
slamming on gravity based bottom mounted structures.

ON THE EFFECT OF 2-LAYER THICKNESS BY HIGH-SPECIFIC GRAVITY ARMOR BLOCKS ON WAVE REFLECTION

Masahiro ITO¹, Yuitch IWAGAKI², Hiroshi MURAKAMI³, Kenji NEMOTO⁴, Masato YAMAMOTO⁴ and Minoru HANZAWA⁴

Abstract

High-specific gravity (HSG) armor blocks have high stability for waves compared with the same size blocks made with normal concrete. Since an armor layer constructed with HSG armor blocks is thinner than the equivalent layer built with normal concrete, it is expected that it will produce significantly higher wave reflection. The goal of the present study is to investigate experimentally the effect of a double layer of HSG tetrapods (referred to as 2-tetrapod layer) on wave reflection. During the tests, regular waves were generated against a breakwater covered with the 2-tetrapod layer, and wave reflection was recorded for several layer thicknesses. Six sizes of tetrapod models were used ranging from 3.1 to 16.6 cm in vertical height, i.e., the 2-tetrapod layer thickness varied from 5.2 to 22.5 cm. Based on the laboratory test data, the effect of the layer thickness on wave reflection was examined using dimensionless factors derived from dimensional analysis. It was concluded that wave reflection increases as the specific gravity of armor blocks becomes larger, in a manner that depends on the deep water wave steepness.

Introduction

Normal concrete armor blocks have been widely used in many countries as armor units or construction units for wave absorbing works, detached breakwaters, artificial reefs, and so on. Armor blocks stable weight against wave action has been usually evaluated by Hudson’s formula. Yet the use of armor blocks is a difficult technique associated with a number of typical problems and weak points. Here are some of them:

1. Armor blocks positioning vs wave action:
   ① Armor blocks are subjected to the combined action of waves and wave-induced currents on the seaward slope and at the crest of breakwaters, groins, wave absorbing works, submerged breakwaters, and artificial reefs. Corners at the sea side front of reclaimed lands also experience complex wave actions.
   ② In the swash zone, in front of breakwaters, armor blocks may be entrained due to the multiple effect of wave breaking, runup and backwash.

2. Use in construction:

2.1 The construction area for the armor blocks casting yard and for the armor layer is usually limited in size.

2.2 Large scale manufacturing devices are difficult to transport in remote places such as distant detached islands.

3. Sea-landscape and coastal structures:

3.1 Harmony between natural beaches and coastal structures requires a good balance between armor block size and natural beach scale.

High-specific gravity (HSG) armor blocks can provide very effective solutions to these problems compared with normal concrete blocks {unit weight: 22.54kN/m$^3$ (2.3tf/m$^3$)}. Given the design wave height and the angle of the armor layer slope relative to the horizontal, coastal structures made with HSG concrete blocks are more compact and smaller in size.

Authors (1994) analyzed the effect of a change of specific gravity on the stability of armor blocks relative to wave action. Results are based on a series of laboratory tests conducted with tetrapod models. It was found that a scaling effect prevails in tests carried out at small or medium scale, which is not accounted for by Hudson’s formula. Yet, once corrected for this effect, the formula can be applied to evaluate the stable weight of HSG armor blocks. If the same wave acts against both normal concrete blocks and HSG concrete blocks, the latter can be smaller in size. Thus, at the scale of the incident waves, the thickness of a layer of HSG concrete blocks appears relatively thin. Indeed, the change of relative armor layer thickness has a considerable influence on wave reflection from armored coastal structures.

About ten years ago, Chevalier at SOGREAH Co. Ltd. in France (1994) developed the Accropod, not only aimed at protecting the slope-surface of breakwaters made with rubble stones and at absorbing the waves, but also designed to present high stability for waves when used in single armor layers. Turk and Melby (1994) at CERC, USA developed the Core-Loc that has also high stability for wave action under a single armor layer. Thus, new types of armor blocks are successively developed by seeking stability for waves, economical efficiency and ease of construction. These high-performance armor blocks are designed to be used in a single layer. Therefore, wave reflection and wave runup cannot be neglected when these blocks are made out of HSG concrete, because the absorption of incident wave energy becomes increasingly worse as the layer thickness decreases.

However, current investigations in this field are incomplete. It is the goal of this study to measure experimentally wave reflection from 2-tetrapod layers under the action of regular waves. The effect of a change of layer thickness is examined by using tetrapods of different sizes. Dimensionless hydraulic parameters such as relative water depth at the toe of the structure, deep water wave steepness, and relative 2-tetrapod layer thickness are used to analyze the data and to discuss the characteristics of wave reflection.
Dimensional Analysis on Wave Reflection

(1) Dimensional Analysis

We examine the effect of a change of specific gravity of armor blocks on wave reflection from an armor layer by means of dimensional analysis. Considering the 2-D case of a wave striking perpendicularly a seawall covered with a 2-tetrapod armor block layer, wave reflection from the seawall is expected to be dependent on the following hydraulic parameters.

a) Armor blocks characteristics
   - $B_{th}$; 2-tetrapod layer thickness
   - $Br$; methods of placement
   - $B_\epsilon$; porosity
   - $B_u$; under layer roughness (crushed stone or smooth surface)
   - $\theta$; angle of armor layer slope, measured from the horizontal

b) Properties of Waves
   - $h$; water depth at the toe of the structure covered with armor blocks
   - $H$; wave height
   - $T$; wave period
   - $\rho$; mass density of water
   - $\mu$; viscosity of water
   - $g$; gravitational acceleration

The reflection coefficient $K_r$ is expected to be a function of these eleven hydraulic parameters:

$$K_r = f \left( h, H, T, \mu, \rho, g, B_e, B_{2h}, B_T, B_u, \tan \theta \right)$$

In dimensionless form, this equation becomes

$$K_r = \left[ \frac{h}{H}, \frac{T}{\sqrt{gh}}, \frac{\sqrt{gh} \cdot H}{\nu}, \frac{B_{2h}}{H}, B_e, B_T, B_u, \tan \theta \right]$$

The right hand second term in Eq.(2), $T/\sqrt{gh}$, is rewritten as $L/H$, using the relationship, $L=\sqrt{gh} \cdot T$. This dimensionless parameters $L/H$ represents the deep water wave steepness. The right-hand second term, divided by the fourth term, becomes

$$\frac{T}{\sqrt{gh}} \propto \frac{\sqrt{gh} \cdot T}{B_{2h}}$$

which can be rewritten as $UT/B_{2h}$ is possible to rewrite as $UT/B_{2h}$, because the term $\sqrt{gh}$ has the dimension of a velocity and is a direct function of the particle
velocity $U$ induced by the waves. This term has the form of a $KC$ number, which is a dimensionless number relating to the generation and separation of eddies. More precisely, the right-hand second term of Eq. (2) can be considered as the $KC$ number based on wave characteristics and layer thickness. Also, multiplying the third term by the fourth term, we obtain

$$\frac{\sqrt{gh} \cdot H}{\nu} = \frac{\sqrt{gH} \cdot B_{2h}}{\nu}$$

(4)

which is the Reynolds number based on wave celerity and layer thickness. So far, we can see that several choices of dimensionless parameters are permitted and Eq. (2) may take the equivalent form:

$$K_r = \int_3 \left[ \frac{h}{L} \cdot \frac{L}{H} \cdot \frac{\sqrt{gH} \cdot T}{B_{2h}}, \frac{B_{2h}}{L}, \frac{\sqrt{gH} \cdot B_{2h}}{\nu}, B_7, B_8, B_9, \tan \theta \right]$$

(5)

In these laboratory tests, tetrapods are randomly placed and the under layer is made out of crushed stone. Therefore, $B_7$ and $B_8$ may be considered as constant and disregarded. The porosity rate $B_8$ is measured by a submerging method. A box-type basin (90cm wide x 100cm long x 50cm high) is used for this purpose. The method consists of filling the basin with water up to the top level of the tetrapods placed randomly on its base. This test is performed with a series of tetrapod models ranging from 3.0 to 16.0cm in vertical height. Porosity values are summarized in Table 1. They vary from 53% to 63% but only tetrapods of 3.1cm height have a porosity of 53%. Taking into account the size of the tetrapods and the accuracy of the present method, we may consider that the scattering of porosity is small and that the porosity term in Eq. (2) can be omitted. Furthermore all tests are carried out with the same breakwater slope: $\tan \theta = 3/4$, so that this term can also be neglected. Taking wave characteristic parameters in deep water as a reference, the dimensionless expression of the reflection coefficient reduces to

From Eq. (6) we can see that the reflection coefficient is governed by four factors only: the relative water depth $h'/L_o$, the deep water wave steepness $H_o/L_o$, the relative armor layer thickness $B_{2h}/H_o$, and the Reynolds number $\sqrt{gH_o \cdot B_{2h}/\nu}$.

**Laboratory Tests**

The laboratory tests for wave reflection were performed in the same basin that was already used for stability tests (Ito et al. 1994). This wave basin is divided into seven flumes by separating walls. The breakwater models which were set to measure wave reflection were constructed within every other flume. They were covered with two layers of tetrapods (referred to as 2-tetrapod layer), placed randomly over an underlayer of crushed stone. The sea-side slope was set to 1V:4/3H. During the laboratory tests, tetrapods were covered by a steel net to prevent accidental displacement due to wave action. Recall that the purpose of the tests is to measure wave reflection in terms of the 2-tetrapod layer thickness only, not including any entrainment by the waves. In order to absorb multiple wave reflections between breakwaters and wave paddle, a slope of 1V:10H was constructed with wave absorbing net-mats within every intermediate flume, i.e. in those flumes where no breakwaters were installed. With this method, stable wave conditions could be sustained for long durations in the flumes with breakwaters, and it is there that wave reflection was recorded. Test conditions are summarized in Table 2. As shown in this table, six sizes of tetrapod models were investigated: 3.1, 5.8, 7.8, 10.5, 14.2 and 16.6cm in vertical height. Time histories of the wave profile, in which the incident wave and the wave reflected from the 2-tetrapod layer overlap, were recorded by a wave meter at the toe of the slope of the breakwater. These analog data were converted to numerical data by an A to D board converter connected to a personal computer. The reflection coefficient was computed from the incident reflected waves separation method proposed by Goda et al. (1976). During the entire duration of the tests, flow characteristics such as nonbreaking waves,

collapsing or surging breakers, as well as plunging breakers were also recorded visually along the slope of the 2-tetrapod layer.

Relationship between Relative Layer Thickness and Specific Gravity

(1) Armor block size

Hudson (1959) made comprehensive investigations and proposed a formula to determine the stability of armor units on rubble structures. The stability formula resulted from extensive model testing, in the form:

\[ W = \frac{w_r H^3}{K_D (S_r-1)^3 \cot \theta} \]  

where

- \( W \): weight of an individual armor unit
- \( w_r \): unit weight of armor unit
- \( H \): design wave height
- \( S_r \): specific gravity of armor unit to water (=\( w_r/w_w \))
- \( w_w \): unit weight of water
- \( \theta \): angle of the breakwater slope measured from the horizontal, in degrees
- \( K_D \): stability coefficient of an armor unit

Given \( H, K_D, \) and \( \tan \theta \), we shall consider the relationship between the weight of an armor block, \( W \), and its characteristic height \( l \). Without loss of generality, this relationship may be expressed as

\[ W = k l^3 w_r \]  

Where, \( k \) is a constant. Using Eq. (8), Eq.(7) becomes

\[ l^3 k = \frac{H^3}{K_D (S_r-1)^3 \cot \theta} \]  

Now, let's denote \( l_n \) and \( l_h \), \( S_n \) and \( S_h \) the characteristic heights and the specific gravities of blocks made out of HSG concrete and normal concrete, respectively. Eq. (9) can be rewritten, for each type of block, as:

\[ l_n^3 k = \frac{H^3}{K_D (S_n-1)^3 \cot \theta} \]  

\[ l_h^3 k = \frac{H^3}{K_D (S_h-1)^3 \cot \theta} \]  

From Eq. (10) and Eq. (11), assuming the design wave height to be a constant and taking a value of \( S_r=2.3 \) for the specific gravity of normal concrete, the size of any HSG block relative to a normal concrete block, \( l_h/l_n \), can be expressed as
It can be seen from that equation that the block size ratio \( l_h/l_n \) is inversely proportional to the high-specific gravity of concrete in water, \( S_{l-1} \). The block size ratio is indicated by a thick solid line in Fig. 1. The case of sea water is also considered and represented by a dashed line. As can be deduced from this figure, the difference between fresh water and sea water is very small. The ratio of the stability weights \( W_h/W_n \) is also sketched in this figure by a solid line and a dashed line, for fresh water and sea water, respectively. This ratio decreases as the 3rd-power of the specific gravity in water as can be deduced from Eq. (7).

\[
\frac{l_h}{l_n} = \frac{S_{l-1}}{S_{h-1}} = \frac{1.3}{S_{h-1}} \tag{12}
\]

(2) Relative Armor Layer Thickness

As discussed in the previous section, the relationship between the size of the armor blocks and their specific gravity was derived from Hudson's formula. We shall now examine the relationship between the 2-tetrapod layer thickness and the specific gravity of armor units. Let's define the relative layer thickness by the ratio of the 2-tetrapod layer thickness to the design wave height. From Eqs. (10) and (11), the following relationship is obtained

\[
\frac{l^3}{H^3} = \frac{1}{K_D (S_{r-1})^3 \cot \theta} \tag{13}
\]

The relative armor layer thickness \( B_a/H \) may be assumed to be proportional to \( l/H \), where \( l \) is the height of a single armor block. Then,
From Eqs. (13) and (14),

\[
\frac{B_{2h}}{H} \propto \frac{l}{H}
\]

(14)

\[
\frac{B_{2h}}{H} \propto \frac{1}{(K_D \cot \theta)^{1/3} (S - 1)}
\]

(15)

Kb and \( \tan \theta \) being usually constant, it can be seen from Eq(15) that the relative layer thickness is inversely proportional to the specific gravity in water, \( S - 1 \). Given the design wave height, it is possible to evaluate the stability weight of tetrapod (\( K_D = 8.3 \)), for various specific gravities, by using Hudson's formula. From the specific gravity and the stability weight, the 2-tetrapod layer thickness \( B_{th} \) can be estimated; it is commonly taken as \( 4/3 \) of the tetrapod height. Define the relative layer thickness \( B_{th}/H \) as the ratio of the 2-tetrapod layer thickness to the design wave height. \( B_{th}/H \) can be considered as the relative layer thickness under critical conditions. It is interesting to derive the critical layer thickness, \( B_{th}/H \), for several sizes of tetrapods. Results are summarized in Table 3 which indicates, for each size of tetrapod, the design wave height and the relative layer thickness, for four values of the specific gravity \( S = 2.3, 2.7, 3.0 \) and \( 3.5 \), respectively. In this table, the designed wave height is derived from Hudson's formula, and the relative layer thickness is obtained from the design manual published by TETRAPOD Co., Ltd. Note, from this table, that the relative layer thickness is nearly independent on the tetrapod size. As listed in Table 3, the values of \( B_{th}/H \) = 0.70, 0.54, 0.45 and 0.36 depend only on the specific gravity \( S \). Block size ratios are indicated with circle marks in Fig.1. As can be seen in this figure, for a high-specific gravity of \( S = 3.5 \), block size is reduced by a factor of two compared to normal blocks \( (S = 2.3) \). As expected, values of the relative layer thickness derived in Table 3 are in the same ratio.

\( H \) : Design wave height ( based on \( K_D = 8.3 \) )

\( B_{th}/Hc \) : Relative two tetrapods layers thickness
Fig. 2 Relationship between wave reflection and relative 2-tetrapod layer thickness

Fig. 3 Effect of deep water wave steepness on the relationship between wave reflection and relative 2-tetrapod layer thickness
Relative Armor Layer Thickness and Wave Reflection

(1) Wave Reflection

We classified the data according to the ratio of the 2-tetrapod layer thickness to the wave height at the toe of the seawall, \( \frac{B_{th}}{H} \), corresponding to the term \( \frac{B_{th}}{H_o} \) in Eq. (6), and plotted them in Fig. 2. As shown in this figure, the relationship between the reflection coefficient \( K \) and the relative layer thickness \( B_{th}/H \) scatters widely. In this figure, dark circles denote reflection from a smooth slope. Data points were obtained by covering the sea-side slope of the seawall with a steel plate; this corresponds to the case where both armor layer thickness and underlayer porosity are zero. We investigated the effect of the relative water depth \( d/L_o \) on the relationship between \( K \) and \( B_{th}/H \), by plotting data according to the parameter \( d/L_o \). The effect of \( d/L_o \), however, couldn't be found; data points remain widely scattered. In a similar way, we examined the effect of the Reynolds number, \( \sqrt{gh_o \cdot B_{th}^2}/\nu \); the effect of the Reynolds number couldn't be found either. Then, by separating the data into seven range-values of the deep water wave steepness, \( H_o/L_o = \sim 0.005, \ 0.005 \sim 0.015, \ 0.015 \sim 0.025, \ 0.025 \sim 0.035, \ 0.035 \sim 0.045, \ 0.045 \sim 0.055 \) and \( 0.055 \sim \), the relationship between the reflection coefficient and the relative layer thickness was rearranged, as displayed in Fig. 3 (for the sake of clarity, only three values of \( H_o/L_o \) have been represented). It can be deduced, from this figure, that the deep water wave steepness strongly affects the relationship between \( K \) and \( B_{th}/H \). Here again, reflection from a smooth slope is indicated with dark circles, as a reference. In each subfigure, Fig. 3(a) to Fig. 3(c), the trend of the reflection coefficient is shown by fitting the data with a solid curve. The relationship between \( K \) and \( B_{th}/H \) is rearranged in Fig. 4 by plotting all solid curves together in the same graph, based on the parameter \( H_o/L_o \). Each value of \( H_o/L_o \) is the mean value of another range of wave steepnesses examined. Dashed lines stand for estimates of the reflection coefficient where experimental data couldn't be obtained. It can be seen in this figure that the relationship between \( K \) and \( B_{th}/H \) changes considerably depending on \( H_o/L_o \).

(2) Wave reflection for storm waves

From this diagram, characteristics of wave reflection, when the design wave acts on the 2-tetrapod layer, can be analyzed. Since the relative layer thickness \( B_{th}/H \), which depends on the specific gravity of armor units only, is already given in Table 3, Fig. 4 can be used directly to derive the reflection coefficient from the wave steepness. For this purpose, values of the relative layer thickness \( B_{th}/H \) have been represented with vertical dashed lines in Fig. 4. The reflection coefficient is easily obtained by reading the \( K \) values at the intersection between these vertical lines and the solid curves of wave steepness \( H_o/L_o \). From these \( K \)-values, it is possible to evaluate the increasing rate of wave reflection \( (K)_{hc}/(K)_{nc} \) when HSG tetrapods are used rather than normal concrete tetrapods. Fig. 5(a) indicates the relationship between \( (K)_{hc}/(K)_{nc} \) and the specific gravity in water, \( S-1 \), according to the parameter \( H_o/L_o \). As can be seen in this figure, for armor blocks designed to sustain the same critical wave height, wave reflection becomes bigger as tetrapod...
Fig. 4 Relationship between wave reflection and relative 2-tetrapod layer thickness, based on the deep water wave steepness

(a) In case of the design wave height       (b) In case of half of the design wave height

Fig. 5 Increase of relative wave reflection for increasing values of specific gravity
specific gravity gets larger. Fig. 5(a) also shows that this increase is proportional to specific gravity, with a rate that depends strongly on the parameter \( H_s/L_o \).

(3) Wave reflection for mild waves

As mentioned in the previous section, the effect of HSG tetrapods on wave reflection was analyzed using the design wave height, which corresponds to the strongest waves the tetrapods are able to resist and which may, in practice, represent storm waves. Now we shall also examine the increase of wave reflection under the condition of mild waves. This condition is set by taking half of the design wave height for the estimate of the reflection coefficient from Fig. 4. The same graphical method is used with values of the relative thickness \( B_{th}/H \) simply doubled. As for the previous case, the rate of wave reflection, \( (K)_{th}/(K)_{nc} \) is plotted in terms of the specific gravity of tetrapod in water, in Fig. 5(b). From this figure, it can be seen that for mild waves too, the rate of reflection increases proportionally to the specific gravity of the blocks.

For both storm waves, Fig. 5(a), and mild waves, Fig. 5(b), the amount of reflection tends to increase with the specific gravity of the tetrapods. Yet, the rate of increase is strongly affected by the deep water wave steepness. As the wave becomes steeper, and as long as the wave steepness remains within the range \( 0.005<H_s/L_o<0.04 \) (storm waves) and \( 0.005<H_s/L_o<0.05 \) (mild waves), the rate of increase tends to become larger. Above these values, i.e. for steeper waves, it shows the opposite tendency and drops. In the case of blocks of HSG \( S=3 \), the reflection coefficient for storm waves is from 1.07 to 1.22 times bigger than the reflection coefficient for normal concrete (from 1.09 to 1.27 times bigger for mild waves), depending on the wave steepness.

Conclusions

This study was intended to investigate experimentally the effect of a change of specific gravity of armor blocks on wave reflection using tetrapod units. From the results of this work, the following conclusions can be drawn:

(1) Given the specific gravity of armor units in water, the relative 2-tetrapod layer thickness, \( B_{th}/H \), is a constant, regardless of the tetrapod weight and of the design wave height.

(2) Given the design wave height, the relative layer thickness, \( B_{th}/H \), is inversely proportional to the specific gravity of armor units in water.

(3) The relationship between the reflection coefficient and the relative layer thickness is considerably affected by the deep water wave steepness.

(4) The reflection coefficient for high-specific gravity concrete blocks relative to the reflection coefficient for normal concrete blocks increases proportionally to the specific gravity, in a manner that depends on the deep water wave steepness.

(5) For both storm waves and mild waves, the larger the specific gravity of the blocks, the bigger the reflection coefficient.

DEVELOPMENT OF TWO-DIMENSIONAL NUMERICAL WAVE FLUME FOR WAVE INTERACTION WITH RUBBLE MOUND BREAKWATERS

Peter Troch\textsuperscript{1}, Julien De Rouck\textsuperscript{2}

Abstract

The numerical wave flume VOFbreak\textsuperscript{2} for simulation of wave interaction with a rubble mound breakwater is presented. The key innovations are a porous flow model and wave boundary conditions. The porous flow is implemented using a Forchheimer model. At the boundaries waves are generated using a combined wave generation-absorption technique and are absorbed using a numerical sponge layer.

1 Introduction

A 2D numerical model for the simulation of free surface breaking waves at permeable coastal structures is developed at the Department. This numerical wave flume VOFbreak\textsuperscript{2} aims at a better description of the wave-induced flows and pressures at porous structures, resulting in a better design (tool) of coastal structures. Special attention is paid to the application of the model to wave interaction with a rubble-mound breakwater. Fig. 1 shows a snapshot of the simulation of a typical numerical wave flume set-up where waves interact with the porous breakwater.

Fig. 1. Snapshot of a typical numerical simulation of wave interaction with a rubble mound breakwater using VOFbreak\textsuperscript{2}.

\textsuperscript{1} Research Assistant, Dept. Of Civil Engineering, University of Gent, Technologiepark 9, B-9052 Gent, Belgium. Email: PeterB.Troch@rug.ac.be.

\textsuperscript{2} Professor, Dept. Of Civil Eng., University of Gent, Technologiepark 9, B-9052 Gent, Belgium.
First the underlying mathematical and numerical models of VOFbreak are presented briefly. Secondly the key innovations in the numerical wave flume that are necessary for simulation of wave interaction with permeable rubble mound structures are discussed in more detail: a porous flow model and wave boundary conditions. Finally an example application illustrates the model features.

2 Numerical wave flume VOFbreak

2.1 Mathematical model
The numerical wave flume VOFbreak, VOF-algorithm for breaking waves on breakwaters, is based on the original SOLA-VOF code (Nichols et al., 1980) capable to compute free surface flow when the fluid domain becomes multiply connected. Incompressible Newtonian fluid with uniform density is assumed in the vertical plane (two-dimensional), governed by the Navier-Stokes equations:

\[
\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \nu \left( \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) + g_x
\]

(1)

\[
\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} = -\frac{1}{\rho} \frac{\partial p}{\partial y} + \nu \left( \frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} \right) + g_y
\]

(2)

and the continuity equation:

\[
\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0
\]

(3)

where \( t \) (s) is time, \( u \) and \( v \) (m/s) are the velocity components in \( x \) and \( y \) direction respectively, \( p \) (N/m\(^2\)) is pressure, and \( g_x \), \( g_y \) (m/s\(^2\)) are horizontal and vertical gravity components respectively, \( \rho \) (kg/m\(^3\)) is the density of the water, \( \nu \) (m\(^2\)/s) is the kinematic coefficient of viscosity.

The free surface is described by introducing a function \( F(x, y, t) \) that represents the fractional volume of fluid in the mesh cells. The volume of fluid evolution equation (4) expresses that the volume fraction \( F \) moves with the fluid:

\[
\frac{\partial F}{\partial t} + u \frac{\partial F}{\partial x} + v \frac{\partial F}{\partial y} = 0
\]

(4)

2.2 Numerical model
Finite difference solutions of the four unknowns \( u, v, p \) and \( F \), are obtained on an Eulerian rectangular mesh in a Cartesian co-ordinate system (x,y).

The Navier-Stokes equations (1)-(2) are discretised using a combined FTCS/upwind scheme. As a result, explicit approximations of the Navier-Stokes equations are used to compute the first guess for new-time-level velocities.
To satisfy the continuity equation (3), i.e. to obtain a divergence free velocity field, the pressure-velocity iteration is used. It is a variant of the Newton-Raphson relaxation technique applied to the pressure Poisson equation for incompressible flow. Using this method, pressures are iteratively adjusted in each cell and velocity changes induced by each pressure change are added to the velocities computed out of the Navier-Stokes equations.

Finally, the volume of fluid function $F$, defining the fluid regions, is updated using the donor-acceptor flux approximation for the calculation of fluxes from a donor cell to an acceptor cell. A unit value of $F$ corresponds to a full cell, while a zero value indicates an empty cell. Cells with values between zero and one and having at least one empty neighbour cell contain a free surface. A line is constructed in each surface cell with the correct calculated surface slope and correct amount of fluid lying on the fluid size, and is used as an approximation to the actual free surface.

2.3 Code portability
The code VOFbreak\textsuperscript{2} is based on SOLA-VOF (Nichols et al., 1980) and includes some selected improvements from its successor code NASA-VOF2D (Torrey et al., 1985). These are mainly a numerical defoamer technique preventing non-physical voids inside the fluid to appear, and fixes in the donor-acceptor algorithm.

The code is implemented on a UNIX workstation using ANSI C, providing general computer compatibility, and providing a flexible code structure for adaptations with little effort. A series of post-processing tools has been developed, using Tcl/Tk (Ousterhout, 1994), for the visualisation, processing and interpretation of the computed results. Numerical instrumentation for the acquisition of relevant phenomena (wave height, run-up level, pore pressure, surface elevation, ...) is included for easy access to calculated data.

3 Porous flow model
A breakwater is composed of a porous core, and porous filter and armour layers, which are made using coarse granular material. For a simulation of wave induced porous flow, this material is considered homogeneous and isotropic within areas where one characteristic porosity $n$ and one characteristic diameter $d$ are assigned. Following assumptions are used for porous flow:

- The discharge (or filter) velocity $u$, in x direction, is replaced by the pore (seepage) velocity $u_p = u/n$; regarded as a macroscopic quantity, i.e. the discharge velocity is averaged over a cross sectional area consisting of a mixture of material and voids. The porosity $n$ of the cell material is defined as the ratio between the volume of the pores and the total volume.

- The F-function is now considered as the fraction of maximum volume of fluid in a cell.

- The Forchheimer resistance terms replace the viscosity terms in the Navier-Stokes equations, these are expressed by the hydraulic gradient $I$ (-), e.g. in x direction (Burcharth et al., 1995):
\[
I = -\frac{1}{\rho g} \frac{\partial p}{\partial x} = au + buu + \frac{c}{\partial t}
\]

where the Forchheimer coefficients \(a\) and \(b\) take the form:

\[
a = \alpha \frac{(1-n)^2}{n^3 \gamma d^2} \frac{v}{\rho g d^2}
\]

\[
b = \beta \frac{1-n}{n^3} \frac{1}{\rho g d}
\]

and the inertia coefficient \(c\) takes the form:

\[
c = \frac{n + (1-n)C_m}{g}, \text{ where } C_m = 1 + C_A
\]

where \(\alpha\) and \(\beta\) are dimensionless constants, \(v\) (m\(^2\)/s) is the kinematic coefficient of viscosity, \(g\) (m/s\(^2\)) is the gravitational acceleration, \(n\) (-) is the porosity, \(d\) (m) is a characteristic stone diameter, \(C_A\) (-) is the added mass coefficient.

The linear term \(au\) in equation (5) constitutes the contribution from the laminar flow. The non-linear term, \(bu|u|\), represents the fully turbulent flow contribution. The term \(c \partial u/\partial t\), taking into account the inertia forces connected with the local accelerations \(\partial u/\partial t\), represents the resistance of the porous medium to accelerate the water.

A verification of the implementation of the one-dimensional porous flow in steady state flow conditions has been carried out by comparing numerical calculated results to experimental measurements (Troch, 1997).

4 Wave Boundary Conditions

4.1 Introduction
In Fig. 2 a conventional numerical wave flume set-up is given. Waves are generated at the left boundary of the computational domain and propagate towards a rubble mound breakwater positioned near the other boundary. The incident waves interact with the porous breakwater causing transmitted and reflected waves to propagate towards the boundaries. At the boundaries, an 'open boundary' or 'absorbing boundary' condition is required, allowing the transmitted and reflected waves to leave the computational domain without disturbing the interaction of the incident waves with the breakwater.
The numerical problem is similar to the wave absorption problems in a physical wave flume. Therefore in principle the same solutions could be applied in the numerical flume. Schäffer and Klopman (1997) give an overview of the basic concepts of wave absorption in physical wave flumes.

However in order to increase the computational efficiency of the calculations a number of constraints are present. These are very important in the final choice of the numerical wave boundary conditions. A very important constraint is that the length of the numerical wave flume should be as short as possible for reasonable CPU time. Therefore the numerical wave flume requires a relatively short foreshore (1 or 2 wavelengths), and a very short lee-side (maximum 1 wavelength). The wave absorption techniques need to perform in these conditions. Also an efficient and simple technique that absorbs waves numerically might be more favourable than the numerical simulation of the physical behaviour of e.g. a progressive wave absorber.

The generation of incident waves is implemented in VOFbreak\textsuperscript{2} using boundary generation. Any wave theory can be used to provide the surface elevation $\eta(x_0, t)$ and the velocity components $u(x_0, z, t)$ and $v(x_0, z, t)$ at the left boundary ($x_0=0$). For the simulations in this paper linear wave theory is used. Another efficient wave generation technique is source generation (Brorsen and Larsen, 1987) where the volume from the incident wave is added inside the computational domain. The advantage of this latter method is that the generation of the incident waves is not disturbed by the reflected waves. The disadvantage is that the length of the computational domain is considerably increased because a relatively long absorption layer is required for absorption of the reflected waves at the boundaries. Iwata et al. (1996) have successfully implemented the source generation technique in a SOLA-VOF model. The absorption layers required up to 6 wavelengths for sufficient wave absorption.

The wave absorption generally is divided into active systems and passive systems. An active system provides an active response to the waves; a passive system damps (mostly by energy dissipation) the wave motion. For this application, the transmitted waves are passively absorbed using an efficient numerical sponge layer technique.
from Larsen and Dancy (1983). This passive absorption system is discussed in more detail in the next section. The reflected waves are actively absorbed at the wave-generating boundary using an active wave absorption technique. A detailed discussion of the active system performance in the VOFbreak$^2$ model is described in Troch and De Rouck (1998).

4.2 Numerical Sponge Layer
Larsen and Dancy (1983) presented an efficient numerical passive wave absorber for use in short wave models. This technique is implemented into the VOFbreak$^2$ model. It has been chosen because of its very elegant and simple use. An absorption function $a(x)$ is applied on velocities and elevation in a numerical sponge layer with length $x_s$, Fig. 3. The absorption function at the start of the sponge layer equals 1 and gradually decreases to 0 near the end of the sponge layer. The sponge layer is located at the closed end of the wave flume. Only a limited number of grid cells is required for absorption of the wave.

![Fig. 3. Numerical sponge layer with width $x_s$ placed at the end of the numerical wave flume. The two absorption functions $a(x)$ are plotted inside the sponge layer.](image)

Two simple absorption functions have been used for testing the performance of the sponge layer technique: an elliptic function $a_1(x)$ (equation (9)) and a cosine function $a_2(x)$ (equation (10)):

$$a_1(x) = 1 - \left( \frac{x - x_1}{x_s} \right)^2$$

$$a_2(x) = 0.5 \left[ 1 + \cos \left( \frac{\pi}{x_s} (x - x_1) \right) \right]$$
The absorption function is applied on the calculated velocity components in the cells of the sponge layer after each time step calculation. In the present simulations no attempt has been made to apply the absorption function on surface elevations. The surface elevation is not a direct unknown of the system of differential equations (1)-(4), but is derived from the F function in each column of cells. A damping of the surface elevation means deleting volume fractions and doing this without adjusting the pressure consequently in each cell would lead to non-converging solutions.

The performance of the two types of sponge layer has been tested by deriving reflection ($K_r$) and transmission ($K_t$) coefficients from a sponge layer located inside the numerical wave flume. The water depth $d = 0.40$ m, the wave height $H = 0.02$ m, the wave period $T = 1.60$ s. The width of the sponge layer varied between 40% and 60% of the wavelength $L = 2.84$ m. The results are summarized in Table 1.

<table>
<thead>
<tr>

<td>0.60</td>
<td>33</td>
</tr>
</tbody>
</table>

*Table 1. Reflection ($K_r$) and transmission ($K_t$) coefficients from sponge layer performance tests.*

The elliptic absorption function $a_1$ with a length $x_s = 0.40L$ still has a considerable reflection coefficient of 27% and transmission coefficient of 7%. Increasing the sponge layer width to 0.60L decreases reflection to about 20% and almost no transmission (3%). In comparison the cosine absorption function with a width of 0.60L still shows 33% reflection but no transmission.

It is concluded from these simple performance tests that the elliptic $a_1$ type function performs better than the cosine $a_2$ type. A slightly larger width $x_s$ of the sponge layer would be required for practical purposes: it is suggested to use a width between 0.60L and 1.0L. It is noted that the absorption function not necessarily should equal 0 at the end of the sponge layer, it is more important to have a gradually decrease causing least reflection of the waves. In order to decrease the number of cells in the sponge layer it might be preferable to increase gradually the cell width towards the boundary.

There are other solutions available to obtain an open boundary.

- The well-known radiation boundary (also referred to as the Sommerfeld or the weakly reflecting boundary (used e.g. in the SKYLLA model, van der Meer et al., 1992) is another efficient solution. This method might become elaborate when working with irregular waves.
- Modelling of a spending beach with a mild slope (1:10 or more) would require a long distance to be modelled. This solution is not efficient for use in a numerical flume.

- Modelling of a physical progressive passive wave absorber with decreasing porosity would need a comprehensive description of geometry, porous flow characteristics, etc. Also for the physical performance of this solution it is required to go through the full model equations resulting in a longer calculation time.

- An active wave absorption system (see next section for more details) provides an active response at the boundary to the transmitted wave leaving the domain. It generally is used at the wave generating boundary in combined wave generating-absorbing mode, but the system is usable for wave absorption only. This solution is very elegant, but more complicated to implement in the numerical model than the sponge layer.

4.3 Active wave absorption system

The active wave generating-absorbing system implemented in the numerical wave flume is based on the AWASYS system (Frigaard and Christensen, 1994) from Aalborg University. The AWASYS system originally is a surface elevation based system to be used in a physical wave flume with two conventional wave height meters. The system for VOFbreak is based on a velocity meter based system because velocities are readily (or computationally cheap) available from the computations. Hald and Frigaard (1996) show that the performance (i.e. the absorption characteristics) of both elevations and velocities systems is similar.

Fig 4. Definition sketch of the numerical wave flume set-up and the principle of the active wave generating-absorbing boundary condition.
The principle of the active wave generating-absorbing system requires two steps. First an on-line detection of the reflected wave field is performed using a set of spatially co-located velocities \((u, v)\). Secondly the wave generator has to generate the incident wave and an additional wave which cancels out the reflected wave propagating towards the boundary. Fig. 4 shows schematically the principle of the system. The correction signal \(\eta^*\) that cancels out the reflected wave, is determined from superposition of the two filtered velocity signals \(u^*+v^*\). The digital Finite Impulse Response (FIR) filters are operated using a time-domain discrete convolution of the velocities \((u, v)\) and the impulse response \(h^i\), where \(i = u \text{ or } v\); e.g. for the \(u\) velocity component:

\[
u^*[n] = \sum_{j=0}^{J-1} h^u[j] \cdot u[n - j]
\]

where \(J\) is the number of filter coefficients, and \(u^*[n] = u^*(n \cdot \Delta t_f)\) is the filter output at time \(t = n \cdot \Delta t_f\), where \(\Delta t_f\) is the filter time interval.

Having outlined the principle of the active wave generation-absorption, the only task remains the design of the corresponding frequency response function \(H(f)\) of the filters from where the impulse response function \(h(t)\) is easily derived using inverse Fourier Transform. The theoretical and practical design of the frequency response function for use in a numerical wave flume is described in Troch and De Rouck, 1998.

5 Example application

To demonstrate the possibilities of the VOFbreak\(^2\) model for coastal engineering applications, a simulation of regular waves attacking a conventional rubble mound breakwater with permeable homogeneous core, is given. Fig. 5 is a snapshot during wave run-up and wave run-down respectively, and shows the induced velocity field in front of the breakwater and inside the breakwater core. From the zoomed slope area (Fig. 6) it is seen clearly that the occurring flow pattern cannot be reduced to one dimension. Both infiltration and seepage of pore water arise simultaneously along the slope.

Therefor this type of 2D model is better equipped to simulate wave-structure interaction than one-dimensional models. The model also gives a better insight in the wave interaction dynamics at the breakwater and may be helpful to assist to improve design guidelines.

The numerical model is verified with both physical model data and prototype data. This latter validation is unique world-wide by using the Zeebrugge breakwater (Belgium) prototype wave and pressure data (Troch et al., 1996). Validation results will help to improve further developments of the numerical wave flume.
Fig. 5. Regular incident waves on and in permeable breakwater. Snapshot of calculated free surface location and velocity field during wave run-up (a - top) and run-down (b - bottom).

Fig. 6. Zoom of calculated free surface location and velocity field at the breakwater slope during wave run-up (a - left) and run-down (b - right).

Nonlinear Wave Forces on a Rubble Covered Pipeline

William G. McDougal¹
Norimi Mizutani²
Ayman M. Mostafa³

Abstract

A nonlinear numerical model is developed for the interaction of waves with a pipeline covered with rubble. The wave field utilizes a fully nonlinear potential formulation while the porous medium is governed by modified Navier-Stokes equations. The model employs the BEM in the water column and the FEM in the rubble layer. Wave forces on the pipeline are calculated by integrating pressure around the pipeline perimeter. The numerical and experimental results for the wave kinematics in the pipeline vicinity are found to be in reasonable agreement. Numerical analyse indicate that the horizontal wave force is larger than the vertical force for all tested wave and rubble conditions. Forces increase with increasing wave height and decreasing depth. However, for the cases examined there is an intermediate water depth at $h/L \approx 1/6$ for which the forces are largest. The armor stone size and rubble layer pososity have little influence on the magnitudes of the forces. The horizontal force is nearly independent of the depth of rubble cover over the pipeline. However, the vertical force increases significantly as the depth of cover decreases. Also, for partial pipeline cover, the maximum horizontal and vertical forces are more in phase, which combined with the larger vertical force, results in a substantially less stable condition.

Background

Marine pipelines in nearshore water are often either buried or covered with an armor layer. This reduces the wave forces on the pipeline and the possibility of seabed scour around the pipeline. This may also protect the pipeline from mechanical damage due to anchor drag or fishing nets. In the case of armor protection, little design information is available for estimating the magnitude of wave forces on the pipeline. As a result, designs for large projects are often verified with physical models. During the past few years, several such model studies have been conducted at the O.H. Hinsdale Wave Research Laboratory at Oregon State University. Typical conditions are shown in Figure 1. These pipelines are all outfalls with pipe diameters that range from 1.1m to 3.7m. The protective armor stone diameter ranges from 0.4m to 1.1m. These conditions are representative of outfall conditions on the west coast of the United States. In the physical model tests, typical design concerns include the following: Is the armor stone stable? What is the minimum stable cross-section for the armor? If the pipeline loses weight due to air or gas in the line, is the ballast sufficient to maintain stability? Will the flow around the pipeline and armor induce seabed scour? The objective of the present study is to develop a numerical model to begin to address these issues. At this point in the model development, the intent is not to replace physical model testing, but rather to narrow the range of conditions tested in the laboratory to the most promising alternatives. The numerical model can also be used to provide fast results prior to the experiment at low cost.

The proposed model is a direct extension of previous work by the authors. Mizutani, et al. (1996) developed a coupled BEM-FEM model to study the nonlinear interaction between waves and a submerged breakwater. This model was successful in predicting 2-D wave transformations over a submerged breakwater. Next, Mizutani, et al. (1998) developed a coupled BEM-FEM model for wave, submerged breakwater, and seabed nonlinear interaction. This model incorporated the seabed and the porewater flow. The validity of the BEM-FEM model was demonstrated in comparisons with experimental measurements for a submerged breakwater on a sand seabed. This progression of model development lends itself well to the inclusion of a pipeline within the rubble structure. The objectives of the paper are to develop a numerical model for wave-rubble interaction and wave forces on a marine pipeline.

Figure 2 shows different armor configurations. The pipeline may be wholly buried within the armor layer, partially exposed or heavily exposed. All three are used in practice. The fully covered alternative provides greater protection and stability, but is also more costly. How much the armor section can be reduced is a major consideration in the design. Figure 3 shows nomenclature used to describe the geometry of the armor protection.
Numerical Formulation

The model domain is shown in Figure 4. The free surface is $S_f$, the mudline along the bottom is $S_b$, the surface of the armor is $S_a$, and the pipe surface is $S_C$. In the water column, the fluid is assumed to be inviscid and incompressible and the flow is irrotational. This leads to a formulation based on a velocity potential. Since this is a potential flow formulation, vortex shedding or other dissipation mechanisms are not included in the water column. The governing equations for the wave field are conservation of mass (Laplace Equation) with pressure recovered from the energy equation. The flow in the porous rubble is modeled by conservation of mass and momentum. The porewater is assumed to be viscous and incompressible and the resistance terms in the momentum equation are based on the Forchheimer equation.

Wave Field:

Governing equation:

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial z^2} = q, \quad q(X, Z, t) = U_s(Z, t) \delta X$$

(1)

Boundary Conditions:

$$\frac{\partial \phi}{\partial n} = n_x \frac{\partial \phi}{\partial a} \quad \text{(on } S_f)$$

(2)

$$\frac{\partial \phi}{\partial n} = 0 \quad \text{(on } S_B)$$

(3)

$$\frac{\partial \phi}{\partial n} = V_n \quad \text{(on } S_s)$$

(4)

$$\frac{\partial \phi}{\partial n} + \frac{1}{2} (\nabla \phi)^2 + g \eta + \mu \phi + \int_{x_3}^{x_1} \frac{\partial \mu}{\partial X} dX = 0 \quad \text{(on } S_f)$$

(5)

$$\frac{\partial \phi}{\partial X} = \frac{1}{\sqrt{gh}} \left( \frac{\partial \phi}{\partial a} + \mu \phi + \int_{x_3}^{x_1} \frac{\partial \mu}{\partial X} dX \right) \quad \text{(on } S_L)$$

(6)

$$\frac{\partial \phi}{\partial X} = -\frac{1}{\sqrt{gh}} \left( \frac{\partial \phi}{\partial a} + \mu \phi - \int_{x_3}^{x_1} \frac{\partial \mu}{\partial X} dX \right) \quad \text{(on } S_R)$$

(7)

$$\mu_{max} = (0.25 \sim 0.50) \sqrt{\frac{g}{h}}$$

(8)
in which $\phi =$ velocity potential, $\eta =$ water surface elevation wrt SWL, $n_z =$ outward normal with respect to the $Z$ axis, $V_n =$ velocity component normal to the boundary, $\mu =$ damping factor, $h =$ still water depth, $X, Z =$ horizontal and vertical coordinates, and $t =$ time. An idealized wave tank similar to that of Ohyama and Nadaoka (1991) is adapted to simulate the nonlinear deformations over a marine pipeline.

The numerical solution technique used for the wave field is the boundary element method (BEM). The BEM formulation maps the 2-D problem onto the 1-D boundary. The boundary is discritized using linear elements at a spacing of approximately 20 elements per wave length in the horizontal and 8 elements along the vertical boundaries at the ends of the domain. Typically about 150 boundary elements were employed.

Porous Flow:

Governing equations:

$$\frac{\partial U}{\partial X} + \frac{\partial W}{\partial Z} = 0$$ (9)

$$A \frac{\partial U}{\partial \alpha} + B(U \frac{\partial U}{\partial X} + W \frac{\partial U}{\partial Z}) + C \frac{\partial P}{\partial X} + EU + FU \sqrt{U^2 + W^2} = 0$$ (10)

$$A \frac{\partial W}{\partial \alpha} + B(U \frac{\partial W}{\partial X} + W \frac{\partial W}{\partial Z}) + C \frac{\partial P}{\partial Z} + EW + FW \sqrt{U^2 + W^2} = 0$$ (11)

$$A = \left(1 + \frac{1 - \varepsilon}{\varepsilon} C_a \right) / \varepsilon g, \quad B = 1 / \varepsilon^2 g, \quad C = 1 / \gamma, \quad E = \frac{6(1 - \varepsilon) \nu C D^2}{g \varepsilon^2 D^2}$$

$$F = \frac{C_{sl} (1 - \varepsilon)}{2gD\varepsilon^3}, \quad P = p - \gamma Z \quad \text{(Mizutani et al., 1996)}$$

Boundary conditions:
\[ P = -\rho \frac{\partial \phi}{\partial t} - \frac{\rho}{2} \left( \frac{V_n}{\varepsilon} \right)^2 + V_s^2 - \gamma Z \quad \text{(on S\_G)} \]  
\[ V_n = W \cos \theta \pm U \sin \theta \quad \text{(on S\_G)} \]  
\[ V_s = \frac{\partial \phi}{\partial S} \quad \text{(on S\_G)} \]  
\[ V_n = 0 \quad \text{(on S\_C)} \]

in which \( U, W \) = horizontal and vertical seepage velocities, \( P \) = total pressure, \( p \) = dynamic pore pressure, \( \varepsilon \) = porosity, \( C_a \) = added mass coefficient, \( g \) = acceleration of gravity, \( \nu \) = kinematic viscosity of water, \( \gamma \) = unit weight of water, \( D \) = stone diameter, \( \theta \) = side slope angle, \( C_{D1}, C_{D2} \) = drag coefficients, and \( A, B, C, D, E, F \) are notational constants.

The rubble flow model is solved using the finite element method (FEM). Since there are internal variations in the flow properties and dissipation, the rubble problem does not conveniently map to a boundary and must be solved in 2-D. The fundamental unknowns are \( U, W, \) and \( P \). These are approximated using isoparametric finite elements. The flow in the rubble includes nonlinear dissipation through the Forchheimer resistance terms.

On the surface of the pipeline, the normal component of velocity is zero. The forces are calculated by integrating the pressure around the pipeline. The force does not include drag. As a result, the solution is most appropriate for large diameter pipelines in which the forces are diffraction dominated. On the surface of the rubble, the pressure and normal fluid flux from the BEM and FEM solutions are required to match. This matching couples the two solution domains. This leads to a large matrix in which the upper left corner is densely populated (the BEM part), the lower right part is sparsely populated (the FEM part) and the off diagonal corners are zero. The form of this matrix allows the use of efficient matrix algorithms. The equations are integrated in time by explicit finite difference. The time step varies from 7724 to 77144 depending upon the degree of nonlinearity in the problem.

This formulation is well suited for the present application. It is reasonably efficient, but includes nonlinear terms at the free surface and in the rubble matrix. The formulation is less suitable for breaking waves, but the application of the model is intended for pipelines outside of the surf zone where breaking is less significant. The model can also be modified to include the influence of wave angle. In this paper, only waves which have crests parallel to the pipeline are considered. In practice, there are many cases where the wave crests are nearly perpendicular to the pipeline.
Physical Model Tests

Several pipeline stability tests have been conducted at the Oregon State University Wave Research Laboratory. Tests were conducted in the large wave flume which is 104m long, 3.7m wide, and 4.6m wide. Simple periodic, random, nonbreaking, and breaking wave conditions have been examined. The model is typically placed near the center of the flume at an orientation to simulate the prototype conditions. Figure 2 gave examples of three tested configurations. Incident and reflected waves are determined using a Goda wave gage array. The transmitted wave height and fluid velocities in the vicinity of the structure are also measured. The stability of the armor is monitored with underwater video. A variety of parameters are varied including the wave conditions, stone size, rubble geometry, and buoyancy of the pipeline.

Table 1 gives several predicted and measured results for the horizontal velocity. Laboratory results are for an 11.4 cm diameter pipe in 158 cm of water armored with 2cm stone. Two wave height conditions are given which differ by approximately a factor of 2; 25.3cm and 54.3cm. Figure 5 shows numerical model results for the horizontal velocity computed for these conditions. These two cases span a range from nearly linear to nonlinear wave conditions. In general, the agreement is reasonable; but as indicated by these examples, the variation can be as much as 30%.

Results

Figure 6 shows the horizontal and vertical forces for a fully buried pipeline and a partially exposed pipeline. The gap at the beginning of the runs is the time required for the waves to propagate from the generation boundary to the pipeline. Result are shown for time durations of 6 and 8 wave periods. The numerical computations remained stable beyond this time. The horizontal force is much less
than the vertical force and is approximately 90° out of phase for the fully buried case. For the partially exposed case, the horizontal force has increased slightly, but the vertical force has increased significantly. The phase difference between the two forces is approximately 60°. For the partially exposed case, there is an increase in the magnitude of the vertical force and the maximum horizontal and vertical forces are closer in phase. As a result, the partially exposed pipeline is much less stable.

Figure 7 shows the pressure field in the rubble around the pipeline and Figure 8 shows the porewater velocity. At this phase, the pressure gradient drives a flow in the direction of wave propagation. The resulting flow is accelerated around the pipeline and may be constricted beneath the pipeline if the clearance above the seabed is small.

The numerical model provides an opportunity to efficiently determine the sensitivity of the pipeline force to wave and rubble conditions. The base conditions for this sensitivity analysis are given in Table 2. First the wave height, period, and depth are considered. Figure 9 shows the dimensionless horizontal and vertical forces on the pipeline as a function of the wave height. The forces are scaled by the weight density of the water, the wave height, and the pipeline diameter. It is seen that this linear scaling captures the wave height dependency over a range of conditions. Figure 10 shows the influence of the wave period on the pipeline forces. There is an intermediate period for which the forces are a maximum. This period corresponds to a dimensionless water depth of $h/L \approx 1/6$ for this particular rubble geometry. The figure shows both the positive and negative forces. The horizontal forces are generally larger in the direction of wave propagation and this difference increases as the waves become more nonlinear. The upward vertical forces are larger than the downward forces. The influence of the water depth is shown in Figure 11 and is as anticipated, the deeper the water, the smaller the forces. The horizontal forces scale as approximately $1/h$ for these shallow to intermediate depth conditions.

Three rubble parameters are examined, the porosity of the rubble matrix, the stone diameter, and the depth of burial of the pipeline. Porosities from $\varepsilon = 0.24$ to 0.40 were examined and found to have little influence on the magnitude of the forces. The stone diameter also has very little influence on the forces on the pipeline. The influence of depth of burial is shown in Figure 12. The results indicate that the horizontal force is not strongly influenced by the depth of cover. The vertical force increases as the depth of cover decreases. The case with the center of the pipe at the top of the armor ($s / D_p = 0$) corresponds to half of the pipe being exposed. For this case the vertical force is much larger; nearly as large as the horizontal force. It was noted in Figure 6 that the phase of the maximum vertical force is closer to the maximum horizontal force which leads to a larger total force. The numerical model does not include friction or dissipation in the water
column and these results may be suspect. However, the calculated value is in agreement with the trend of the covered pipeline cases.

Figure 13 shows the influence of the pipe diameter. The dimensionless horizontal force increases nearly linearly with the pipe diameter. Since the forces are calculated based on diffraction theory, this is an anticipated result. The vertical force also increases slightly with the pipeline diameter.

Conclusions

A nonlinear numerical model using BEM in the water column and FEM in the porous rubble has been developed. The numerical model results compared reasonably well with model test results and can adequately simulate the nonlinear interaction between waves and a pipeline covered with rubble protection. It was observed that the horizontal wave force is larger than the vertical force for all wave conditions and rubble configurations examined in this paper. The dimensionless wave forces on a buried pipeline generally decrease as the depth increases. However, there is a wave period dependency that yields a maximum wave force corresponding to $h/L \approx 1/6$. The armor stone size and armor layer porosity have little influence on the magnitudes of the forces. The depth of pipeline burial has little influence on the magnitude of the horizontal force. However, the vertical force on a partially exposed pipeline is much larger than for a fully covered pipeline and is closer to being in phase with the horizontal force. As a result, the partially buried case is much less stable.

ABSTRACT

This paper reports some of the results of a theoretical and experimental study of submerged, detached, segmented, trapezoidal rubble mound breakwaters. It focuses on the phenomenon of sea level set-up which occurs at these structures. A theoretical analysis is presented which gives an explanation for the occurrence of set-up and the experimental results so far confirm the proposed relationship, which is given by Equation 4. Various other checks are presented in the paper, such as a demonstration that the set-up can be eliminated by pumping out from behind the breakwater and the measurement of a net drift velocity offshore in the core of the breakwater.

INTRODUCTION

Any detached breakwater where the waves are able to pass over or through the structure will experience a rise in the mean sea level on the shoreward side. This “set-up” can have a significant effect on the performance of the structure, but it has been very little researched and is still not well understood. It is created because the wave inflow or overflow is greater than the backwash. The means of restoring equilibrium to the situation is either for the sea level to rise behind the breakwater in order to create more backflow or for a transverse current behind the breakwater to be created, if this is possible.

The results of our research into this set-up have shown, so far, that the magnitude of the set up is a maximum when the freeboard, $R_c$ is zero i.e. when the breakwater’s crest is at mean sea level. However we have not yet tested any impermeable breakwaters and these will exhibit slightly different behaviour displacing the maximum set-up position.

Detached breakwaters are now widely accepted as one of the three main methods of protecting eroding coastlines; the other methods being groynes and shoreline armouring. Detached breakwaters have greatly increased in popularity in recent years and many papers on their design have been reported at recent coastal engineering conferences. Few if any of them have discussed the phenomenon of (breakwater created) set-up. Yet we believe that an understanding of this set-up and the other effects it produces is essential to the correct design of detached breakwater schemes. Furthermore, as designs of detached rubble mound breakwaters have evolved, designers have tried to use lower crested breakwaters. This is because since the cost of the breakwater system is proportional to the volume of rock per km. of coastline it probably follows that the cheapest rubble mound scheme will minimise the crest height and width and maximise the side slopes. Indeed the first author recommended nearly 12 years ago (Loveless 1986) "From the evidence available it can be argued that a crest level over one metre below the MHWS level would be sufficient for many cases of coast and beach protection."

Unfortunately, the recent experience of researchers (Murphy 1996) (Van der Biezen 1998) and practising engineers (Browder et. al 1997) when investigating or designing low crested or submerged detached breakwaters, has been that they produce large longshore currents which can result in more beach erosion instead of less. Some of these researchers are now advising against the use of detached breakwaters altogether. It is our view however that these longshore currents are mainly due to the phenomenon of set-up. Once all the mechanisms governing the creation of set-up have been identified it will be possible to produce designs which minimise it and so eliminate its adverse consequences on beach erosion and minimise overtopping of the final sea defences.

This paper reports on a 2-D flume study of detached trapezoidal rubble mound breakwaters which was carried out to investigate the nature of the set-up. In most detached breakwater schemes the potentially very large levels of set-up do not in fact occur because they are relieved by 3-D current circulations. However, in this study, a way of transferring the data obtained from the 2-D flume research was devised so that the advantages of control and increased scale offered by the 2-D flume research could be retained. The new technique enabled the applicability of these 2-D results to be extended very simply so that they could be used to predict the performance of the kind of 3-D installations common in the field. The method used was simply to install a pump behind the breakwater in the flume so that a relationship between the pumping rate and the reduction of set-up could be obtained. The paper also reports briefly on some 3-D experiments in the UK’s National Coastal Research Facility at HR Wallingford.

A detailed report of the original research is obtainable from the Department of Civil Engineering at the University of Bristol (Debski & Loveless 1997) and a previous paper (Loveless & Debski 1997) presents the findings with respect to wave transmission which were found to be generally as predicted by earlier researchers.

**Figure 1**: Definition sketch and major variables for breakwater cross-section and analysis
PROBLEM DEFINITION

The problem studied in the research was the performance and design of submerged, detached, (trapezoidal) rubble mound breakwaters. A definition sketch, which also shows the major variables involved in the problem, is shown in Figure 1. The freeboard, $R_c$, which is a key variable in the problem, is negative when the crest is submerged.

The main purpose of a detached breakwater is to reduce the wave energy between it and the shoreline. The incident waves transfer quantities of water inshore over and through the breakwater. Since the waves inshore are smaller and the return flow resistance is generally greater, the return velocities over and through the breakwater are less than the inshore velocities and this results in a net transfer of water to the inshore zone at the breakwater. However, the shoreline behind the breakwater is usually relatively impermeable so there can be no net flux of water inshore. The excess flow must therefore be driven back offshore either through the breakwater (if it is permeable) or over the breakwater (if it is submerged) or around the ends of the breakwater (if it has gaps) or by a combination of these three flow paths. All three routes offer resistance to a flow of water and require a head difference to drive the flow. Therefore a rise in water level will occur inshore to maintain a zero net flux of water transfer in the near shore zone.

It can be shown that the volume of flow backwards and forwards in half wave period of a progressive wave is $HL/T$. At a breakwater (or other bar like structure) there is greater resistance to the return flow than the overflow. Therefore there is a net inflow which must be balanced (in 2-D) by a set-up of the water surface behind the breakwater (or inshore of the bar).

If the resistance is dominantly turbulent (which it is for both bars and breakwaters) then the set-up, $\delta$ should be proportional to $u_o^2$ where $u_o$ is the mean offshore set-up driven velocity. If $h$ is the water depth then it follows that

$$\delta \propto \left[ \frac{H, L}{hT} \right]^2$$

and this was found to be true in the experimental results.

Because the resistance to flow is dramatically reduced when the breakwater is submerged it is also likely that the relative submergence $R_c/h_c$ will be an important variable and since the resistance to flow within the breakwater is a function of $D_{50}$ the stone size (or permeability of the breakwater) will also affect the set-up.

If the set-up height is non-dimensionalised using the crest width, $B$ we have a hydraulic gradient $\delta/B$ which is related to $u_o$ by means of the Forcheimer equation.
Hence,
\[
\frac{\delta}{B} = f \left( \frac{(H/L \times hT)^2}{hT^2}, \frac{R_c}{h_c}, D_{n50} \right)
\]
Eq. 2

or alternatively
\[
\frac{\delta}{B} = f \left( \frac{(H/L \times hT)^2}{8gD_{n50}}, \frac{R_c}{h_c} \right)
\]
Eq. 3

So far we have found that for our admittedly limited range of tests that
\[
\frac{\delta}{B} = \frac{(H/L \times hT)^2}{8gD_{n50}} \cdot e^{-20(R_c/h_c)}
\]
Eq. 4

best describes the results.

**DESCRIPTION OF THE 2-D MODELS**

The experiments were performed in a large random wave flume, 15m long, 1.5m wide and 1.1m high with a 5m long, 0.5m wide test section. A total of six different model breakwater cross-sections were tested utilising three different sizes of carefully graded rock. A schematic layout of the flume showing the position of the breakwater models is shown in Figure 2 and a picture showing the three rock sizes used is presented in Figure 3. All the breakwaters were 500 mm high, but the crest widths varied from 200 to 600 mm. A range of wave and water level conditions were tested with incident waves ranging from 50 to 200 mm height and water depths being varied between 400 and 650 mm giving both submerged and emergent conditions. Both random and regular waves were tested.

As can be seen in Figure 2 a submersible pump was located behind the wave absorber at the end of the flume so that the set-up could be artificially lowered in order to simulate 3-D conditions and investigate the nature of set-up.

**RESULTS FOR SET-UP IN 2-D MODELS**

An example of the results obtained is given in Figure 4 where the set-up for one of the breakwater models is plotted against the incident wave height for various water levels. The set-up was found to be a maximum when the water level is just below the crest of the breakwater.

As can be seen from Figure 4 when \( R_c = 0 \), the set up is greatest. For a regular wave of height 3.0 m the maximum (unrelieved) set-up was found to be 1.0 m. The results for random waves were found to given equivalent amounts of set up provided that the mean wave height rather than the significant wave height was used. Figure 5 shows
Figure 2: Schematics of the experimental flume and some breakwater cross-sections
Figure 3: The three grades of rocks used in the breakwater models
Figure 4: Set-up inshore of breakwater at prototype scale (averaged for three different models: 2; 2a; 2b for $T = 11.2s$)

Figure 5: Set-up inshore of breakwater at prototype scale for $T = 11.2s$ (Models 2, 2a, 2b shown separately)
how set-up is affected by the crest width. Model 2b has the narrowest crest and 2a has the widest. It can be seen that set-up generally increases with crest width.

The only previous study of set-up at a trapezoidal rubble mound breakwater was that of (Diskin 1970). However, the results of our experiments, which are shown against Diskin's curve on Figure 6 gave much lower results. This was attributed to the fact that we had used a larger stone size in our tests. From all the results we have obtained so far the best fit curve is that given by Equation 4 which, as explained earlier, also has a firm theoretical basis.

PUMPING TESTS AND VELOCITIES

Besides the measurement of set-up the research in the 2-D flume provided accurate data on the quantity of flow necessary to suppress it. Thus, by reference to Figure 7, it may be seen that, with model 5, a set-up of 0.5 m could be reduced to zero with a rate of pumping of 1.8 m$^3$/s/m width of breakwater.

Velocities both within and around the model breakwaters were measured using an ADV velocity probe. Figure 8 shows an example of the net velocity vectors obtained. From this figure it is possible to identify clearly both the circulation cell just beyond the crest of the breakwater and the presence of a horizontal jet in front of the breakwater. Figure 9 shows the velocity vectors at the four key points of the wave cycle and clearly shows that the velocities within the core of the breakwater are subject to a net drift velocity offshore due to the set-up. In fact the magnitude of the drift velocity in the core of the various breakwaters was found to be as predicted by the Forcheimer equation and this result is shown in Figure 10.

SET-UP IN 3-D

All these flume measurements of set-up are those that would occur where it is not possible to relieve the very large rises in mean sea level by transverse currents or some other means. i.e. the pure 2-D situation. In 3-D the set-up is frequently dissipated by being converted into strong transverse currents so that, in many 3-D configurations, only a very small amount will occur. Nevertheless all the set-up drivers are still present and when converted into these strong currents may result in beach erosion and scour at the ends of the breakwaters. These unwanted results, as mentioned earlier, have been reported by a number of researchers and practitioners. We have also observed them in our own 3-D studies in the UK's National Coastal Research Facility. Figure 11 shows that the maximum set-up that we measured in one test was only 70mm (prototype scale), but the current measurements taken indicated, as expected, strong transverse flows. It is our view though that they can be eliminated once appropriate remedial action has been taken by the more appropriate design of submerged breakwaters.

CONCLUSIONS

We believe that coastal engineers in their search for cheaper forms of coastal defence will increasingly seek to deploy segmented detached trapezoidal rubble mound breakwaters with lowered crest elevations.

In this paper we have shown that these designs are subject to the phenomenon of set-up of the sea level inshore and we have gone a long way towards defining exactly how this set-up is created.

In breakwater configurations where transverse currents are constricted or prevented the set-up can be very large. In most 3-D configurations however it is not readily observable, but the forcing elements are still present and they create instead strong currents which are capable of eroding the beach.

Further research, it is confidently expected, will lead to improved designs which will minimise these unwanted effects and make the use of detached breakwaters still more advantageous.

ABSTRACT
It is well known that the littoral drift carries much sand into a sheltered area caused by the presence of coastal structures such as detached breakwaters. As a result, the shoreline in the sheltered area advances, whereas the shoreline of the neighboring coast recedes to balance a sand budget of the coast. An artificial island for storage of crude oil was constructed off the Kashiwabara coast, Shibushi, Kagoshima Prefecture, Japan since 1985. The island has a rectangular shape roughly 1.5 km long and 1.5 km wide. This paper describes coastal processes related to the construction of the artificial island, and proposes a new dredging and beach fill scheme including a groin to decrease the coastal erosion due to the sheltering effect by the artificial island.

INTRODUCTION
When coastal structures such as detached breakwaters and artificial reefs are constructed, sheltered areas are created. The littoral drift carries much sand into these sheltered areas. As a result, the shoreline in the sheltered area advances, whereas the shoreline of the neighboring coast recedes. The sand from the neighboring shoreline becomes the sediment source for the sheltered area. A plan view of the shoreline configuration changes significantly after the construction of sheltering coastal structures in a nearshore region. These kinds of engineering issues in Japan are documented by Uda (1997) in detail. To overcome this problem, it is proposed that a single groin should be set at the boundary of the sheltered and non-sheltered beaches to block the excess longshore sediment transport into the sheltered area. This scheme will also ideally prevent additional coastal erosion along the non-sheltered beach.

An artificial island for storage of crude oil was constructed off the Kashiwabara coast, Shibushi, Kagoshima Prefecture, Japan since 1985 (see Figure 1). The construction of outer facility of the island was completed in 1987 and then the island was reclaimed by dredged material from the nearshore area in front of the island. The island has a rectangular shape roughly 1.5 km long, 1.5 km wide, and the size of

the island is 192 ha. The length of the island is nearly eighteen times longer than the wave length of mean energy wave and 3.8 times longer than the observed longest significant wave length, respectively in this area of the Pacific Ocean. The refraction and diffraction patterns are modified by the shape of the borrow site for reclamation and the presence of the island to cause an uneven wave height distribution along the shoreline. Because of its size, this artificial island generated a large sheltered area as shown in Photograph 1 and caused significant beach and dune erosion on the neighboring coasts. Thus, monitoring projects in terms of a shoreline configuration, bathymetry, dune and beach scarp, and incident wave climate have been conducted since the construction of the island at the Kashiwabara coast. This study aims at the investigation of coastal processes related to the construction of the artificial island and a beach nourishment scheme involving a single groin based mainly on the monitoring data.

Figure 1  Location of study area.

Photograph 1.  Aerial view of the artificial island.
SUMMARY OF STUDY AREA

Location of study area

The Kashiwabara coast is located on the south side of Shibushi Bay which opens to the southeast direction as shown in Figure 1. Shibushi Bay is 16.8 km long and faces to the Pacific Ocean. Shibushi Port and the artificial island lie on the northeast and southwest sides of the bay, respectively. The sandy beach extends nearly 14.2 km along the coast. Five rivers, i.e. Mae, Anraku, Hishida, Tabaru and Kimotsuki Rivers, run into the coast and supply the sediment to the beach. However, the length of each of these rivers is only 14.5, 27.1, 49.3, 14.7 and 34.0 km, respectively, therefore the sand discharge from the river mouths are probably minimal. For instance, the annual mean water discharge of the Kimotsuki River is only 35.12 m³/sec. The Kimotsuki and Tabaru Rivers run into the southwest and northeast side of the study area, respectively.

Wave climate

The entire coast in the bay opens to southeast direction and both sides of the coast are surrounded by the capes as shown in Figure 1. Therefore, the incident wave direction is limited nearly to the southeast direction with some seasonal fluctuation. The incident wave conditions have been monitored by an ultrasonic type of wave gauge which is installed at the -35m water depth and located just off the Birou island. The monthly mean energy wave conditions is shown in Table 1, where as of the highest significant wave since 1980 are shown in Table 2. The incident angles are positive to clockwise from southeast. As can be seen in Table 1, the mean energy wave height during the winter season (December to February) is smaller than that in summer season (July to September). In addition, mean incident wave angle in June, July and August is slightly southward compared to that during the period from September to May, because the mean wind directions in winter and summer are from landward and seaward, respectively. Moreover, high waves generated by typhoons approach to the coast in the summer season.

Characteristics of bed material

Sediment samples were taken from the beach face to the nearshore. A transect for the sediment sampling was set in the middle of the eroded coast where shoreline recession by the presence of island was the most significant. The median diameter of the sediment on a beach during the summer season is of the order of 0.5 mm and is larger than that during the winter season, whereas the median diameter in the shallow water area is of the order of 0.19 mm. The average density of sediment is nearly $2.55 \text{ g/cm}^3$ with a variation between 2.35 and 2.7 g/cm$^3$.

OVERVIEW OF THE COASTAL PROCESSES BY AERIAL PHOTOGRAPHS

Aerial photographs have been regularly taken at Kashiwabara Coast since 1984. An overview of coastal processes will be given first based on these photographs. Photograph 2 taken in 1984 shows the natural condition of the Kashiwabara coast before the construction of the island. The mouth of the Kimotsuki River and parallel jetties can be seen on the left side of photograph. The curved breaker line in front of the river mouth shows that there is a shallow water area. This river mouth terrace was generated by the sediment deposition discharged from the Kimotsuki River. In addition, the shorelines during a high and a low water levels are easily recognized as dry and wet beaches, respectively. The width of wet beach near the north jetty is narrow implying that the beach face is steep compared to the northern beach, because this area is highly depositional.

The outer facility of the island was completed in 1987. After that, a large tombolo was formed in the sheltered area by the refracted and diffracted waves. The major sediment source for the depositional features are neighboring northern sandy beach. The shoreline retreated nearly 80 m compared to the shoreline before the construction of island (in November 1984). The steepening and narrowing of beach face caused pronounced dune and beach scarps. The highest dune scarp attained to

Photo 3. Plan view before the beach nourishment (Sept. 27, 1992).

Photo 4. Plan view after the beach nourishment (May 13, 1993).

Photo 5. Coastal damage after the first typhoon season (Feb. 16, 1994).
nearly 7 m at that time. To prevent further coastal erosion and shoreline recession, a beach nourishment project with single groin was carried out. Photograph 3 dated on May 27, 1992 is the situation just before the beach nourishment.

Photograph 4 shows the plan view just after the beach nourishment. The sand for the nourishment had been taken from two borrow sites between a groin and Hami fishery harbor. Therefore the sandy beach behind the island is somewhat uniform. The non-sheltered beach north to the groin was filled by the sand from the sheltered area, and thus the beach was widened nearly 80 m offshore. As a result, the shoreline configuration became more straight. In addition, a T-shaped single groin was installed between the sheltered and non-sheltered beaches to block the excess southern longshore sediment transport.

Photograph 5 shows the shoreline configuration of nourished beach just after one typhoon season. As seen in the photograph, the shoreline in the entire nourished beach receded and scarp generation had initiated. The profile adjustment after the beach nourishment is accelerated by two of the largest typhoon since 1980. It was observed that foot of scarp exists at an elevation of berm height at that time. So it is expected that the scarp generation can be avoided if the elevation of nourished beach is kept to be the natural berm height in the design.

LONGSHORE PROCESSES

![Figure 2. The orientation of coastal structures and transects.](image)

The orientation of artificial island, groin, fishery harbor is shown in Figure 2. The incoming waves are refracted and diffracted by the island and tend to transport much sediment into the sheltered area located just behind the island. The bathymetry and shoreline data have been collected twice a year since 1984, and wave data is collected since 1980. The bathymetry survey covers the region from the southwest end of the bay, where the Kimotsuki River runs into, to beyond the Tabaru River.
The length of this study area extends to 7.5 km. The origin of the x-coordinate for a survey is set to the northeast end of the study area. The number of survey transects increases from the Kimotsuki River to the Tabaru River as shown in Figure 2. The borrow sites for the reclamation sand were in front of the island and the Kimotsuki River mouth.

Shoreline Change (Plan View) after the Construction of Artificial Island

Shoreline configurations of the Kashiwabara coast after the construction of artificial island are shown in Figure 3. The reference shoreline is set to be the shoreline in July 1985. As seen in the shoreline in June 1986, when an outlying facility of the artificial island was being constructed, the wave sheltering effect on the sandy beach had initiated especially in further south area than x = 4.3 km. It is clearly seen that sediment had been deposited in the sheltered area, and the shoreline configuration showed quasi-double-tombolo features. The peaks in the shoreline were located at x = 4.9 km and x = 6.3 km in June 1987. The migration of southern quasi-tombolo along a shore was blocked by an outer facility of the Hami fishery harbor, but the size of this depositional area had continued to grow. The sediment supply from the Kimotsuki River partially contributed to the generation of the south depositional feature. The north tombolo had shifted south along shore and the size of the tombolo had enlarged year by year.

Regarding the growth of the north tombolo, where significant amount of sand had been deposited, the offshore distance of peak of the tombolo had advanced from 40 m in June 1986 to 170 m in June 1992. The maximum shoreline advance in this period was 130 m, resulting the mean advance speed 21.7 m/yr of the shoreline. In addition, the peak of the tombolo was migrated from x = 4.75 km in 1986 to x = 5.25 km in 1992 to south direction, hence the tombolo had been shifted 500 m in this period. The mean migration speed was 83 m/yr after the construction of island. Once the tombolo generation was initiated by the diffracted waves in the sheltered area, the water depth at the tip of the tombolo was getting deeper according to its offshore growth. As a result, more diffracted waves with higher wave energy flux tend to act toward south direction in the sheltered area. Therefore, the peak of the tombolo migrated southwards while the size of tombolo was increasing in the sheltered area. As seen in the figure, the boundary of northern tombolo and southern quasi-tombolo had been also shifted 270 m to south with an annual mean speed of 45 m/yr. In accordance with the migration of tombolo behind the island, the boundary of depositional and erosional areas of this coast shifted 132 m toward the sheltered area.

The sandy beach in the sheltered area had widened, but the neighboring sandy beach in non-sheltered area had suffered severe coastal erosion after the construction of artificial island. As can be seen in the first and second rows of the figure, there is little shoreline recession in 1988 and 1989. The shoreline recession in non-sheltered area seems to be delayed two years compared to the quick shoreline advance in sheltered area. The shoreline started to retreat over 1360 m stretch from 1988, and then the total length of shoreline recession had become nearly 2.5 km by June 1992. The maximum shoreline recession was nearly 100 m at that time. The northern boundary of erosional area had shifted from x = 2.8 km to x = 1.8 km in June 1992, while the peak of erosion has shifted from x = 4.1 km to x = 3.2 km with an annual speed of 200-250 m/yr. The shoreline recession triggered the dune erosion and scarp generation as well. Because the shoreline is located closed to the upper beach face and dune face, the steeper the cross-shore profile, avalanching tends to occur on the steep slope to cause the scarp. Following the severe dune and beach erosion, a beach nourishment project with single groin had been carried out to prevent further coastal erosion. The project was completed in May 1993.
Shoreline Change after the Beach Nourishment

A volume of $1.15 \times 10^6$ m$^3$ of sand was dredged from two borrow sites just behind the island and filled into the eroded beach. The two borrow sites for the beach nourishment were deployed between $x = 5.3$ km and $x = 6.24$ km, respectively. The shoreline changes after the beach nourishment is shown in Figure 4. The reference shoreline is set to be the shoreline in June 1992 when the nourishment project had conducted thereafter. As seen in the figure, the shoreline advanced in a region from $x = 4.94$ to 6.3 km (= 1.36 km extension) in June 1992. The maximum shoreline advance was 152 m at $x = 5.34$ km. On the other hand, the shoreline receded in the region from $x = 1.43$ to 4.75 km (= 3.32 km extension) with a convex plan view in June 1992 before the beach nourishment. This maximum shoreline retreat in November 1992 was nearly 80m at $x = 3.74$ km.

To prevent further erosion and property damage, sand was filled in the non-sheltered area in May, 1993 as shown by the shoreline in Nov. 1993. The nourished shoreline around $x = 2.63$ km was smoothly connected to the natural shoreline at $x = 2.43$ km. The shoreline was advanced 80 to 100 m in the eroded section of the beach by the beach nourishment.

A single T-shaped groin 230 m long was extended from the beach face to the water depth of -2.3 m at $x = 4.6$ km. The function of this groin is to block the excess longshore sediment transport into the sheltered area from the northern neighboring beach. In addition, beach and dune scarps were scraped by bulldozers to guarantee...
safe accessibility and utilization of the beach. Then a mild-slope revetment with 200 m extension was installed at $x = 3.5$ km.

Following the beach fill project in May 1993, the largest typhoon since 1980 generated a maximum significant wave with $H_{1/3} = 8.3$ m and $T_{1/3} = 12.8$ sec period on August 10, 1993. Then unfortunately the third largest significant wave caused by Typhoon 9313 approached the shore with 7.72 m wave height and 11.2 sec wave period on September 3, 1993. As a result, the filled shoreline quickly receded nearly 50 m in the first six months just after the beach fill project as shown by solid line in Nov. 1993. Following this shoreline recession in the first six months, successive shoreline recession including a crescentic shoreline configuration between $x = 3.27$ km and $x = 4.68$ km occurred until 1995. In contrast, the shoreline in the non-sheltered area was advanced in Nov. 1996, because the Typhoon wave condition in this year was smaller than previous years. However, Typhoon 9713 which lasted three days (in terms of the significant wave height condition higher than 3.0 m) and Typhoon 9719 caused the shoreline recession in the entire region except the river mouth of the Tabaru River and the sheltered area. Finally, the shoreline configuration became as shown by the solid line in December 1997.

![Figure 4. Shoreline change after the beach nourishment.](image)

Figs 5 (a), (b) show the time series of shoreline position at representative transects. The mean shoreline changes at $x = 5.34$ km and $x = 3.74$ km were nearly $+19.3$ m/yr and $-10.5$ m/yr, respectively. In contrast, the shoreline...
changes in the sheltered area after the beach nourishment show either small positive trend or stabilization.

The shoreline changes on the nourished beach were accelerated during the first 2.5 years after the nourishment due to attack of two of the three largest typhoons in the wave record in 1993 and profile adjustment relating to the overfill. For instance, an annual rate of shoreline change at transect $x = 3.74$ km was 60.2 m/yr. Following this period, the shoreline change seems to have stabilized or shows some positive trend except the shoreline position in Dec. 1997.

Figure 5. Shoreline changes of each transect.
The inverse exponential behavior of the shoreline changes on the nourished beach (on non-sheltered beach) clearly means that a single groin installed between sheltered and non-sheltered beaches functions to block an excess longshore sediment transport into the sheltered area.

**SAND BUDGET ALONG THE COAST**

A time series of the change in sand volume over the entire Kashiwabara coast is shown in Figure 6. The change in sand volume along the shore is calculated by multiplying the cross-sectional change by the transect spacing. The volumetric change beyond the -9 m water depth was not taken into account for the estimation, since the sounding survey was conducted to this water depth. The profile analysis which will be shown later and the cross-shore distribution of sediment diameter show that the critical water depth for profile change in this study area is nearly -8 m. Therefore the change in sand volume in Figure 6 can be used as the first approximation. The change in total sand volume in the sheltered area \( x = 4.55 \) to \( 6.30 \) km was nearly \( 600 \times 10^3 \) m\(^3\), thus the annual depositional rate in this area was \( 160 \times 10^3 \) m\(^3\)/yr after the construction of the island (June 1986 to November 1990). On the other hand the change in total sand volume in the erosional area from \( x = 2.68 \) to \( 4.55 \) km was roughly \( 970 \times 10^3 \) m\(^3\). Thus, the annual erosional rate in this area was \(-220 \times 10^3 \) m\(^3\)/yr.

![Figure 6. Change in sand volume in the study area.](image-url)
The beach nourishment project with the single groin was completed in May 1993. The change in sand volume in the area from $x = 4.75$ to $5.71$ km was $+220 \times 10^3$ m$^3$ after the beach nourishment, and thus the annual depositional rate in this area is $50 \times 10^3$ m$^3$/yr. This means that the transmission rate of this groin for longshore sediment transport is estimated by comparison of depositional rate before and after the beach nourishment as follows:

$$P_{tr} = \frac{50 \times 10^3 (m^3/yr)}{130 \times 10^3 (m^3/yr)} \times 100(\%) = 38\%$$

Volumetric change in the northern area from the groin after the beach nourishment was $-830 \times 10^3$ m$^3$, thus the annual erosion volume was $-200 \times 10^3$ m$^3$/yr.

**CROSS-SHORE PROCESSES**

The profile variations in space during the post-construction period, beach nourishment period, and post-nourishment period are examined here. Figure 7 shows the change in profile along shore from November 1984 to June 1992. The coordinate $x = 4.94$ km is located in the sheltered area and $x = 3.53$ km is located in the middle of erosional area. In addition, an entire profile at $x = 3.53$ km is lowered by more than 1.4 m.

![Figure 7. Profile change along the shore after the construction of the island.](image)

Figure 8 shows the profile change along the coast before and after the beach nourishment. The nourished sand was filled from a landward boundary of erosional area to $-4$ m water depth. As can be seen in the figure, the profile was designed to have composite slopes. The beach slopes higher than 1m elevation are 1/25, 1/29, 1/27 and the offshore slopes are 1/60, 1/59 and 1/51 at $x = 2.68$, 3.53 and 4.34 km, respectively.

Figure 9 shows that the profile changes along the coast in the first typhoon season after the beach nourishment. Because two of the three largest typhoons since 1980...
struck on the shore during this period, the nourished beach had been extensively damaged and scarp generation has commenced again. Typhoons 9307 and 9313 produced 8.3 m and 7.72 m significant wave height, respectively. The elevation of the scarp base is nearly 2 m along the shore.

Figure 8. Profile change along the shore during the beach nourishment.

Figure 9. Profile change along the shore after the beach nourishment
CONCLUSIONS
Field observations were carried out to study the mechanism of coastal erosion due to the presence of artificial island, and to access the performance of new beach nourishment scheme as well as develop database for future numerical work. The main conclusions are as follows;

(1) A quasi-double-tombolo feature was generated by the sheltering effect of the artificial island at the Kashiwabara coast. The northern tombolo moved into the sheltered area with the speed of 75m/year due to the wave refraction and diffraction. Sediment was supplied from the northern neighboring coast. As a result, the neighboring coast eroded over a 2.0km stretch.

(2) A single groin, which was set between the sheltered and non-sheltered areas, decreased the southward longshore sediment transport. The transmission rate of the groin is estimated to be 38% in terms of annual transport rate. Despite rapid shoreline recession due to profile adjustment and severe typhoon conditions during the first 2.5-year period after the beach nourishment, shoreline position tends to be stabilized or slightly progressed in the last few years. It can be concluded that the nourished beach close to the groin tends to be partially stabilized.

(3) Part of the nourished sand has been transported still beyond the single groin, because the water depth at the tip of groin was set to be -4m and thus it is shallower than the depth of closure which is roughly -8m in this area. In addition, a large amount of nourished sand, which exceeded the equilibrium berm height has been transported to north direction due to the excess longshore slope of nourished beach, and partially to offshore beyond a typical closure depth due to severe typhoons.

ACKNOWLEDGEMENT
The authors would like to express their special thanks to Mr. Nishihara, former Chief of River Section, Kagoshima Prefectural Government Office, for his kind permission to release the field data. The author also wishes to extend special thanks to Dr. Nicholas C. Kraus at the Coastal and Hydraulic Laboratory, US Army Engineer Waterways Experiment Station for his kind proofreading.

Abstract

The morphological aspects of the design of shore-parallel breakwaters are investigated through a series of tests using a two-dimensional (in the horizontal plane) morphological modelling system. The analysis focuses on the optimisation of the breakwater length and its distance to shore in order to achieve the desired type of response. The results obtained are compared to empirical formulas from the literature and observations from the field.

Introduction

Shore-parallel breakwaters are frequently used in coastal protection and restoration schemes. An important aspect of the design of these structures is the prediction of the morphological response (i.e. the type of planform that will develop) in their vicinity. Depending on the intended purpose of the structure, a tombolo may be desired in some cases, whereas a stable salient behind the breakwater, without significant down-drift erosion, may be the preferred solution in other cases.

In this paper we concern ourselves only with the morphological aspects of the design of shore-parallel breakwaters. From this perspective, the design of the breakwater consists of defining appropriate dimensions for the length of the structure and its location in the nearshore area, in order to obtain the desired morphological response.

A coastal area morphological modelling system is applied to systematically investigate the morphological response behind a detached breakwater subjected to wave action. Tests are made with various combinations of breakwater length and distance from shoreline for given incident wave conditions, beach characteristics and sediment properties. The results of these tests are analysed to derive practical guidelines for the design of the structures.

\textsuperscript{2} Dr. Nik & Associates, 20-2 Jalan 10/55 A, Taman Setiawangsa, 54200 Kuala-Lumpur, Malaysia
The following aspects of the study are discussed in the ensuing sections:

- the phenomena leading to the special planforms that are observed in the vicinity of detached breakwaters.
- the modelling system used to simulate the morphological evolution in the vicinity of shore-parallel breakwaters
- the test matrix defined on the basis of the findings from the dimensional analysis of the parameters controlling the morphological response
- presentation and discussion of the results

Processes in the vicinity of a detached breakwater

At a macro-scale level, the presence of the shore-parallel breakwater shelters the coast immediately behind the structure and the adjacent areas from the incoming waves. This means that the wave height at breaking will be smaller in the sheltered areas than elsewhere, which in turn will result in larger wave-induced set-up along the exposed beaches than in the sheltered areas.

The longshore variability in the wave set-up results in gradients of the mean water surface. These gradients tend to accelerate the longshore current flowing towards the sheltered area behind the structure and to change the direction of the current which is driven away from the breakwater by the breaking waves in the region immediately downdrift of the breakwater. The two current systems merge behind the structure, giving rise to complex circulation patterns.

The acceleration of the littoral current that takes place updrift of the shore-parallel breakwater causes initial erosion of the beach in that area. The same occurs in the area immediately downdrift of the structure. The currents carry the eroded material towards the sheltered area, where it deposits. These mechanisms cause the pattern of deposition behind the breakwater and erosion on either side of it that can be observed in nature.

The 2DH Morphological Modelling System

The coastal-area morphological modelling system applied in the present analysis was described in detail by Johnson et al. (1994). At that moment, the emphasis was placed on the selection of the wave model, the description of the bed roughness under combined waves and current, etc.

Briefly, the morphological modelling system is based on an explicit forward-time integration scheme for the evolution of the bathymetry. The system consists of a number of modules capable of reproducing the governing processes that were discussed in the previous section:

(i) a wave module, MIKE 21 PMS, based on the parabolic approximation to the mild-slope equation, used to calculate wave parameters as well as radiation stresses over
the model area. MIKE 21 PMS accounts for the effects of shoaling, refraction, diffraction, breaking, directional spreading and bed friction on the incident waves

(ii) a hydrodynamic module, MIKE 21 HD, in which the flow field is found from the solution of the depth-integrated continuity and momentum equations. The currents driven by the breaking waves and the gradients in mean water level are calculated on a mobile bed evolving at the rate of \(dz/dt\) calculated by the sediment transport module

(iii) an intra-wave sediment transport module, MIKE 21 ST, accounting for the combined influence of waves and current on the transport rates of graded sediment

(iv) a bed level update scheme using an improved second-order Lax-Wendroff scheme

Further details on the morphological modelling system can be found in Johnson et al. (1994, 1995).

**Dimensional Analysis and Test Matrix**

Using dimensional analysis, Johnson et al. (1995) showed that the morphological response behind shore-parallel breakwaters on an initially plane beach can be expressed as a function of the dimensionless numbers \(\phi_1\) and \(\phi_2\) according to

\[
\text{Morphological Response} = f(\phi_1 \ast \phi_2)
\]

with

\[
\phi_1 = \phi_1(H_b/L_0, \theta_b, m/(H_b/L_0)^{0.5}, H_b/d_{50})
\]

and

\[
\phi_2 = \phi_2(t/T, X/X_{80}, L/X_{80})
\]

where \(H_b\) is the wave height at breaking, \(L_0\) is the deep-water wave length, \(\theta_b\) is the direction of wave propagation at breaking, \(m\) is the beach slope, \(t\) is time, \(T\) is wave period, \(d_{50}\) is the median grain size, \(L\) is the length of the structure, \(X\) is its distance to the coast, and \(X_{80}\) is the distance from shore within which 80% of the undisturbed littoral transport takes place. Therefore, \(X_{80}\) can be seen as a measure of the width of the surf zone.

\(\phi_1\) and \(\phi_2\) in (1) can be interpreted as being dimensionless parameters that describe the dependence of the morphological response on the magnitude of the sediment transport and the geometry of the structure, respectively.

In order to systematically investigate the dimensions of the detached breakwater that are required to obtain the desired response, tests in which the morphological
response obtained by varying $X/X_{80}$ and $L/X_{80}$ in (3) while keeping constant the dimensionless parameters in (2) have to be defined. Therefore, 8 tests in which $X/X_{80}$ and $L/X_{80}$ were systematically varied while keeping the incident wave characteristics, the initial beach slope and the sediment properties unchanged were defined for the present analysis, as detailed in Table 1 below.

Tests KM1 to KM5 were aimed to investigating the influence of the location of the structure with respect to the coast on the morphological response. Tests KM3, KM6, KM7 and KM8, in turn, were defined to investigate the influence of the length of the structure on this response.

In all the tests, irregular unidirectional waves were applied. The root-mean-square wave height $H_{RMS}$, peak wave period $T_p$ and direction of wave propagation $\theta$ at a water depth of 10m were defined as equal to 2m, 8s and $10^5$, respectively. The initial beach slope $m$ was kept as 1:50 in all tests, and a sediment with median grain size $d_{50} = 0.25mm$ and geometrical standard deviation $\sigma_g = (d_{84}/d_{16})^{0.5} = 1.1$ was used over the whole model area. With this definition of parameters, a value of $X_{80} = 240m$ was found.

Each morphological simulation test was carried out for a minimum period of nine days, after which the results were analysed. Even though it can be argued that the "final" morphological response of a natural beach to the local wave conditions will arise after a number of years, it must be kept in mind that this response will be mainly dictated by some significant (from a sediment-transport point of view) events. Normally, these events will have a limited persistence over an average year. Since the same (relatively rough) wave conditions were kept during the entire morphological simulation period reported here, it can be reasonably expected that the time scale required for the bathymetry to adapt itself to the incident waves will be much shorter in the model tests than in nature.

**Presentation and discussion of results**

Fig 1 shows the initial model bathymetry for tests KM3, KM5 and KM8. The area shown is 720m wide and 1800m long. The length of the structure is the same in tests KM3 and KM5, but the breakwater is located further away from the shore in KM5. On the other hand, the two breakwaters are located at the same position with respect to the
coast in tests KM3 and KM8, but the length of the structure is almost double for the case of tests KM8, see table 1 for additional details.

Figs 2, 3 and 4 show the initial wave, current and sediment transport fields calculated over the same area as shown in Fig 1 for the three tests. Inspection of the figures shows how the dimension and location of the structure influence the nearshore hydrographic and transport conditions.

For example, it can be seen that placement of the structure further away from the coast for test KM5 permits more penetration of wave energy in the area behind the structure, cf. Fig 2. On the other hand, the sheltered area created by the structure along the coast is largest for this case (KM5), as shown by the extension of the recirculation area downstream of the breakwater in Fig 3. For test KM8, the penetration of wave energy behind the relatively long structure is so limited that two independent regions (from a sediment-transport point of view) exist in the vicinity of the tips of the structure, cf. Fig 4.

Fig 5 shows the bathymetry predicted by the morphological model after 10 days. All bed levels above -2m have been shown in black in order to facilitate interpretation of the results.

Figure 1. Initial model bathymetry
Figure 2. Initial wave fields

Figure 3. Initial wave-driven current fields
Figure 4. Initial sediment transport rates

Figure 5. Predicted bathymetry after 10 days of simulation
The bathymetry predicted by the morphological modelling system at the end of each test was inspected and classified. The predicted planform was either classified as tombolo (for those cases in which the structure had become connected to the shore), or salient (if a widening of the beach had occurred without significant changes of the bathymetry beyond the shallower area) or salient/tombolo (if a significant salient not attached to the structure had developed at the end of the test).

The predicted response was compared to empirical formulas from the literature. The results of this comparison have been summarised in Table 2. It is observed that the predicted morphological response is generally in good agreement with the predictions from the empirical formulations.

The results obtained are summarised in graphical form in Fig 6 as a function of \( L/X_{80} \) and \( X/X_{80} \). The empirical relationship \( L/X = 1 \), proposed among others by Herbich (1989) and Suh and Dalrymple (1987) to identify the occurrence of tombolo or not, has also been indicated. Points located above the line \( (L/X > 1) \) will correspond to tombolo formation, whereas points below the line \( (L/X < 1) \) will indicate salient formation, and points close to or right on the line will correspond to the case of unstable tombolo formation.

It is observed that the response predicted by the morphological modelling system is in good agreement with this empirical criterion.

</table>
The coastal features observed behind three breakwaters located respectively on the West coast of Jutland, Denmark (stable tombolo), SW coast of Sri Lanka (unstable tombolo) and Sergipe (Brazil) have also been included in the figure. Again, good agreement between the model predictions and the observed response in the field is found.

Figure 6. Calculated morphological response as a function of the length and location of the detached breakwater. Triangles: field data. Circles: model results. Open symbols: salient. Filled symbols: tombolo.

The dependence of the modelling results on the dimensions and the position of the breakwater were investigated through the total volume of sediment deposited on the initial bathymetry after 9 days of simulation.

The results have been plotted in Fig. 7 as a function of the distance from the coast to the structure for breakwaters of constant length (tests KM1 to KM5) and in Fig. 8 as a function of the length of the breakwater for breakwaters with constant distance to the coast (tests KM3, KM6, KM7 and KM8). The labels close to the symbols in both figures indicate the corresponding ratio L/X for the breakwater.
Fig 7 shows that for a detached breakwater of given length, there is an optimal location from the point of view of the amount of sediment that the structure will trap. In the extremes, a breakwater located very close to the coast will trap small amounts of sediment, as it will only marginally interfere with the surf zone.

On the other hand, a breakwater located too far away from the coast will also trap moderate amounts of sediment, since there will be space enough behind the structure for wave energy to penetrate and for the waves to reform before reaching the outer edge of the surf zone.

Fig 8 shows that for a breakwater located at a certain distance from the shore, a limiting length exists beyond which the amount of sediment trapped by the structure will not increase with its length. This is due to the fact that no penetration at all of wave energy behind the structure is possible due to its length, and therefore the transport processes at both ends of the structure occur independently of each other.

Figs 7 and 8 can be used in combination to optimise the design of a shore-parallel breakwater from the point of view of the desired morphological response. If the length of the breakwater has been defined beforehand, or if it is restricted by external requirements, then Fig 7 can be used to determine the location of the structure that will yield the maximum deposited volume (if desired). The morphological modelling system will in turn predict the type of planform that will be created behind the structure.

If the position of the breakwater with respect to the coast is fixed, then Fig. 8 can be used to optimise its length, and the morphological modelling results (or, alternatively, Fig 6) to verify the type of morphological feature that will be generated.

Figure 7 Influence of distance to coast on the amount of sediment deposited on the initial bathymetry. All breakwaters have \( L = 312 \)m. Figures on the plot correspond to values of \( L/X \). Symbols as in Fig 6.
It is important to keep in mind that Figs 7 and 8 are not general design curves, but have been created for a particular wave climate and beach profile. Application of the morphological modelling system as described in the previous sections to the particular hydrographic and sedimentological conditions found at a given study site will therefore allow the optimisation of the dimensions of shore-parallel breakwaters from the point of view of the associated morphological response.

**Currents generated in the vicinity of shore-parallel breakwaters**

Shore-parallel breakwaters are frequently used as coastal structures in connection with recreational beaches, either to stabilise the coastline or to provide swimming areas that are sheltered from the incoming waves.

Since complex current patterns are generated in the vicinity of detached breakwaters, the sheltered areas may prove hazardous for inexperienced swimmers, who will be attracted to the apparently calm areas where they may be trapped by the current and be dragged offshore.

In order to quantify the magnitude of these currents, the maximum current speed predicted by the hydrodynamic model on the initial bathymetry for each of the eight tests has been listed in Table 3 below. These strong currents always take place shoreward or close to the tips of the breakwater.

The figures in Table 3 may be compared to the maximum value of 1.33 m/s attained by the wave-driven current along the open stretch upstream of the breakwater.

It can be seen that the currents generated by the presence of the shore-parallel breakwater can be up to 40% stronger than the maximum value of the wave-driven current.

Conclusions

The application of the coastal morphological modelling system to the design of shore-parallel breakwaters allows determining the optimal geometry of an isolated structure for given wave conditions and characteristics of the beach profile and the bed material.

The morphological response predicted by the modelling system is in good agreement with observations from the field and the guidelines provided by commonly used empirical formulas.

Even though the results obtained indicate that depth-integrated currents are the dominating mechanism from the point of view of the morphological response, there is a number of additional effects, the significance of which is not fully understood yet, and should therefore be the subject of future investigations. Among them, the vertical structure of the wave-driven currents and the suspended sediment transport, bed-slope and space-lag (non-equilibrium suspended load transport) effects on sediment transport may be mentioned.

Abstract

The application of shore parallel offshore breakwaters in coastal engineering is discussed. Four well-defined practical coastal engineering problems are the starting point of discussion. The possibilities of a new morphological model and a design support model are indicated.

1 Introduction

Within the CUR-framework (CUR: Centre for Civil Engineering Research, Codes and Specifications), many Dutch partners (Governmental institutes, Consulting firms, Contractors and Universities) recently participated in a joint Dutch research project concerning the application of shore parallel detached breakwaters in combination with beach nourishments.

Shore parallel detached breakwaters are increasingly used as a tool in coastal engineering practice. All over the world series of detached breakwaters have been constructed. In the Netherlands, however, shore parallel breakwaters have not yet been applied in the open sea. Whether this is wise or not is an almost ever lasting debate amongst experts in the Netherlands. The CUR project was partly initiated with the aim to provide the debaters with some joint background information. A second aim was of course to enhance the knowledge concerning this intriguing tool in coastal engineering.
Many series of shore parallel breakwaters have been built along many coasts all over the world. To build detached breakwaters calls generally for huge investment costs. Thus consequently serious problems had apparently to be resolved with the help of detached breakwaters. It is striking that in the overwhelming number of books, papers and reports which appeared concerning the detached breakwaters topic, often the very reason to apply this tool is hardly discussed. In literature often great successes of the application of series of offshore breakwaters are reported. But, what was the problem which had to be resolved with the help of offshore breakwaters? Often this very basic question is not dealt with in the papers.

In the study a slightly different approach was followed. First four well-defined practical coastal engineering problems were stated and next the possible application of shore parallel breakwaters to resolve these four problems was investigated. (Of course realizing that the use of shore parallel breakwaters is only one tool out of many other tools, and realizing that in more cases than the restricted number of four defined problems, shore parallel breakwaters can be used.) In the investigation it was analyzed how the use of breakwaters could resolve the problem. Special attention was paid to possible additional effects of the application of shore parallel structures. The study was restricted to the application of shore parallel (rock) structures, whether in combination with artificial nourishments or not.

2 Outline of study

The entire study was divided in three phases. In Phase I 'Introduction and inventory' amongst others four well-defined practical coastal engineering problems were outlined; one case was subdivided in two alternatives, viz.:
A  Erosion of a continuous coastline;
B1  Coastline with interrupted sediment transport: near harbour breakwaters;
B2  Coastline with interrupted sediment transport: near a tidal inlet;
C  Artificial beaches along coastlines with a lack of natural sediments (recreational beaches);
D  Seaward shifted coastline of a large-scale land reclamation project.

The several cases were defined and the possible use of shore parallel breakwaters was indicated. Typical design problems were pointed out concerning each of the cases. In the Phase I report (CUR, 1997a) also a brief summary was given of more than 100 papers related to the application of shore parallel breakwaters.

In Phase II 'Modelling of sand transport' of the study a method was developed to quantify the effect with time, of (series of) shore parallel breakwaters on coastal morphology in the vicinity of the breakwaters. An existing multi-layer computational model was adapted to a large extent. New formulations were derived. The effect of diffraction behind the breakwaters was taken into account. One case of the four cases, Case A 'Erosion of a continuous coastline' was studied in detail.
The use of shore parallel breakwaters is often an alternative for the application of artificial (beach) nourishments. The application of breakwaters will often only reduce the erosion rate in the area under consideration; a real zero erosion rate, however, is difficult to achieve. It must be stressed that any reduction of the erosion rate in the area under consideration is often at the spent of the lee-side area. In that area increased erosion rates are to be expected.

The efficiency of an applied shore parallel system of breakwaters was defined in the model as the ratio between the savings in erosion rate and the original erosion rate in the area to be protected. The expected increased erosion rates in the lee-side area are not taken into account in the efficiency to be determined. An essential feature of the model is the easy way in which the efficiency of a given (arbitrary) series of breakwaters can be determined. The results of the study in Phase II are summarized in (CUR, 1997b).

With the help of the model developed in Phase III 'Evaluation by a design support model' (CUR, 1997c), the consequences of the application of shore parallel structures related to costs and several other aspects, can easily be evaluated. By filling out some Menu's, the user defines the problem to be studied and the characteristics of the solution with offshore breakwaters in mind. Alternative offshore structures schemes are easily to be generated by the user; the model next calculates the costs.

The basic comparison parameter to evaluate different alternatives is the net present value (NPV) of an alternative. Interest rate and assumed lifetime of a project are to be defined by the user. Also for the zero option (compensation of the observed erosion rate in the area to be protected by artificial nourishments) NPV calculations are made.

The models as developed in Phase II and III of the study are further discussed in Paragraph 4 and 5. In Paragraph 3 the four basic coastal engineering problems where shore parallel breakwaters might be used, are discussed in more detail.

3 Basic problems and the application of shore parallel breakwaters

General

Coastal erosion is in fact a tricky notion. Erosion of the part of the coast which is often considered to be the most valuable part, viz.: beach and dunes (or mainland), can be because of two fundamentally different processes:

i) erosion during a severe storm surge;
ii) structural erosion.

To a first approximation process i) can be considered as a typical (temporary) cross-shore redistribution phenomenon. Sand from the dunes and upper part of the beach is transported during the storm surge to deeper water and settles there. (Under common weather conditions the sand will return to its pre-storm position.) The total volume of sand between some fixed limits in a cross-shore profile \[m^3/m\] does not essentially change because of the storm surge.
Process ii), structural erosion, is quite different from erosion due to a storm surge. Because of the structural erosion process the volume of sand within a cross-shore profile reduces gradually with time. Sooner or later also the upper part of the profile (dune area) is lost permanently.

If erosion control is required, both types of erosion call for quite different solutions. In the present study structural erosion problems are mainly considered. If in the following erosion is mentioned, the erosion is meant to originate from structural erosion processes. When, however, an erosion control scheme to a structural erosion problem is designed, one always needs to take into account the consequences of the selected alternative for the erosion process during storm surges.

**Case A: Erosion of a continuous coastline**

The present, more or less autonomous, behaviour of many stretches of coast is often annoying the coastal zone managers involved. E.g. structural erosion of a part of the coast calls often for adequate countermeasures. Artificial nourishments have proven to be a good solution for this type of problems, despite the fact that this solution does not resolve the basic cause of the erosion problem. The gradual erosion still continues; only the detrimental effects of the erosion process (e.g. the final loss of beaches) is ultimately prevented. The occurring losses are replenished at a regular basis. (Say every 5 till 10 years.) Application of artificial nourishments in this case can be considered as a curing-the-symptoms approach.

With the application of structures (either groynes or shore parallel breakwaters) the coastal zone manager intends to interfere in such a manner in the present sediment transport processes in the erosion area, that the gradual erosion stops or at least is reduced. This approach may be characterized with a curing-the-disease approach.

Because many structural erosion problems are due to gradients in longshore sediment transport, it means in fact that often the longshore transports have to be reduced along some parts of the eroding coast. An effective application of structures to stop or to reduce the gradual erosion in the area under consideration, always results in a reduced input of sediments to the lee-side area. Often this reduced input leads to (increased) erosion in the lee-side area compared to the previous situation. Whether this is acceptable or not depends on the particular case. The lee-side consequences must always be taken into account properly in studying solutions for erosion problems.

The unavoidable lee-side consequences of a for the rest even perfect protection scheme, are a serious draw-back of this type of shore protection. Nevertheless in some cases the (extra) lee-side erosion might be acceptable. E.g. in cases where the lee-side area is considered to be less valuable than the protected area, or in cases where artificial nourishments can be better (cheaper) carried out in the lee-side area than in the area to be protected. If the erosion area concerns for instance an important recreation area, artificial nourishments on a regular basis may yield extra costs with respect to economic losses.
A structural erosion problem can be characterized with several parameters, e.g.:

i) length of area to be protected;
ii) rate of autonomous erosion in that area;
iii) longshore sediment transports passing the boundaries of the erosion area;
iv) boundary conditions with respect to wave climate and tide characteristics;
v) 'value' of the lee-side area with increased erosion.

With the actual values of these parameters as starting point, different schemes of shore parallel breakwaters provide an equal number of solutions, each with its own related costs. The main emphasis of the study was to acquire facts to judge the quality of different alternatives. That means that one should be able to quantify in sufficient detail the morphological impact of a chosen system of shore parallel breakwaters. Although some rules of thumb exist, it is generally felt that our knowledge of this topic is far from sufficient. A quote from the US Corps of Engineers Technical Report (Chasten et al., 1993) may illustrate this:

'Although numerous references exist for functional design of U.S. detached breakwater projects, the predictive ability for much of this guidance is limited. Knowledge of coastal processes at the project site, experience from other prototype projects, and a significant amount of engineering judgement must be incorporated in the functional design of a breakwater project.'

(Page 10 of Chasten et al., 1993.)

Within the study in Phase II an important step forward has been made towards our ability to model (and thus to quantify) the effects of arbitrary breakwater schemes properly. (See Section 4.)

Case B: Coastline with interrupted sediment transport

The classical example of a port, built along a sandy coast with a significant longshore sediment transport, shows large morphological changes at both sides of that port. Because of the interruption of the sediment transport by the breakwaters, at the up-drift side of the port continuous accumulation of sediment is observed. Erosion occurs at the down-drift side. (Lee-side erosion.) Although eventually also the accumulation of sediments will yield serious problems for a smooth operation of the port (sediment transport along the up-drift breakwater and sedimentation in the approach channel to the port), in the first years after the construction of the port the gain of new areas is often considered as advantageous. The lee-side erosion, however, is in most cases a serious detrimental side effect of the new port. If this lee-side erosion is not accepted, series of offshore breakwaters might be helpful to mitigate the erosion problem. As long as the breakwaters entirely interrupt the longshore sediment transport, the sediment input into the erosion area remains zero. In order to avoid continuous erosion in the down-drift area the only and best solution with the use of structures is to achieve resulting zero longshore sediment transports in the down-drift area to be protected. At the very end of the protection scheme the lee-side erosion (again) will take place. Indeed only a shift of the local erosion problem can be achieved. Whether this is acceptable or not depends on the particular case. With a well-designed shore parallel offshore breakwater scheme this goal can be achieved in principle.
Although an artificial sand by-pass system with a capacity equal to the full interrupted transport would resolve most of the morphological problems, in practice often under-designed systems are applied (if a system is applied at all). If only a part of the required volume is by-passed (say 75 %), still some lee-side erosion can be expected. Mitigating the remaining erosion with the help of an offshore breakwater scheme to an area further down-drift, puts quite different requirements to the scheme than compared to the zero sediment transport option. Now the scheme should be designed allowing to pass continuously 75 % of the original sediment transport. Undoubtedly quite different design characteristics of the protection scheme are required than in the zero transport case.

The coastlines of the stretches of coast near tidal inlets often show continuous erosion. A tidal basin which is out of equilibrium (e.g. by land reclamation projects in the basin area) continuously 'calls' for sediment imports in order to reach a new equilibrium state. Often the required import of material is at the spent of the sediment volumes in the ebb tidal delta in the initial phase, but eventually also at the spent of the adjacent stretches of coast. This results in a gradual erosion of the coast for a rather long time. This erosion can be prevented by application of an offshore breakwater scheme; a proper design is, however, complicated because the erosion is often (partly) due to effects of tidal currents at deeper water.

If a proper design of the protection scheme is achieved, one has to take into account that less material will reach the tidal basin. The 'demand' of the tidal basin for sediments in order to reach a new equilibrium has then to be fulfilled by other sources.

*Case C: Artificial beaches along coastlines with a lack of natural sediments (recreational beaches)*

Coastal areas which rely heavily on recreational use of their beaches are often faced with a lack of natural sediments. Consequently small and poor beaches are only available. (E.g. many beaches along the Mediterranean.) Improving the beaches in a restricted area will have large economical benefits for these areas. Since often only in a small area improvements are required and to restrict the volume of sand, artificial nourishment schemes call for additional projects in order to keep the nourishments in place. Shore parallel breakwaters, probably in combination with end-groynes, serve this goal. Wide beaches and a rather long waterline can be achieved in this way. Behind the breakwater segments often tombolo's are designed and constructed.

In order to be able to make a proper design, one should know what is the equilibrium position of the bay-shape behind the gaps between the breakwater segments in relation to the breakwater lay-out and boundary conditions. Sometimes also the case of a non-equilibrium position of the bay-shape (seaward shifted bay-shape in comparison with the equilibrium shape), but with some yearly maintenance nourishments, might be a proper solution. In order to apply this possibility one should have a proper insight in the (yearly) losses as a function of the deviation from the equilibrium position of the bay-shape.
Because of variations (within a year) of the predominant wave direction in fact a real equilibrium position of a bay-shape does not exist. What are the expected variations in this position in a particular case? For a coastal zone manager and the users of the beaches a clear answer to this question is important.

An equilibrium position of a bay-shape under (yearly averaged) common conditions might be a proper notion. However, for a total judgement of an applied scheme, also the behaviour of the scheme under severe storm conditions should be known. Probably irreversible losses of sediments through the gaps will occur. Quantifying these losses as a function of the particular conditions is a difficult design task.

**Case D: Seaward shifted coastline of a large-scale land reclamation project**

A large land reclamation project in front of a (straight) coastline in open sea calls for huge volumes of sediment. Provided that the new situation calls again for a beach as sea front, a zero option would be to shift all depth contours with the required distance (say two kilometers) in seaward direction. In this case the shape of the cross-shore profile is after the reclamation project the same as before the project. To a first approximation the coastal processes (longshore and cross-shore sediment transports) are expected to change only slightly by the reclamation project. Shifting all depth contours (say from Datum +5 m to Datum -17 m) means that for each m$^2$ of new land 22 m$^3$ of sand is required. Indeed a huge total volume of sand is thus needed for a large reclamation project. Much of the eventual required volume is stored in deeper water in the 'toe' of the cross-shore profile. If one would be able to avoid the fill of the toe, large savings can be achieved.

Shore parallel submerged breakwaters could be used to 'support' the upper part of the cross-shore profile, while the toe can be omitted (a 'perched beach'). In the present example (2000 m seaward shift and 22 m$^3$ sand for each m$^2$ new area) 44,000 m$^3$ sand is required per running meter alongshore. A submerged breakwater supporting the upper part of the profile above Datum -8 m which is situated in the original profile at Datum -13 m yields a reduction with approximately 13,000 m$^3$ sand per running meter (approximately 30% reduction). In this application 1 m$^3$ of stone 'saves' approximately 130 m$^3$ of sand; in other cases slightly different values are found.

The savings figures as given seem promising. Before the application of submerged breakwaters will be considered as a real alternative, however, various problems have to be resolved (and quantified). What are the losses of sand from the upper part of the profile over and across the submerged breakwater? Is the equilibrium shape of the supported part of the profile still the same as in the shifted case? What are the details of the transition between submerged breakwater and supported profile? Is the transition at crest level of the breakwater or at some distance below the crest?

Comparable to the application as discussed under Case C also a series of emerged shore parallel breakwaters could be considered as a seaward boundary of a large land reclamation project. Instead of a straight new coastline, now a series of bay-shapes serves as sea front. Equilibrium shapes as well as non-equilibrium shapes (but then with some additional maintenance nourishments) are to be considered. Each
alternative has advantages and disadvantages. Before real applications are considered, quantification of the morphological consequences is necessary.

Discussion of possible applications of shore parallel breakwaters in some coastal engineering problems

In the discussion of the possible application of shore parallel breakwaters for Cases A to D it became clear that these breakwaters have to be considered as promising alternatives for the problems as indicated. However, it also became clear that before application still some fundamental problems have to be resolved. One should e.g. be able to quantify, as reliable as possible the morphological impact of a proposed scheme. It is felt that no standard methods are yet available to do so. Different boundary conditions only already yield quite different morphological responses and hence quite different protection schemes are to be applied.

Taking some clearly defined real life coastal engineering problems as a guide, has turned out to be a good starting point in notifying the required complex design process of a shore parallel breakwater scheme. Sediment transports play a leading part in the morphological behaviour. Phase II of the study was meant to reveal some of the needed sediment transport quantification aspects of a possible application of shore parallel breakwater schemes. (See Section 4.)

4 Model of Phase II

In Phase II of the project an existing multi-layer computation model is adapted and extended in order to cope with the complicated processes occurring near (especially landward of) offshore breakwaters. In the multi-layer concept distinction is made between longshore transports and cross-shore transports.

In the multi-layer concept the cross-shore profile is schematized in a series of horizontal (rectangular) layers. (See Fig. 1.) After schematization the cross-shore profile looks like a staircase. Cross-shore transport occurs from one layer to another; along each vertical part of the staircase a part of the total longshore transport takes place.

The present mutual distance between two adjoining layers \( a_{\text{pres}} \) (the present length of a step) is compared with the mutual distance of these layers under equilibrium conditions \( a_{\text{eq}} \) (equilibrium distance of a step). The rate of cross-shore transport \( S_y \) is assumed to be proportional to the difference between \( a_{\text{eq}} \) and \( a_{\text{pres}} \).

\[
S_y = s_y (a_{\text{eq}} - a_{\text{pres}})
\]

where \( s_y \) is the cross-shore transport constant. The values of \( s_y \) depend amongst others on the depth in the profile. In this approach a cross-shore profile which is out of equilibrium, 'returns' because of cross-shore profile adjustments to equilibrium again after some time. Based on many calculations with a detailed cross-shore morphological computation model (UNIBEST-TC developed by Delft Hydraulics) a distribution over depth of \( s_y \) is determined.
Fig. 2 shows the well-known distribution of the longshore sediment transport over a cross-shore profile because of an obliquely approaching wave field for a uniform coast in longshore direction. If this distribution is plotted as a function of depth, a (remarkable) triangular distribution is found (see also Fig. 2). Such a triangular distribution was found for many different cases (different cross-shore profiles; different wave conditions; different particle sizes). The characteristic water depths \( d_{\text{top}} \) and \( d_{\text{zero}} \) (see Fig. 2) appeared to be simple functions of the significant wave height \( H_s \).

\[
\begin{align*}
    d_{\text{top}} &= \alpha H_s; \quad \alpha \approx 1.4; \\
    d_{\text{zero}} &= \beta H_s; \quad \beta \approx 3.0.
\end{align*}
\]

Also in cases with a combination of waves and currents typical distributions of the longshore sediment transport over depth have been derived. (See CUR 1997b.)

Reliable distributions of the longshore sediment transport over the horizontal layers are required in the multi-layer model. In the model the orientation of a horizontal layer determines the rate of longshore transport in the part of the profile which is schematized by the layer.

With the existing multi-layer concept the morphological behaviour of large coastal stretches, however, without structures could be simulated with time. To be able to handle also offshore breakwaters in the model, did require serious adaptations of the model. A typical effect of shore parallel breakwaters (either submerged or emerged) is the reduction of the wave height in the ‘shadow’ zone of the breakwater. Since the wave height is an important determining parameter in the sediment transports, these wave height reductions have to be quantified as a function of breakwater layout (e.g. position with respect to waterline; gap width; length of breakwater segments; crest height) and boundary conditions (e.g. wave height; wave direction; tidal currents).

![Diagram](image-url)  
**Fig. 1** Schematized cross-shore profile.  
(*Cross-shore transport \( S_y \) occurs at different levels; longshore transport \( S_x \) is distributed over profile.*)
Taking wave transmission and wave diffraction into account, the wave height adaptation has been quantified for some general cases.

The adapted model has been applied in a typical Case A problem with a series of different shore parallel breakwater schemes. The morphological development with time after inserting a breakwater scheme in the model, could be simulated. Some test cases showed reliable results; at least showed a behaviour as qualitatively expected.

![Diagram of Longshore Sediment Transport Distribution](image)

**Fig. 2** Longshore sediment transport distribution because of obliquely approaching waves.
(Upper panel: top view; lower panel: horizontal and vertical distribution of longshore transport.)
The efficiency of a given breakwater scheme is an important parameter in a design process. The efficiency of a scheme is defined as the ratio between the savings in erosion volume and the original erosion volumes strictly in the area to be protected. The model is provided with a very useful 'auto-nourishment' option. With that option the efficiency of a given scheme can be directly determined. Assume that the policy is to keep the waterline at least seaward of a limit position. If somewhere in the area to be protected at any time the waterline surpasses the limit position in landward direction, the computational model adds the required volume of sand in order to restore the position of the waterline to the limit position. Comparing the volumes still to be added in a case with a shore parallel protection scheme, with the volumes to be added in the unprotected case, yields the efficiency of that scheme. (See Figs.3 and 4 for examples.)

Fig.3  Development of eroding coast after 10 years with auto-nourishments. (A stretch of coast of 10 km shows a large gradient in longshore sediment transport; \(dS/dx = 130 \text{ m}^3/\text{m per year}\). The waterline of the middle part is kept at position with the auto-nourishment option. The figure shows the development of 5 different layers.)
Fig. 4 Development of eroding coast protected by a series of offshore breakwaters after 10 years.

(Same stretch of coast of Fig. 3. In this case protected by a series of shore parallel offshore breakwaters. Notice the accumulation of sediments at the up-drift side behind the breakwaters and the lee-side erosion.)

The Phase II model has been applied in only a restricted number of cases. The model has shown its abilities. The model is still a research version; it will be upgraded in future to a general applicable model. (See Steetzel et al., 1998.)

Applying a multi-layer model to simulate the very complex morphodynamical processes in the vicinity of offshore breakwaters is in fact a sign of weakness. Applying process-based morphological models would be strongly preferred. Although this type of models is improving very fast, the present versions are not yet able to simulate the development of the coast over a longer time for offshore breakwater cases satisfactorily. As a part of the studies in Phase II of the project some simulations of a few basic lay-outs of offshore breakwaters have been made with the Delft 2D morphological model of DELFT HYDRAULICS. The results are promising, but further research is necessary before this approach can be used in general applications. It is expected that as a result of the EU sponsored SASME project (SASME: Surf and Swash zone MEchanics), much progress will be made in the morphological modelling abilities.
5 Model of Phase III

A design support model was developed in Phase III of the project. It has proven to be a useful tool during the first phases of a design process. Different alternatives can be fast and easily evaluated. The model is Menu-oriented; the user has to fill out the basic characteristics of the design in mind. The model is available in a LOTUS 123 release 3.4, and in an Excel version.

The problem, indicated as Case A (erosion of a continuous coastline) has been studied in detail. The autonomous behaviour of the stretch of coast under consideration yields erosion. The detrimental effects because of the retreat of the coast can be mitigated by regular beach nourishments. This solution is considered as zero option. Also with different shore parallel breakwater schemes the erosion problem can be (partly) resolved. Often the problem is indeed only partly resolved, because the scheme does not prevent the erosion entirely. Some additional (but reduced) regular artificial nourishments are still required to keep the coastline at the prescribed position. Four sets of input data are required to run the design support model. These four sets of data can be generated with the Phase II model. Consequently a strong link exists between the Phase II and the Phase III model. Based on experience, rules of thumb or engineering judgement these four sets of data can of course be simply changed.

The model thus requires the input of a (restricted) number of efficiency values as a function of characteristic breakwater lay-out parameters like:
(i) the position of the offshore breakwaters from the coastline;
(ii) the relationship between offshore distance and length of the breakwater segments;
(iii) the ratio between gap width and length of the breakwater segments;
(iv) the crest height of the segments relative to the mean water level.

Within the program some basic dimensions of a breakwater scheme and some boundary conditions have to be specified by the user; next 'automatically' a simple static stable cross-section is calculated (Hudson formula). With (freely to select) fixed costs and unit prices for primary layers, secondary layers and core material, the construction costs of the breakwater scheme are determined.

The model is primarily developed for the use of rock structures as breakwaters. If for instance the use of geocontainers (large bags of geotextiles filled with sand) is considered as construction material for the offshore breakwaters, the user can 'simulate' this application by simply using appropriate unit prices.

The basic comparison parameter to evaluate different alternatives (including the zero option) is the net present value (NPV) of an alternative. Interest rate and assumed lifetime of a project are to be defined by the user.

If along a continuous eroding stretch of coast an offshore breakwater protection scheme is applied, the reduction in erosion in the protected area is always at the expense of the lee-side area. If at the end of the day also the (increased) erosion problem in the lee-side area has to be resolved, a shore parallel breakwater scheme can never be
an adequate solution. In some special cases, however, this firm statement might be relaxed. If, for example, regular nourishments in an area to be protected yield huge additional cost (e.g. economic losses in an important recreation area), concentrated nourishments in the lee-side area could be ultimately cheaper. The design support model has been provided with opportunities to take such cases into account.

6 Concluding remarks and recommendations

Concluding remarks

Although many day to day coastal engineering problems can be properly resolved with 'soft' methods (artificial nourishments), the application of shore parallel structures ('hard' method) could be a promising alternative in some cases. [Often a combination of 'hard' and (additional) 'soft' seems a good solution.]

Although the project has not resolved all problems, and not all aims have been achieved, the study has certainly increased the knowledge concerning the possible application of shore parallel structures. The project has served as a fruitful starting point for further studies. A promising approach to resolve the remaining problems has been found.

Recommendations

The Phase II part of the study has revealed that a promising modelling tool has been developed. It is recommended to extend and to generalize the use of this computation model. See e.g. Steetzel et al., 1998.

Process-based morphodynamic modelling of complex cases (like offshore breakwaters applications) is developing very fast. It is recommended to spend additional efforts in attempts to model some typical cases with this type of morphodynamic models.

Sediment Transport Around a Mound Breakwater: the Toe Erosion Problem

Asunción Baquerizo¹ and Miguel A. Losada²

Abstract

The combined action of waves (incident and reflected) and the alongbreakwater current driven by wave energy dissipation inside an infinitely long porous breakwater under oblique wave attack (Baquerizo and Losada, 1998), is taken into account to study the formation of bars in front of the structure and the sediment transport at the toe of it. The main features of the bars are explained in terms of the incident wave characteristics, remarking the wave incidence angle dependence, and the structural and hydrodynamic properties of the breakwater. Results may explain the existence of erosion/deposition patterns at the toe of the structure.

Introduction

Some coastal structures, designed to protect an area from wave action are built with quarry or rip-rap. Generally speaking, they reflect part of the incident energy modifying the wave field in the neighborhood of the structure. Moreover, part of the energy is dissipated inside the porous medium due to pore friction.

On sandy beds, it is known that wave action may induce the erosion of the toe of the breakwater, producing the failure of the structure. However, sometimes it is found that sand accumulates at the toe, filling up the structure and reducing its functionality as a wave dissipator.

Dalrymple et al. (1991) obtained the wave field in front of and inside a porous vertical structure when a monochromatic wave impinges obliquely on it. On the other hand, Baquerizo and Losada (1998) showed that for waves approaching obliquely an infinitely long porous structure, wave energy dissipation inside the pores drives an alongbreakwater current inside the structure that is transferred to the water regions by

turbulent diffusion. Moreover, they studied the combined action of waves and the current to study the sediment transport patterns in front of the porous structure showing that these mechanisms explain the formation of bars parallel to the breakwater, producing in some cases the erosion of the toe of the structure.

In this paper, the shape of the bars and the conditions under which erosion/deposition occurs at the toe of the structure are analyzed in terms of the characteristics of the incident wave and the structural properties of the breakwater. The reflection coefficient and the phase lag between the incident and reflected waves is presented first, next the drift velocity and the alongbreakwater current profiles are analyzed, finally the sediment transport patterns are obtained and the tendency of the bed is studied.

Theoretical Background

Let us consider an infinitely long vertical porous structure of width $b$, in water of constant depth, $h$, and a monochromatic wave train that impinges obliquely on it with an angle of incidence $\theta$. The origin of the reference frame is in the seaward face of the structure with the $x$-axis normal to it, the $y$-axis lying along the breakwater and the $z$-axis pointing upwards (see Fig. 1).

Figure 1. Definition sketch showing waves approaching an infinitely long vertical porous breakwater at an oblique angle.

The presence of the breakwater modifies the incident wave field. In the first region, part of the incident wave energy is returned in the seaward direction. Some of the remaining energy, transmitted to the porous structure is dissipated because of friction losses within the pores. Inside the breakwater, part of the wave energy is reflected...
because of the discontinuity at the leeward face of the structure and some is transmitted to the third region.

**Wave field inside and outside the structure**

Under plane wave assumption, Dalrymple et al. (1991) obtained the velocity potentials in each region. The corresponding water surface elevation can be expressed as:

\[ \eta_a(x,y,t) = a_a(x)e^{-i(k_a x - \omega t)} \quad \alpha = I, II, III \]  

where the amplitude of the oscillations, \( a_a(x) \), in each region \( \alpha = I, II, III \) is constant along lines parallel to the breakwater.

Seawards of the structure, the amplitude of the water surface elevation is:

\[ a_f(x) = \left( |A_1|^2 + |B_1|^2 + 2|A_1|B_1|\cos(2k_a \cos \theta x + \varphi) \right)^{1/2} \]

where \( A_1 \) is the amplitude of the incident wave, \( R = |R|e^{i\theta} \) is the reflection coefficient of the structure and \( B_1 = A_1R \) is the amplitude of the wave reflected at the seaward face of the structure. \( a_f(x) \) varies periodically with \( x \), with a characteristic wavelength \( L_b = L/2\cos(\theta) \), showing lines of maximum (quasi antinodes) and minimum (quasi nodes) amplitude, whose distance to the breakwater depends on the phase lag between the incident and the reflected trains.

Inside the structure, the amplitude is:

\[ a_i(x) = |s - if| \left( |A_2|^2 e^{2q_x x} + |B_2|^2 e^{-2q_x (x-b)} + 2|A_2||B_2|e^{q_x \cos(q_x (2x-b)+\varphi_A_2-\varphi_B_2)} \right)^{1/2} \]

where \( A_2 = |A_2|e^{iq_x A_2} \) is the amplitude of the wave transmitted to the structure and \( B_2 = |B_2|e^{-iq_x B_2} \) is the amplitude of the wave reflected at the leeward face of the breakwater. \( s \) and \( f \) are parameters describing the porous medium and \( q_R, q_F \) are, respectively, the real and imaginary parts of the wave number inside the coastal structure (see Dalrymple et al., 1991; Losada et al., 1993 for details). The waves transmitted at \( x=0 \) and reflected at \( x=b \) are dissipated as they propagate inside the structure and consequently, the oscillations of the amplitude of the water surface elevation inside the porous medium decrease with \( x \). As the characteristic length of the oscillations is again \( L_b = L/2\cos(\theta) \), they can be observed only for breakwater widths larger than \( L_b \).

**Alongbreakwater current**

Wave energy dissipation inside the pores produces a variation, in the acrossbreakwater direction, of the radiation stress, \( S_{x\nu} \), inside the porous medium (Méndez, 1997) driving a current, \( V(x) \), that flows parallel to the structure (Baquerizo and Losada, 1998). Due to the turbulence induced by temporal and spatial fluctuations of the velocity flow inside the pores, the current is transferred to the water regions.
The velocity profile shows a maximum inside the structure, close to the seaward face of it, and decreases towards 0 far from the structure. The magnitude of the velocity profile depends on the structural properties of the breakwater and on the characteristics on the incident wave.

Summarizing, in the proximity of the structure, particularly at the toe of the structure, there are the combined action of waves and the alongbreakwater current, which may provide an efficient mechanism for initiating and transporting the sediment.

**Sediment transport**

Using Bailard's formula (1981), the sediment transport patterns under the influence of waves and currents are obtained in terms of the total velocity, $\vec{u}_t$, at the bottom, which results from the superposition of the orbital velocity, $\vec{u}_o$, and a small perturbation which does not depend on time, $\vec{U}$. Notice that the orbital velocity is due to the incident and the reflected waves.

Far from the structure, $\vec{U}$ is the drift velocity, $\vec{U}_d$, at the top of the bottom boundary layer. Close to the structure, both alongbreakwater current, $V(x)$, and drift velocity have to be considered. Although $V$ may modify the mean motion of the boundary layer, in a first approach, as $|U_d|$ and $V$ are both very small compared to the orbital motion, they may be linearly superimposed without significant error.

**Bed morphology in front of the coastal structure**

Dalrymple et al. (1991) showed that the reflection coefficient on a porous structure depends on the angle of incidence and that there is a value, called the Brewster angle, for which the modulus of the reflection coefficient is minimum. That means that the same breakwater may behave as a highly reflective or as a low reflective structure depending on the angle of wave attack. Baquerizo and Losada (1998) showed that the drift velocity patterns in front of the structure and the alongbreakwater current also depend on the breakwater reflectivity. This property justifies the choice of two case studies representing a moderately permeable and dissipative breakwater, and an almost impermeable and fully reflective one, with special attention in the effect of the angle of incidence. Table 1 summarizes the principal characteristics of the breakwater and wave conditions for the two cases, which will be referred to Structure A and Structure B, respectively.

$^1$friction factor of the porous medium
$^2$porosity of the porous medium

Table 1. Incident wave and breakwater characteristics
For Structure A, the reflection coefficient varies from to $R=53$ at $\theta=0^\circ$ to $R=0.04$ at the Brewster angle, $\theta_B=70^\circ$, then it increases. The phase lag between the incident and the reflected trains is very small for $\theta<\theta_B$. At $\theta_B$ it changes rapidly until it achieves a constant value $\phi=\pi$ for angles larger than $\theta_B$ (Fig. 2 a). This means that for angles smaller than $\theta_B$ the antinodal lines will be at $x_n=-nL_b$, $n=0,1,2,...$ whereas for higher values they will be at $x_n=-nL_b-L_b^2/2$, $n=0,1,2,...$. For the almost impermeable breakwater (Case B), the structure behaves always like a highly reflective structure and the Brewster angle converges asymptotically to $\theta=\pi/2$. The phase lag is close to $2\pi$ and therefore, the antinodal lines will be at $x_n=-nL_b$, $n=0,1,2,...$.

**Figure 2.** Magnitude and phase of the reflection coefficient

The drift velocity $\vec{U}_d=U_d \hat{j}+V_d \hat{j}$ at the top of the boundary layer in a three-dimensional small-amplitude oscillatory flow was obtained by Hunt and Johns (1963) and applied later by Carter et al. (1973) to a field resulting from the superposition of an incident wave and a reflected wave with normal incidence. For the wave field in front of the structure, $\vec{U}_d$ is a function uniform in $y$, varying periodically with the distance to the breakwater. The velocity component in the $y-$ direction, $V_d$, is in phase with the wave amplitude, that is, it is maximum at $x_n=-nL_b-\phi L_b/(2\pi)$, $n=0,1,2,3,...$. The component in the $x-$ direction, $U_d$, has a lag of $-L_b^2/4$ with respect to $V_d$ with maximum values at $x_n-L_b^2/4$. $V_d$ is always a positive function, whereas $U_d$ changes the sign for values of the reflection coefficient above a threshold value which is about $R_t=0.82$.

Fig. 3 shows, for Cases A and B, the $x-$ and the $y-$ component of the drift velocity as well as the alongbreakwater current profile obtained for $\theta=45^\circ$. For Case A and small angles of incidence, $U_d$ and $V_d$ are of the same order of magnitude, and as $\theta$ increases, the $y-$ component of the drift velocity dominates over the $x-$ component. The resulting sediment transport patterns (Fig. 4 a) are essentially in the direction of propagation of the incident wave, except at the antinodes where the angle with respect to the $x-$ axis increases slightly. For Case B, the drift velocity in the $y-$ direction is larger
than $U_d$ and, because it corresponds to a highly reflective structure with reflection coefficients above $R$, $U_d$ changes the sign. The resulting sediment transport converge towards the antinodes and diverges at the nodes (Fig 4 b).

For Structure A, the alongbreakwater current at the face of the structure is of the same order of magnitude than the drift velocity (see Fig. 3 a), and the maximum values of the alongbreakwater current profile are achieved for $\theta \approx 50^\circ$. For structure B the alongbreakwater current is negligible compared to the drift velocity.

Fig. (5) shows, for Cases A and B, the evolution with the angle of incidence of the local time variation of the bed. For Case A, it can be seen that the tendency of the bed is to form bars parallel to the breakwater almost sinusoidal in shape, with a distance between crests of $L_b$, and a distance from the first crest to the structure of $L_b/4$. The higher bars are expected to develop for small angles of incidence. As the angle of incidence increases, the height of the bars decreases and the effect of alongbreakwater current becomes more important. Consequently, it is expected that the bed erodes at the toe of the breakwater.

For Case B the bed develops bars with double peak crests and deep troughs. Again, the higher bars are expected to be for small angles of incidence. The distance between troughs is $L_b$ and the first bar through is $L_b/2$ away from the structure. For all angles of incidence, sediment accumulates at the toe of the structure.
Figure 4. Sediment transport patterns in front of the breakwater
Figure 5. Local time variation of the bed in front of the breakwater
Conclusions

The combined action of waves (incident and reflected) and the alongbreakwater current, driven by wave energy dissipation inside a porous structure, is considered to study the sediment transport patterns and the associated local time variation of the bed in front of an infinitely long porous breakwater of finite width when a monochromatic wave train impinges obliquely on it.

The modulation of the $x$- and the $y$- components of the drift velocity with the distance to the breakwater is found to produce sediment transport patterns that explain the formation of bars parallel to the breakwater whose characteristics depend on the characteristic of the incident wave train (wave number and angle of wave attack) and on the reflection coefficient of the structure. Moreover, the alongbreakwater current modifies the sediment transport in the neighborhood of the breakwater.

For a moderately permeable and dissipative structure, the reflectivity depends strongly on the angle of incidence and the bars are expected to be almost sinusoidal in shape, with a distance between crests of $L_b = L/(2\cos \theta)$. For small angles of incidence, the effect of the alongbreakwater current is negligible and the first bar crest is likely to be $L_b/4$ away from the structure. For larger angles of incidence, the alongbreakwater erodes the bed in the vicinity of the breakwater; this effect is maximum at $\theta \approx 50^\circ$.

For an almost impermeable and fully reflective structure, the alongbreakwater current is negligible compared to the drift velocity and has no significant effect on the sediment transport patterns. The $x$-component of the drift velocity changes the sign, and as a result, the sediment transport converges towards the antinodes and diverges at the nodes. The tendency of the bed is to form bars with two peaks and deep troughs, with a distance between troughs of $L_b$ and the first trough located $L_b/2$ away from the structure. It is expected that sand accumulates at the toe of the structure.

STABILITY OF NEAR-BED RUBBLE-MOUND STRUCTURES

César Vidal 1, Íñigo J. Losada, Associate Member, ASCE 1
and Francisco L. Martín 2

Abstract

This paper describes the experimental and theoretical analysis carried out to improve our knowledge of the stability of near-bed rubble-mound structures. Laboratory tests have been performed to improve the data base on the stability of this kind of structure. The experimental results are compared with the results of three different approaches to stability: dimensional analysis, Morison forces and forces derived from bed shear stresses. In all cases considered, the influence of the geometry of the structure has not been taken into account, and the characteristics of the flow around the structures have been obtained from linear wave theory. The analysis of the data shows that the mobility parameter, a non-dimensional form of the bed shear stress, gives the best representation of the damage in these structures. From the analysis it can also be concluded that inertia forces are not relevant in the representation of the damage using Morison forces. Based on these approaches, some formulations of damage are presented. These formulations indicate that, for the first stages of damage, damage varies almost linearly with force (Morison or bed shear stress).

Introduction.

Near-bed structures are those whose height is low compared with water depth. The depth of submergence of these structures is enough to assume that wave breaking does not affect the hydrodynamics around the structure. This definition separates them from the low-crested or submerged breakwaters. Rubble-mound, near bed structures are used in coastal engineering for the protection of other structures such as pipelines or outfalls, for scour protection, as toe or lateral beach support or for the construction of artificial reefs for marine life. Stability under wave action and currents is usually the

design condition while other loads such as those induced by anchors or fishing nets may be of secondary importance.

In recent years, experimental and theoretical efforts have been undertaken to fill the lack of information on the stability of submerged rubble-mound structures. Much of the experimental work has been directed towards low crested or submerged breakwaters, Vidal et al. (1992), van der Meer (1993) and today, some guidelines for the design of these structures are available. In the field of near-bed structures, experimental information is scarce, Lomónaco (1994), Levit et al. (1997), and mostly dedicated to assess the transport of rubble units. Therefore, most engineers are using sediment transport formulas developed for horizontal bottom to determine the stone size.

The approaches that scientists and engineers apply to assess the damage of rubble-mound structures are based on one of the following general methodologies:

- **Dimensional analysis**: Using the methods of dimensional analysis, the damage is expressed as a function of some non-dimensional parameters. The experimental data are used to obtain the function that gives the better fit between the calculated and the measured damage. This approach is the most widely used in the assessment of damage of rubble-mound breakwaters. This functional will vary any time the geometry of the structure or the type of the armor units changes the hydrodynamics, gravity or interlocking forces involved in the movement of the units.

- **Quasi-empirical approach**: This approach makes use of the knowledge of the flow around and inside the structure which is possible due to the continuous improvement of the flow models. With a flow model and a formulation for the hydrodynamic forces (similar to those of the dynamical analysis) the quasi-empirical model is based on the assumption that the damage should be a functional of some non-dimensional parameters that represent the hydrodynamic forces acting on the units. This functional will be general for all structures with similar interlocking and gravity forces, that have not been taken into account in the force formulation.

- **Dynamic analysis**: This approach makes use of some analytical model of the flow around and inside the porous structure. Once the flow is known, the vector forces over the units are expressed, including the interlocking forces. This approach allows the study of the dynamics of the armour stones in real time. As a result, the deformed profile of the structure after the wave attack can be obtained. Although this approach is improving as more knowledge on the flow and interlocking forces is achieved, the state of the art does not allow its use for the design of structures.

In this paper, some work in the frame of the first and second approaches to the stability problem of near-bed rubble-mound structures, carried out at the Universidad de Cantabria is presented. First, some model experimentation has been done to improve the
existing data sets on stability, paying special attention to the initial stages of damage. After that, the data analysis is compared with two different parameters for the quasi-empirical model; one based on the Morison drag forces (drag parameter) and the other based on a bed shear stress parameter (mobility parameter). These two approaches are also compared with a conventional non-dimensional approach using two parameters, the stability number and the relative submergence, that have been found to be the most relevant for the assessment of the damage.

Methodology

Detached near-bed rubble-mound structures are usually very flat, and are deployed in relatively deep waters. Typical ratios of crest height/structure width, are in the range $0.1 < h_c/B < 0.2$ while the ratios of crest height/water depth are in the range $0.1 < h_c/h < 0.5$. Waves propagate over these structures with little transformation and reflection is very low. In the case of very steep waves, the breaking takes place after the waves have overtaken the structure and the perturbation of the breaking wave does not affect the flow over the structure. This means that flow around the structure can, in a first approximation, be described by wave theory.

For the implementation of a fully quasi-empirical model of damage, a model of the flow around and in the porous structure will be necessary. But before that, an appropriate flow-force parameter should be chosen in order to relate damage with forces. If enough experimental data is obtained with only one geometry and rubble type, the geometry and porous characteristics of the rubble will not affect the results, and the suitability of different flow-force parameters could be studied using a simple wave theory to describe the flow around the structure. To do this, the next steps will be followed:

1- Stability model tests of a single near-bed rubble-mound structure using regular waves.
2- Dimensional analysis of the experimental data and formulation of damage in terms of the most relevant non-dimensional parameters.
3- Analysis of the relative importance of the drag and inertia terms in the description of the structure's measured damage. Definition of a proper flow-force parameter based on Morison-type forces.
4- Analysis of the observed damage in terms of the Morison drag parameter.
5- Definition of an appropriate bed shear stress flow-force parameter.
6- Analysis of the observed damage in terms of the bed shear stress parameter.
7- Comparison between the three different approaches to damage analysis.

Stability model tests

Experimental set-up

In the wave tank of the laboratory of the Ocean and Coastal Research Group of the Universidad de Cantabria 167 stability tests have been carried out. Regular wave trains of 230 waves have been used to test the stability of a single low-crested, rubble-
mound structure. Figure 1 shows the general layout in the wave tank and the geometric properties of the structure. The structure is a detached protection, 150 cm long, 42 cm wide and 6 cm high. The crest width is 6 cm and the slopes are 3/1. The rubble is composed of uniform angular marble stones, with the following characteristics: $W_{15} = 0.18 \text{ g}$, $W_{50} = 0.23 \text{ g}$, $W_{90} = 0.37 \text{ g}$, $\rho_s = 2675 \text{ Kg/m}^3$ and $n = 0.47$, where $\rho_s$ is the density of the stones and $n$ is the porosity of the rubble. With these data, the following cube-equivalent nominal diameters can be calculated: $D_{n15} = 4.1 \text{ mm}$, $D_{n50} = 4.4 \text{ mm}$ and $D_{n90} = 5.2 \text{ mm}$.

The structure was installed in the bottom of the wave tank, over a rigid steel plate that can be lifted with the laboratory crane to assess the damage without draining the tank. Between the structure and the wave board there is a mild slope, 32/1, that shoals the waves. Behind the structure, a rubble beach, with a slope 15/1 dissipates the generated waves.

For the experiments, three different orientations of the structure axis with respect the wave rays have been considered: 90° (normal incidence), 30° (oblique incidence) and 0° (parallel incidence). In this paper, only the results of the 62 tests carried out with normal incidence will be considered. Three water depths and three wave periods have been selected for the tests. The number of wave heights tested for each water depth and period is variable, depending on the measured damage. Free surface has been measured in four locations, three resistive wave gauges were installed in front of the structure in order to separate incident and reflected waves. Another wave gauge was installed in the rear of the structure, to measure the transmitted waves.
Test methodology.

For each test, the model was rebuilt over the steel plate, outside the water tank. The model shape was obtained using a steel plate that glided longitudinally over two rails, see Figure 2-a. A gap at the top of the plate allowed the input of more stones, if necessary. When the model was finished, no single stone of the model touched the gliding plate. With the laboratory crane, the steel plate that supported the model was lifted to its position in the wave tank. The model was moved carefully to avoid any movement of stones when the model was submerged in the water, Figure 2-b. Each test was defined by the wave incidence angle, water depth, wave period and wave height. After the wave run, the model was carefully lifted again and moved to a working table to assess the damage, which was measured counting the number of stones in the accreted area of the structure and those removed from the structure. The test area of the model was a section 50 cm long, that in the case of normal incidence was located in the center of the model. To obtain the accreted stones, the gliding plate is moved along the model. All the stones of the test area touching the gliding plate were collected and added to those stones removed from the test area.

![Fig. 2- Experimental methodology. (a) Model over steel plate. (b) Submerging the model.](image)

Test results

The wave gauge data were analyzed to obtain incident, reflected and transmitted wave trains. Due to the low $h_s/h$ ratio, wave reflection from the structure was very low, less than 5%. For the longer periods, wave reflection from the dissipating beach was higher (about 10%) than the reflection from the structure. Conventional up-crossing analysis of the incident waves was carried out to determine the statistical properties of the waves.
The measured water depth, incident wave period and wave height as well as the number of displaced stones are presented in table 1.

Table 1. Measured wave parameters and number of displaced stones for normal incidence

Although the waves are regular there are always slight differences in wave heights that have to be taken into account in the statistical analysis. The average of the 100 biggest waves, $H_{100}$, of the incident wave train has been used as the wave height parameter for the following stability analysis.

Data analysis

As stated earlier, the objective of this research is the comparison between the suitability of two flow/force parameters (Morison forces and bed shear stress forces) to explain the observed damage. A conventional non-dimensional approach will be used as a reference.

Dimensional analysis of stability

The number of stones in the accreted area is the measured damage. In a conventional dimensional analysis, this damage should be a functional of all the flow and geometry parameters involved:

$$N = f(H, T, \theta, h, h_c, B, \alpha, D, \rho_s, \rho, \mu)$$

where:

- $H$: Wave height
- $T$: Wave period
- $\theta$: Angle between wave ray and the structure axis
- $h$: Water depth
Crest height of the rubble protection
- Width of the rubble protection
- Slope angle of the rubble protection
- Nominal diameter corresponding to the W50 stones of the rubble
- Density of the rubble stones
- Density of the water
- Dynamic viscosity of water.

In this work the geometrical characteristics of the structure will be held constant, and only normal incidence results will be used, so the expression (1) can be simplified to:

\[ N = f(H, T, h, c, D, p, \rho, \mu) \]  (2)

The measured damage is defined as the number of stones, \( N \), counted in the accreted area. This accreted area is assumed to be the same as the eroded area, so \( N \) is also the number of stones lost in the eroded area. Once \( N \) and the mound porosity is known, the average eroded area, \( A_e \), in a section of length \( X \), can be estimated using the non-dimensional parameter \( S \) expressed as:

\[ S = \frac{A_e}{D_{n50}} = \frac{ND_{n50}}{(1 - n)X} \]  (3)

It is well-known that the non-dimensional parameter that relates the stone size and density with the wave height is the stability number or Hudson number:

\[ N_s = \frac{H}{\Delta D_{n50}} \]  (4)

Where \( \Delta = \frac{\rho_e}{\rho} - 1 \)

The freeboard of the structure has a great influence on the damage. Its influence can be taken into account using the non-dimensional parameter \( h_c/h \). Other non-dimensional parameters that could be important for the damage are the relative water depth, \( h/L \) and the wave steepness, \( H/L \), where \( L \) is the wave length.

The viscosity of the water affects the flow around the stones. This influence is taken into account using the Reynolds number. In the hypothesis that model tests are such that the flow above the rubble is rough turbulent, the Reynolds number would not affect the drag over the stones and the influence of the water viscosity on the resulting damage can be neglected. After the previous statements, eq. (3) can be simplified to the following non-dimensional form:

\[ S = f(N_s, h_c/h, h/L, H/L) \]  (5)

Figure 3 shows the influence of \( N_s \) on damage. The points clearly show the exponential increase of damage with \( N_s \). It is also clear from the figure that damage is decreased when the crest submergence, \( h_c/h \), decreases. Although the general trend is an
exponential growth of damage with $N_s$, if only low values of $S$ are taken into account, $S<2$, the growth of $S$ with $N_s$ can be considered to be linear.

The influence of wave steepness and relative water depth is not that clear. Following the results shown in Figure 3, for a water depth of 0.2 m and a period of 1.2 s, damage increases slightly faster than for a period of 2.0 s. However, for a period of 2.8 s the evolution of damage is similar again to that of the former period of 1.2 s. This behavior is different for the two other water depths considered, indicating that the influence of these two parameters is small and that it cannot be easily evaluated with independent potential fits of any of them. For this reason, and as a first approach, the influence of these two parameters is discarded in the analysis, and only the two main parameters will be taken into account:

$$S = f(N_s, \frac{h_c}{h})$$  \hspace{1cm} (6)

Figure 3 shows also the best fit lines for the function $f()$, using an exponential form for the influence of $N_s$ and a potential form for the influence of $h_c/h$.

**Fig. 3.** Damage parameter, $S$, versus stability number, $N_s$ and crest sumergence $h_c/h$. Experimental data and best fit lines.

**Morison forces analysis**

The Morison equation relates the flow properties with the parallel and normal forces generated by that flow above a solid object:

$$F_D = \frac{1}{2} \rho C_D D_{10}^2 \bar{u} |\bar{u}| + \rho C_M D_{10}^3 \frac{Du}{Dt}$$  \hspace{1cm} (7)
\[ F_L = \frac{1}{2} \rho \, C_L \, D_{n50}^2 \, \bar{u} \, |\bar{u}| \]  

(8)

where \( \bar{u} \) is the velocity vector and \( C_D, C_M \) and \( C_L \) are drag, inertia and lift coefficients, respectively, that depend on the shape of the solid and on the characteristics of the flow. These coefficients should be obtained experimentally.

Tørum (1994) measured forces over individual armour units of a rubble-mound breakwater laboratory model and determined the drag, inertia and lift coefficients. Among other conclusions, two are enhanced here:

- Maximum parallel (to the slope) forces are in phase with maximum velocities. This implies that maximum parallel forces are dominated by drag.
- Maximum normal forces are a combination of drag, lift and inertia forces. Their magnitude is less than half the maximum parallel forces.

In the threshold of initiation of damage, the armor units will be displaced only by the maximum forces, that are dominated by drag. If that is true, damage will only be a function of the maximum parallel velocities affecting the units. Maximum parallel forces over the crest of the rubble protection can be represented as a function of the oscillatory velocity amplitude at the crest level, \( U_c \), by the following non-dimensional drag force parameter:

\[ F_{dp} = \frac{\rho_w \, U_{c,}\,^2}{\rho g D_{n50}} \]  

(9)

where,

\[ U_{c,} = \frac{\pi \, H \, \cosh \, kh_c}{T \, \sinh \, kh} \]  

(10)

![Fig. 4. Damage parameter vs. drag parameter. Data and best fit.](image)
Figure 4 shows the damage data as a function of the drag force parameter (9) with the best exponential fit. As can be seen, the fit for low levels of damage, $S<4$, is fairly good, but the spread increases above that value of $S$, indicating that above that level, transport of stones is not well related with drag forces.

Figure 5 shows a zoom of the data below $S=4$. As can be seen the data trends for different periods and water depths can still be separated, indicating that there should be more flow information in the force parameter. Also shown in the figure is that, for $S<2$, a linear relation between the drag force parameter and damage is nearly as good as the exponential fit.

\[
S = 0.41 \exp \left[0.598 \frac{U^*U}{(gD)}\right], \quad \text{for } U^*U/(gD) > 0.4
\]

\[
S = 0.875 U^*U/(gD) - 0.0746, \quad \text{for } U^*U/(gD) < 0.4
\]

**Bed shear stress forces analysis.**

Formulations of sediment transport make use of the Shields parameter or mobility parameter, $M_p$, that relates the shear stress at the crest, $\tau_{cw}$, with the submerged weight of the sediment grains:

\[
M_p = \frac{\tau_{cw}}{\Delta g D_{50}}
\]  \hspace{1cm} (11)

The shear stress over the crest due to the oscillatory motion of waves can be expressed as a function of the oscillatory velocity amplitude at the crest level, $U_b$, using the following quadratic expression:

\[
\tau_{bw} = 0.5 \rho \ f_w \ U_c^2
\]  \hspace{1cm} (12)

where $f_w$ is a wave friction factor, that can be expressed following Swart (1976) as follows:
\[ f_w = \exp \left[ -6 + 5.2 \left( \frac{A_c}{k_s} \right)^{0.19} \right], \quad \text{for} \quad \frac{A_c}{k_s} > 1.57 \] (13)

\[ f_w = 3, \quad \text{for} \quad \frac{A_c}{k_s} \leq 1.57 \] (14)

where \( A_c \) is the amplitude of the oscillatory horizontal displacement of the water particles under the wave motion at the crest level that for linear wave theory is given by:

\[ A_c = \frac{H \cosh kh_c}{2 \sinh kh_c} \] (15)

and \( k_s \) is the bed roughness that can be related to the stone size through the expression given by Kamphuis (1975):

\[ k_s = 2D_{90} \] (16)

In Figure 6 the damage results as a function of the mobility parameter is presented. Again, for damage levels \( S > 4 \), the dispersion increases, indicating that the mobility parameter alone is not appropriate to explain high levels of damage, where formulations of transport could be more suitable. Figure 7 shows a zoom of the damage data in the range \( S < 4 \). It can be seen that dispersion is lower than for the drag force parameter case. Again, in the first stages of damage, the evolution of damage with the mobility parameter is very linear; in particular in the range of \( S < 1 \). For damages \( S > 1 \), dispersion increases, giving some information about when transport starts.

**Fig. 6.** Damage parameter vs. mobility parameter. Data and best fit.
Comparison between the three approaches.

Figure 8 is a plot of the measured damage parameter against the calculated one, using the three approaches and fits indicated above: non-dimensional with two parameters, drag force parameter and mobility parameter. Only damage data in the range $S<4$ have been taken into account. $S$ calculated versus $S$ measured has also been drawn in the figure. In the legend, the mean square error ($mse$) between the measured and the calculated damage is also shown. As can be seen from Figure 8, the mobility parameter gives the lowest $mse$, while the drag force parameter and the biparametric formulas give similar results for the $mse$. For $S<1$, the suitability of the mobility parameter is still better than the other approaches.
The sharp increase of dispersion between the calculated and the observed damage parameters could be an indication of a change in the transport modes: for $S<1$ the stone jumps or rolls once until a more stable position in the mound is achieved. In this case, only the least stable units are affected and the number of waves (regular waves) should not influence the measured damage. For $1<S<2$, units can be moved many times until they find a stable position on the rubble. In that case the number of waves necessary for the stabilization of damage increases with the damage level but the damage continues its linear increase with the mobility parameter. If the total number of waves is maintained, dispersion increases. For $S>2$ stones are not able to find a stable position in the rubble and can be transported away. In that case, damage never stabilizes and depends on the number of waves. As the transport is not well described by the mobility parameter alone, dispersion increases again. The change from linear to exponential in the relation between the damage and the mobility parameter is a clear indication that new parameters should be added to describe the influence of the transported stones.

Engineers are not comfortable with the idea of having the stones of their protection rolling away (and perhaps appearing in the nearby beach). For that reason, it seems reasonable to design these structures for damages in the $S<1$ region.

Conclusions.

The results of the analysis show that the approach considering the forces generated by the bed shear stresses gives a better agreement between the observed and the calculated damage than the conventional approach using Morison forces on the units. If dimensional formulas of damage are restricted to a maximum of two parameters, the more relevant parameters for damage are the stability number and the relative submergence of the structure. In that case, the bed shear stress gives a better fit to damage than the dimensional approach.

In the first stages of damage, for damage parameters in the range $S<1$, the evolution of damage with the mobility parameter is very linear. In the range $1<S<2$, the evolution of damage with the mobility parameter is also linear, but dispersion increases. In the range $S>2$, the evolution of damage with the mobility parameter is exponential, with dispersion increasing as the mobility parameter increases.

The sharp increase of dispersion between the calculated and the observed damage parameters could be an indication of a change in the transport modes: for $S<1$ the stone jumps or rolls once until a more stable position in the mound is achieved. In that case, only the least stable units are affected and the number of waves (regular waves) should not influence the measured damage after the first tenths of waves have stabilized the damage. For $1<S<2$, units can be moved many times until they find a stable position on the rubble and the number of waves necessary for the stabilization of the damage increases with the damage level. If the total number of waves is maintained, dispersion is increased. For $S>2$ stones are not able to find a stable position in the rubble and can be transported away. In that case, damage never stabilizes and depends on the number of waves. As the transport is not well described by the mobility parameter alone, dispersion
increases again. The change from linear to exponential in the relation between the
damage and the mobility parameter is a clear indication that new parameters should be
added to describe the transported stones.

It can be concluded that it seems reasonable to design near-bed rubble mound
structures considering damages in the $S<1$ region.

ABSTRACT - 100 Years of Experience In a High Energy Wave Climate
This paper uses the examples of Coffs Harbour breakwaters and the training wall head on the Richmond River at Ballina to outline some of the developments in coastal engineering design and construction over the last century. Most of the 63 major structures along the New South Wales (NSW) coastline are similar. Recent developments in data collection and analysis as well as the evolution of physical modelling techniques used for coastal structure design at the NSW Department of Public Works and Services' Manly Hydraulics Laboratory (MHL) are discussed using these two projects. The use of computational models in conjunction with physical models and the introduction of new variables such as wave obliquity and groupiness into breakwater design are discussed. The need to evaluate the performance of artificial units such as Accropodes, concrete cubes and Hanbars for primary armour at breakwater heads due to restrictions on the availability of quarry armour and available construction techniques is briefly addressed.

1. Introduction
The first European settlement of NSW at Sydney in 1788 was by sea. The first public works in the new colony included landing steps and wharves constructed in Sydney Cove. The involvement of Public Works in coastal engineering extended along the coastline with the growth of the new colony. To a very large extent, the need for these works to improve navigation and trade formed the basis for the development of coastal engineering practice in NSW.

1 NSW Department of Public Works and Services, Manly Hydraulics Laboratory, 110B King Street, Manly Vale, NSW, Australia, 2093
2 Department of Land and Water Conservation, 10 Valentine Avenue, Parramatta, NSW, Australia, 2150

1744
Coastal engineering in NSW has gone through a series of stages which are identifiable in the public (coastal engineering) works and government programs of the time. These included:

• From 1788 to the 1950s the emphasis on coastal engineering was for the improvement of navigation for the coastal trade, including the development of major ports, construction of wharves, dredging of navigation channels and construction of shipbuilding and repair facilities. By the 1950s the coastal trade had all but ceased to exist and could not compete with the expanded rail and road network. The major ports of Newcastle, Sydney, Port Kembla and Botany Bay were established and have continued to develop the capacity to handle larger ships and containers.

• From the 1950s to the present there has been an emphasis on the use of all but the major ports for the fishing industry. From 1959 to 1966 Public Works constructed nine fishing ports under the fishing ports program. This program was augmented in 1976 and further works included wharves, facilities, entrance works, breakwaters, boat harbours and mini-ports.

• From the mid-1970s to the present there has been an increasing awareness of the coastal environment and its fragile nature and the need to preserve the natural environment and the recreational amenity it provides. This increased awareness has coincided with a boom in the tourist industry, together with an unparalleled increase in coastal development. The number of registered vessels in NSW increased from 12,000 in 1979 to 90,000 in 1989 and 160,000 in 1997 (NSW Waterways pers. comm.) Coastal engineering focus has changed to beach protection works, beach regeneration and the provision of tourist and recreational infrastructure. These works have been supported by government programs since the mid-1970s.

2. The Coastal Structure as an Asset
The NSW Government recently undertook an asset appraisal of breakwaters and river entrance training walls, including aspects on the history of design, construction and performance over a period of nearly 100 years. A total of 63 structures which are 22,600 m in length (Figure 1) were appraised. The figure also shows the location of 12 rock quarries from which armour was obtained for construction. The study (MHL648 1993) placed the value of the structures at $550 million.

MHL has been closely linked with many of the designs of the structures on the NSW coastline through its data collection and physical modelling capabilities which have been built up over a period of nearly 40 years. Some of the original designs as constructed (with irregular maintenance) have withstood wave energy over the last 100 years. In designing a coastal structure a number of different factors have to be considered by the engineer. These include the practicalities of construction, the short- and long-term requirements of the construction, the availability of materials, environmental factors and the hydraulic criteria. After arriving at a preliminary design or, more commonly, a number of options the design is usually optimised using either a physical or numerical model or both.
3. Some Examples of Historical Developments in Coastal Engineering Structures

For over three decades both numerical and physical modelling have been found to complement each other and have been used in investigations such as on the Coffs Harbour breakwater layout (MHL110, 1966). To illustrate the evolution in design philosophy examples of the training walls at Ballina on the Richmond River (Figure 2) and Coffs Harbour eastern breakwater (Figure 3) are discussed. These two structures are examples of a training wall and a breakwater at a harbour. Most of the 63 major structures along the NSW coastline are in these two categories. This section also describes recent developments in data collection and analysis as well as the evolution of physical modelling techniques used for coastal structure design at MHL. The paper also traces the rationale for using computational models in conjunction with these physical models.

3.1 Richmond River Entrance

The Richmond River entrance was charted by Captain Henry Rous in August 1828 while inspecting the coast between Brisbane and Port Macquarie. His records include a note on manoeuvres for getting inside the tricky entrance bar.

"The sandbar at the entrance to the Richmond River was notorious - it shifted across the 6,000 ft wide entrance sculpting mazes of sand which discouraged ships" (Coltheart 1997). The bar was regularly dredged from 1878. By the turn of the century the Public Works Department maintained a fleet of 39 dredges working along the NSW coast.

A plan to train the entrance was drawn up by the Chief Engineer of Public Works, Sir John Coode. In 1889 the entrance was completely blocked by natural sand shoals so that produce had to be carted overland to the Clarence River to the south. Work on the entrance training was commenced that year comprising internal training walls and the southern breakwater. Figure 2 shows a design cross-section developed and presented for the Richmond River breakwaters. The design consisted essentially of the placement of a pile of rocks to form the structure, as shown on this original design drawing.

Rock for the northern breakwater was quarried locally at Pilot Point while rock for the southern breakwater was punted from a quarry at Rileys Hill, 19 miles upstream.

In the spring of 1891 it is reported that "the channel again broke through the southern spit, moving in one day a distance of nearly 3,000 feet." (Coltheart 1997). A training wall was under construction at west Ballina on the north arm upstream. A larger training wall on the southern side was added, enclosing a reclamation site of 63 acres. Dynamite was used to break up the shoals and two dredges were deployed working 16 hours a day to clear the shoals. This was unsuccessful as the southerly weather continued to wash sand around the southern breakwater and into the entrance. Work on the northern breakwater was stopped in 1899 and for more than two years the total workforce of 200 men was deployed night and day on the southern breakwater to try to stop the sand ingress.

By May 1901 the southern breakwater had reached a length of 7,542 feet and the night force recommenced work on the northern breakwater. By mid-1902 the
southern breakwater was 800 feet short of the design length and the northern breakwater 1,000 feet short. Several times the ends had to be restored as they were flattened by storms. A new quarry was opened to provide larger armour stone. A locomotive was used to haul the blocks along the northern wall while four horses hauled the tip trucks carrying rock from 1 ton to 20 tons along one mile of track to the ends of the breakwater.

The entrance works had totally reformed the entrance, reconfiguring the channels with the dredges reclaiming swamps and tidal flats and creating new channels. Dredging and bank protection works were ongoing to maintain the navigability of the river. Vessels with a draft of 10 feet could steam 63 miles up river and, in 1904, 300 steamers and two schooners crossed the Richmond River bar.

In the 1930s the storm damage required constant repairs and unemployment relief funds were used in setting 30 ton concrete blocks onto the southern wall. Five dredges worked regularly in the river during the 1930s. The northern breakwater was damaged and repaired in 1947 and the southern wall again in 1949.

By the 1960s dredging was only used to maintain a 6 foot minimum depth over the bar for smaller vessels.

In contrast, the upgrading of the Richmond River entrance training walls today included intensive numerical assessment, modelling to determine inshore wave conditions, and physical model testing of various primary armour materials in a random wave basin at MHL. The modern design is based on one of the most thorough and longest wave databases used anywhere in the world.

### 3.2 Coffs Harbour

Coffs Harbour is situated on the mid-north coast of NSW approximately 600 kilometres north of Sydney. The area was settled in the 1840s by timber loggers and the harbour developed as a timber trading port.

The Coffs Harbour jetty was completed and opened to shipping in August 1892. It was severely damaged in storms two years later. The port had the highest net tonnage in NSW and was the busiest on the north coast averaging 399 ships per year between 1909 and 1924. Ship visits reduced to 26 in 1960 and to seven by 1970. The last freighter to use the jetty was in 1973. The jetty has been subsequently shortened to its original length and restored, primarily as a tourist feature. Figure 3 indicates the period in time that construction at Coffs Harbour took place. It is seen that construction of the breakwater took place from 1918 to 1974.

In 1912 the decision was taken to construct an artificial harbour by constructing breakwaters at Coffs Harbour to protect the jetty. Work began immediately on the causeway connecting the mainland to South Coffs Island and this effectively intersected the alongshore drift past the islands and to the northern beaches. A quarry was established on the island to provide rock for the proposed eastern and northern breakwaters which enclosed a harbour of 217 acres. Construction of the breakwater private contract commenced in 1915 and the contract was cancelled and taken over by Public Works in 1917.
Work on the eastern breakwater which commenced in 1918 was washed away by heavy storms in 1919 and 1920. The northern wall was two thirds complete when heavy storms in 1921 destroyed the end and washed away five tipping wagons leaving the railway track suspended in mid air. The northern wall was finally connected to Muttonbird Island in 1924. Continual maintenance was required as the wall was low enough to be overtopped in storms. In 1925 storms levelled 400 feet of the northern wall which had to be reconstructed.

Storm damage was a major cost factor on the eastern wall construction. Following major damage in 1925 it was noted that "the quarry could not provide stone big enough to withstand the seas" (Coltheart 1997) and use of concrete blocks with a toe of 100 tonne blocks was recommended for the seaward face. In gales during 1937, 110 feet of the wall was demolished and had to be replaced. The wall was completed in 1939 and the concrete capping in 1943. Major repairs required upgrading of the railway line and carriages in 1953.

Major impacts on the coastal processes in the study area have resulted from the harbour construction. The breakwaters have intersected the estimated south to north littoral drift of 75,000 m$^3$/annum resulting in accretion of Boambee Beach to the south and Jetty Beach within the harbour. At the present time, following many years of lower than average wave energy conditions the beaches north of Coffs Harbour are still in a depleted condition.

4. Historic Aspects of Data Collection for Coastal Engineering Design

The necessity to use accurate site specific data for coastal engineering construction has been acknowledged for over a century. Data has also been used to evaluate the performance of a structure after it was constructed and to refine and improve coastal engineering design. Some of the first evidence available on the collation of wave data for Coffs Harbour is the documentation of wave heights at the seaward end of the wharf (Figure 3) during rough seas on six occasions from December 1936 to July 1954 (MHL186 1974).

An example of continuous wave data recording prior to the use of data buoys is obtained from wave pole records as reported by White (MHL109 1966) taken half a mile from the coast at Nobbys Head, Newcastle in 1965 (Figure 4). A significant step in wave data analysis on the NSW coastline was taken when wave hindcasts were calculated for Port Kembla for the years 1950 to 1964 by Stone and Foster (MHL109 1966). The results of these analyses are indicated in Figure 5 and compare well with present day hindcast wave data. Long-term continuous offshore wave measurements were begun in Sydney in 1974 and have continued since, using a network of seven wave data buoys. Increased accuracy in extreme wave height (Goda et al 1988) and storm duration (Sobey 1997) analysis are of interest to the coastal engineer. Analysis techniques have been developed over the last three decades to make maximum use of short time series. The relevance of long-term wave measurement is seen in the variations obtained for the 100-year wave height for Port Kembla (Figure 6).

Presently, MHL measures wave height and directions using a number of methods such as a network of wave data buoys (Kulmar 1995). These include a directional buoy in Sydney (Figure 6); radar imagery; aerial photography; electromagnetic current meters; hindcasting and satellite imagery. Whilst the data buoy network is a
continuous measurement program, the other methods of measurement were used for specific projects. The NSW measured wave climate represents one of the longest continuous measured wave data sets anywhere in the world.

4.1 An Example in the Change in Requirements for Data
The requirements for data to aid coastal engineering design projects have changed over the last few decades. This can be illustrated by the equation used to obtain armour size. Many design equations have been developed to obtain armour size. Of these equations those suggested by Irribarren (1938), Hudson (1958) and Van der Meer (1987) have been the most accepted and utilised.

Iribarren's equation for stability (1938):
\[
\frac{H}{\Delta D_{50}} = \frac{\cos \alpha - \sin \alpha}{K^{1/3}}
\]

Hudson's equation for stability (1958):
\[
\frac{H_S}{\Delta D_{50}} = (K_D \cot \alpha)^{1/3}
\]

Van der Meer's equations for stability (1987):

For plunging waves:
\[
\frac{H_s}{\Delta D_{50}} = 6.2P^{0.18} S^{0.2} \sqrt{\frac{N}{\xi}}
\]

For surging waves:
\[
\frac{H_r}{\Delta D_{50}} = 1.0P^{-0.13} S^{0.2} \sqrt{\frac{\cot \alpha}{\xi}}
\]

where:

- $\xi$ = surf similarity parameter
- $\alpha$ = slope angle
- $\Delta$ = relative mass density
- $D_{50}$ = nominal diameter of a stone
- $W_{50}$ = 50 percentile value of mass distribution
- $P$ = permeability coefficient of structure
- $S = A/D_{50}^4$ = damage level
- $A$ = erosion level in cross-section
- $N$ = number of waves
- $H_i, H_r$ = wave height
- $K_i, K_D$ = coefficient of damage

Variables such as storm duration or number of waves ($N$), permeability coefficient of the structure ($P$) and surf similarity parameter ($\xi$) have been included in design criteria to obtain the mass of primary armour over the last decade. Water level and therefore the influence of breaking waves was included in Hudson's physical modelling regime though not in his formulae. Variables such as wave obliquity (Galland 1994) and wave groupiness (Funke 1979), though not included in the design formulae, have to be considered in the finalisation of designs when using physical models. To this end MHL has included the analysis of wave groups during storm and
calm conditions (Jayewardene 1993) and the influence of wave obliquity on primary armour (Jayewardene 1997) in its research and development programs.

5. A Short History of Physically Modelling Coffs Harbour Breakwaters
Two physical models were carried out on Coffs Harbour, one in 1966 and the most recent investigation in 1998. The main aims of the 1966 model were to provide improved berthing at the existing jetty (Figure 3) and improved anchorage conditions for the existing fishing fleet. The 1998 model attempted to simulate damage conditions to the eastern breakwater head where thirteen 40 tonne blocks were displaced during a storm in May 1997. Although the aims of the two investigations were different, it is instructive to compare the techniques of wave generation and data collection used in these models to obtain an understanding of the material changes that have taken place in coastal engineering design.

5.1 Wave Data
Hindcast wave data was used to obtain the deep water design wave for the 1966 model (MHL 109 1966). Extreme wave analysis was carried out to obtain design wave data for the 1998 model (MHL 914 1997). Regular waves were used in the early model whereas long crested irregular waves were used in the more recent model. Irregular waves have been used in physical models since the late 1970s and the advantages over regular wave modelling are well documented in the literature (Graveson 1974). In the mid-1980s the importance of wave grouping in harbour layout and the importance of correct reproduction of these groups particularly for ship movement investigations was established (Sand 1983, Bowers 1988). This is probably the reason for the observation made at the conclusion of the 1966 study that “Reproduction of the surge motion by detailed observation of the prototype were not successful in the model” (MHL110 1966). Accurate wave height (Figure 7) and wave direction (Figure 8) data during the May 1997 storm in conjunction with numerical modelling (Figure 9) aided in establishing that relatively long period waves (15-17s) of relatively low return period (1-2 year) resulted in the damage of the head. This damage was reproduced accurately in the physical model (Figure 10).

5.2 Water Level Data
Table 1 indicates some water levels used in physical model investigations carried out at MHL for previous projects. In addition to the 90 years of tidal data recorded at Fort Denison, Sydney a network of tide recorders established in 1984 has enabled MHL to predict tides utilising 69 tidal constituents (MHL591 1991). The ability to predict tides has in turn enabled MHL to estimate anomalies accurately and, hence, obtain accurate return periods for extreme water level statistics (MHL591 1991). The water level recorder at Coffs Harbour was able to record the extreme water levels during the May 1997 storm and helped to accurately simulate storm conditions in the physical model. The database generated by the MHL network has monitored some extreme storms such as the one that occurred in May 1974 when waves up to 12 metres associated with large tides and storm surges affected the NSW coastline over several days. A decade ago this storm was adopted as a design storm. With improved tools for extreme event analysis (AWACS 1992) it has been shown by Monte Carlo simulation techniques (Goda 1988) that this storm was more extreme than the 100-year event. This resulted in considerable lowering of crest heights of
structures such as the Sydney parallel runway (AWACS 1992) that have been constructed recently.

Table 1 Design Data - Physical Models

6. Physical Model of Ballina Training Wall Head

Historical records indicate that 30 tonne artificial concrete cubes were used instead of rock armour in the early 1930s on the Ballina Heads. Recent physical modelling carried out at MHL (MHL860 1997) compared the performance of artificial armour units such as Accropodes, Antifer cubes and Hanbars (a NSW patented unit) with that of rock armour. Table 2 indicates the values for the mass of primary armour using a coefficient of damage ($K_d$) obtained from testing carried out by Foster and Gordon (1973). Their tests were conducted using regular waves, whereas present day (MHL) tests use Pierson Moskowitz spectra with spectral peak period and wave height associated with extreme event analysis. Reflection analysis (Mansard 1980) carried out in the flume to accurately assess the incident wave height and numerical modelling using REFDIF (a numerical refraction/diffraction model) was utilised to obtain inshore wave conditions which were replicated in the physical model.

7. Numerical Modelling Used in Conjunction with Physical Models

Constant updating and improvement of short and long wave computational models in the last three decades has significantly extended the design situations for which they can be used. These include the use of directional wave spectra, bed friction, flow separation and recirculation near jetties, radiation damping near harbour entrances and diffraction through breakwater gaps. However, in cases such as the simulation of the May 1997 storm at Coffs Harbour, nearly all the damage was caused by wave overtopping and instabilities caused by flows in the secondary armour. These are
better simulated in a properly scaled physical model with gravitational and inertial forces dominating frictional forces (Cornett 1995). Conditions at the water depth corresponding to the long crested irregular wave generator were obtained for the 100-year event by using the numerical model REFDIF. A similar approach was used when comparing the performance of artificial armour units such as Hanbars, Accumods and Antifer cubes (MHL897 1997).

Table 2 indicates values for the mass of primary armour using coefficient of damage ($K_d$) values obtained from testing carried out by Foster and Gordon (1973). These values were compared with those obtained by using Van der Meer’s breakwater design criteria (Van der Meer 1988). The results obtained from Hudson’s formula and from oblique wave testing are shown in Table 2.

### 8. Methods of Construction and Quarrying

Up to the mid-1970s the construction methods used at both Ballina and Coffs Harbour generally involved the sourcing of local armour rock and random placement by tipping. Natural armour stone was sourced on site from adjacent coastal headlands and nearby purpose quarries. In most instances these stones were tipped from specially constructed tipping frames on rail wagons and later from modified truck bodies. To increase the primary armour mass, concrete armour units ranging from 10 to 38 tons were cast and then tipped on training wall slopes. Smaller units up to 2 tons were frequently cast on top of the wall and pushed over the crest by bulldozers. The lack of control resulted in haphazard positioning of the units and poor interlocking. Where rail systems were adopted for armour placement (at Ballina and Coffs east breakwater) the crests were capped with concrete to support the loads.
imposed by the construction plant and armour unit. The concrete caps often deteriorated as the structure settled. Current construction techniques have emphasised the need to optimise armour size by careful design utilising both single layer and double layer, placed and tipped primary armour (MHL860, MHL897 1997). Cost considerations have also favoured single layer placement of even rock armour as tipping of rock results in significantly increased material costs. Other factors relevant to single layer placement of rock are a reduction in environmental cost of quarry utilisation, difficulty in sourcing large armour and the increasing distance and cost of material transport.

Physical modelling has enabled the designer to evaluate the influence of wave grouping, wave obliquity and permeability of the structure. It has also aided in comparing the performance of the single layered Accropode unit with units that have already been placed on structures on the NSW coastline such as the Hanbar, dolos and rectangular cube.

Many of the NSW coastal structures are located adjacent to popular holiday towns and villages and hence provide waterway recreational facilities. Presently construction and repair is regulated from the planning approval stage to the on-site placement of material, and must fulfil the mandatory requirements of NSW occupational health and safety legislation.

9. Conclusions

Manly Hydraulics Laboratory has been closely linked with many of the designs of the structures on the NSW coastline through its data collection and physical modelling capabilities which have been built up over a period of nearly 40 years. Some of the original designs as constructed have withstood wave energy over the last 100 years which, by design standards, should have failed. However recently introduced design variables such as wave obliqueness offer quantitative explanations for this stability. This paper has used the examples of Coffs Harbour breakwaters and the Ballina training wall head construction and repair to outline some of the developments in coastal engineering design and construction in NSW over the last century. An example of the design equations for primary armour size was used to indicate the influence of new variables such as permeability, storm duration and wave obliqueness on training wall construction at Ballina. The present day focus on the awareness of and need to care for a fragile environment which provides many recreational amenities is emphasised. The establishment and maintenance of extensive water level and wave databases is shown to increase design wave height and wave periods used in physical model investigations. The return period for design water levels has been established. The paper highlights the shortcomings of physical modelling when tools such as the proper generation and control of wave groupiness were unavailable.

10. Acknowledgments

The authors acknowledge the approval of the NSW Department of Public Works and Services and the Department of Land and Water Conservation to present this information. The historical development of the NSW coast is based on information contained in the book *Between Wind and Water* which was prepared by Lenore Coltheart. The assistance of Rob Jacobs and Mark Kulmar from MHL and Helmut Rangger from DLWC in preparation of information for the paper is also gratefully acknowledged.

Abstract

Alderney is the northernmost of the Channel Islands, lying 13km off the Normandy coast. The main breakwater at Alderney, known as the Admiralty Breakwater, provides essential shelter to the commercial and fishing quays and swing moorings for fishing boats and visiting yachts. It also provides protection to the shoreline around Braye Bay.

Wave conditions at Alderney are frequently severe. In response to this severe wave attack the Admiralty Breakwater (constructed between 1847 and 1864) has required continual maintenance (costing £447,000 in 1998). Even with this level of investment, however, the long-term decay of the structure and occasional breaches continue.

This paper explores the history to the Admiralty Breakwater, why there is a need for works and how a range of disparate designs have evolved over time leading ultimately to a small number of viable solutions.

Introduction

Alderney Breakwater has been the subject of many studies since Vernon Harcourt gave an account of the construction of the Breakwater at the Institute of Civil Engineers in 1873 (Vernon Harcourt, 1873). In more recent times, HR Wallingford have been employed by successive owners of the Admiralty Breakwater to investigate its structural behaviour (see for example HR Wallingford 1963 and Allsop et al 1990) and latterly to propose an appropriate long-term solution for the protection of Alderney Harbour (Sayers et al, 1996a).

The complex history and structural of the Admiralty Breakwater combined with the severe wave climate at Alderney provides an interesting topic for study. This paper brings together some of the recent studies and discusses some of the options for
solving the significant problems associated with providing a long-term solution at Alderney.

The history of Alderney Harbour

At the start of the last century Napoleon threatened to invade England. In response, the Royal Navy conceived the idea of a deep-water naval anchorage on Alderney, the northernmost of the Channel Islands, close to France (Figure 1).

\[ \text{Figure 1 Location Plan} \]

From here, the Admiralty claimed, they would be able to watch and, if necessary, blockade the French Port of Cherbourg and so repel French aggression. The Admiralty's original proposal was an ambitious plan enclosing all of Braye Bay (Figure 2). With a receding threat of invasion and escalating project costs however, construction of the planned second (east) breakwater was never realised.
The overall length of the Admiralty Breakwater at completion in 1864 was 1430m. By 1872, however, continual storm damage, in some instances complete breaches, had led to unsustainable maintenance costs. To limit their financial commitment, the Admiralty abandoned the outer end of the Breakwater and chose to maintain only the first 871m where a temporary head, which had served to protect the 'scar end' of a seasons work during construction, formed a suitable point for termination. It is this remaining length that continues to provide shelter to Alderney Harbour today (Plate1).
The existing structure

A review of the original construction method reveals the Admiralty Breakwater to consist of two distinct sections: a rubble mound foundation which had been placed on the seabed (in water depths frequently greater than 40m) to a formation level near low water (+0.8mCD); and a masonry superstructure constructed on top of the rubble mound to +12.1mCD (Figure 3).

![Figure 3 Section through the existing breakwater](image)

The failure mechanisms of the existing structure have been analysed by a number of authors (Hall J et al (1995), Allsop et al (1990)). Based on this analysis, an event tree of the likely failure mechanisms was developed (Figure 4). From this analysis it is clear that any attempt to rehabilitate the existing structure will need to ensure stability of the masonry superstructure and protect it from aggressive abrasion by the highly mobile rubble mound and undermining of its toe.

![Figure 4 Likely failure mechanisms of the Admiralty Breakwater](image)
The severe wave and tidal climate

Wave and tidal conditions at Alderney are frequently severe. The large open fetch to the north-west of the island exposes the island to the full force of Atlantic swell and the large tidal range drives notoriously strong tidal currents through The Swinge and the Alderney Race (5.5m tidal range on Mean Spring Tides and tidal currents up to 3.0m/s – see Table 1).

Swell is an important component of the wave climate at Alderney and needs to be included in prediction of the design wave conditions. Therefore, the extreme offshore wave climate has been derived using data from the Meteorological Office Wave Model1 of the Atlantic Ocean. Using a wave refraction model (PORTRAY, HR Wallingford, 1995) which includes the refactoring effects of the strong tidal currents at Alderney, the predicted offshore waves were propagated inshore to the -10mCD contour close to the face of the Admiralty Breakwater (Table 2).

Why is there a need for rehabilitation or replace works

The States of Guernsey, Board of Administration (the body responsible for the maintenance of the Breakwater since 1987) currently spend approximately £500k per annum (£447,000 in 1998) on maintenance of the superstructure. Even with this level of investment however, the long-term decay of the structure and occasional breaches continue (Plate 2).

---

1 This data has the distinct advantage over the more usual method of deriving an offshore wave climate from a wind-wave prediction model based on local winds in that it includes the effects of swell.
2 Interestingly, the most severe waves impact on the Breakwater at approximately normal incidence, and originate from the 255°-285° N offshore sector; not the expected north-west direction (the largest fetch). The reason for this is the strong wave-current interactions that cause significant wave refraction. It was also found that wave-current interactions cause the largest waves occur at the ebb mid tide condition.
Studies by HR Wallingford in 1990 (Allsop et al, 1990 and 1991) and more recent analysis (Sayers et al, 1996b) confirms that the rubble mound upon which the superstructure is founded continues to erode. If this trend continues, future maintenance costs are likely to increase as toe support to the super-structure is lost and breaches become more frequent.

In addition to these long-term changes in the level of the mound the level at the toe of the super-structure is highly volatile in the short-term (Figure 5). In combination the long term processes and short-term volatility of the toe level lead to considerable uncertainty as to when the mound will reach a level that critically undermines the super-structure.

Figure 5 Toe level of the Admiralty Breakwater superstructure from dip measurement
Evolving a solution: Study terms of reference

In 1995 the States of Guernsey Department of Engineering on behalf of the Board of Administration, commissioned HR Wallingford to undertake studies to assess and design in outline the most appropriate long term solution for providing shelter to Alderney. The Terms of Reference for this study were:

“To assess the viability of alternative solutions for replacing or upgrading the Admiralty Breakwater based on the need to satisfy the following requirements:

- Minimise maintenance commitment
- Maintain access to a commercial quay
- Maintain mooring facilities for fish storage
- Maintain small craft moorings
- Limit impact on the coastline
- Minimise financial risk”

It should be noted here however, that the States of Guernsey have responsibility for protecting a harbour on the Island of Alderney and providing the financial backing (subject to financial constraints) for any capital project undertaken (if and when necessary). Therefore, not surprisingly, their objective is to minimise expenditure without compromising (but not necessarily improving) existing operations in Alderney Harbour. The objective of the States of Alderney however, is to seek an improved Harbour facility and one that provides potential for future development. These are somewhat disparate viewpoints and are not easily reconciled by a single solution.

This paper largely addresses the needs and solutions based on the Terms of Reference set out by the States of Guernsey (the Client). The arguments developed in terms of structural performance, navigation and other operational issues for the various options are however, generic to any solution proposed.

Design criteria

An important precursor to any study to propose remedial or replacement works is to understand the design criteria against which the 'solutions' are to be judged. Below is an outline of the main design criteria set for this study.

Cost limits

For the construction of a new breakwater to be viable it will need to be justified in economic terms. For the States of Guernsey this means that the primary cost of any given solution should be justified based on reduced maintenance of the Admiralty Breakwater. Based on an annual present expenditure by the States of Guernsey on maintenance of £0.5 million and a 50 year design life the capital expenditure that may be directly justified is approximately £8 million (based on a discount rate of 6%). Continued loss in the volume of the rubble mound and the known volatility of its level at the toe of the super-structure are expected to increase the frequency of major breaches in the Admiralty Breakwater. Hence, the annual maintenance cost may be expected to rise. To avoid the repair and maintenance becoming uneconomical and
unsustainable it is, therefore, appropriate to consider options for rehabilitation or replacement of the Admiralty Breakwater with present day values in excess of £8 million.

*Navigation issues*

At present the largest vessel conducting commercial operations at Alderney is the Ariante (79.15m LOA x 13.1m beam). It is noteworthy that although there is a marked trend for smaller vessels (such as the Ariante) to be difficult to source, as they become increasingly uneconomic to operate, the Ariante has been defined as the 'design vessel' for a number of locally applicable reasons. For all designs therefore a nominal navigation channel of about 60m in width has been set (based on five times the beam of the Ariante). (Note: If it does become necessary then it is accepted that any design developed using the Ariante may require significant alteration.)

*Wave disturbance at the Commercial Quay*

Wave disturbance at the Commercial Quay is a function of wave transmission through the Harbour entrance and over/through the breakwater. The wave disturbance criterion adopted is that any proposed solution should provide the same standard of shelter at the Commercial Quay as is afforded at present. Based on more detailed study of the operational limitations at the Commercial Quay the limiting wave height for safe mooring at the Commercial Quay has been set as approximately 0.45m (Thoresen (1988), PIANC (1995), Iceland Harbour Authorities (1987), Brattleland (1974) and 3-dimensional physical model tests by Sayers et al, 1996a). This wave height is expected to cause total horizontal movements in the Ariante of up to 1.5m in surge and in sway, and angular movements of 2 to 5 degrees.

*Small craft moorings*

A total of 135 multi-point moorings are laid and maintained in Braye Bay by the Harbour Authorities. If some or all of the facilities for small craft moorings in the lee of the Admiralty Breakwater are lost a small craft marina may be required as an integral part of any solution considered.

*Wave overtopping*

No limit on wave overtopping for serviceability in terms of safety of access has been imposed. When overtopping is expected to represent a high risk to persons on the breakwater an overtopping hazard warning will be issued and access to the breakwater prevented. The design criterion in terms of wave overtopping was, therefore, based only on the protection afforded against wave disturbance. The criteria was set such that wave heights in the lee of the structure should be no more than that experienced at present.

*Armour layer stability*

Any solution proposed is likely to involve the use of rock or concrete armouring. The required performance of any armour layer is to:

- Require no more than limited maintenance in the aftermath of a 1:100 year return period storm (i.e. a storm that has a 63% chance of being exceeded during any 100 year period).
• Be able to resist 'failure' (defined as a total breakdown of the form of the design) during a 1:2000 year return period storm (i.e. a storm that has a 5% chance of being exceeded during any 100 year period).

Impact on coast protection in Braye Bay and swing moorings
Wave activity in Braye Bay will be an issue when selecting the most acceptable option. The acceptability of the design proposals in terms of the impact on wave activity within Braye Bay has been based on the relative increase when compared to the existing situation and the significance of that increase. A prescriptive criterion has not, therefore, been set.

Scheme options and design

A number of solutions have been proposed:

• Rehabilitation/protection of the existing structure
  - Improved maintenance
  - Rock / concrete armouring, Option A
  - Grouting
• Offshore breakwaters
• Abandonment and construction of a new breakwater in the lee of Admiralty Breakwater, Option B

Some of the above form part of the studies undertaken by HR Wallingford and others have been investigated by independent consultants and those employed by the States of Alderney. This paper focuses on the detailed studies undertaken in the investigation of the performance of two of these options: Option A and Option B.
Option A
Option A consists of a shortened length of the existing Admiralty Breakwater armoured using a composite structure of concrete armour units (Accropodes) and rock. A 'spur' breakwater is then 'returned' through the superstructure of the Admiralty Breakwater to afford protection against wave penetration up to the Commercial Quay (Figure 5 and 6).

Figure 5 Plan view: Option A

Figure 6 A typical cross-section: Option A
Option B
This option abandons the Admiralty Breakwater and proposes the construction of a new breakwater within Alderney Harbour. The new breakwater is set back 70m landwards of the Admiralty Breakwater. Its construction uses concrete armour units (Accropodes) and rock armour (Figures 7 and 8).

Figure 7 Plan view: Option B

Figure 8 A typical cross-section: Option B
Comparing Options A and B

Based on detailed 2 and 3-dimensional physical modelling, numerical modelling of waves and currents, engineering design, investigation of construction risks and cost estimates it has been possible to compare the performance of Options A and B and comment on their ability to satisfy the study terms of reference. A discussion of this comparison is given below.

Impact on the coastline of Braye Bay
Physical model tests suggest that when the Admiralty Breakwater is replaced with either Option A or B wave activity within the Bay is increased. This will adversely impact on the tenability of present swing moorings within the Bay and can be expected to accelerate coast erosion in the east of the Bay. Increased coastal erosion will, in the medium term, result in the need for remedial measures. There is, however, no significant difference between the two Options A and B in terms of their likely impact on the coastline of Braye Bay.

Impact on navigation
Navigation simulations were undertaken to establish the feasibility of continuing to navigate into Alderney Harbour using the Ariante following construction of the proposed breakwater Option B.

Prior to these studies two principal concerns regarding the approach and berthing of a ship if the Alderney Breakwater was shortened were raised. These were:

- The ability of the ship to counter the strong cross currents in the existing approach.
- The ability of the design ship to slow its approach to a near zero speed in a controlled manner in the distance from the end of a new breakwater to the Commercial Quay.

To investigate the validity of these concerns comprehensive navigation simulations were undertaken in the HR Wallingford simulator\(^3\) (Sayers et al, 1996a).

---

\(^3\) The mathematical model used in the HR Wallingford simulator is of a standard type, using Newtonian equations in three degrees of freedom, and having a modular structure. The effects on the hull of all the influences due to the hydrodynamic, effect or and disturbance forces are added, and the accelerations found in three degrees of freedom, i.e. in the surge, sway and yaw directions. Integration and transformation will yield the position of the ship in the playing area. Once the ship position is known, this position can be used to access the databases for current and depth, so as to produce new currents and depths for use in the next iteration of the model equations. The outputs of the model are the position and heading of the ship as a function of time, taking account of the effects of wind, current, depth of water and tugs (as necessary). The mathematical models used to represent the Ariante must also behave in such a way that the position, swept path and heading of the simulated ship are always representative of real behaviour (including the combined influence of wind, waves and currents).
Prior to undertaking the simulations it was important to reliably predict the strong tidal currents and include them in the simulations. To obtain the required variable resolution, with a finer mesh in the area of the Admiralty Breakwater and a coarser grid further away, the numerical model TELEMAC-2D (developed by LNH, Paris and HR Wallingford) was selected as the most suitable.

Once calibrated (against various existing sources of current data and specially commissioned surveys) TELEMAC-2D was used to predict in detail the existing flow regime and the likely future changes if the Admiralty Breakwater was abandoned and Option B constructed (Figure 9).

![Figure 9 Tidal flows: Existing and future conditions](image)

It can be observed that in the existing situation an eddy current is generated offshore of the Admiralty Breakwater during the late flood (generated as the strong tidal currents in the Swinge flow past the Admiralty Breakwater). This leads to a strong cross current at the head of the Admiralty Breakwater. This current flows westward at about 1 m/s causing difficult for vessels approaching the existing harbour.

With Option B the eddy is affected by changed breakwater location and is generally significantly reduced with the proposed scheme when compared with the existing condition.

---

4 For most of the runs it was assumed that the existing Breakwater had totally collapsed, so that there was no protection beyond the head of the Option B breakwater. For many years this is unlikely to be the case, and the entrance channel will be afforded some additional protection from waves, particularly for winds from north through to west. The condition of an Admiralty Breakwater in a partially collapsed condition was not considered.
The simulations confirmed that at present it is not practicable to start to slow the ship significantly from its approach speed of about six knots until the ship is in the shelter of the Admiralty Breakwater. Once in shelter, the Ariante at present needs around five ship lengths to slow in a controlled manner. However, when the Admiralty Breakwater is replaced, the improved tidal conditions in the approach to the Harbour facilitate a slower approach speed past the head of the new breakwater. Consequently, the distance required for the ship to slow once inside the shelter of the breakwater is reduced.

In summary the navigation simulations concluded that the adopted position of the head of the proposed breakwater, Option B2, is an optimum compromise between the two conflicting requirements, of shelter and ease of approach, given above. When combined with approach navigation aids Option B allows satisfactory access to Commercial Quay.

**Provisions for small craft moorings**

The disadvantage both Options A and B is loss of harbour space and the restricted flexibility for future harbour.

To minimise encroachment into the existing harbour space of Option B concrete armour units (15t Accropode units) are used as the primary armour layer. This enables a steep seaward face of 3 in 4 to be used to minimise the breakwater footprint without compromising structural stability. Even so, in the case of Option B seventy moorings are lost, including twenty local, service and store box moorings. A slightly reduced number are lost if Option A is constructed.

To offset the loss of moorings it was shown that it would be possible to relocate the majority of moorings in to the space just outside of Little Crabby Harbour. (Further details of the proposed new anchorage / marina development may be found in Sayers et al, 1996a)

**Interaction with a decaying Admiralty Breakwater**

The unpredictable decay of the Admiralty Breakwater may adversely affect the performance of Option B. However, the physical model investigations allay many of the early concerns. The potential for wave energy to be focused through breaches in the Admiralty Breakwater causing structural damage to Option B has been explored and discarded. In addition, fouling of the navigation approaches by mound material and abrasion of the Accropode units by mound material carried landwards by incoming waves have both been considered and discounted as a significant risk.

**Construction risks and costs**

The novel idea of constructing a new breakwater 'set-back' in the lee of the Admiralty Breakwater (Option B) has two distinct advantages over construction on the seaward side of the Admiralty Breakwater (Option A). Firstly, the existing breakwater could be used as shelter to the construction, significantly reducing construction risk and lengthening the safe construction working period. Secondly, it is predicted that the rubble mound foundation of the Admiralty Breakwater will remain in place in the long-term, albeit at a reduced level, providing partial shelter to the completed works
during the worst of the Alderney storms. In-turn this eliminates the need for the very heavy armour rock required if construction were to take place on the seaward face of the Admiralty Breakwater, material that is often difficult to source.

For each of the main breakwater Options A and B the estimated construction costs are given below in Figure 10.

![Figure 10 Estimate construction costs: Options A and B](image)

These cost estimates have been developed based on detailed dialogue with would-be contractors and reflect the higher construction risks associated with Option A. For example, potential future increases in price of rock would add considerable cost to Option A due to the large quantities of large armour rock required (an increase of £10/m³ placed would add £0.9 million to the total construction cost). Option A is further disadvantaged by severe construction risks; heavy downtime during a necessarily long construction period spread over several seasons is also expected to add considerable cost to the project. The difficulty in excavating the existing mound to secure the toe of the Accropode slope and the susceptibility of part-completed structures to storm damage will add further risk, and hence cost, to the project. In addition, Option A requires large volumes of heavy armour rock (87056m³ of 15 to 20t rock). This will be difficult to source and may have a slow rate of supply.

Option B however is less sensitive to fluctuations in the price of large armour rock and has no significant risk attached to construction due to its sheltered position in the lee of the Admiralty Breakwater (giving a high degree of certainty to the cost estimates). It can also be constructed in one year (assuming sufficient lead in time is given to facilitate pre-casting and stockpiling of the Accropode units and rock).

To over-come some of these issues a procurement route involving a design and construct package is recommended.
Summary: Options A and B
Option A partially retains the visual appearance of the Admiralty Breakwater from the Harbour side and maintains an area for swing moorings to the north of the ‘Safety Fairway’ (albeit for a reduced number of vessels). In addition, existing access to Little Crabby Harbour is maintained. However, Option A involves the abandonment of the outer 365m of Admiralty Breakwater. Therefore, a considerable number of swing moorings will be lost.

Following the demise of the Admiralty Breakwater and the construction of Option B, it is predicted that the tidal current regime in the approaches to the new Harbour will be generally improved over that experienced at present. This facilitates access to the Commercial Quay under similar environmental restricts to those applied at present. In addition, access to Little Crabby Harbour is also maintained, the historic value and appearance of the Admiralty Breakwater is, however, lost.

Both Options A and B lead to the loss of protection to majority of swing moorings currently available in Braye Bay and Harbour space. Most of these, could, however to relocated. Effective protection to the east coastline of Braye Bay is also lost together and the likely erosion will have to be management appropriately.

What are the alternatives to Options A and B

The rehabilitation or replacement of Alderney Breakwater has caused considerable interest; both in Alderney and Guernsey. As a result, various consultants have been engaged by the States of Alderney to propose ameliorative works that attempt to address the Terms of Reference as given by Alderney (as opposed to those defined by the States of Guernsey). The “solutions” proposed range from armouring the full length of the Admiralty Breakwater (at an estimated cost of at least £40million) to the use of salvaged ship hulls as offshore reefs.

Some of the “solutions” proposed by the various consultants offer little in the detailed understanding of the existing Breakwater and how any future works may perform. Others, however, are more interesting and worth of further investigation. Due to the present status of this project (currently in the hands of the Board of Administration, States of Guernsey) it is, unfortunately, outside the scope of this paper to discuss the details of these “alternative” proposals.

Conclusions

Options A and B provide well-engineered and robust solutions to the problems perceived by Guernsey. The costing exercise associated with Options A and B has however, demonstrated that due to the harsh physical environment at Alderney the cost of construction is sensitive to the method adopted and the availability of the required sizes and volumes of rock. In particular the construction risks associated with undertaking works on the seaward side of the Admiralty Breakwater (for example Option A) are vast.

This study has clearly demonstrated that if different questions are posed different solutions will result. At present the States of Guernsey (would-be funders of any scheme) have differing requirements to the States of Alderney (would-be users of any
scheme). It is clear therefore, that until consensus is achieved on the ultimate objectives of the project there will be continued debate over the selection of the most appropriate solution for rehabilitating or replacing the Admiralty Breakwater.

Acknowledgements

The authors are grateful for advice and assistance received from the colleagues at HR Wallingford, in particular Jim Hall and Jonathan Simm. The cooperation of Mr Stephen Shaw (the Harbour Master at Alderney), Captain Tim Spencer (the Harbour Master at Guernsey) and Mr Keith Webster, the Breakwater Supervisor, is also gratefully acknowledged.

Abstract

The trunk section of the south breakwater, at the entrance to the Port of Richards Bay, has suffered some damage since its construction which was completed in 1976. This paper briefly discusses the changes in the design conditions as a result of sand-trap dredging off the breakwater, the annual photographic monitoring results showing the excessive rates of damage, and the model testing of various repair options, using 20t and 30t dolosse. Both 2D flume and 3D basin model tests were carried out at various scales, with fixed and movable bed models. Finally the construction of the optimal repair, carried out in 1997/98, using a heavy duty mobile crane (with 48m boom reach) and DGPS positioning, is described.

Introduction

The Port of Richards Bay, on the east coast of South Africa, has two dolos breakwaters, a shorter straight breakwater on the northern side of the harbour entrance channel and a longer curved breakwater on the southern side. The south breakwater consists of an “S” shaped rubble mound structure (Figure 1), constructed between 1973 and 1976, which stretches for approximately 1km, almost perpendicular to the coastline. The original armouring on this breakwater consists mainly of 20t dolosse on both sides of the trunk (Figure 2), but includes 30t dolosse on the roundhead. The south breakwater forms the main protection of the Richards Bay harbour entrance channel, against dominant southerly storms and the nett littoral drift, which is from south to north.

Annual photographic monitoring of the south breakwater has shown a gradual increase in damage to localised areas on the southern side of the trunk, despite spot repairs using 20t dolosse, carried out by Portnet in 1985. A detailed evaluation of the
damage was undertaken by Zwamborn in 1988 (CSIR, 1988) which lead Portnet to commission the CSIR in 1991 to carry out investigatory model tests in an existing 3D 1:100 scale model of the entrance to the Port of Richards Bay. These tests were to check different repair options, taking into account the position of a dredged sand-trap along the seaward side of the breakwater. The original idea was to use 20t and 30t dolosse, available from a stockpile of spare dolosse at the root of the south breakwater.

![Figure 1: Aerial View of South Breakwater](image)

Due to delays in the commissioning of a suitable crane, and the use of most of the spare dolosse on repairs to the north breakwater head (Phelp, 1996), the construction of the repairs to the south breakwater were delayed until 1997/98. This also required the casting of 1000 additional 30t dolosse. Between 1991 and 1996, additional 2D flume tests were carried out at a 1:40 scale to check the stability of the rock toe of the repair slope. These tests were carried out with a movable (sand) bed to model the effects of toe scour. Before the commencement of the repair work it was found that, due to a gap in the dredging programme, there was a buildup of sand along the breakwater toe. Final model tests were therefore carried out to re-check the toe stability at this shallower depth.

**Monitoring Results**

The crane/helicopter photographic survey method (Phelp, 1994) has been used to annually monitor the breakwater since 1979 on an ad-hoc basis, but regularly since 1987, and crane and ball profiling surveys have been carried out since 1981. The photographic survey stations are spaced at 25m, and the ball profiles at 5m intervals. Figure 2 shows the position of the survey stations and Figure 3 the rate of damage increase since 1987.
The original breakwater construction used a total of 13 400 20t dolosse on the trunk, and 2 200 30t dolosse on the roundhead, which amounts to approximately 10 dolosse per metre of breakwater. The original depth at the head was -18m and -14m along the outer curve of the trunk. The worst damage prior to the repair, located at station C8, was 17% dolosse displaced or broken (Figure 2).

Ad-hoc spot repair work was carried out in this area in 1985, when 52 new 20t dolosse were placed. Although this showed a significant improvement in the measured profiles, the photo survey showed that half of these dolosse were broken and/or lost by 1987. This type of spot repair, which was not model tested, with non-reinforced dolosse in a single layer not interlocking with the surrounding dolosse, proved to be ineffective.

Factors Contributing to the High Damage

The occurrence of low pressure cyclonic storms (cyclones Demoina and Emboa in 1984) subjected the breakwater to wave heights exceeding the 7.9m 1:50 year design $H_{mo}$. Storm wave set-up and low atmospheric pressure associated with these storms also had the effect of raising the water level, thereby raising the depth limited wave heights reaching the breakwater. There have also been a number of lesser, but still powerful storms with wave heights in excess of 6m - the latest being experienced in 1990. The rates of damage are shown in Figure 3 for the worst stations on the trunk section.

A nett littoral drift of up to 800 000m$^3$ northwards has necessitated the dredging of a sand-trap against the outside of the south breakwater. Bathymetric surveys carried out regularly by Portnet in the sand-trap area have shown that dredging has taken place.
much closer to the breakwater than originally anticipated (up to 60m closer). The depth of the sand-trap has reached -24m and the side slope as steep as 1:4.7. Figure 4 shows the dredger and Figure 5 the average position and sections through the sand-trap.

![Figure 3: Rates of Damage to Worst Stations since 1987](image)

Besides the deeper trap and steep side slopes, there has also been scour at the toe of the original breakwater (seismic surveys carried out by CSIR in 1993 confirmed the toe erosion (CSIR,1994)). The damage profile along the breakwater (shown in Figure 2) matched the plan of the sand-trap, with the highest damage area aligning with the deepest parts of the trap. The 3D basin model tests, which modelled various trap layouts, confirmed that the sand-trap allowed higher depth limited waves to reach the breakwater.

![Figure 4: Portnet Dredger Trail Dredging in the Sand-trap](image)
Constraints to the Repair Design

Model tests were carried out in an existing 3D model of Richards Bay, to save both time and costs. This original model was built at a scale of 1:100 and covered the harbour entrance and part of the inner channel. The model test options were also originally restricted to using available 20t and 30t dolosse from a stockpile near the southern breakwater. A number of repair options were tested using either the 20t or 30t dolosse, with different repair slopes between 1:1.5 and 1:2.5, both with and without a rock toe.

The removal of rubble and pre-repair slope preparation was limited due to poor underwater visibility and rough sea conditions normally experienced along the outer breakwater. Contour plots of the outer slope, drawn from crane and ball profile surveys, were used to locate damage cusps below water and guide the filling of these holes at the toe of the armour slope. A double layer repair slope was then designed to cover the worst damaged areas. The top and sides of the repair are then tied into the original breakwater slope by tapering the repair. The width of the repair was limited to 40m from the splash wall, which was the limit for the boom of the crane lifting a 30t dolosse. This mobile crane (Figure 10) was specially designed to fit onto the 6.7m wide mass-concrete capping.
Choice of Model Scale

The scale of 1:100 used for the tests gives a Reynolds number of approximately $1 \times 10^4$, which is just within the minimum range recommended by Van der Meer (Van der Meer, 1988). Some scale effects were expected, but have been found to make the model results more conservative. The scale effects, being similar for all the test runs, allowed for comparisons to be made between the repair options tested. The calibration test showed that the hind-cast of the damage which occurred in the cyclonic storms of 1984, is in qualitative agreement with the observed prototype damage confirming the validity of the physical model. Details of the chosen repair section were confirmed at larger scales (1:63) in a 3m wide flume with a fixed bed and at 1:40 in a 2m wide flume with a movable bed. Figure 5 shows the section through the sand-trap and breakwater which was modelled in the 2D flume tests.

Wave Generation and Measurement

Up to 14 standard wire resistance wave probes were used which were coupled so that measurements could be carried out over prescribed areas. A hinged paddle wave generator bank for the 3D tests was 30m long situated approximately 30m seawards of the breakwater (representing 3km by 3km in prototype). Based on a review of existing wave data and analysis of the cyclonic storm data as recorded by a waverider buoy off the breakwater, the following main test conditions were chosen:

- Wave direction, harbour entrance area (12s) $140^\circ$
- Storm input, Richards Bay Spectrum, $\gamma = 2.74$ with the following 1.5 m steps $H_{\text{m0}} = 2.5, 4, 5.5, 7, 8.5$ m with wave periods $T_p = 12$ s to $16$s. This is above the design wave height of 7.9 m and cyclone wave recording of 8.4 m.
- Water level MHWS = +2.0 m CD which resulted in the highest damage.

The above conditions were considered applicable to reproduce the damage on the breakwater which has been subjected to a minimum of one 1:1 year storms ($H_{\text{m0}}>5$m) per year, three 1:10 year storms ($H_{\text{m0}}>6$m) and one storm exceeding a 1:50 year storm ($H_{\text{m0}}>7.9$m) during the lifetime of the breakwater.

Test Procedure

In order to calibrate the physical model, a calibration test was carried out in which the prototype damage resulting from the storm history was reproduced in the 3D model (Figure 6). A number of repair options were then investigated, starting with the simplest option, and extending the repair until a stable solution was found. Before each repair was constructed, the original damage was replicated in the model. The repaired breakwater was then exposed to the conditions described above.

After each test, the repair was removed and the original damage reconstructed, after which the next repair option was implemented. The optimum repair option chosen from the 3D tests was then reproduced at a larger scale in the 2D flume tests, initially with a fixed bed and then with a movable sand bed. These larger scale flume tests were used to give special attention to the ability of the breakwater to withstand some toe scour resulting from sand-trap dredging.
Prototype damage is assessed by counting the broken or lost dolos units and adding the units which have been displaced more than \( \frac{1}{2} h \) (dolos height). A number of swing tests were carried out on full-scale 9t doloses to determine the degree of movement these doloses could sustain without breakage (Zwamborn and Phelp, 1989). Based on the results of these tests it was recommended that all movements greater than half the height of a dolos be included as damage. This damage is then expressed as a percentage of the total number of dolos in a particular section of breakwater (Figures 2 and 3).

In the model, the number of dolos movements was determined by the digital analysis of video images taken before and after each run. In addition, the number of dolos which were rocking was recorded visually and by cine camera during each test. However due to the difficulty in observing movements over the whole test area, it was decided to use the video measurement of small movements (< \( h \)), as an estimation of rocking dolosse. This was then calibrated against the recorded prototype damage to give a calibration factor of 0.4(<\( h \)) + (>\( h \)), which gave an accurate simulation of the prototype damage profile along the trunk of the breakwater between stations 5 and 17 (Figure 6).

Figure 6 also shows, both in model and prototype results, that the worst damage occurred between stations 7 and 9. Hydrographic surveys of the sand-trap between 1977 and 1991 have shown that, almost since completion of the breakwater, the deepest area of the sand-trap was located opposite stations 7 to 9 (Figure 5). This also coincided with the area where the sides of the sand-trap were steepest and closest to the toe of the breakwater. One model test which was carried out with a larger deeper sand-trap resulted in an increase in damage proportional to the extension of the sand-trap, which indicated that the increased breakwater damage could be linked to the sand-trap dredging.

**Discussion on the Repair Strategy Followed**

Static tests on dolosse have shown that a dolos can carry 4 to 6 times its own weight without breaking; this implies that a number of layers can be constructed without breakage under static load. Thus it was considered feasible to place a 1 to 2 layer thick 20t to 30t dolos strengthening layer, safely on top of the existing damaged 20t dolosse.
Although the quality of the underlying 20t dolosse is questionable, the dynamic loading over the past 20 years has caused the weaker dolosse to break, and careful placing of new dolosse should not result in significant further breakages, besides the initial “shake down damage”. However, since most parts of the repair sections will consist of a number of already broken units, the repair itself was designed as well interlocked armour, finished to a uniform slope, which should be able to stand on its own. Although stresses cannot be modelled, extensive prototype observations and structural tests on full size dolosse support the above conclusions.

**Repair Options Tested in 3D Basin**

Comparative tests were first carried out using the same wave conditions and sand-trap configuration. Later tests included the option of extending and deepening the sand-trap. The first repair option tested involved covering only the worst stations (C7 and C8) with a double layer of 30t dolosse, with 20t dolosse on either side to tie into the existing slope. A total of 150 30t and 250 20t dolosse were used for repair option 1, placed at 1:1.5 slope with no rock toe. After this proved unsuccessful, repair option 2 was tried, with 30t dolosse and a rock toe stretching from stations C5 to C12. A total of 504 dolosse were placed covering a distance of 165m. Although repair option 2 showed less damage, it was still unacceptably high. Repair option 3 was similar to option 2 but with a flatter 1:2.5 slope from +3.5m. A total of 670 30t dolosse were used. This repair 1:2.5 slope option was repeated unsuccessfully with 950 20t dolosse and then with 785 30t dolosse but without a rock berm.

**Repair Options Tested in 2D Flume**

Repair option 3 was then repeated in a larger 1:63 scale 2D flume (3m wide). The effect of extending and deepening the sand-trap was also re-tested in the 2D flume. The latter test confirmed the relationship between high damage and the deepest part of the sand-trap (Figure 5). Because of the vulnerability of the breakwater toe to scour resulting from sand-trap dredging, it was decided to optimise the size and position of the rock toe by running some tests at an even larger 1:40 scale in a 2m movable bed flume. This was done to check stability of the toe at low tide, and its ability to accommodate settlement and erosion, but still maintain support for the bottom row of repair dolosse. The movement of the rock and change in profile of the toe were carefully monitored. These tests showed the need for the rock toe and first two rows of dolosse to be placed first, and allowed to settle, before the rest of the repair dolosse were placed.

**Change in design conditions**

After acceptance of the above repair design, a total of 1000 new 30t dolosse were cast near the root of the south breakwater (Figure 7). The start of construction of the repairs was however delayed for more than a year because the Portnet crane that was to be used for the repair at Richards Bay was unavailable. In this time there was substantial accretion, (of up to 3m) especially along the trunk of the breakwater (Figure 8). The breakwater repair section was again tested in the 2D flume with the reduced depth. The depth at the toe at some sections was as shallow as -5m CD. During the re-testing of the
model it was found that the proposed rock toe was unstable, with the rocks being displaced into the dolos slope. The dolosse would have sustained more damage and become clogged (lower porosity) in such a scenario. Various options were then investigated to solve this problem, such as dredging a trench in front of the breakwater to lower the toe, or to use heavier rock (> 5t), or to do away with the rock altogether.

Figure 7: Casting Yard for New Dolosse

Figure 8: Final Repair Design Profile

Implementation of Model Test Results

A comparison of the damage at the end of each test run in the 3D basin showed that option 3, with the 30t repair dolosse at a flatter 1:2.5 slope was clearly the best option, although some "shake down" damage was expected from the repair settling into the existing dolosse, from the pre-settlement of the first rows of repair dolosse and from possible future toe scour. Research by the CSIR (Zwamborn and Phelp, 1989 and Luger, 1994) has shown that armour unit strength can be enhanced by rail reinforcing and by increasing the size of the dolos fillet between the fluke and shank. For this reason, the new dolos shape with large curved fillets was used and one third of the repair dolosse were rail reinforced for use in potentially high damage areas.
The solution that was eventually found to provide a stable repair at the shallower toe depth was to replace the rock toe with an additional three rows of “sacrificial” dolosse. There would ultimately thus be 5 rows of dolos lying on the accreted seabed. These dolos were allowed to pre-settle into the sand over a length of time, before placing the rest of the repair slope. In the model, the maximum settlement was recorded at 2-3m at the toe (Figure 9). It was also found that the dolos had to be placed at a packing density of 0.75 for the maximum pre-settlement to occur. The rest of the breakwater repair was then placed at a packing density of 0.85.

In reality the dolos would settle 2-3m or until they reached the previous rock toe, or the remnants thereof. The pre-settlement dolosse placed directly onto the sand were all to be rail reinforced for additional strength, and their settlement was monitored by ball surveys. Figure 9 gives a typical profile before and after placing the first 5 rows of dolosse, which shows the dolos 2m above the sand, indicating a settlement of about 2m. The results of the crane and ball survey were analysed and contours plotted of the data. These contours were then analysed and large holes were identified where additional dolosse were placed to ensure a smoother profile before placement of the new double layer repair. Each dolos was given a fixed co-ordinate (Figure 10), calculated to achieve the desired packing density and final repair profile.

Construction Methods

Based on the results of the model tests, only 30t dolosse were to be used for the repair. These dolosse were brought from the casting yard (1001 new 30t units) and old stockpile (37 old 20t and 88 old 30t units left over from the original breakwater construction) on the south side of the entrance channel directly onto the breakwater. Three double direction trailers were then used to transport the dolosse, but as these trailers could only pass when unloaded, it meant that only one 30t dolos could be brought onto the breakwater at any one time (Figure 11). A portal crane was used to handle the dolosse from the casting yard onto the stockpile and from there onto the trailers.
Initial crane and ball surveys were done with 5m profile intervals over the damaged areas. Repair dolos placing grids were then calculated and the pre-settlement dolosse were placed. Another ball survey was then carried out to check the pre-settlement, from which the final repair dolos placing grid could be recalculated if necessary. The smoother the under-layer profile, the easier it was to set placing grids for uniform packing density.

The crane hook was fitted with a 15m sling (to ensure the hook and pulley remained out of the seawater), a quick release hook and a double cable sling. The double slings which support the dolosse were hand spliced (instead of swage joined) to allow easy removal of the slings once the dolos was in position. The quick release hook was hung from a swivel and fitted with two torque bars, which allowed easy rotation of the dolosse to ensure good interlocking. The torque bars were attached to 10mm nylon (light and water resistant) ropes, which were pulled perpendicularly from the mass capping to orientate the dolosse. The front row of toe dolosse were placed with the vertical fluke facing seawards.

It was found that to ensure correct packing density, the dolos placing must be kept as close as possible to the grid coordinates. The final orientation and positioning of the dolos is then done by eye to ensure good interlocking. Dolosse are placed with a minimum of three contact points to reduce the chance of rocking under wave action. After all the grid positions were full, it was found that up to 5% additional dolosse (using old 20t and 30t units from the stockpile) had to be placed “in holes” to ensure a well interlocked uniform profile. To identify these “holes” an aerial view of the slope was studied from a helicopter.
DGPS for Crane Positioning

For both the crane and ball surveys of the slope profiles, and the correct placing of the dolosse, there was a need to accurately position the hook of the crane. A differential GPS system was introduced using satellite positioning linked to a portable computer onboard the crane. The satellite receiver is positioned on top of the crane boom, directly above the position of the hook. The pre-determined positions are entered into AutoCAD software on the computer, and standard survey software enters the real-time navigation parameters which indicate the position of the boom. By entering the standing position of the crane along the breakwater, the boom reach and safety circle can also be indicated on the screen. The crane operator can then immediately see which dolosse can be placed from the present position of the crane. The AutoCAD dolos placing grid is shown in Figure 10.

The positioning software includes the following useful features:

- Zoom in and out, and centring the cranes position on the screen.
- The entry of up to 20 predetermined crane standing positions on the breakwater, including facility to orientate and offset.
- The entry of up to 1000 top and bottom layer dolosse, including an indication of size and numbering (colour options)
The facility to import and do editing of an AutoCAD or other CAD drawing of the breakwater eg: the “as-built” layout.

Indication and editing of the safe radius of the cranes reach.

The input and storage of the placed positions of the dolosse.

A backup system where the polar coordinates can be entered to position the crane, should the DGPS signal fail.

The dolosse were numbered as per their sequence of placement. A top layer dolos was always placed centred between 4 under-layer dolos. The sequence thus entailed the placing of alternate bottom and top rows of dolos, moving up the slope. The placing of the pre-settlement under-layer dolosse started at the root of the breakwater and progressed towards the head. The crane then returned to the root to place the rest of the repair dolosse after the lower dolosse had had a chance to settle. The end of the repair was always left tapered at 45° up the slope, thus ensuring no unstable units which might be displaced before the repair could be completed (during storm conditions or breaks in construction). The limiting operating conditions for the crane were wind speeds of 50kph or swell heights above 2m.

Figure 11: Successfully Completed South Breakwater Repair
Conclusions

Close cooperation was maintained between Portnet, the Client/Port Authority who also partook in the model tests and constructed the repairs, the CSIR Research Laboratory which undertakes the annual breakwater surveys and who carried out the model studies, and Entech Coastal Consulting Engineers who assisted with parts of the design and construction. This ensured problems encountered could be quickly investigated and amendments incorporated into the final design. The early warning provided by the annual breakwater monitoring also meant that there was sufficient time to carry out the model tests and come up with an optimum repair design.

The completed repair can be seen in Figure 12, which shows the uniform profile and good integration with the original structure. A final ball survey of the repair showed that for most profiles, there was a perfect match between the design and surveyed profile. This was achieved by accurate dolos placing with the aid of DGPS on the crane. This repair which was completed in June 1998, has already withstood two storms in excess of the 1:1yr design wave height above 4m. A photographic aerial survey done after these storms showed less than 1% damage resulting from the initial “shake down”. Annual surveys will be continued, to monitor the performance of the new shaped 30t dolosse.

DIGITAL IMAGING PROCESSING TECHNIQUES FOR THE AERIAL FIELD MONITORING OF HARBOUR BREAKWATERS

Gavin Hough¹ & David Phelp²

Abstract

The entrances to the six largest ports in South Africa are protected by rubble mound breakwaters, which have Dolos armouring. PORTNET, the national Port Authority, have commissioned the CSIR to conduct detailed monitoring of existing rubble mound breakwaters including records of the wave conditions to which they are subjected in service. This paper presents the image processing techniques used to monitor breakwater damage as well as the wave field causing the damage. Wider applications of these techniques have been commissioned during pipeline outfall construction as well as during the design & modelling stage of a proposed new harbour. The image processing techniques have been used to measure both breakwater settling and damage as well as moored ship motion for competing breakwater designs constructed as in scale models, of proposed harbours at the CSIR's physical modelling facilities in Stellenbosch. The image processing techniques developed by TECHTRIX International are reported here.

Context and Background

Recent trends highlighting the increased use of global satellite mosaics are impacting on the research, infotainment, and animation industries. National Geographic Television have for example, in a joint effort with Jet Propulsion Laboratory, taken over 500 satellite images and stitched them together digitally covering the entire globe at 1km resolution. Cloudy areas are replaced with cloud free data, colours are balanced, and the infrared channels converted from infrared (for vegetation) to natural hues.

This process is now recurring on smaller scales, with image mosaics, recorded from helicopters, aircraft and balloons using GPS to log viewing positions. These images are then projected onto digital terrain models of the area of interest. By repeating flybys at well-chosen intervals, changes, which would otherwise be too slow or subtle for the human eye, are clearly resolved.

In the United States, highway surveys from slow flying helicopters are used for road maintenance programs, and in South Africa annual harbour breakwater surveys use helicopters with differential GPS for imaging. Both digital and analogue images are recorded on pre-determined flight paths. The video sequence is digitised to supplement

1789
the image sequence recorded using a digital camera. This current image sequence can then be compared with archived reference photographs, which are scanned or digitised using a CCD camera. These image sequences are analysed to monitor storm damage and movement of Dolos and more recently Core-loc armour units. A significant data archive, spanning a decade of wave damage to South African breakwaters, can now be analysed using these new image-processing techniques.

Breakwater Imaging
The primary goal of this ongoing breakwater-monitoring project is to quantify damage to breakwaters protecting all major harbours along South Africa’s 3000km coastline. Broken and missing armour units, as well as individual displacements of these units are quantified on an annual basis, or more frequently in the case of major storm damage.

Flight paths following GPS stored way stations are flown annually with images typically recorded at 25m intervals along the breakwater from a position, which is normal to the plane, defined by the bank of armour units. Figure 1 illustrates a typical imaging configuration and the position of the photographer on the outrigger.

Movement Logging
This image sequence is digitised and stored as the digital reference breakwater. This image sequence defines the reference frame against which future breakwater images are compared. Where the flight paths differ despite the deployment of differential GPS, the images are warped in such away as to optimise the fit between the earlier “reference breakwater” images and the more current images. The imaging system then flicks between these two images (the reference and the registered current image) allowing small movements (<10cm) to become immediately apparent to the operator who logs the displacement, damage and disappearance of armour units with a few simple mouse clicks.

Figure 1 illustrating the positioning of the photographer for breakwater imaging. Images are recorded at 25m intervals.
Figure 2a: Model breakwater view with ripples on right hand side barely visible.

In Figure 2a and b the movement of a single armour unit cluster is illustrated using simple image subtraction techniques. Note the barely visible ripples being resolved in this 1:100 scale model. Outdoor harbour surveys often require edge detection techniques in order to resolve small movements despite differing lighting conditions. Typical images as well as the program for illustrating these techniques can be downloaded from http://flyer.ph.und.ac.za/~techtrix/.

Figure 2b illustrating the registered image subtraction technique which is applied in real-time for identifying significant breakwater movement.
Figure 2c highlight recorded movements during a series of design storm tests in this model application.

Scope of Application

This Breakwater Monitoring System is focussed on four specific areas of application:

- Rapid recovery of quantitative breakwater damage from existing photographic archives. In this case a live video digitising station is used to allow freehand movement of the current image until it overlays the reference image (already digitised). The ergonomics of this operation are significantly better than having to pair up common reference positions in every image pair before applying the appropriate image transform. It is however important that the before-and-after image pairs differ only in position and orientation. Should the images differ in size then the zoom has to be adjusted which slows the process down, making it as slow as the cursor controlled “drag and stretch” operation performed on scanned images.

- Real-time multi-camera system for model applications. Both systems, (a 4 CCD camera system for B&W imaging and a 3 camera system for colour imaging) are

3 This is achieved using either of two methods:

[1] the “blink-comparator” method traditionally used by astronomers when scanning for commits by blinking between two images of a given star fields where fixed stars have been used to register the images or

[2] the “flicker optics” method (South African patent No 94/10303) which interlaces the live video of the current image with the fixed reference image.
used for logging breakwater damage in scale model applications where design storms expose the strengths and weaknesses of different harbour breakwater designs. This kind of work has been labour intensive in the past and has not resolved the details of the breakwater settling process, as well as the myriad of smaller displacements which will propagate over considerable distances from a racking armour unit. The current set-up in the CSIR’s model hall in Stellenbosch, SOUTH AFRICA allows for a 10-fold saving in data sampling and processing, making the systematic study of multiple large scale design variations more feasible.

- **Off-line digital image archive analysis.** When analysing an existing digital image database sampling stations, scanners and digital frame grabbers are not required. These systems are typically run in parallel with the multi-camera sampling systems during a run. In this way several personnel can analyse images pairs as current breakwater image sequences are sampled by running both systems on a common LAN.

- **Remote surveillance and environmental monitoring systems.** Cameras located on coastal high-points are able to monitor breakwaters and surrounding wave fields during daylight hours. These cameras running at full video frame rates can measure wave orientation and period by continuously sampling video intensities along lines parallel to and at right angles to the nominal direction of wave propagation. Breakwater images can be triggered by wave drawback ensuring image sampling when the bulk of the breakwater is exposed. The research objective here is to log all significant armour movements by time and position and then analyse the statistics as a function of different sea states. The sea-state system has been deployed and a feasibility study undertaken for PORTNET on their Durban Bluff Signal tower – one of the few land based high points with a view of the exposed side of a harbour breakwater. Both modem dial-up for downloading processed data, and microwave links for transmitting live video between camera and frame grabber, have been deployed with reliable performance for environmental monitoring contracts ranging from 2 months\(^4\) to 2 years\(^5\).

Daytime Wave Field Monitoring in the Vicinity of Breakwaters

The *WaveWatch\(^\circledast\)* system developed by TECHTRIX International is set up during good seeing conditions when the horizon is well resolved. The calibration procedure automatically locates the horizon, and asks the operator to click on the positions of several locations with known GPS co-ordinates within the field of view. This information is used to set up a mapping locating any part of the picture in real-world co-ordinates, allowing any sampling line to resolve true bearing and length. The operator will then position a sampling line, which is roughly orientated along a wave front. Intensity profiles along this wave front are then sampled 25 times a second (using the PAL video standard) and the phase lag between intensity modulations at opposite ends of the sampling line, used to track wave bearing in real-time on an ongoing basis during daylight hours.

\(^4\) Sappi-Saiccor 6.5km outfall pipeline construction which required pipe-flooding in the event of design storms (1-in-1 year storm from 60° and a 1-100 year storm from 170°) to avoid pipeline displacement on the seabed.

\(^5\) Multi-camera systems using remote cameras on pan-tilt platforms linked by microwave to a central operations centre where digital image processing techniques are used for forest fire detection in forest plantation environments.
Figure 3a illustrates the horizon fix, GPS landmark selection and video sampling line placement. The keograms which follow illustrate the time stack output of the intensity profiles extracted from the sampling line at the full TV frame rate and averaged in order to focus on the phenomena of interest. (For details see the appendix at the end of the chapter.

This time stack is compiled from 576 video images. A fixed video intensity profile running along the shore-line is extracted from each video image and "stacked" from left to right in sequence.

This particular view was selected to illustrate the effect of a rip current near the base of Durban's south breakwater. Surface water is shown converging (through time) on the rip channel. The inset bottom right is 1 (of the 576 profiles) displayed as a plot of intensity for the vertical sampling line passing through the cursor.

Figure 3b is a time-stack illustrating along shore movements in the vicinity of an off shore rip current near the base of a breakwater in the surf zone.
Figure 3c: In contrast to the previous time-stack sampled along a fixed line parallel to the shore, this time stack is sampled from the beach at the base of the breakwater straight out through the surf zone. The shoreward propagation of the swells and the gradual sea-ward drift of the white water is illustrated here. One can clearly make out larger swells "overtaking" smaller swells en route to the beach visible at the base of this video mosaic. On the opposite side of the breakwater ships entering and leaving the harbour can be tracked in this format keeping a record of their arrival and departure times through the harbour mouth.

Figure 3d displays the digital video record (in time stack mosaic form) of ships entering and leaving the harbour.
Decision Support for Harbour Breakwater Management

Breakwater movement after the settling stage following construction is required when compiling a set of practical management directives supported by the emerging trends in breakwater damage (when is it best to repair the breakwater?). Early repairs may be too frequent and therefore expensive while late repairs stand the risk of having to repair runaway damage events like leading to total breakwater failure. The current directive is for immediate repairs when displacement, loss and breakage approach 30% of armour units along any given section. Historical records do however include results where these directives were not applied in the past ensuring that management evaluation data is available over a wide range of management regimes (*CSIR reports.....1987-1997*).

Once the repair has gone ahead, its implementation can be significantly improved with the use of GPS assisted armour placement cranes, streamlining the process from movement detection to the physical positioning of the replacement armour unit (*Phelp et al 1998*).

**Ship Dynamics in the Vicinity of Breakwaters**

The recent advent of wave field monitoring with view to highlighting the risks associated with specific storms on a more quantitative bases, has been focused on developing operational criteria for storm related port closure to shipping. The narrow Durban harbour entrance, which only exceeds the large ship beam by a factor of three, is monitored for wave sea conditions impacting on the safety of the ships approaching the harbour entrance. As vessels enter the lee of the south breakwater strong yawing motion as well current shear have been measured. The figure below is a time-stack montage illustrating the cross-current in the vicinity of the harbour entrance displacing the ship's wake from the path followed by the ship's bow through the water.

![Ship Dynamics in the Vicinity of Breakwaters](image)

Figure 4: This remarkable keogram of a ship approaching the harbour entrance from a distance of 2 nautical miles. The cross-current in the surface layer is evidenced by the gradual sideways drift of the wake (by 25m over 50 seconds) resolved here at progressively lower positions towards the right hand side of this time stack mosaic.
Figure 5a displays a single sweep of the radar field. This is digitised and analysed over any portion of the wave field for wave propagation speeds, wavelengths and periodicity. Qualitative wave amplitude estimates can also be made.

24 Hour Monitoring of Wave Fields in the Vicinity of Breakwaters

Machine vision based ship tracking and wave field sampling are limited to daylight hours and can be effected during heavy sea conditions when visibility can deteriorate. For this reason radar data have been digitised enabling around the clock monitoring of storm-time wave fields up to a distance of 6 nautical miles from the bluff signal station. The radar field is digitised in time series allowing for accurate wave celerity, wavelength, period and qualitative wave height variation measurements to be made. The radar image mosaic below illustrates in space-time (or time-stack) format, how wave length and period as well as phase velocity can be measured. It is interesting to note that the "envelope" modulating the amplitude propagates at close to half the phase velocity. This allows one to estimate the group velocity, which is effected by both the surface current and bottom topography.
Figure 5b illustrates the propagation of individual wave fronts during heavy sea conditions which necessitated the closure of the Durban port during May 1998.

**Breakwater Design and Moored Ship Dynamics**

Remote measurement of moored ship movements is illustrated below allowing for the quantitative comparison of different design storms and breakwater designs in the model environment, as well as useful information for harbour records and container loading availability on a daily basis in the port environment. The most recent system can measure all 6 degrees of freedom with a single camera in the model environment.

Figure 6a showing the model ship with all the attachments required for performing conventional measurements of model ship dynamics. This is contrasted with the techniques deployed here where images are analysed and displacement profiles are
measured at 25 or 30Hz. These techniques have been scaled up to field trials with change in hardware or increase in cost.

Figure 6b showing a typical feature trace, which is automatically tracked when extracting displacement time series data. One or more sets of data can be sampled for each degree of freedom.

Design of Rock Armoured Single Layer Rubble Mound Breakwaters

T. Hald ¹, A. Tørum², T. Holm–Karlsen³

ABSTRACT

There have been several investigations on the stability of site specific single layer breakwaters, e.g. for Søvær Fishing Port, Bratteland and Tørum (1971) and for Berlevaag Harbour, Kjelstrup (1977). However, despite the frequent use of the single layer design only little systematic investigations of the stability have been conducted until now. During the winter/spring 1997 a series of physical model tests have been conducted at SINTEF with focus on the hydraulic stability of the single layer rubble mound breakwater armour layer and the wave induced loading (Hald and Tørum (1997)). The present paper describes the results of these tests.

1. INTRODUCTION

Along the Norwegian coastline more than 600 breakwaters have been build since 1866. Some of these breakwaters are located on severely exposed locations with significant wave heights up to 6.5 m. The present value of these breakwaters is estimated to approximately 4.000 mil. NKr. The far most build breakwater type is the socalled single layer rubble mound breakwater utilizing only one layer of rock in the armour layer. This type of breakwater has developed from the time when heavy equipment was not easily available and the armour layer was constructed by dumping the stones from the breakwater crest.

Obviously the use of one layer rock in the armour layer requires fewer blocks than the traditional two-layer rubble mound breakwater. Despite the fact that heavier blocks are required for the single layer breakwater there is normally a better balance in quarry yields between large armour blocks and the smaller fractions used in the core for the single layer than for the two-layer breakwater.

¹Hydraulics & Coastal Engineering Laboratory, Aalborg University, Denmark.
²SINTEF Civil and Environmental Eng., Dep. of Coastal and Ocean Engineering, Norway.
³Norwegian Coast Directorate, Oslo, Norway.
The use of one layer rock in the armour layer is in most countries not allowed because of apparent weaknesses in the construction. However, the Norwegian experience with respect to low maintenance cost is fairly good. The total maintenance budget is normally 2–4 mil. NKr. per year and in extreme winters the maintenance budget may occasionally raise to approximately 15 mil. NKr, c.f. Holm–Karlsen and Tørum (1998).

Thus, regarding both construction and maintenance the single layer breakwater has been considered to be a cost effective structure in Norway.

1.1 Construction of a single layer breakwater

Many of the older breakwaters in Norway were designed and built before any good knowledge of wave climate and on breakwater hydraulics was available, i.e. before the sixties. Thus experience and subsequent trial-and-error procedures were used.

Traditionally, the armour layer was constructed by dumping the armour stones from the breakwater crest from rail wagons or trucks. This dumping of the stones has to some extent been an art and the result depended also on the skills of the foreman. If an armour stone did not come into its right position it was necessary to use dynamite to blow it away before any new stones were placed. During the construction it was aimed at placing the stones orderly with the longest side almost perpendicular to the filter layer and the smallest area facing the waves, but often the result was a random placement. In order to make the stones roll in position the slope needed to be fairly steep and typical breakwaters were constructed with a slope of 1:1.25 to 1:1.5.

The period of construction was frequently over several years with longer breaks during winter and autumn due to hard weather. The winter storms have settled the unfinished breakwater incurred small damages to it. Possible damages were subsequently repaired during the following construction period and the net result was an improved stability of the finished breakwater.

In some cases today backhoes have been used to place the stones orderly in the armour layer. This method can only be applied from a level of approximately 2 m below LWL because of the limited range of the backhoe. Below this level the armour stones are placed traditionally by dumping from crest. This calls for special attention paid to the lower part in order to secure a safe foundation for the orderly placed upper part. Recently some of the newer build breakwaters built this way have suffered heavy damage.
2. MODEL TEST SETUP

Based on investigations of cross sectional parameters and armour stone characteristics of the Svartnes, Årviksand and Sørvær breakwaters a 3D scale model of 1:30 – 1:40 has been designed. Characteristics of the armour stones are given in Tab. 1.

Table 1: Armour stone characteristics.

The breakwater scale model was composed of a core with stones of 4–8 mm, a toe of 118 g stones, a filter layer of 6.4 g stones and a superstructure. The filter layer stone size has been designed according CIRIA–CUR (1991) and with a thickness of 50 mm corresponding to 3–4 stone diameters. On the filter layer the armour layer was constructed with a constant slope of 1:1.5. Two types of armour stones with different weight but similar grading and shape characteristics were used, see Tab. 1, type A and B. The toe has been designed to withstand the most severe waves in order to avoid reconstruction after every test. In Fig. 1 the model cross section is shown.

![Figure 1: Model test cross section.](image-url)
depth of 0.4 m corresponding to the water depth at the toe. To measure the up- and downrush a resistance type gauge was placed on the slope. The sampling frequency was kept constant at 20.0 Hz.

3. STABILITY OF ARMOUR LAYER

3.1. Damage registration

The damage was registered by counting the accumulated number of moved stones $N_m$ and by measuring the average eroded area $A_e$ after each sea state run. The stones included in $N_m$ were defined as the stones moved more than one $D_{50}$ from their original position and the stones that does not have a stabilizing effect. With respect to the average eroded area profiles were measured by laser for every 10 cm over the width of the breakwater. On the trunk 10 profiles, corresponding to a measurable width of 0.9 m, were averaged to obtain the average profile $z_i(x)$. The vertical difference between two individual profiles was calculated so erosion becomes negative, i.e.

$$\Delta z(x) = z_{i+1}(x) - z_i(x)$$  \hspace{1cm} (1)$$

Followingly, the average eroded area was calculated by integration of negative values of $\Delta z(x)$ between the toe and the breakwater crest.

$$A_e = \int_{x_{toe}}^{x_{break}} (z_{i+1}(x) - z_i(x)) \, dx$$  \hspace{1cm} (2)$$
The damage level $S$ was then calculated by

$$S = \frac{A_e}{D_{n50}^2}$$

(3)

Physically $S$ can be interpreted as the number of squares with the length $D_{n50}$ that fits into the average eroded area.

As a comparison between the two damage measures, the equivalent number of stones moved $N_{mS}$ corresponding to the measured damage level $S$ was calculated.

$$N_{mS} = \frac{Sl(1-n)}{D_{n50}}$$

(4)

where

$l$ : Length of measurable part of trunk section, i.e. 0.9 m

$n$ : Porosity of armour layer, $n = 0.4$

For small degrees of damage the counting method is considered the most reliable since the profiling also includes settling while profiling is considered better for larger degrees of damage when counting is more difficult.

Corresponding to the accumulated number of moved stones after each sea state the percentage damage $N_{pD}$ and $N_d$ that represents the number of stones moved in a down-slope row with the diameter $D_{n50}$ were calculated.

The reason for using two damage measures is that the total number of stones in the armour layer is different for tested cross sections. E.g. when comparing the orderly and the randomly placed armour layers the same percentage damage corresponds to the same amount of erosion, but a different number of displaced stones. Same $N_d$ gives same number of displaced stones but different eroded area.
3.2. Test programme

The tests were performed according to the test programme in Tab. 2.

Table 2: Test programme for stability investigations.

In each test the steepness $s_m$ was kept constant and the wave height was increased by 1.5 cm until failure was reached. The waves were generated according to a JONSWAP spectrum with $\gamma = 3.0$. Each sea state was run for app. 2000 waves.

Due to the stochastic nature of the waves and the constructed model all tests were repeated up to 3 times in order to provide some statistical sound data.
3.3. Stability of orderly placed stones

The damage begins above SWL by displacement of single stones from the armour layer followed by down-slope rolling of the stones. When the wave height increases the damage develops by displacement of more and more stones from the armour layer. As the stones are moved from the armour layer the remaining stones in the armour layer begin to turn downwards. In some cases the armour stones are hindered from turning by a high degree of interlocking and support from neighbouring stones. When sufficient stones have been displaced or turned downwards the high degree of support decreases and failure is inevitable.

In more quantitative terms the damage development for orderly placed stones on the trunk is shown in Fig. 3 for the wave steepness of 3% and the wave steepness of 5%, respectively.

![Figure 3: Damage development for orderly placed stones on trunk, $s_m = 3\%$ (left) and $s_m = 5\%$ (right).](image)

From Fig. 3 only little spreading between repeated tests and no or only little influence of wave steepness is observed. Furthermore, the damage develops slowly. Considering a damage level of 5% the stability number is approximately 2.3 which corresponds to a stability coefficient $K_D$ in the Hudson formulae of 8.1.

3.4. Stability of randomly placed stones

For a randomly placed armour layer the damage begins around SWL as a result of large settlements of the armour layer below water level. In single tests a long transverse fissure just above SWL with a width of 2-4 cm was observed. An increase in wave height resulted in displacement of more and more stones in the area around SWL.

In Fig. 4 the damage development for randomly placed stones on the trunk is shown for the wave steepness of 3% and the wave steepness of 5%, respectively.
Figure 4: Damage development for randomly placed stones on trunk, \( s_m = 3\% \) (left) and \( s_m = 5\% \) (right).

From Fig. 4 only little spreading between repeated tests and only little influence of wave steepness is observed. Opposite the orderly placed armour layer the damage development for the randomly placed armour layer is very rapid. Considering a damage level of 5\% the stability number is approximately 1.05 for a steepness of 3\% and 1.1 for a steepness of 5\% which corresponds to a stability coefficient \( K_D \) in the Hudson formulae of 0.8 and 0.9, respectively.

3.5. Stability of armour with combined placement methods

Fig. 5–6 depicts the damage development for the tests with orderly placed armour stones on top of an armour layer constructed by randomly placed stones. For a more complete description of the combined placement methods it is referred to Tab. 2.

In Fig. 5 the damage development for the construction type Ca (left) and Cb (right) is shown for a wave steepness of 5\%.

Figure 5: Damage development for combined placement methods, type Ca (left) and Cb (right), closed = stone type A, open = stone type B.

For the construction type Ca the stone type A have been used in both the orderly and in the randomly placed armour layer. In Fig. 5 (left) a slow damage development is seen. However, this is not a true picture of the behaviour since only stones in the lower randomly placed armour layer are moved up till a certain damage level. Above
this level the orderly placed part starts to slide. At a damage level of 5% the stability number is 1.6 corresponding to a stability coefficient of 2.7.

For the construction type Cb the stone type B have replaced stones type A in the randomly placed lower part of the armour layer in type Ca. The damage development for type Cb is shown in Fig. 5 (right). Compared to the Ca–type the behaviour of the armour layer is similar: Almost same slow damage development of the lower randomly placed armour layer followed by a rapid damage development of the upper orderly placed armour layer. At a damage level of 5% the stability number is 1.2 corresponding to a stability coefficient of 1.2. This level is significantly lower than for type Ca since the transition between the two methods of placement is at a higher level, see Tab. 2.

In Fig. 6 the damage development for the construction method D is shown for a wave steepness of 3%.

The construction method D differs from the C–types by the use of only one layer of stones in the randomly placed lower part of the armour layer and when comparing the way damage develops a more rapid damage development for the randomly placed part and a more slowly developed damage for the orderly placed part is observed. This is due to the larger settlements related to the single layer randomly placed armour layer. Corresponding to 5% damage the stability number is more or less similar with the Cb–type.
4. WAVE INDUCED FORCES

4.1. Wave force registration

For measuring forces a single stone was selected and a reprint was made in coated plastic foam and succeedingly mounted on a load transducer able to measure two force directions. The load transducer was designed and manufactured by MARINTEK A/S, SINTEF. The principle of the transducer is measuring shear strain in different cross sections enabling measurements of the force both parallel and normal to the slope. To avoid any contact with neighbouring stones a chicken wire was wrapped around the mounted stone with a distance of approximately 1 cm.

The load transducer with mounted stone was placed in four positions over the slope as shown in Fig. 7. Also the definition of force directions is shown. Before positioning, the load transducer was calibrated in dry conditions up to 500 g.

![Figure 7: Position of load transducer and positive direction of forces.](image)

Both tests with regular waves and irregular waves were conducted with the transducer positioned in all four positions but only results for regular waves are treated herein, see Hald and Tørum (1997) for full reference. For regular waves a wave steepness of 3% and of 5% was tested by increasing the wave height in three steps: 9.0 cm, 12.0 cm and 15.0 cm. Forces were sampled at 500.0 Hz and subsequently lowpass filtered with a cutoff frequency of 250.0 Hz.

In the measured force time series maxima and minima peaks have been determined by zerocrossing analyses of the time derivative of the measured force time series. In order to determine only independent peaks, registered peaks within a desired filter width are sorted out leaving only one peak within one wave period.
4.2. Wave force characteristics

Measured force characteristics are shown in Fig. 8. Generally, force characteristics are almost invariant with varying wave height and wave steepness why only $H = 15\,\text{cm}$ and $s_m = 3\%$ is presented. Notice that the largest forces occur 10 cm below and 10 cm above SWL (in position 1 and 3) despite that the waves break directly upon the stone positioned in SWL (in position 2).

![Sample normal and parallel force time series for $s_m = 3\%$, $H = 15\,\text{cm}$](image)

*Figure 8: Sample normal and parallel force time series for $s_m = 3\%$, $H = 15\,\text{cm}$.*
4.3. Regular wave induced forces

To illustrate how the total force and corresponding direction varies down the slope all combinations of normal and parallel force within one test are plotted in a (x,y)–coordinate system – a so-called hodograph. As the total force varies in each direction, the average force $F_m$ within intervals of 5° was calculated. In Fig. 9 hodographs for each position and each combination of wave height and period are shown.

Generally, the shape of each hodograph for all combinations of wave height and period within each position is very similar, c.f. Fig. 9. The largest forces occur below and above SWL in position 1 and 3. In position 1 the dominating forces are either directed outwards and down-slope or inwards and up-slope. In position 2 the forces are smaller and of more or less the same magnitude in all directions. Further up-slope in position 3 the largest forces occur in up slope direction and mainly parallel to the slope. In position 4 the force is of the same character as in position 3 but only smaller.

The most interesting forces are the destabilizing forces in outward directions and in order to get an impression of the vertical distribution along the slope three outward directions are selected: 45° down-slope, 90° slope normal and 45° up-slope, see Fig. 10.
Considering Fig. 10 it is observed that each position except 0.25 times the water depth above SWL, i.e. position 3, the force magnitude is of the same order of magnitude for all directions. In position 3 the force increases as the direction becomes more upward directed.

4.5. Comparison with stability

Comparing video recordings from the model tests it is observed that for the randomly placed stones, damage is initiated below SWL. However, for the orderly placed stones damage is initiated above SWL.

Relating the stability observations to the force measurements it is interesting to see that only in the case of random placements, the downward directed force is able to remove the individual stones from their original position. This downward directed force is not sufficient to remove any stones when placed orderly because of the higher degree of
interlocking and support from neighbouring stones. In this case high normal/upward forces are required to remove any stone. These forces are present above SWL in position 3, especially in the 45° upslope direction.

5. CONCLUSIONS

The stability of different types of single layer rubble mound breakwaters have been investigated in a scale model for two characteristic wave steepnesses. The scale model and the sea states correspond to typical Norwegian breakwaters in scale 1:30 to 1:40 and typical prevailing storm situations in the Norwegian Sea.

Different methods of placing the armour stones in the armour layer have been investigated, see Tab. 2 and the stability performance is presented in individual damage curves. The highest degree of stability is obtained by placing the stones orderly. This placement method more than doubles the stability in terms of the Hudson-type stability coefficient compared to the conventional random placement method in two layers. Placing the stones randomly in one layer a very low stability of one third of the stability obtained by the conventional method is found. Generally, no influence of steepness was observed.

With respect to the wave induced forces on single armour stones the normal and the parallel force have been measured in 4 positions over the slope. Tests with regular waves have been conducted with two wave steepnesses. Large destabilizing forces were identified both above and below SWL. The influence of wave period was little as was the case for the stability tests whereas the influence of wave height was significant in some cases, especially in the positions above and below SWL.

ACKNOWLEDGEMENTS

The work is jointly supported by the Danish Technical Research Council under the frame programme Marin Teknik 2 and the Norwegian Coast Directorate.

The form of the mound of rubble dumped by a barge

Prof. Drs. Ir. J.K. Vrijling¹ and Ir. G. van Oord¹

Introduction

In coastal engineering many structures are (partly) made of rubble or concrete blocks. The usual way of construction is by gradually discharging a specified amount of rubble from a stone dumping barge. The stone dumping barge is steadily repositioned along the structure. To ascertain a geometry as designed in case of a breakwater, a specified evenness in case of a caisson foundation or an acceptable coverage in case of a scour protection a reliable prediction model of the deposition mound of the rubble is needed. Such a model can be helpful in designing and in calculating the cost of the structure. First a model to describe the process of a single stone falling through water, the single stone model (SSM) is given. A mathematical model that describes the dumping from a point source was developed based on the SSM. By integration this model is extended to a description of a line dump as executed by a stationary dumping barge. Finally using the same principle the model is adapted to describe a dump by a laterally translating dumping barge, the area dumping model. In order to verify and to calibrate the SSM a number of experiments were carried out in the Hydraulic Laboratory of Delft University of Technology.

The mathematical model

The model divides the gradual deposition of rubble or blocks in three stages. In the first stage the deposition of rubble is governed by a random walk of many independent steps with zero mean. If the rubble is dumped from a single point the diffusion to a cross section of the mound of rubble shaped like a two-dimensional Gaussian p.d.f. From first physical principles it is derived that the standard deviation should be governed by:

\[ \sigma_N = \alpha \sqrt{h \cdot D_{50}} \]

¹ Delft University of Technology, Faculty of Civil Engineering, P.O. Box 5048, 2600 GA Delft, The Netherlands, E-mail: H.Vrijling@ct.tudelft.nl
in which \( \alpha \) = constant depending on the mass density and the shape of the rubble particles
\( h \) = water depth
\( D_{n,so} \) = nominal diameter of the rubble particles.

A detailed derivation of this single stone model (SSM) is given by Vrijling et al. For regularly shaped blocks the random walk consists of one single step and consequently the deposition mound has a circular pattern with a radius proportional to the waterdepth. The cross-section of the ring is gaussian shaped and the standard deviation increases linearly with the waterdepth.

During the first stage the slope of the cross section increases with the amount of rubble dumped, until it exceeds the angle of repose of the rubble at the inflection of the Gaussian shaped mound. This second stage of the build up ends, when in every point of the slopes of the mound the angle of equilibrium is reached. In the third stage the shape of the mound of rubble can then be described by a triangle. If dumping continues the mound maintains its triangular shape. The triangle can also be characterized by its radius of inertia or standard deviation:

\[
\sigma_N = \sqrt{\frac{A}{6 \cdot \tan(\varphi) }}
\]

in which \( \iota_h \) = radius of inertia of the triangle
\( A \) = area of the cross section of the mound
\( \varphi \) = angle of repose of the rubble

It should be noted that in the third stage the radius of inertia of the cross section depends only on the dumped volume of rubble and the angle of equilibrium. The second stage, when the Gaussian cross section is reshaped into a triangular form, can be treated as a transition stage of lesser importance.

The deposition from a single point leads for reasons of symmetry to a bi-Gaussian shaped mound: the Point Dumping Model (PDM). To find the theoretical shape of the mound of rubble formed by a side-dumping barge with deck-length \( L \) moored at a fixed point with a constant heading is found by the integration of an infinite number of single point dumps along the length-axis \( Y \) of the barge. The Line Dumping Model (LDM):

\[
z(x, y) = \frac{V}{L \sqrt{2 \pi} \sigma_g} e^{\frac{-x^2}{2 \sigma_g^2}} \int_{-\infty}^{\infty} \frac{1}{\sqrt{2 \pi} \sigma_g} e^{\frac{-y^2}{2 \sigma_g^2}} dy
\]

Solving the integral leads to a slightly simpler form containing the standard normal distribution \( \Phi_{\sigma}(x) \):
\[ z(x, y) = \frac{V}{L \sqrt{2\pi \sigma_G}} e^{\frac{-0.5(x-x_0)^2}{\sigma_0^2}} \left[ \Phi_N\left(\frac{Y_1-y}{\sigma_N}\right) - \Phi_N\left(\frac{Y_0-y}{\sigma_N}\right)\right] \]

It should be noted that the endpoints of the line dump are described by the standard normal distribution, while the cross-section is given by the normal p.d.f. The center-line of the mound shows a offset with reference to the board of the barge. This offset is not included in the mathematical model.

If the barge is translated perpendicular on it's length axis during dumping, to cover an area with rubble the theoretical form of the deposition mound is found by a double integration over the area covered by the dumping edge of the deck of the barge. The Area Dumping Model (ADM):

\[ z(x, y) = \frac{V}{(X_1-x_0)(Y_1-y_0)} \int_{-\frac{1}{\sqrt{2\pi \sigma_G}}}^{\frac{1}{\sqrt{2\pi \sigma_G}}} e^{\frac{-0.5(x-x_0)^2}{\sigma_0^2}} dX \int_{-\frac{1}{\sqrt{2\pi \sigma_G}}}^{\frac{1}{\sqrt{2\pi \sigma_G}}} e^{\frac{-0.5(y-y_0)^2}{\sigma_0^2}} dY \]

Now the four edges of the dumped area are described by a normal distribution:

\[ z(x, y) = \frac{V}{(X_1-x_0) L} \left[ \Phi_N\left(\frac{X_1-x}{\sigma_N}\right) - \Phi_N\left(\frac{X_0-x}{\sigma_N}\right)\right] \left[ \Phi_N\left(\frac{Y_1-y}{\sigma_N}\right) - \Phi_N\left(\frac{Y_0-y}{\sigma_N}\right)\right] \]

The constant thickness of the layer is equal to the volume \( V \) divided by the area covered by the edge of the translating barge.

**Experimental verification**

In order to validate the mathematical model and to find values for the constant \( \alpha \) and for the angle of equilibrium of the rubble, model tests (see appendix) were carried out at the laboratories of Delft Hydraulics and the Delft University of Technology in a tank of 2 x 2.5 x 2.5 m. An extra aluminum bottom was installed to facilitate experiments at (four) different waterdepth. Two sides were made of 60 mm thick glass.

To validate the SSM stones were dumped individually from a fixed point in the center of the tank. The dumping of single stones was continued until the stones started to fall on top of each other thus making the positioning less accurate. After the dumping the tank was drained and digital pictures were taken to produce a top view. From the picture the radius from the center of the tank to every individual stone was determined. Afterwards the cumulative distribution function of the measured radii was compared to the Rayleigh-distribution, which gives the theoretical distribution of radii for bi-normally distributed points (SSM,PDM).

In other tests small amounts of rubble were dumped, taking pictures through the glass sides of the two cross sections of the build up of the rubble mound at regular
intervals to follow the forming of the Gaussian profile and the gradual transition to the triangular profile, when the angle of repose was exceeded.

The test results will be discussed in three categories: natural stone, cubes and spheres and thin shapes.

For broken rubble the agreement between the experiment and the theoretical Rayleigh distribution was quite good (Fig.1). The difference might in part be explained by the fact that the size of the rubble follows a sieve curve.

![Cumulative distribution function of the radii of dumped rubble particles](image)

**Figure 1.**

Also the relation between the horizontal displacement and the square root of the waterdepth was confirmed by the tests (Fig.2). The value of the constant $\alpha$ was 0.72 on average with a standard deviation of 0.09. If the rubble is dumped simultaneously the average value of $\alpha$ increases by 6%.

The gradual transition from the Gaussian profile with a width dependant of the waterdepth to a triangular profile with a width dependant of the volume dumped was experimentally verified. In Fig.3 the depth and the volume dependant models are drawn together with the experimental results.

For rounded rubble the value of the constant $\alpha$ was 0.60 on average with a standard deviation of 0.012. If the rounded rubble is dumped simultaneously the average value of $\alpha$ increases by 22%.
horizontal displacement $\sim \sqrt{h}$

Figure 2.

Figure 3.
Surprisingly aluminum cubes formed a ring when dumped. It appeared that the regular sharp edged cubes started rotating after falling over 8 to 15 D. So the formation of the ring may be attributed to the Magnus-effect, which results in an randomly directed, extra and stable horizontal force causing a ring shaped deviation from the center. The cumulative distribution function of the radii of the dumped cubes is not Rayleigh but normal (Fig.4). The total horizontal displacement is not the result of many independant steps with zero mean but of one single with a distinct mean. It appears that the mean radius increases proportionally with the waterdepth irrelevant of the size of the cubes (Fig.5). The previously found relation for the broken rubble is also depicted in this graph.

Figure 4: Aluminium cubes with $D_{50}=0.0145\text{m}$ and $h=1.10\text{m}$.

The result for concrete cubes with a diameter of 0.015m was strikingly similar. Also for glass balls ($D=0.0156\text{m}$) the same behaviour was found. The average deviation for the balls was exactly equal to that of the cubes, but the standard deviation around the ring was slightly bigger.

For reasons of comparison also some experiments were performed with square plates 0.05m thick with the same size as the cubes. Here the falling motion was very stable and the horizontal deviation of the center was almost zero. However experiments with Dutch guilders ($D=0.025\text{m}$), which have approximately the same size, behaved quite differently. A guilder falls with loopings leading to considerable deviations of the center. The c.d.f. of the radii conforms exactly with the Rayleigh distribution (Fig.6). Dutch rijksdaalders ($D=0.029\text{m}$) show exactly the same behaviour but with a bigger
standard deviation around the center. The strikingly different behaviour of falling objects depending on form and mass is also reported by Field et al and earlier by Stringham et al.

Tests were carried out to verify the theoretical shape of the mound of rubble formed by a side-dumping barge. An amount of gravel was shoveled off a board with a length of 0.70 m, mounted on top of the tank, the form of the mound was analysed and compared with the theory (LDM). A reasonable agreement was found, but not all differences are yet well understood.

Relation between horizontal displacement and waterdepth for aluminium cubes

Figure 5.
A practical model to predict the deposition of rubble dumped from a stone dumping barge was developed and validated in principal form. The model shows that three phases have to be discerned in which different variables govern the width and the form of the deposition.

The model is extended to describe the dumping process of a side dumping barge. With this model the form of the mound and the evenness of the resulting surface can be predicted.

The single stone model (SSM) gives a good description of the falling motion of rubble in water. Also the further build up when the angle of repose is exceeded is confirmed.

The horizontal displacement of the falling motion measured at the bottom is proportional to the square root of the waterdepth as found in the SSM. The influence of the diameter $D_{n50}$ of the rubble needs however further verification.

The development of the Gaussian profile into a triangle after the angle of repose has been exceeded was also confirmed for rubble.
Due to rotation the SSM does not give a good description of the falling of cubes and spheres. Here a ring is formed with a radius proportional to the waterdepth irrespective of the size of the particles.

The SSM gives a good description of platelike objects. However due to stronger lift-forces the horizontal displacement is far greater than for rubble.

In view of the good agreement for rubble, the model has shown to be of great practical value in the construction of rubble mound structures.

HYDRAULIC MODEL TEST OF STABILITY OF AMENITY-ORIENTED BREAKWATER

Shoji Kunitomi¹, Hajime Mase², M. ASCE, and Tomotsuka Takayama³

ABSTRACT: A slit caisson breakwater has now been under construction at Takamatsu Harbor, Kagawa Prefecture, Japan, as an amenity-oriented breakwater (that is, a human friendly breakwater opened for citizen). However, wave pressures and forces acting on the slit caisson have not been evaluated. Hydraulic experiments are carried out to examine the stability of the slit caisson breakwater and uplift forces on an upper board, and to investigate a desired type of upper board of the breakwater.

INTRODUCTION

This paper examines the stability of an Amenity-Oriented Breakwater against sea waves. Here the term of amenity-oriented breakwater is defined as a human friendly breakwater opened for public.

A main function of breakwater is to protect harbors against sea waves and keep them calm. Recently, because of small amenity space near urban area, there has been an increasing demand for breakwaters to be served as a recreation space for citizen. From the view point of amenity, breakwaters should be surrounded by clear water and allow easy water exchange.

A slit caisson breakwater is now under construction at Takamatsu Harbor, Kagawa Prefecture, Japan, as an amenity-oriented breakwater. Initially, this breakwater was designed only for protecting waves. However, as one of city plans of Takamatsu City, this breakwater was determined to be opened for amenity space. However, wave pressures and forces acting on such slit caisson have not been evaluated adequately. Here, we examine the stability of slit caisson breakwater by hydraulic model tests in order to propose a desired type of upper board of the caisson.

Photo. 1 shows a view of the slit caisson breakwater now being constructed at Takamatsu Harbor, and Fig. 1 shows an image view of the breakwater.

HYDRAULIC MODEL EXPERIMENTS

The breakwater will have parapets, handrails, boardwalk, footlights and stand-lights, as shown in Fig. 1. One of problems is to determine what kind of boardwalk we should employ from the viewpoint of uplift forces and stability of the breakwater. We adopted three kinds of upper board for experiments: 1) boardwalk, 2) boardwalk on a slab, and 3) boardwalk on a slit slab. In actual, boardwalk is made by wood.
We carried out hydraulic experiments of sliding stability of the slit caisson and uplift forces on three kinds of the upper board due to wave motion inside the caisson. Photo.2 shows the model caisson made by transparent acrylic, and Fig.2 shows the size of cross section of the model. The model scale of the caisson is 1/30. The slit opening ratio is 30.1 % on the front side and 4.3 % on the rear side. The experimental wave flume was
70 cm deep, 70 cm wide, and 40 m long. The model caisson was installed at 27 m far from the wave paddle.

The design wave height and period are 1.9 m and 5.5 s, respectively, as a fifty-years return period wave in the field. We carried out experiments by using regular and random waves. In the case of regular waves, the wave period was fixed as 1.1 s. Wave heights were changed from 6 cm to 13 cm so as to include the design wave height of 6.3 cm in the experiment. The water depth was set constant at 38 cm corresponding to the high water level. Concerning random waves, the significant wave height and period were 6.3 cm, and 1.1 s, respectively. The water depth was 38 cm (high water level) and 41 cm (highest high water level).

EXPERIMENTAL RESULTS AND DISCUSSION

Regular Wave Tests

Figure 3 shows the results of sliding stability tests for the caisson with three kinds of upper board against a parameter of wave height. The friction factor between the caisson and rubble mound was measured and found to be 0.51 on average. The displacements of the caisson under wave action were measured by two displacement gages installed at back side of the caisson. The vertical axis of the figure indicates the mean displacement per one wave. The horizontal axis indicates the sliding resistance force defined as the product of friction factor and caisson weight in water. From the results, we can obtain

![Fig. 3](image-url)

(a) Board walk

(b) Slab without slit

Fig. 3 Relation between sliding resistance force and caisson displacement
the critical resistance force for different wave height conditions as shown by arrows in the figures.

Figure 4 summarizes the non-dimensional critical resistance forces. The horizontal axis is the non-dimensional wave height normalized by the design wave height and the vertical axis is the critical resistance force nondimensioned by $W(d/w_0)$ ($w_0$: the weight of water per unit volume; $H$: the wave height; $d$: the water depth). The circles, triangles and squares denote the results for the cases of the slab without slit, the slit slab, and the boardwalk, respectively. This figure shows that the critical resistance force becomes smaller as the slit opening ratio of the upper slab becomes larger.

Figure 5 shows the modification factor against the wave height. Here the modification factor is defined as the ratio of measured critical resistance force to the predicted one by Goda's formula (1985). This figure shows that, in the case of the slab without slit, the modification factor becomes largest, and its value is about 1.0 at $H/H_D=1.85$ (corresponding to the maximum wave height of random waves). The maximum modification factor is about 0.9 for the slit slab, and about 0.8 for the boardwalk. By formu-
lating the modification factor for the slit caissons generally, we can estimate the resistance force by utilizing the Goda's formula (1985).

After the sliding stability tests, we measured wave pressures and uplift forces on upper boards by using five wave pressure gages and by utilizing strain gages.

Figure 6 shows the spatial distribution of wave pressures on upper board. The \( x \) is the distance from the edge of the slab, and \( w \) is the width of the slab, shown in Fig.2. The vertical axis is wave pressure normalized by \( w_o h \). Normalized wave pressures become the maximum around \( x/w = 0.45 - 0.5 \) (in front of the rear wall of caisson). Wave pressures decrease to be zero towards the rear end of the caisson. We also see that wave pressures depend on the incident wave heights for the case of the slab.

Figure 7 shows the normalized uplift force per unit length against normalized wave height. The uplift force coincides with the integrated value of wave pressures as a whole. Figure 7 shows that uplift force is proportional to the wave height in the range of this experimental condition. Besides, we can see that uplift force on the slab without slit is larger than that on boardwalk. From the viewpoint of hydrodynamics, employment of boardwalk is preferable for small resistance sliding force and small uplift force. However, it is dangerous to walk on the boardwalk when the water splashes out of slits at wave attack on the boardwalk, and how to set wooden boardwalk to the caisson against local wave pressure, shown in Fig.6, is a remaining problem.

**Random Wave Tests**

Total record time was 20 minutes. We analyzed 700 individual waves excluding first 100 waves from the start of wave making. Figure 8 shows the measured and target wave spectra which are represented by solid and dash lines respectively. Random waves were well generated in the flume.

From random wave experiments, we obtained the critical sliding forces as 0.21 kgf/cm for the boardwalk, 0.25 kgf/cm for the slab, 0.21 kgf/cm for the slit slab. These critical sliding resistance force correspond to those by regular waves of \( H/H_D = 1.58 \). This means that we can estimate the sliding resistance force of random waves from regular wave experiments by employing the regular wave smaller than the maximum wave \( (H/H_D = 1.8) \).
Fig. 6 Horizontal distribution of wave pressures on upper board

![Boardwalk](image1.png)

![Slab without slits](image2.png)

Fig. 7 Horizontal distribution of wave pressures on upper board
Fig. 8 measured and target wave spectra

Fig. 9 Horizontal distribution of occurrence frequency of wave pressures on upper board
CONCLUSIONS

Main results of this study are summarized as follows:
1) From experiments of regular waves, the critical sliding resistance force becomes smaller as the slit opening ratio of the upper board increase.
2) Wave pressures and uplift forces on the upper board decrease as the slit opening ratio becomes larger.
3) However, the problem is how to fix wooden boardwalk to the crown against wave pressures which locally become strong.
4) From experiments of random waves, critical resistance forces are found to be estimated from regular wave experiments by using waves of which wave height is a little smaller than the maximum wave height.
5) Besides, we can find the occurrence of large wave pressures and uplift forces is infrequent. But the boardwalk should withstand against large wave pressures even if it rarely occur.

From the results we proposed a type of upper board such as boardwalk installed on a slit slab by taking into account its life time.

Stability of mound breakwaters: dependence on wave reflection.

Cristina López ¹, Miguel A. Losada ², Member, ASCE and Nobuhisa Kobayashi ³, Member, ASCE

Abstract

Since the work by Ahrens and McCartney (1975) and Bruun and Johannesson (1976), it has been accepted that, for given slope, unit type and damage level, the stability number, $N_s$, and the so called $K_d$ factor depend on Iribarren number, $I_r$, and that the worst stable conditions are related to collapsing wave breakers. The plotted values of $N_s$ and $K_d$ from laboratory tests, as a function of $I_r$, show a large scatter. This scatter is larger for large values of $I_r$. It is shown here that the scatter almost disappears once the data are plotted against $kh$, or $I_n$, using the total wave height at the toe of the structure instead of the incident wave height. The total wave height, $H_t$, results from the interaction of the incident and reflected wave trains on the slope and depends not only on the magnitude of the reflection coefficient but also on its phase.

Introduction

The weight of the armor unit of a rubble mound breakwater depends on the geometry of the mound, the type of units, the characteristics of the incoming wave train represented by the wave height and period, and on the level of damage. One of the early formulas to calculate the weight of the armor units, $W$, of a mound breakwater was given by Castro (1933). Iribarren (1938, 1965) and Iribarren and Nogales (1950, 1954) based on this former work, proposed a more general formula, which was tested under monochromatic waves. Hudson (1959) proposed a simplified formula using the so called $K_d$ factor or stability coefficient. These formulas based on monochromatic wave tests are still being used in many countries. All of them can be written as follows (Losada and

---

³ Center for Applied Coastal Research. University of Delaware. Newark, Delaware 19716, USA.
Giménez-Curto, 1979):

\[ W = \gamma_w \cdot \Psi \cdot S \cdot H^3 \]  

(1)

with,

\[ S = \frac{\gamma_s}{\gamma_w} \left( \frac{\gamma_s}{\gamma_w} - 1 \right)^3 \]  

(2)

where \( H \) is the incident wave height, \( H_i \), which will be used later to differentiate \( H \) from \( H_s \). \( \gamma \) and \( \gamma_w \) are the unit weight of armor unit and water, respectively. \( \Psi \) is the stability function, which is related to the \( K_d \) factor by,

\[ K_d = \frac{1}{\Psi \cdot \cot \alpha} \]  

(3)

where \( \alpha \) is the angle of the structure slope. The stability number is given by

\[ N_s = (K_d \cot \alpha)^{1/3} \]  

(4)

For given slope, unit type and damage level, \( K_d, N_s \) and \( \Psi \) depend on Iribarren number, \( I_r \), defined as follows:

\[ I_r = \frac{\tan \alpha}{\sqrt{\frac{H}{L_0}}} \]  

(5)

where \( L_0 \) is the linear wave length in deep water and \( H \) is the characteristic wave height, \( H_i \) or \( H_s \).

For irregular waves there is no unique characteristic wave height. Van der Meer (1988) recommends to use the significant wave height, \( H_s \); The Shore Protection Manual (1984) recommends to use higher wave heights such as \( H_{1/10} \) or \( H_{1/20} \). In order to consider the influence on the damage level of the number of waves in the train higher than a certain height, Vidal et al. (1995) examined characteristic wave height statistics and recommended \( H_{1/20} \).

Moreover, \( K_d, N_s \) and \( \Psi \), based on the experiments using any of those characteristic
wave heights, and plotted against Iribarren number, showed a considerable scatter. Figure 1 shows $\Psi$ versus $I_r$ obtained from the experiments carried out by Iribarren and Nogales (1965) for several slopes. Furthermore, the best fit curve to the data points was given by Losada and Giménez-Curto (1979). The data points scattered about the best fit curve by a factor of about 3. This empirical scatter exists for both monochromatic and irregular waves. Figure 2 shows the stability number versus $I_r$ for quarry stones given by Van der Meer (1988). The data were plotted in terms of the nominal diameter of the unit, that is proportional to the $1/3$ power of the weight. The scatter appears to be reduced because of the use of $W^{1/3}$, but is still apparent.

Figure 3 summarizes the scatter of the experimental results depending on Iribarren number, where $\Delta\Psi$ and $\Psi_{\min}$ are the range and minimum value of $\Psi$, respectively, in each range of $I_r$. The largest scatter occurs under collapsing and surging waves. For these types of waves, mound breakwaters reflect a considerable potion of the incident energy: more than 60% of the incoming wave energy may be reflected.

![Stability function of parallelopipedic blocks versus $I_r$ for monochromatic wave test.](Losada and Giménez-Curto, 1979)

The interaction of the incident and reflected wave trains leads to a partial standing wave in front of the structure. Flow kinematics and dynamics on the slope depends on this partial standing wave pattern.
Figure 2. Stability results for irregular waves. (Van der Meer, 1988)

Figure 3. Scatter of monochromatic wave data depending on Iribarren number.
In this paper, the connection between the partial standing wave and the stability of the units of the cover layer is analyzed. First, the reflection process is considered and the magnitude and phase of the reflection coefficient are evaluated. Next, the total wave height of the incident and reflected wave trains at the toe of the structure is calculated. Finally, this total wave height is used to calculate the stability function, \( \Psi_t \), for the experiments by Iribarren and Nogales (1965) and the new tests conducted in the flume of the University of Cantabria. It is concluded that, for plunging-collapsing, collapsing and surging waves, the stability function, \( \Psi_t \), does not depend on Iribarren number, but only on the breakwater slope, unit type and damage level. Furthermore, the use of \( \Psi_t \) based on the total wave height at the structure toe is shown to reduce the data scatter.

Wave Reflection from Porous Structures

Wave reflection from permeable rubble mound breakwaters were examined by Ahrens and McCartney (1975), Losada and Giménez-Curto (1979), van der Meer (1988), Wurjanto and Kobayashi (1992) and Seelig and Ahrens (1995), who showed the dependence of the reflection coefficient on Iribarren number. More recently, Hughes and Fowler (1995), and Sutherland and O'Donoghue (1998), analyzed the phase shift of the reflected wave train at the toe of coastal structures. The modulus, \( R \), and the phase, \( \epsilon \), of the reflection coefficient as a function of the structure geometry and the hydraulic properties of the porous medium were discussed only partially.

For vertical porous medium the dependence of the reflection coefficient on those factors can be analyzed theoretically following the work by Dalrymple et al. (1991) and Méndez (1997). Figure 4 shows the modulus and phase of the reflection coefficient versus \( kh \), where \( k \) is the wave number in front of the structure and \( h \) is the water depth, for a breakwater located at a certain distance from the flume end wall. Several values of the breakwater width, \( b \), are considered, where the porosity \( P = 0.45 \) and the median diameter \( D_{50} = 0.03 \text{ m.} \) for the porous material. This figure clearly shows that the reflection coefficient modulus and phase depend strongly on the experimental setup.

If the breakwater is sloped, waves breaking may occur, but similar patterns may be found. Figure 5 shows the modulus, \( R \), of the reflection coefficient versus the width and porosity of the cover layer, and Figure 6 shows the dependence of \( R \) on the slope angle, \( \alpha \). Both figures are obtained by the numerical computation using PBREAK (Wurjanto and Kobayashi, 1992).

Figure 7 shows the envelope of the wave crest on the slope and in front of the breakwater. The data points were recorded by Iribarren and Nogales (1965), and the curve was obtained by the best fit of the wave envelope to the experimental data points. Two different cases of \( kh \) for \( \cot \alpha = 2.0 \) are shown, where \( h \) is the water depth at the structure toe. In Figure 7a, for \( kh=0.47 \), the underwater slope is under the node of the standing wave. For the second case, \( kh=1.26 \) in Figure 7b, the underwater slope is under the antinode of the standing wave.
Figure 4. Modulus and phase of reflection coefficient versus $kh$ for breakwater located at 5 m. from the flume end wall.
Figure 5. Modulus, $R$, of the reflection coefficient, computed using PBREAK, versus the width and the porosity of the cover layer.

Figure 6. Modulus, $R$, of the reflection coefficient, computed using PBREAK, versus $kh$ for different slopes.
From these results it can be concluded that the characteristics of the reflected waves depend strongly on the structure geometry, materials properties and experimental setup. Once the modulus and phase of the reflection coefficient is known, the total wave height, $H_h$, at the toe of the structure can be evaluated as follows:

$$H_h = H_i + \frac{2R}{1 + R^2 + 2R \cos(2\pi x + \phi)}$$

(6)

where $H_i$ is the incident wave height and $R$ is the reflection coefficient modulus

$$R = \frac{H_r}{H_i}$$

(7)

where $H_r$ is the reflected wave height, $\phi$ is the phase shift obtained from the experimental data and $x$ is the cross-shore coordinate with $x=0$ at the toe of the structure.

In the following, if the $K_d$ factor, the stability number, $N_s$ or the stability function, $\Psi$, are calculated using $H_h$ as the characteristics wave height, the empirical scatter shown in Figure 1 turns out to be reduced significantly.
Stability Analysis

The stability of armor units placed on the cover layer is analyzed using both incident and total wave heights. First, the experimental data of Iribarren and Nogales (1965) on the stability of uniform quarry stones for four slopes, \( \cot \alpha = 1.25, 1.50, 2.0 \) and 3.0 are re-analyzed. The \( K_d \) factor and the stability function, \( \Psi \), are computed using the incident wave height, \( H_i \), and the total wave height, \( H_t \).

Figure 8 shows the values of the stability function, \( \Psi \), given by (1), plotted as a function of \( kh \), using the incident wave height, in Figure 8a, and the total wave height, in Figure 8b. Figure 8b, shows that the experimental points for each slope follow approximately a straight line. The value of the stability function decreases with the decrease of the slope, \( \tan \alpha \). The dependence of the stability function on \( kh \) is very weak. For slopes \( \cot \alpha \geq 1.5 \) and the range \( kh < 2.5 \), \( \Psi \) is practically constant for each slope and independent of the wave period.

![Figure 8. Stability function versus \( kh \) for the data of Iribarren and Nogales (1965): (a) using the incident wave height and (b) using the total wave height.](image)

Experimental technique and damage criteria.

A burst of waves were generated, ensuring that the re-reflected waves from the paddle did not impinge on the slope. After the water surface calmed, a new burst of the same number of waves was generated. Damage was evaluated by counting the number of units displaced by a nominal diameter from its placed position. The test was repeated with the same burst until no unit was displaced by the burst. The slope was not repaired after the burst. Two levels of damage were considered: (1) *Iribarren damage*, defined by the number of displaced units at the time when the second layer of the cover layer was attacked by the waves, and (2) *initiation of damage*, defined as 5% of the number of units corresponding the Iribarren damage were displaced, as explained in detail by López (1998).

Results

Figure 9a shows the stability functions, $\Psi_i$ and $\Psi_t$, versus $kh$ for the new monochromatic wave tests using the incident wave height and the total wave height, respectively, for the initiation of damage. The values of $\Psi_i$ are in the wide range 0.04-0.14, while $\Psi_t$ is in the narrow range 0.06-0.075. The same trend is found for the stability functions plotted versus Iribarren numbers, $I_{r,i}$ and $I_{r,t}$, calculated using the incident and total wave heights as shown in Figure 9b.

For the Iribarren damage, as defined above, the values of $\Psi_t$ plotted versus $kh$ are in the narrower range 0.038-0.043.

Conclusions

From this research it may be concluded that:

(1) Wave reflection from the breakwater modifies the incident wave characteristics such that the flow velocities and accelerations on the slope are produced by the interaction of the incoming and reflected wave trains.

(2) The values of the $K_d$ factor and the stability function, $\Psi$, depend on the total wave height, $H_t$. The scatter of the experimental data points can be reduced significantly by the use of $H_t$. The reduction is greater for larger damage.

(3) For the practical application of this method, the reflection coefficient modulus, $R$, and its phase shift, $\varepsilon$, produced by the reflection process on the breakwater need to be evaluated in advance. $R$ and $\varepsilon$ depend on the geometry and the hydraulic properties of the coastal structure as well as the boundary conditions on the landward side of the
structure.

(4) The extension of this method to irregular waves is being examined to clarify the connection between the irregular wave reflection and armor stability.

IMPACT STRUCTURAL RESPONSE OF CORE-LOC®

George F. Turk¹, Member and Jeffrey A. Melby¹, Member

ABSTRACT

In 1996, the U.S. Army Corps of Engineers, Waterways Experiment Station, Coastal and Hydraulics Laboratory in conjunction with Oregon State University and Concrete Technology Corporation, Tacoma WA, conducted the first structural response experiments of the new concrete armor unit, CORE-LOC®. Large scale 32-kg and prototype 9.2-tonne core-loc units, were molded, cast, and fitted with surface-mounted strain gages. The units were subjected to repeated impact loads generated during drop tests. In addition to the CORE-LOC® drop test, similar tests were conducted on 26-kg and 10.9-tonne dolosse. The structural response to these loads were recorded and analyzed. Measured maximum tensile stresses in CORE-LOC® were approximately half those in similar size dolosse.

INTRODUCTION

The CORE-LOC® (heretofore referred to as Core-Loc), invented and developed at the U.S. Army Engineer Waterways Experiment Station, is a new-generation optimized breakwater concrete armor unit for protecting shoreline and navigation structures (Figure 1). The versatile unit can be used for a wide range of coastal armoring applications including the repair and rehabilitation of dolos armor layers. Until recently the majority of experiments on Core-Loc focused on hydraulic stability. Because of the very difficult construction, in-service, and repair conditions associated with high energy wave environments, a need was identified to characterize the dynamic impact structural response of Core-Loc. The most common method of accomplishing this is the drop test. In the past

¹ U.S. Army Engineer Waterways Experiment Station, Coastal and Hydraulics Laboratory, Vicksburg MS, USA
two decades, these types of tests have been conducted on other types of concrete armor units. Nishigori et al (1989), Zwamborn and Phelp (1989), Burcharth (1981), and others have tested both dolosse and tetrapod to destruction using drop tests.

Figure 1. The first 9.2-tonne prototype CORE-LOC™ units

DEVELOPING CORE-LOC® DROP TESTS

Drop tests are used to evaluate the structural performance of an armor unit when exposed to impact loads. In 1996, the U.S. Army Corps of Engineers, Waterways Experiment Station, Coastal and Hydraulics Laboratory in conjunction with Oregon State University and Concrete Technology Corporation, Tacoma WA, conducted the first structural response experiments of the new concrete armor unit, Core-Loc. In the experiment described herein, two sizes of Core-Loc were tested, 32-kg and the 9.2-tonne. Also, 26-kg and 10.9-tonne dolosse were tested for comparison. The test configurations were essentially the same except for scale. The experiment involved measuring impact strains with surface-mounted strain gages, as the armor units were dropped from incrementally increasing heights onto a rigid concrete base. The units were tested to failure where the unit completely broke apart. For the smaller units, shims of various thicknesses were pulled from under the unit allowing it to freely drop to the concrete base pad. For the prototype, a crane was used to lift the unit to the pre-determined drop height. A quick-release mechanism attached to slings was used to release the unit, dropping it onto the one meter thick concrete base. The drop height was then increased and the unit dropped again.
The Core-Loc units cast at CTC were the first prototypes ever built. A rational decision had to be made as to standard drop test configurations. One aim of the experiment was to compare results with past drop test experiments of other popular types of concrete armor units. In order to best accomplish this, several types of drops were performed. To best compare Core-Loc to dolos, the "hammer drop" was chosen. These two drops are shown in Figure 2. Tetrapods are typically dropped by lifting the unit completely off the concrete base. The Core-Loc drop configuration, dubbed "anvil drop" is similiar to the tetrapod drop in that it also is completely lifted off the base. These are shown in Figure 3. A third Core-Loc drop configuration (Figure 4), unlike any other armor unit drop test, was needed to emulate the typical manner by which a non-interlocked Core-Loc rocks on slope or how a Core-Loc can fall over due to handling mishaps. This drop is called a "tipping drop." Each of these three drop configurations were performed during the experiment at CTC.

Figure 3. Drop Tests, (a) standard tetrapod, (b) anvil drop
PREPARATION FOR EXPERIMENT

The preparation for the experiment consisted of making molds, fabricating, and instrumenting a single 32-kg Core-Loc and four 9.2-tonne Core-Loc. In addition, three two-year old surplus 10.9-tonne dolosse were fitted with strain gages for measurement of strain in the unit's shank section. The drop tests of 26-kg dolosse, referred to in this report, were conducted in 1994 during the Large Scale Dolos Flume Study (Melby and Turk, 1994).

The first major task in preparing for the experiment was to build molds for both the 32-kg and 9.2-tonne Core-Loc units. For the smaller units, a two-piece fiberglass mold was fabricated. A sophisticated four-part steel "clamshell" mold (Figure 5) was constructed and used to cast four 9.2-tonne units. This unique mold design simplified the difficult casting and mold stripping process usually associated with concrete armor units.

The 32-kg model Core-Loc unit and the 26-kg dolos were cast using concrete with prototype properties. The properties of the large scale model units were as follows:

Figure 5. Four-piece “clamshell” mold

After the concrete was poured in the mold, it was cured for 24 hours. It had been CTC’s experience that accelerated curing is not required to achieve high release strength for this type of concrete product. Insulated “curing houses” were placed over the forms to control heat loss during curing. This system effectively forms a heated envelope with a uniform, controlled temperature gain of 4-7° C/hr. This curing method has a long history of successfully attaining transfer strength requirements within a daily production cycle.

The high strength concrete mix allowed the molds to be stripped after 24 hours and the drop tests to be performed after seven days. During each casting, test cylinders and beams were made so the compressive and modulus of rupture strength, along with the modulus of elasticity, could be determined. The concrete used for the Core-Loc units cured for one week before the drop tests were conducted. The 10.9-tonne dolosse tested were two years old. Core samples were taken from the concrete used in the three dolosse and tested immediately prior to the drop tests. Like the Core-Loc, the dolos concrete compressive and tensile strength, and modulus of elasticity were determined. The
specimens for a given Core-Loc or dolos were tested on the day of its drop test. The mean properties of the concrete and prototype units were as follows:

**INSTRUMENTATION AND DATA ACQUISITION**

For most drop tests in the past, failure was characterized by some arbitrary crack width. Thus results were subject to interpretation. Melby and Turk (1994) first collected drop test data with a sophisticated Data Acquisition System (DAS) attached to 26-kg dolosse. Sensitive surface-mounted strain gages were applied directly to the concrete surface. With this technique, direct precise measurements of strain and rate of strain were obtained. This same system and strain gAGING technique was used on the 32-kg and 9.2-tonne Core-Loc, and the 10.9-tonne dolosse.

The new strain gaging technique and data acquisition technologies increased signal-to-noise ratio and range such that accurate impact measurements could be made. The waterproofed 350 $\Omega$ polyester-backed gages were capable of detecting minute strains on the surface of the concrete Core-Loc with a variable range of around 1000 $\mu$e, depending on the gain and sampling rate. The strain gages were sensitive enough to respond to small changes in strain with a resolution of $\pm 2 \mu$e (a change in length of $2E10^{-6}$ cm per cm). The gages proved extremely sensitive yet robust enough to survive repeated impacts. They were repeatedly checked for integrity, and except for the anvil drop performed flawlessly throughout the experiment.

The strain gaging for the dolosse was different than that used on the Core-Loc. With the principle stress direction well defined for the dolosse drop test, single gages were placed longitudinally along the axis of dolosse shank, near the intersection of the vertical fluke (Figure 6a). This is the primary gage location used for both the 26-kg and 10.9-tonne dolosse. The 26-kg dolos had additional gages placed on the fluke. For the dolosse, strain was converted to stress by application of Hooke's Law, $\sigma_T = E\epsilon_T$, where $\sigma_T$ is tensile stress, $E$ is modulus of elasticity, and $\epsilon_T$ is tensile strain.

The stress state for the Core-Loc is more complex, and principal stress direction ill-defined. Thus for the 32-kg and the 9.2-tonne Core-Loc, five critical stress locations on the surface of the units (Figure 6b) were selected from finite element analyses of computer simulated drop tests. Instead of the single gage quarter bridge configuration
used on the dolosse, strain gage rosettes (three gages per rosette) were used for the Core-Loc. Each time an instrumented Core-Loc impacted against the hard concrete base surface with enough force to trigger any one of the 15 individual gages in the five rosettes, strain data were recorded. The individual strains measured by the three gages in the rectangular rosette were converted to principal tensile stress by:

\[
\sigma_T = E \left[ \frac{\varepsilon_A + \varepsilon_C}{2(1-\nu)} + \frac{1}{2(1+\nu)} \sqrt{\left(\varepsilon_A - \varepsilon_C\right)^2 + \left(2\varepsilon_B - \varepsilon_A - \varepsilon_C\right)^2} \right] \tag{1}
\]

where

- \(\nu = \) Poisson's Ratio
- \(\varepsilon_A, \varepsilon_B, \varepsilon_C = \) strains from three gage rosette

The 15 channels of raw data were decimated and reduced by selecting the peak or maximum impact stress for each individual triggered impact. Therefore, for example, if a single impact duration lasted one second, the 150,000 data points collected (10 kHz x 15 channels) would be reduced to five data points representing the maximum principal tensile stress at the five locations on the Core-Loc for a single impact.

Figure 6. (a) Dolos gage locations, (b) CORE-LOC® gage locations
LARGE SCALE AND PROTOTYPE DROP TEST RESULTS

For all the results presented herein, the maximum tensile stress or the mean of the maximum tensile stresses (for multiple drops at the same height), $\sigma_T$, was expressed as a non-dimensional tensile stress, $\sigma_T/(E\gamma C)^{1/2}$. These stress values are plotted as a function of the centroidal drop height, expressed as the non-dimensional parameter $(h/C)^{1/2}$, where $h$ is the drop distance between the centroid of the armor unit at rest and lifted off the concrete base the predetermined drop height distance. By expressing results in these terms, it becomes simpler to compare results between different types and different sizes of units.

The drop tests for Core-Loc and dolos are similar but not directly comparable. When dropping the dolos, almost 1/3 to 1/2 of the total weight of the dolos is supported on a pedestal, whereas the full weight of the Core-Loc is unsupported at impact. The first set of drop test results compares the 32-kg Core-Loc to the 26-kg dolos. Figure 7 shows the stresses generated in the similar size Core-Loc and dolos units. For the dolos, the plot shows stresses in both the shank and fluke sections (Figure 6a). For the Core-Loc, the maximum tensile stresses produced during the hammer and tipping drops are compared to the dolos stresses. The highest stresses in the dolos are in the shank where dolosses typically fail. Fluke stresses are approximately 75% of the shank stresses. The hammer drop and tipping drop stresses are 48% and 31%, respectively, of the dolos shank stresses. And the hammer drop and tipping drop stresses are 68% and 41%, respectively, of the dolos fluke stresses.

![Figure 7. Drop test results from 26-kg dolos and 32-kg CORE-LOC.](image)

A complimentary data set to the 32-kg Core-Loc and dolos drop test compares the prototype 10.9-tonne dolosse to the 9.2-tonne Core-Loc. It is to be noted that the prototype dolosse were only instrumented in the shank section. Figure 8 shows the same divergent trends between the prototype dolosse and Core-Loc as found for the smaller units. In this case, the Core-Loc hammer drop test is compared to the standard dolos
As in Figure 7, the same trends emerge for the prototype tests. In this case, the Core-Loc stresses are 55% that of the dolosse. Figure 9 shows the results of the prototype tipping drop test for the 9.2-tonne Core-Loc. In comparing these results to the dolosse, the mean stresses are 52% of the dolos stresses. The anvil drop test was also conducted. In this test the Core-Loc was lifted completely off the concrete base before being dropped. Figure 10 shows the results. Only a single Core-Loc was used for the anvil drop, and the test was conducted in stormy weather. The data show lower stresses than either the tipping or hammer drop, which appears suspect. Some problems were encountered with collecting data as some of the strain gages started to malfunction during inclement weather.

Figure 8. Drop test results for 10.9-t dolos and 9.2-t CORE-LOC*

Figure 9. 9.2-t CORE-LOC* tipping drop test
DISCUSSION OF DROP TEST RESULTS

All the drop tests conducted at CTC used a very stiff base over a meter in thickness. Dropping units on this type of base creates one of the most severe impacts that can occur. Defining impact strength in itself is very difficult. There is no definite or unique relationship between the static strength of concrete and impact strength; but Neville and Brooks (1987) reported that, in general, the higher the compressive strength of the concrete the lower the energy absorbed per blow before cracking. Thus the impact strength and total energy absorbed by the concrete increases with compressive strength and age. It can be surmised that older units would have more impact resistance. However, in comparing drop test results, the two-week old Core-Loc consistently showed more impact resistance than the two-year old dolosse. Also, when dropping dolosse in the “standard” configuration, 1/3 to 1/2 of the weight of the dolos is supported on a pedestal, whereas the full weight of the Core-Loc is unsupported at impact.

For the prototype armor units tested, the mean flexural tensile strength of the dolosse was 140% of the Core-Loc and the mean compressive strength of the dolos was 188% the Core-Loc. The modulus of rupture for the Core-Loc was approximately 12% of the compressive strength and it is expected that it would be similar for the dolos since the mix design was the same for the two types of units. Thus the dolos concrete was nearly twice as strong as that of the Core-Loc. The modulus of elasticity was minimally higher for the dolosse (107% of the Core-Loc). But repeatedly, the Core-Loc significantly outperformed the dolosse either in drop height and/or number of repeated blows to failure.

The data sets collected during the drop test experiment were relatively limited and warrant significant expansion. The prototype drop tests were conducted with four Core-Loc units of one size and the same type concrete. As with all experiments concerning
tensile strength of unreinforced concrete, there is fair amount of scatter in the data. Definitive trends are difficult to ascertain.

CONCLUSIONS

For the prototype drop tests conducted at CTC, the Core-Loc proved more robust than the dolosse tested. In the dolosse armor units tested, the tensile strength of the concrete was 140% of the Core-Loc and the compressive strength of the dolos concrete 188% of the Core-Loc. Young's Modulus was minimumly higher for the dolos (107% of the Core-Loc). In comparing drop test results, the two-week old Core-Loc consistently showed more impact resistance than the two-year old dolosse. Stresses generated in the Core-Loc are approximately half of those generated in similiar size dolos. Reaply, the Core-Loc outperformed the dolos either in drop height and/or number of repeated blows to failure.

RESULTS OF FIELD MONITORING OF THE NEW CORE-LOC BREAKWATER at PORT ST FRANCES - SOUTH AFRICA

D Phelp ¹, A Holtzhausen ², J Melby ³

Abstract

The newly completed fishing and recreational harbour at Port St Francis, on the south-east coast of South Africa, has a 220m outer rubble mound breakwater and an inner revetment, both protected by Core-loc® armour units. This paper briefly discusses the breakwater layout and armouring design, the effect of severe storm conditions during construction, and the performance of the Core-loc armouring, as based on the results of photographic monitoring, crane-and-ball profile surveys, visual observations and diver surveys below water.

Introduction

The first prototype application of a Core-loc armoured breakwater was constructed for the small craft harbour of Port St Francis, South Africa in 1996/97. Port St Francis is a small coastal town situated on the south-east coast of South Africa, on the northern side of the Cape St Francis peninsula, adjacent to the Krom River estuary (Figure 1). In the past the squid fishing industry has used the estuary for anchorage and access to the sea. Using the unprotected river mouth for access to and from the sea is dangerous and conditions are often unsafe resulting in accidents and loss of life and fishing vessels. The dangerous conditions, together with the growth squid fishing

³ CERC, WATERWAYS EXPERIMENT STATION, P O Box 631, Vicksburg, USA
industry and urban recreational developments highlighted the need to establish a small craft harbour on the east coast to support the squid fishing industry as well as recreational sport fishing and yachting. It was decided to construct a small craft harbour at the Port St Francis condominium resort to serve these needs. Construction of the harbour breakwater, marina and luxury resort facilities started in February 1996 and was completed in November 1997. The port is the first privately developed small craft harbour in South Africa.

The Core-loc armour unit was developed by the Waterways Experimental Station, Coastal Engineering Research Center (CERC) in the United States of America (Melby and Turk, 1994, 1995). CERC participated in the design, testing and monitoring of the breakwater together with the South African consulting engineers AR Wijnberg Inc. Design and testing included full 3D model tests at a scale of 1:60 undertaken at the laboratories of the CSIR in Stellenbosch, South Africa. Initial baseline and subsequent breakwater surveys have been undertaken by the CSIR to monitor the performance of concrete Core-loc armour units. The use of the South African developed dolos units was also investigated, with the Core-loc units proving to be a more economic solution.
Location and Design Details of Main Breakwater and Peninsula Protection

The harbour is located on the east coast of South Africa, south of Port Elizabeth. The shoreline in the vicinity of the harbour consist of a rocky beach with a sandy beach and Krom River mouth to the south and Cape St Francis peninsula to the north (see Figure 2).

The total protective structures include a main outer breakwater and an inner peninsula revetment, both protected by 15 ton Core-locs. The breakwater consists of a rubble mound at a slope of 1:1,5 with 1,5 ton median under-layer rock and a concrete mass capping. A total number of 800 Core-loc units were used plus 20 spare units cast (approximately 560 for the breakwater and 260 for the revetment). The finish level of the mass capping is +4,4 m MSL and splash wall at +6,5 m MSL. The inner slope of the main breakwater is rock protected towards the head (Figures 3 and 4) and abuts directly onto the main harbour quay wall.
Figure 3: Cross section of the breakwater

Figure 4: Layout of small craft harbour of Port St Francis - showing the positions of the photo stations and crane and ball profile positions
Sea Conditions

Although the bathymetry off the harbour causes depth limited wave conditions, four near design storms were experienced during construction (i.e. when the breakwater was uncapped and at +3.5m MSL working level). This resulted in overtopping and breaching of the uncompleted breakwater. As a result several Core-loc units required replacement and re-packing. One design storm has also been experienced after completion of the construction of the breakwater and the first baseline survey in October 1997. This caused little further damage to the well compacted (shaken down) slope.

The initial Core-loc design was base on Melby and Turk (1995). Maximum design depths of 8 m can be expected for the main breakwater, which means that the design is depth limited. With a foreshore slope of 1:50 and peak wave periods of up to 16 s, the maximum wave height at the structure is estimated to be approximately 7.2 m. using Hudson $K_d$ factor of 16, a unit mass of 15 t was selected as a preliminary design. Further details of the design and construction of the breakwater see the ICCE '98 paper “The First Core-loc Breakwater” by Holtzhausen.

Construction Problems

To ensure sound breakwater concrete armour protection, it is imperative that good interlocking is achieved, especially when placing a single layer armouring system such as with Core-loc. This is done by accurately placing the individual units on a prescribed grid. This grid must be correct, right from the toe units which then form the foundation for the upper rows to lock onto. On the main breakwater it was apparent from diving surveys that some Core-loc were incorrectly placed seawards of the design toe.

Unfortunately at Port St Francis, the extreme storms experienced during early stages of construction also contributed to the displacement of many Core-loc units out of their allocated positions. This gave rise to poor interlocking in some areas and resulted in a non-uniform slope, especially on the bend of the breakwater. Additional Core-loc units were needed to fill gaps in the armouring, sometimes resulting in a semi-double layer. Up to 20 loose or damaged units were also removed from the toe and re-used on the breakwater.

These problems experienced during the construction phase of the breakwater, contributed to the majority of damage (displaced and broken Core-loc units) found on the breakwater. During this phase the low crest (+3.5 m MSL) working level was unprotected against wave overtopping, resulting in the displacement of a number of units during the near design storms that were experienced before construction of the mass-capping. During one of the storms, overtopping caused a breach of the core material and the displacement of Core-loc units into the harbour. Most of these units were recovered and re-packed on the front slope. Some grading problems with the under-layer rock also caused an irregular profile. Figure 5 shows the breakwater, revetment and marina still under construction.
Initial placement problems were largely overcome during the construction of the revetment as this was constructed after the breakwater. This lead to a better constructed armour protection in this area, with good interlocking and a uniform slope (Figure 9). The revetment was also partially protected by the main breakwater and the working level during construction was higher, so that there were no serious overtopping problems.

Breakwater Monitoring Methods

The baseline survey of the breakwater and revetment included an aerial photographic survey, a “crane and ball” survey (Phelp, 1994), a visual inspection and a diving inspection. These were used to provide as-built data (against which future monitoring could be compared) and document the breakage type, providing a count and location of damaged Core-loc armour units. The baseline surveys were carried out in October 1997 to capture the damage which occurred during construction, while follow-up surveys were done in May 1998.
Visual Inspection

A visual inspection was carried out to record the location and type of Core-loc breakage. This was done by climbing over the Core-loc slope during low spring tide and relating the positions to the ball survey lines. The recorded damage was later correlated with that seen in the aerial photographs taken by the CSIR.

Photographic Survey

A “Robinson 44” 4-seater helicopter, was used for the photographic survey. It allowed the camera to be elevated to a position perpendicular to the slope of the Core-loc armouring. Pre-determined coordinates were chosen to give good coverage, with photo stations spaced at 26m centres on the straight sections of breakwater and 13m over the curved sections. Figure 4 shows the layout of the survey stations on both the outer breakwater and inner revetment.

Navigation of the helicopter was carried out with the aid of a “Landstar” Differential Global Positioning System (DGPS) which was fitted to the helicopter (Figure 6). DGPS is a satellite-based positioning system which achieves high accuracies by utilizing real time radio transmitted corrections from a reference station, placed at a known location. This then provides dynamic positioning of the survey camera, to an accuracy of plus/minus 0.5 m. The altitude of the helicopter was kept at 65 m above the breakwater slope.

Figure 6: DGPS system fitted to helicopter for position fixing.
The photographs were taken with a Nikon FM 35 mm camera with a 50 mm lens and using 200 ISO colour film. The photo stations were marked on the breakwater and the revetment and numbered 1 to 12 and 13 to 21 respectively (Figure 4) and were positioned at the centre of each photograph. This allowed for each station to include approximately 50 Core-loc units per photograph. By careful observation of the approaching waves, the photographs were taken at maximum wave draw-down to ensure the maximum area of Core-locs (approximately 90%) exposed, including those toe units located below the still-water line.

Crane and Ball Survey

A mobile crane with an 18 m reach was used for the “crane and ball survey”. The radius of the ball used for the survey was 1 metre. The survey was carried out by positioning that crane at each station (Figure 7) with the boom perpendicular to the breakwater. The profile of the Core-loc armour units was then measured by suspending the ball from the boom by a calibrated staff. Starting from the splash wall the levels were measured at 3 m intervals, horizontally along the boom.

A DGPS satellite system was mounted on the top of the boom to fix the positions at which the levels were taken. The level of the ball were recorded by dumpy level from the capping and related back to the top of the splash wall at a level of +6.5 m. At each position the ball was lowered until it touched the Core-locs. The levels were then plotted with Figure 8 showing the plot for stations 1 to 5.

The ball survey gave a profile generally 1 metre higher than the design profile. The latter was closer to the levelling survey taken by holding a staff on the centroid of each Core-loc, as carried out by A.R. Wijnberg Inc. (Figure 8).

Figure 7: Crane and ball survey stations
Diving Inspection

A diving inspection was undertaken by a diver in the water and one assistant on the breakwater to record the position and state of the underwater part of the breakwater. The diver swam along the toe of the main breakwater from the inner roundhead, along the outer slope to the root. The inner revetment was not included in the diving survey, as the toe was mostly exposed during low spring tide, and could be monitored by the aerial photographic survey.

Poor visibility reduced the effectiveness of the main breakwater diving survey to counting broken units and recording those units which had moved away from the breakwater toe. The latter were no longer interlocked with the rest of the armour slope, and therefore not contributing to the stability of the structure. Some of these units, displaced by the storm, were recovered and re-used higher up the slope. The diving inspection also confirmed the buildup of sand along the toe which had completely covered the rock berm and the first row of Core-loc. This buildup occurred within the first year after completion of the breakwater.

The diving inspection also revealed the importance of the manner in which the first row of Core-locs are placed behind the toe berm. Where good toe placement was achieved, such as on the revetment, it provided a stable foundation on which to build the rest of the slope. Areas where the toe units were loose, the armour slope had become flattened (e.g. storm damage around the bend in the main breakwater) resulted in looser packing and poorer interlocking of the Core-loc above. The slope of the revetment was more uniform with each row of Core-loc anchored by the row above, resulting in a strong well interlocked slope (Figure 9).
In October 1997 the first detailed “as-built” survey was undertaken of the first Core-Loc armoured breakwater. A visual inspection of the breakwater was conducted by CERC while the CSIR carried out an aerial photographic survey to record the location and type of breakages. As discussed above, most of the damage recorded can be attributed to difficulties arising from several design storms experienced during construction of the breakwater, and to the placement of Core-loc units too far in front of the design toe. The type and position of the breakages were categorised as H-tip breaks, double H-tip breaks, nose-tip breaks, middle breaks and multiple breaks (Figure 11).

It was noted from the analysis of the photographs that almost double the damage was recorded than that recorded from the visual survey alone. This is possibly because it was difficult to reach the lower units due to wave action, whereas the helicopter could
hover while waiting for wave draw-down, before taking the photograph. The broken Core-loc units were indicated by highlighting them on the photographic records.

Although there was unusual storm damage during construction, the normal “shake down” or “settling in” damage (for dolos breakwaters this was found to be more than double the average annual damage - Phelp, 1994) took place before the baseline survey. Additional Core-loc units were also placed on the upper slope of the breakwater, after completion of the mass capping, to complete the armour slope up to the top of the splash wall. Without a complete re-pack of the entire slope, it proved difficult to fit additional units in the open spaces. Minor further damage to the breakwater occurred after shake down, as shown by the follow-up survey in May 1998. The repairs to the bend in the breakwater have resulted in an “S” shaped cross-section similar to a dynamically stable rock berm.

The revetment was built to a final height of +7 m MSL, whereas the main breakwater was built to an interim height of +3.5 m before the mass-capping was cast. The revetment was also built after the main breakwater, which meant that, besides being partially in the lee of the main breakwater, the construction crew had more experience with handling the single layer Core-loc units. The underlying rock layer also appeared to be more uniform which allowed for easier placing of the Core-loc units, correctly positioned right from the toe of the slope. The free Core-loc units at the northern end of the revetment were secured by a concrete buttress/caissons anchored to the sea-bed, which proved very successful. In general, the revetment has shown minimum shake down damage.

Figure 10: View of completed small craft harbour
Of the total 800 Core-loc used for the breakwater and the revetment, a total of 35 units were damaged during the construction of the harbour, i.e. before the baseline survey. The majority of the damaged units being on the main breakwater (30 on the breakwater and 5 on the revetment). The reasons for the high construction damage have been discussed above.

A follow-up aerial photographic survey done in May 1998, showed very little further damage to the breakwater (and no further damage to the revetment), despite the occurrence of another near-design storm after the baseline survey. Only 3 Core-loc units were recorded as new damage resulting from extreme storm conditions between October 1997 and May 1998. Two of the previously damaged units, which were already weakened, were found to have broken further. This low damage figure represents the true performance of the new Core-loc breakwater, excluding the problems experienced during construction.

It was however felt that it would be useful to classify the different types of breaks which took place during construction (see Figure 11). These were identified for each damaged Core-loc unit and totals were calculated accordingly. The percentages of the various breakage categories is indicated in the table below:

<table>
<thead>
<tr>
<th>Breakage Type (during construction)</th>
<th>% Breakage</th>
</tr>
</thead>
<tbody>
<tr>
<td>H-tip breaks (one tip only) = 5% wt. Loss</td>
<td>61%</td>
</tr>
<tr>
<td>Double H-tip breaks = 10% wt. Loss</td>
<td>5%</td>
</tr>
<tr>
<td>Nose-tip breaks = 5% wt. Loss</td>
<td>13%</td>
</tr>
<tr>
<td>Middle breaks (unit broken in half)</td>
<td>13%</td>
</tr>
<tr>
<td>Multiple breaks (more than 2 pieces)</td>
<td>8%</td>
</tr>
</tbody>
</table>

Of the breakage that did occur, 13% were located towards the top of the breakwater slope, 47% in the middle and 40% at the bottom. Some of these broken units were however re-used during remedial work and are no longer located at the position where they were originally damaged. Large Core-loc movements (> 3H, where H is the height of a Core-loc unit) were recorded without breakage, especially at the section that was breached during the construction phase. Breakages that were noted at the breached section may have resulted from the tumbling that occurred as a result of the erosion of the lee side of the breakwater. Several Core-locs displayed signs of impact (spalling) without breakage.

It is important to note that the units that experienced the H-tip and double H-tip breakages still retain 90% of their original weight allowing them to adequately provide the necessary protection. Furthermore, the majority of these units still appear to be well interlocked with the surrounding units. Other types of breakages recorded may also have occurred as a result of poor quality control during the making and placing of the units in the construction phase.
Figure 8 gives an example of the results of the "crane and ball" survey. Included on the figure is a plot of the design slope. The "S" shape damage apparent in the cross-sections nearest the bend in the breakwater was most likely caused by breaching during storm conditions and by poor placement.

![Diagram](Image)

**Figure 11: Types of breakages of Core-loc unit**

Some loose Core-locs were found in front of the rock toe of the breakwater during the diving inspection. These units were mostly placed too far seawards of the designed position of the toe, but were also subject to displacement due to poor interlocking. The interlocking also appears to be less effective where the slope of the toe is flatter. Most loose Core-locs were recovered and re-used on the breakwater where a toe unit could be removed without affecting the stability of the slope, it was reused elsewhere on the slope. This accounted for up to 15 of the damaged units. Since the baseline survey it was also evident that sand has built up along the main breakwater toe, thus making it more stable and resulting in reduced wave heights.

The toe of the revetment showed no displacement damage compared to the breakwater. This was due to better placing allowing for the effective interlocking achieved for most of these units.
Conclusions

- The Core-loc breakwater armour unit, as used for the first time at Port St Francis, has proved successful, despite some difficulties during construction.
- Excluding the damage recorded during the breakwater construction, the damage recorded by a follow-up survey was 3 broken units, which is less than 0.5% of the total of 800 units, despite the occurrence of further design storm sea conditions.
- Minimal as-built damage was found on the revetment, and no additional damage was recorded by the follow-up survey. This was no doubt due to the good packing and interlocking achieved on this part of the protection structure.
- CERC research showing improved structural stability (over other slender units) has proved itself in the field, with less breakage under extreme conditions. This allows recovery and re-use of displaced units (> 3H displacement recorded without breakage).
- Despite the high damage during construction, almost 80% of the total number of breaks consisted of either single “H-tip” fluke breaks, “nose-tip” breaks or double “H-tip” breaks, which still leaves 90% of the original unit weight allowing the units to remain well interlocked and functional. This will reduce the maintenance required during the lifetime of the structure.
- Good interlocking (as achieved on the revetment) is especially important for single layer armour units such as Core-loc. A well placed toe and a uniform slope are essential to achieve this, as is accurate placement of the armour units on a pre-determined grid.
- The stability of the toe units is especially important for a “shallow water” breakwater, such as is the case at Port St Francis, where the waves break directly onto the toe of the structure.

THE FIRST CORE-LOC BREAKWATER

Anton H Holtzhausen¹

Abstract

The first project in which Core-Locs were used as the main breakwater armour unit, is a small craft harbour on the south east coast of South Africa named Port St Francis. The Core-Loc was selected based on economic advantages over other units. Stability of 15 t units was confirmed in a full three-dimensional model study. Construction of the harbour commenced in early 1996 and was successfully completed towards the end of 1997. Practical construction issues are discussed in detail. Core-Loc performance under construction stage storms was excellent and virtually no damage has taken place under design storm conditions subsequent to the completion of the structure.

Background

The Core-Loc was developed at the Waterways Experiment Station (WES) Coastal and Hydraulics Laboratory (CHL) in 1992 and patented in 1995 (Melby and Turk 1995). During the initial stages of breakwater design for Port St Francis in 1995, the advantages of the Core-Loc over the commonly used dolos unit became apparent.

Figure 1 shows an aerial view of Port St Francis where Core-Locs were used

Figure 1. Port St Francis small craft harbour and marina development.

¹Associate, Watermeyer Prestedge Retief, Marina Centre, West Quay Road, Victoria & Alfred Waterfront, 8001 South Africa (Previously A R Wijnberg Inc).
on the main breakwater and peninsula. Previous attempts to develop a small craft harbour at St Francis Bay were unsuccessful. One of the main reasons for the viability of the present project is minimization of harbour costs. Since the breakwaters make up a large component of these costs, the savings achieved by using Core-Locs as the primary armour, were substantial.

A further significant saving was achieved by optimizing the layout with regard to rock excavation and fill. The harbour basin was positioned to produce sufficient rock excavation for use as breakwater core and armour rock, as well as rock fill required for reclamation of the peninsula as shown in Figure 1.

Core-Loc Design

The initial Core-Loc design was based on Melby and Turk (1995). Maximum design depths of 8 m can be expected for the main breakwater, which means that the design is depth limited. With a foreshore slope of 1:50 and peak wave periods of up to 16 s, the maximum wave height at the structure is estimated to be approximately 7.2 m. Using a Hudson $K_d$ factor of 16, a unit mass of 15 t was selected as a preliminary design.

A three dimensional model study of the proposed design was conducted at a scale of 1:60 in the CSIR hydraulics laboratory in Stellenbosch. The Core-Loc proved to be very stable and even on the breakwater head zero percent damage was achieved. Together with a representative of CERC, Mr J A Melby, who attended part of the model study, the design was finalized as shown in Figure 2.

![Figure 2. Design cross section for Port St Francis](image)

The rock toe shown in the figure was included to allow for settlement in the case of scour. Probing results indicated that scour would be limited to a depth of approximately 1.5 m by a rock layer underlying the sand on which the breakwater and peninsula was to be constructed.
The packing density and placing grid for the Core-Locs were determined by experimentation since there were no set guidelines established at the time of the study.

A final packing density of $\phi = 0.58$ was used, where $\phi$ is defined as the number of units per area $D_n^2$, with:

$$D_n = V^{1/3}$$

$V =$ Volume of one armour unit

The equivalent solid concrete layer thickness, $t$, for a given armour size and packing density is given as:

$$t = \phi D_n \quad \text{......... (1)}$$

The total volume of concrete, $V_{\text{total}}$, required to cover a given area of slope, $A$, is:

$$V_{\text{total}} = tA \quad \text{......... (2)}$$

The packing density $\phi$, can therefore also be expressed as:

$$\phi = t/D_n$$

The number of Core-Locs per area is given by:

$$N = \phi / D_n^2 \quad \text{......... (3)}$$

For a 15 t Core-Loc with a concrete density of 2.4 t/m$^3$ the volume is 6.25 m$^3$, and $D_n = 1.842$ m. The number of Core-Locs per area is:

$$N = 0.58 / 1.842^2$$
$$= 0.1709 \text{ units/m}^2$$

The total slope area that had to be protected was 4 680 m$^2$, which required 800 Core-Locs for both the breakwater and peninsula, with a total volume of concrete of 5 000 m$^3$. The equivalent solid concrete layer thickness, $t$ was:

$$5 000 / 4 680 = 1.068 \text{ m}$$

The only displacements of Core-Locs in the model took place in shallow areas under angular wave attack. This was especially the case at the root of the peninsula where severe plunging breakers caused some displacements of toe units in
cases where they were not interlocked with units behind them. Dolosse with a unit mass of 15 t were also tested and showed the same instability along the toe as that found with the Core-Locs. Since this problem only existed in shallow areas, it would be possible to construct these areas carefully with toe units being visible at low tides. A number of repeat tests were conducted to investigate the probability of toe displacements. These tests confirmed good stability if toe units are placed with reasonable care.

Comparison of Core-Locs with dolosse

Although the focus of the model study was to confirm and refine the Core-Loc design, some tests were conducted with dolosse that allow a comparison of the two units. In general the stability of the two units, both with a mass of 15 t, was good and appeared to be similar (a more rigorous testing program would be required to allow a good estimate of the relative stability of the two units). Dolosse are traditionally placed at a packing density of $\phi=1$ in South Africa which implies a 72 percent increase in both the volume of concrete and the number of units to be placed relative to the Core-Locs (packing density of $\phi=0.58$). CERC (1984) indicates a packing density of $\phi=0.83$ for dolosse, which would bring the 72 percent increase in concrete down to 43 percent, but this is still a very large difference. The minimum packing density that can be used for dolosse is probably $\phi=0.8$, which still implies a 38 percent saving if Core-Locs are used.

Due to the larger packing density of a dolos structure, it can withstand more damage than lower packing densities, without exposing the rock under layers. Another aspect that makes it difficult to directly compare the two units, is that a dolos is more likely to break than a Core-Loc when being displaced by wave action. Since a comparison of units with the same unit mass contains a certain degree of subjectivity, the comparison was also done for equal volumes of concrete. In Table 1, dolos options that have the same total volume of concrete are compared to the 800 Core-Locs with a total volume of concrete of 5 000 m$^3$. Options with equivalent volumes of concrete have the same equivalent solid concrete layer thickness (Equation 1):

$$\phi D_n = 1.068 \text{ m}$$

Using this relationship, dolos options with packing densities of 1.0, 0.83 and 0.8 are compared with the 15 t Core-Locs in Table 1.
Table 1. Comparison of dolos options with Core-Locs that require a total volume of concrete of 5 000 m$^3$ (12 000 t concrete at a density of 2.4 t/m$^3$).

This table indicates the sensitivity of unit mass to packing density if the same total volume of concrete is specified. A graphical illustration of this comparison is shown in Figure 3.

![Figure 3](image_url)  
Figure 3. Comparison of dolosse with Core-Locs for equal concrete volumes

The best dolos option is obviously a packing density of 0.8, however the unit mass of 5.7 t is more than 2.5 times lighter than the 15 t Core-Loc and would undoubtedly sustain significantly more damage than the Core-Locs under design wave conditions. This would result in increased maintenance that once again makes the Core-Loc option less expensive. Also, the number of dolosse to manufacture and place is more than 2.5 times the number of Core-Locs. In terms of handling and time for construction, this would tend to make the dolos option more expensive than the Core-Locs.
Construction

The developers of Port St Francis decided against an open tender. A contracting company was formed and a negotiated contract was accepted after a number of modifications to further optimize costs and layout. The contractor had no in-house experience of breakwater construction. Since it was also the first time that Core-Locs would be used, a test section was built in the dry to check the tolerances that would be achieved with the type of construction proposed by the contractor.

The rock toe and under layer were dumped from a skip. Tolerances achieved with this method were checked by measuring rock profiles. It also provided an opportunity to check the toe placement proposed for shallow areas of the breakwater. Figure 4 shows an example of this type of placement and Figure 5 shows the completed test section in which toe units were placed according to this orientation. In general the rock profiles and Core-Loc placement achieved on the

Figure 4. Toe placement used for shallow areas

Figure 5. Completed test section

Figure 6. Temporary coffer dam built to allow dry excavation and construction of slipway, mooring piles and quay walls
test section was found to be acceptable. This, together with a specification based on CIRIA (1991), would form the basis for approving actual breakwater sections.

Excavation of the harbour basin commenced in January 1996. It was possible to excavate this area in the dry by constructing a temporary coffer dam as shown in Figure 6. Figure 7 shows the construction site before the harbour basin was excavated. The rock appeared to be good quality sandstone and it was estimated that this quarry would yield approximately 15 percent armour rock based on results obtained from a trial blast and excavation.

Figure 7. Harbour basin before excavation with location of test hole

Figure 8 shows the excavated harbour basin (quarry) which only yielded approximately 6 percent armour rock. This required the opening of a new quarry some 11 km away from the site, causing extensive delays to the breakwater construction.

In addition to the low yield in armour rock, the basin excavation also produced fines and clay that fell outside specifications for breakwater core material and fill material for the peninsula. In spite of the specification, some of this material was used for breakwater construction, leading to the rejection of these sections of breakwater. A compromise was reached where areas containing fines were excavated and sluiced before being replaced.

Figure 8. Harbour basin after excavation. Armour rock yielded ~ 6%
Storms during Construction

At least 3 severe storms hit the breakwater during construction while a number of smaller storm events caused delays due to the breakwater being inaccessible for the crane. The first major storm hit without any warning. Luckily the waves only started picking up around mid-morning, allowing some time for emergency rock dumping on the breakwater crest. Figure 9 shows the last truck leaving the breakwater just in time. Surprisingly, the Core-Locs sustained almost no damage during this storm and only the unprotected head of the breakwater was eroded by some 15 to 20 m.

Figure 9. Emergency rock dumping during the first major construction storm. The Core-Locs sustained virtually no damage.

Figure 10. Largest storm that hit the breakwater during construction
The breakwater was constructed all the way to the head at the level corresponding to the foundation level of the crown wall. Crown wall sections were then cast from the head towards the root of the breakwater (Figure 6 shows the first section of crown wall that was cast on the head). The crown wall construction had just reached the bend in the breakwater when the biggest storm during construction hit the breakwater. Figure 10 shows a wave photographed during this storm with a crane on the completed section of crown wall. Apart from some broken windows the crane was not seriously damaged but the breakwater experienced significant damage along sections where the crown wall had not yet been constructed.

Over the section where the crown wall had been completed, almost no damage took place. However, the section from the bend in the breakwater to the root sustained significant damage. The damage was caused mainly by erosion of the breakwater crest to a level that caused top row Core-Locs to roll toward the lee of the breakwater. This is illustrated in Figure 11 where some Core-Locs rolled over a distance of more than 10 m without breakage.

**Engineering Evaluation**

Construction of the first section of breakwater in relatively shallow water, proceeded without many problems. However, the crane and ball survey method that was used for surveying core and underlayer rock, had obvious limitations that gave rise to differences between the Contractor and Engineer. The survey was done using the breakwater crane shown in Figure 12. The height of the crane coupled with wave action made horizontal...
positioning of the ball very difficult so that surveys often took very long to complete. This was especially frustrating when rising wave conditions made it urgent to protect breakwater sections where under layers had been placed. Before placement of Core-Locs could proceed, under layers had to be surveyed, plotted and approved by the engineer.

When the breakwater reached the bend it appeared that some problem was experienced with the positioning system since a number of Core-Locs were placed too far seaward, resulting in units that were isolated from the rest of the slope. This presented a problem since the isolated units could not interlock and were obviously rolled during some of the storms, as revealed by diving inspections during periods when underwater visibility was sufficient to evaluate the toe of the structure.

In some instances underwater inspections also revealed gaps between Core-Locs that were outside the placing specification. To resolve a differences between the Contractor and Engineer regarding these issues, an accurate survey of the structure was undertaken. A survey system was specifically made up for this purpose that could measure accurately and quickly. It consisted of a measuring staff that slid vertically within a pipe fixed to a crane. The pipe was fixed vertically so that the horizontal position of the staff was always directly below the pipe. The entire breakwater was surveyed in one day, with both the Engineer's representative and the Contractor's site agent agreeing on each point that was measured.

The survey results showed that some sections of the breakwater did not conform to the contract specifications. Figure 12 shows 3 profiles spaced at 7 m intervals approximately 50 m from the breakwater head. In some instances the toe Core-Loc was more than 3 m too far seaward. Areas were identified where remedial work was required. This mainly entailed removal of toe units that were positioned
away (seaward) of the slope. Approximately 20 units were removed underwater and re-positioned on other areas of the breakwater.

In one area (approximately 15 m length of breakwater) Core-Locs had to be removed to enable rectification of underlayer profiles (placing additional underlayer rock) before replacing the Core-Locs. Removing units from the slope was easy, even underwater, and the remedial work could be completed in less than one week.

Figure 13 shows some typical breaks that occurred during storm conditions on uncompleted sections of the breakwater and on units that were placed incorrectly (mostly seaward of the toe). In most cases the percentage loss in mass is as low as 5 percent. It was therefore decided not to reject Core-Locs with such minor breaks, especially where a displacement causing the break resulted in the unit moving into a more stable position.

![Figure 13. Percentage loss in mass for different types of breakages](image)

Placement of Core-Locs on the peninsula was done after the majority of Core-Locs had been placed on the main breakwater. The experience gained on the breakwater lead to much improved work on the peninsula. Also, no major storm hit the peninsula before the structure had largely been completed. The final Core-Loc protection on the peninsula was of a high standard and was accepted without qualification in terms of the contract specification.

Figure 14 shows parts of the Core-Loc structures that were accepted in terms of the contract specifications, with one section of the breakwater being accepted subject to reduced payment. The acceptance of this part of the breakwater was qualified since it was not built to the original contract specification. However, the relatively minor deviations from the design profile was evaluated as possibly resulting in increased maintenance rather than causing major damage during the design storm event. An amount relating to the estimated increase in maintenance was used as the basis for reducing payment on this section of the breakwater.
Conclusions

The first Core-Loc breakwater has been successfully completed. It played a significant role in the viability of the Port St Francis development by saving an estimated 30 percent on the cost of the breakwater armouring, compared to the traditional dolos protection used on most South African breakwaters.

Three storms, that approached the breaking wave design condition, were experienced during the approximately 2 year construction period. Core-Loc stability on the uncompleted structure was excellent under these conditions. During one storm, the breakwater crest and core was eroded by overtopping waves, causing some of the top row Core-Locs to roll on to the eroded area. Some units rolled up to 10 m and more without any breakage, clearly illustrating superior structural characteristics.

Post construction performance has been good so far and very little maintenance is expected in future. The structure will be monitored on a yearly basis by the CSIR as part of their research work on prototype breakwater performance.

Abstract
An experiment is described consisting of seven relatively long-duration breakwater damage test series. The test series were conducted in a flume using irregular waves. New damage measurement techniques were developed and damage development data were acquired for breaking wave conditions. Wave height, wave period, water depth, storm duration, storm sequencing, and stone gradation were all varied systematically. The experiment yielded relationships for both temporal and spatial damage development. The relations by Melby and Kobayashi (1998a,b) for predicting temporal variations of mean damage with wave height and period varying with time in steps are shown to describe damage reasonably well (within one standard deviation) for new test series, although damage initiation is consistently underpredicted by more than a standard deviation. The prediction is shown to improve significantly if the initial profile adjustment is accounted for in the test series with relatively small cumulative damage.

1 INTRODUCTION
Contemporary breakwater armor stability design is founded on the well known work of Iribarren and Hudson. Much work has been done to extend these stability models for no-damage design conditions; but little work has been done to quantify damage progression. With only limited knowledge of damage progression, it is difficult to rationally determine life cycle costs or to evaluate and prioritize maintenance requirements for various projects. Further, determining the reliability with adequate accuracy for a particular design is impossible without prediction models for damage progression.

Existing stability formulas are limited to constant wave conditions [e.g. Hudson(1959) and van der Meer (1988)]. They are primarily intended to give a stable armor layer for a design level storm. These existing formulas can be used to design a new armor layer, but are not sufficient to predict life-cycle costs or to determine maintenance requirements for
damaged rubble mounds. Additionally, existing formulas only predict the average damage, where damage is characterized by eroded area or number of displaced units. Melby and Kobayashi (1998a,b) showed that the damage variability along the structure is significant. Van der Meer (1988) showed that the shape of the eroded profile may be important in assessing the remaining capacity of an armor layer. Mansard et al. (1996) utilized the minimum cover layer thickness to describe failure of an armor layer. Melby and Kobayashi (1998a,b), hereafter referred to as M&K, showed that this cover layer thickness as well as the depth and extent of erosion can be used to characterize the profile and all are quite variable along the slope. Existing stability formulas give no predictive capabilities for these profile parameters. Thus, existing stability prediction techniques cannot fulfill the need for predicting the future performance of existing structures.

2 PHYSICAL MODEL EXPERIMENT

A small-scale physical model experiment was designed to provide the basis for an empirical model for spatial and temporal breakwater damage development. The experimental design was focused on quantifying damage for long duration tests composed of sequences of storms. The objectives of the experiment were as follows:

1. Quantify the progression of damage for multiple storm events, with water level, breaking wave height at toe, and storm duration being the primary variables of interest. Wave period and stone gradation were also varied systematically.
2. Quantify the uncertainty or scatter in damage due to natural variability.
3. Determine whether the ordering of storm events effects the ultimate damage level.
4. Promote laboratory experimental standards for breakwater damage progression.

The experiment utilized two small-scale rubble mound breakwater sections in a wave flume. Figure 1 shows the flume profile and Figure 2 shows a typical structure cross section. A total of seven irregular wave test series were conducted as shown in Table 1. M&K describe the first three series. This paper summarizes results from all seven series. Each series was composed of a sequence of storms of varying wave height and water level. Parameters varied systematically from series to series were storm duration, storm ordering, wave height, water depth, wave period, and armor gradation. The structures were profiled using a newly developed automated profiler (Winkelman 1998). The profiles were used to determine the eroded cross sectional area and profile characteristics. The experimental setup, instrumentation, and initial tests are described in detail in M&K and will only be summarized herein.

Figure 1. Flume Profile

Figure 2. Model structure cross section
The experiment was conducted in a 61 m long by 1.5 m wide by 2 m deep flume, with a beach slope of 1V:20H. Two side-by-side identical conventional rubble mound cross sections were constructed with seaward slopes 1V:2H, crest heights 30.5 cm, and angular armor stone. Irregular waves corresponding to the TMA spectrum were run in bursts of 15 min. The undamaged underlayer and armor layer for the two identical structures were profiled before each series. Then both structures were profiled after each 30 min of irregular waves.

The seven series, summarized in Table 1, were designed to define spatial and temporal damage development under irregular depth limited breaking wave conditions. Series A', lasting a total of 28.5 hr, was run until failure of the armor layer occurred, where failure was defined as exposure of the underlayer through a hole of diameter of at least $D_{50}$. This series was intended to define the long term response of a structure. Series A' was run once yielding 16 alongshore profiles every 30 min. Series B', C', D', E', F', and G', each lasting approximately 9 hr, were run twice producing 32 alongshore profiles per 30 min. These latter series were not run to failure but were intended to define the damage development for various conditions. Series B' and C' were designed to investigate storm sequencing by running low water first then high water in B', and then reversing the water levels in C'. Series B', D', and E' investigated period effects, each having a different peak period. Series F' and G' investigated stone gradation effects. The average damage $S$ and the standard deviation of damage, $\sigma_s$, were computed using the 16 or 32 profiles after each 30 min of waves.

Two very different armor stone gradations were utilized. The armor stone for Series A', B', C', D', and E' was uniformly sized with a median mass $M_{50} = 128$ g, nominal diameter $D_{n50} = (M_{50}/\rho_a)^{1/3} = 3.64$ cm, stone density $\rho_a = 2.66$ g/cm$^3$, and $D_{85}/D_{15} = 1.05$, where $D_{85}$ and $D_{15}$ are the nominal diameters corresponding to 85 and 15 percent finer for the stone mass distribution, respectively. The armor stone for Series F' and G' was widely graded riprap with a median mass $M_{50} = 256$ g, nominal diameter $D_{n50} = (M_{50}/\rho_a)^{1/3} = 4.58$ cm, stone density $\rho_a = 2.66$ g/cm$^3$, and $D_{85}/D_{15} = 1.53$. The riprap followed the widest recommendation of the SPM (1984) of approximately $0.125M_{50} < M < 4M_{50}$. For all series, the underlayer had a gradation of $D_{85}/D_{15} = 1.32$ and was sized such that $(M_{50})_{armor} / (M_{50})_{filter} = 25$ and $(D_{50})_{armor} / (D_{50})_{filter} = 2.9$.

Damage can be defined according to Broderick and Ahrens (1982) as

$$S = \frac{A_e}{(M_{50}/\rho_a)^{2/3}} = \frac{A_e}{D_{n50}^2}$$

where $A_e$ = eroded volume per unit length or cross-sectional eroded area. The eroded area was measured using a profiler composed of eight rods which spanned a width on one structure of 35 cm. The alongshore profiler rod spacing was 5 cm. The width of one structure was 0.76 m so the profiled section did not include the side wall effect. The profiler
design was similar to that used by Davies et al. (1994). Each profile rod had a sphere of diameter 3.64 cm at the profiling end that followed the slope as the profiler was moved along the flume. The position of each sphere was determined from digital measurements of the angular rotation of each profile rod and translational position of the profile carriage. This technique provided an accurate and complete profile as the cross-shore spatial sampling interval was less than 1 mm. The eroded area, shown in Figure 3, was defined as the area between the undamaged profile and the damaged profile, but limited to the eroded region. The profile points were averaged over a small cross-shore spatial interval in order to eliminate contributions to the eroded area from minor downslope shifting of the armor layer.

![Sketch of breakwater profile with definition of damage parameters](image)

As stated above, the eroded depth $d_e$, eroded length $l_e$, and cover depth $d_c$, shown in Figure 3, were used to define the profile shape. $d_e$ was computed for each profile as the maximum distance between the eroded profile and the undamaged profile, measured normal to the structure slope. Similarly, $d_c$ was computed as the minimum slope-normal difference between the undamaged underlayer slope and the damaged profile. Note that $d_e = (t_u - d_c)$ where $t_u$ is the undamaged armor layer thickness, due to irregularities in the original armor layer thickness. The eroded length was defined as $l_e \approx 2A_e A_c$ corresponding to a roughly triangular shaped region along slope. These three profile parameters were normalized by M&K, in order to generalize the test results, as $E = d_e D_{n50}$, $C = d_c D_{n50}$, and $L = l_e D_{n50}$. The mean values were computed and denoted as $\bar{E}$, $\bar{C}$, and $\bar{L}$ while their standard deviations along the slope were $\sigma_E$, $\sigma_C$, $\sigma_L$. These statistical representations will be used throughout the remainder of this paper.

Incident wave statistics for all series are listed in Table 2. For all tests, the structure toe water depths were limited to $h_t = 11.9$ and 15.8 cm. The combination of wave periods and water depths produced low depth-to-wavelength ratios which resulted in severely breaking waves at the toe of the structure, which is typical of design conditions on most U.S. coastlines and represents the worst case for stability. In Table 2, $T_p = \text{spectral peak period}$, $H_{m0} = \text{spectral significant wave height}$ defined as $H_{m0} = 4m_o^{1/2}$ with $m_o = \text{zero moment of the}$. 
incident wave spectrum, \( R = [(m_o/m_o)^{1/2} = \text{average reflection coefficient, with } (m_o)_r = \text{zero moment of the reflected wave spectrum, } T_m = \text{mean wave period, } H = \text{average height of the highest 1/3 of waves, } H_{1/10} = \text{average height of the highest 1/10 of waves, and } H_{2}\% = \text{wave height exceeded by 2 percent of the waves in the wave height distribution. Time domain statistics } T_m, H, H_{1/10} \text{ and } H_{2}\% \text{ were all computed from a zero-upcrossing analysis.}

3 PREDICTIVE EQUATIONS

M&K showed that the normalized damage was in the range $-2.7 \leq S^* \leq 3.0$, where $S^* = (S - \bar{S})/\sigma_S$. This relation can be used to predict the range of damage on the armor layer. For instance, the damage at failure of Series A' was $\bar{S} = 13$ and $\sigma_S = 2.65$ yielding a range of $6 \leq S \leq 21$. This clearly shows that the variability of damage on this short section of structure was significant, especially considering that the waves were uniform alongshore. $E^* = (E - E)/\sigma_E$ and $C^* = (C - C)/\sigma_C$ were shown to have similar ranges with $S^*$, $E^*$ and $C^*$ all in the range from -3 to 3. The standard deviation of damage was shown to be a function of the mean damage, following the relation $\sigma_S = 0.5 S^{0.65}$. This relation indicates that the variability in damage increases with mean damage. Figure 4 shows $\sigma_S$ for the four new series (D', E', F', G') plotted as a function of $\bar{S}$, where Series B' is included for reference in this and the following figures. This figure indicates that the previously derived relation slightly underpredicts damage variability for the new series. The greater variability in damage for the wider gradation (Series F' and G') is expected; but the reason for the greater damage variability for shorter wave periods is not clear.

M&K also showed that the number of variables could be reduced because the mean and standard deviation of the profile parameters were a function of the mean damage. The relation for the eroded depth was $\bar{E} = 0.445 S^{0.52}$ indicating that the shape of the eroded area remained geometrically similar during damage progression. Figure 5 shows $\bar{E}$ for the four new series as a function of $\bar{S}$. It is clear that the relation for $\bar{E}$ based on Series A', B', and C' describes the new data well. Similarly M&K showed that the normalized eroded length followed $\bar{L} = 4.6 S^{0.48}$. This relation along with data from the four new series are shown in Figure 6. Again, the previously derived relation provides an excellent fit to the new data. Finally, the mean cover depth was shown to be described by the relation $(\bar{C}_0 - \bar{C}) = 0.1 \bar{S}$, where the subscript 0 indicates the initial value at $\bar{S} = 0$. This relation also provides a good fit to the new data, as shown in Figure 7. In addition, the standard deviations for maximum eroded depth and remaining minimum cover depth were shown to be described by the relations $\sigma_E = [0.26 - 0.00007 (\bar{S} - 7.8)^2]$ and $\sigma_C = [\sigma_{C_0} + 0.098 - 0.002 (\bar{S} - 7)^2]$, respectively.
The agreement of these relationships for the four new series is similar to that shown in Figure 4. The above relations in this paragraph were developed using only profile data without regard to incident wave conditions or water levels.

![Figure 5. Mean normalized eroded depth as a function of mean damage](image)

![Figure 6. Mean normalized eroded length as a function of mean damage](image)

![Figure 7. Mean normalized cover depth as a function of mean damage](image)

The relations for the damage variables as a function of mean damage allow prediction of profile shape and alongshore variability of damage. A preliminary empirical equation was
also proposed by M&K for predicting the temporal progression of mean eroded area as a function of time domain wave statistics as

$$
\dot{S}(t) = \dot{S}(t_{n}) + a_{s} \frac{(N_{s})^{5}_{n}}{(T_{m})^{b}_{n}} (t^{b} - t^{b}_{n}) \quad \text{for} \quad t_{n} \leq t \leq t_{n+1}
$$

(2)

where $\dot{S}(t)$ and $\dot{S}(t_{n})$ are predicted and known mean damages at times $t$ and $t_{n}$, respectively, with $t > t_{n}$. $N_{s} = H_{s} / (\Delta D_{50})$ is the stability number based on the average of the highest one-third wave heights from a zero-upcrossing analysis, $\Delta = S_{i} - 1$ where $S_{i}$ is the specific gravity, $T_{m}$ is the mean period, and $a_{s}$, and $b$ are empirical constants. A similar equation relating mean damage to spectral wave characteristics was given as

$$
\dot{S}(t) = \dot{S}(t_{n}) + a_{p} \frac{(N_{mio})^{5}_{n}}{(T_{p})^{b}_{n}} (t^{b} - t^{b}_{n}) \quad \text{for} \quad t_{n} \leq t \leq t_{n+1}
$$

(3)

where $a_{p}$ and $b$ are again empirical coefficients and $N_{mio} = H_{mio} / (\Delta D_{50})$. The empirical coefficients in (2) and (3) will be a function of structure slope, wave period, beach slope, structure permeability, and armor gradation. Figures 8 and 9 show (2) and (3) fitted to the profile data of Series A', which is characterized as the mean damage from 16 profiles. M&K showed that the generalized formulas (2) and (3) with $a_{s} = 0.025$, $a_{p} = 0.022$ and $b = 0.25$, for wave conditions during multiple storm events, predicted the progression of damage quite well for the first three series in Tables 1 and 2. Figures 10 and 11 show (2) plotted along with data from Series B' and C'. The fit of (3) for Series B' and C' with coefficients given above is similar to that shown in Figure 9 for Series A'. It is noted that the final damage was similar for both series consisting of different sequences of storms of similar cumulative wave action.

Figures 12 through 15 show (2) plotted against data from Series D', E', F', and G'. Although (3) is not shown, the fits look very similar to those shown for (2). Series D' and E' were similar to Series B' except that the peak wave period was changed for the three series. Series F' and G' were again similar except that the uniform armor was replaced with riprap. Two different peak wave periods were tested in Series F' and G'. It can be seen that the damage progression equations predict overall damage reasonably well for Series D' through G' using $a_{s} = 0.025$, $a_{p} = 0.022$, and $b = 0.25$, although there are noted discrepancies. For example, it can be seen that damage initiation is underpredicted if only 1 or 2 stones are displaced at the beginning of each test series. This underprediction appears to be produced by the variability in damage initiation. Thus, a second prediction curve has been added to Figures 12 through 15 which starts at the first measured damage point. As can be seen, the prediction is much better for this advanced damage. Figures 12 through 15 indicate that the empirical coefficients in (2) and (3) may vary somewhat with wave period and stone gradation for the
range of experimental conditions described herein.

4 CONCLUSIONS
An experiment is described consisting of seven relatively long-duration breakwater damage test series. The test series were conducted in a flume using irregular waves. New damage measurement techniques were developed and damage development data were acquired for breaking wave conditions. Wave height, wave period, water depth, storm duration, storm sequencing, and stone gradation were all varied systematically. The experiment yielded relationships for both temporal and spatial damage development.

It is shown that the damaged profile can be described by the eroded area $A_e$, maximum eroded depth $d_e$, minimum cover depth $d_c$, and maximum eroded length $l_e$. These parameters
are normalized as \( S = A / D_{50}^2 \), \( E = d / D_{50} \), \( C = \delta / D_{50} \), and \( L = I / D_{50} \) and the mean and standard deviation of each are shown to be a function of the mean damage \( \bar{S} \). Relations are given for the standard deviation of \( S \) as a function of the mean as well as the mean and standard deviation of \( E \), \( C \), and \( L \). Using these relations, the statistical variability of the profile and \( S \) can be quantified, which is a necessary step in a modern minimum cost analysis.

The relations by Melby and Kobayashi (1998a,b) for predicting temporal variations of mean damage with wave height and period varying with time in steps are shown to describe damage reasonably well (within one standard deviation) for four new test series, although damage initiation, where only 1 or 2 stones have moved, is consistently underpredicted by more than a standard deviation. This appears to be due to the variability in damage initiation. It is shown that the prediction is significantly improved if the damage progression is predicted immediately after the initial profile adjustment lasting 30 min. The initial profile adjustment may need to be accounted for in test series with relatively small cumulative damage. These relations are a reasonable first step in developing a damage prediction technique for predicting life-cycle costs and assessing maintenance needs. The empirical parameters in these equations may need to be varied somewhat with wave period and armor gradation. Employment of a critical stability number for measurable damage may be necessary to reduce the number of storms required in a life-cycle analysis.

The Influence of Pressure Fluctuations on the Flow Between Armour Elements

Robert Booij¹, Wim S.J. Uijttewaal¹, Patrick van Os¹,
Harry L. Fontijn¹, Jurjen A. Battjes¹

Abstract

To reduce the high expenses of armour layers for the protection of sandy beds in rivers and coastal areas around structures a so called geometrically open armouring, consisting of a single layer of large rocks, is often tried nowadays. In most models it is assumed that the mean flow (and shear stress) above the armour layer penetrates in the pores between the armour elements and that this penetrated flow is responsible for the erosion of the sand bed below the armour layer. However, the relatively thin armour layer these models predict does not always suffice for a safe armouring of the sand bed in practice. Measurements of the flow velocities in the pores between armour elements in a flume using the laser-Doppler technique suggest a completely different erosion mechanism. Erosion appears not to be caused by the mean pore flow. Instead small-scale locally generated velocity fluctuations in the pores lift the sand particles from the bed; large-scale fluctuations, due to large-scale turbulence in the main flow, transport the sand particles through the armour layer into the flow above.

Introduction

In coastal areas and rivers, cover layers consisting of rocks or other armour elements are applied locally to protect the underlying sandy bed from erosion. Armour layers are used:
- as bed defense in rivers
- around piers and other structures
- around breakwaters and groynes
- downstream of sluices

¹Fluid Mechanics Section, Faculty of Civil Engineering, Delft University of Technology. P.O. Box 5048, 2600 GA Delft, The Netherlands.
- at the toe of dikes and banks
- as "falling aprons"

The dimensions of the rocks used and the thickness of the cover layer are chosen such that the underlying sand bed is shielded from the eroding currents and waves. A relatively safe armouring, so-called geometrically closed armouring, consists of several layers of rocks of different dimensions, such that the rocks in a layer cannot escape through the holes between the rocks in the next higher layer, see figure 1. To reduce the very high expenses of this way of armouring a single layer of large rocks, so-called geometrically open armouring, is often tried nowadays, however with at best varying success.

In most models that are used for the design of rock beds it is assumed that a direct coupling exists between the mean flow above the bed and the flow through the porous bed. The mean velocity profile is supposed to penetrate a certain distance into the bed and the turbulent fluctuations in the bed to be generated locally by the flow between the rocks. Beyond this distance only a small depth-independent pore velocity, \( v_p \), remains, driven by the same pressure gradient (or slope) as drives the main flow above the armour layer, see figure 2. This pore velocity leads to a very small shear stress at the sand bed below the rocks and a supposedly small erosion. This suggests that in general a relatively thin single rock layer would suffice for a safe armouring.

**Figure 1.** Geometrically closed and open armouring.

**Figure 2.** Penetration of main flow.
From a fluid mechanical point of view, however, one can expect that the turbulence present in the main flow above the armour layer generates pressure fluctuations that in their turn lead to a fluctuating flow through the pores of the armour layer. These flow fluctuations may have an important influence on the erosion of the sand bed. Introductory measurements of the fluid velocity and its fluctuations inside the armour layer were executed in order to find out which erosion mechanism is predominant.

**Experimental setup**

The fluid velocity and its fluctuations inside the armour layer were measured in a flume of the Laboratory of Fluid Mechanics of the Delft University of Technology, using the well-established laser-Doppler (LDA) technique. The typical diameter of the rocks used for the armour layer in the experiments was $D_{r50} = 21$ mm, and of the sand below this rock bed $D_{b50} = 0.10$ mm. The ratio of over 200 between the two diameters makes this a case of geometrically open armouring. Optical access to a cavity in the rock bed was established by guiding the laser beams through the bed using small tubes that have negligible effect on the flow (see figure 3). Special care was taken to avoid distortion of the natural rock configuration around the location of measurement. Doing so it was possible to measure the horizontal velocity component between the rocks of the armour layer. The measurements reveal the mechanism of flow generation in the porous bed.

Figure 4 shows an example of a histogram of instantaneous velocities from a time series of 200 seconds, measured 5 cm beneath the bed-stream interface for a 30 cm deep free surface flow. It shows that the mean velocity is small (in this example ~ 0.6 cm/s), whereas the standard deviation of the velocity fluctuations is rather large (~ 0.9 cm/s). This velocity distribution suggests that the fluctuating velocities do not stem from the mean flow through the bed. Instead they might be related more directly to the turbulence of the flow over the bed in the following way: The large turbulence scales in the main flow lead to pressure fluctuations at the bed-stream interface. The fluctuating pressure gradients, which can be much larger than the pressure gradient associated with the mean flow, induce a fluctuating flow through the rock bed.

![Figure 3. Schematic side view of the laser-Doppler velocimeter set-up.](image-url)
To investigate the consequences for the erosion of the sand bed, part of the flume was covered by a caisson acting as a lid over the water flow, see figure 5. In the resulting slit both the large turbulence scales and the flow velocity could be varied by adjusting the height of the slit $S$ and the water level difference upstream and downstream from the caisson (or the hydraulic gradient in the slit).

The measurements were all executed at a value of the hydraulic gradient just below the critical value at which the sand bed starts to erode. This critical value was well-defined as the rate of erosion started abruptly to grow with increasing hydraulic gradient, see figure 6. As LDA measurements require transparent water the sand bed was replaced by a fixed bed during those measurements. The LDA measurements were executed directly above the fixed bottom beneath a 10.5 cm thick armour layer and at the critical hydraulic gradient, $i_{c}$, determined in advance in experiments with a sand bed.

Figure 4. Histogram of pore velocity.

Figure 5. Experimental setup.

Figure 6. Determination of the critical hydraulic gradient.
Results of the measurements in the armour layer

The LDA measurements yielded mean values and fluctuations of the longitudinal velocity component of the pore flow at the measuring volume in the cavity. Table 1 gives the dependence of the mean pore velocity \( v_p \) on the height of the slit. Considering that all measurements were at the critical hydraulic gradient, the results in table 1 show that the mean pore flow is not the cause of the erosion of the sand bed below an armour layer. If that was the case an equal mean pore velocity was to be expected as only the flow condition changes, whereas all other conditions of cavity and bed remain unchanged. Moreover the magnitude of the mean pore flow appears not to be sufficient to lead to erosion. (The critical bed shear velocity of the sand according to the Shields condition is \( u_{cc} = 0.6 \text{ cm/s} \).)

Table 1. Mean pore velocity.

The cause of the erosion has to be found in flow fluctuations. To investigate this, the autocorrelation functions of the velocity fluctuation were determined. Figure 7 gives an example. Two time-scales are apparent, a large time-scale (of the order of half a second) and a small time-scale of less than 20 ms. (The sample rate used does not allow resolution of the small-scale autocorrelation.) Thus, two kinds of flow fluctuations are present: the small-scale fluctuations, due to locally generated turbulence or small eddies behind flow separations at irregularities in the pore walls, which may be carried away by the mean pore flow, and large-scale fluctuations, caused by the free stream turbulence in the main flow above the armour layer.

Figure 7. Example of an autocorrelation function, \( R(\tau) \).
Measured values for both kinds of fluctuations in a series of experiments with different slit heights $S$ are combined in table 2. The columns give respectively $S$ and the measured values for the standard deviation of the small-scale velocity fluctuations $\sigma_h$, the standard deviation of the large-scale fluctuations $\sigma_v$, the longest time-scale of the fluctuations observable in the correlations $T_i$ and the estimated vertical distance $L$ over which the sand particles move (see below).

Table 2. Measured characteristics of the velocity fluctuations.

From the results in table 2 the following picture of the erosion of the sand bed below a geometrically open armour layer emerges. The very short time scales of the small-scale fluctuations mean that in the flow between the armour elements strong accelerations occur. These accelerations are caused by strong pressure gradients in the flow. The forces on the sand grains by these pressure gradients initiate the lifting of the sand grains from the sand bed. However these pressure gradients last too short to displace the grains through the armour layer. The large-scale fluctuations, which are too slow to generate strong enough pressure gradients to do the initial lifting, move the grains through and out of the armour layer into the free stream.

The estimated distance $L$ over which the sand grains are displaced by the large-scale fluctuations is taken proportional to the standard deviation $\sigma_v$ and the time-scale measured. For the beginning of erosion the strongest and longest lasting fluctuations are important. Fluctuations of 4 or more times the standard deviation $\sigma_v$ are present and a few fluctuations lasting about 10 times the time-scale $T_i$ were observed in the executed flow measurements, see figure 8 (which is taken from a different measurement). This is taken into account in the estimated value for $L$:

$$L = (4 \cdot \sigma_v) \cdot (10 \cdot T_i)$$

Considering the large uncertainty in the measurement of $T_i$, the value for the displacement distance $L$ estimated in this way (see table 2) is a consistent fraction of the total thickness of the armour layer, more or less independent of the slit height. This is what is to be expected as all measurements are executed at the same erosion condition. The time-scale and the standard deviation of the large-scale fluctuations appear to determine the erosion.
The small-scale fluctuations are generally strong enough to perform the initial lifting.

Figure 8. Presence of very large time scales.

Conclusions

In the flow between the armour elements several contributions can be distinguished:
- Mean pore flow. In the upper part of the armour layer it concerns penetrated main flow; deeper in the armour layer the mean pore flow is driven by the hydraulic gradient which also drives the main flow above the armour layer.
- Small-scale fluctuations: locally generated turbulence or small eddies behind flow separations at irregularities in the pore walls, which may be carried away by the mean pore flow.
- Large-scale fluctuations due to turbulence in the main flow.

Based on the magnitudes and characteristics of the different flow contributions between the armour elements the following erosion mechanism is derived:
- Contrary to the assumption used in most models erosion is not caused by the mean pore flow.
- The small-scale fluctuations lift the sand particles from the bed.
- The large-scale fluctuations transport the sand over the armour layer into the flow above.
- The erosion appears to be determined by the time-scale and standard deviation of the large-scale fluctuations. The small-scale fluctuations are generally strong enough to perform the initial lifting.

The conclusions above mean that the design of geometrically open armouring requires knowledge of the large-scale turbulence in the main flow and on the large-scale fluctuations.
it brings about in the armour layer.

Analogous processes can be observed with pressure fluctuations under waves due to the wave motion itself or associated with the turbulence under the waves. Knowledge concerning the erosion processes due to the large turbulent fluctuations above the bed as well as the fluctuations under waves are of key importance for the design of the armouring for the protection of erodible beds.

To give the conclusions reached above a firmer base, further research is suggested:

To check the description of the erosion process:
- measurements of correlations of velocities and pressures in and above the armour layer,
- check on the presence of very large-scale turbulence in the main flow above the armour layer,
- high frequency velocity measurements,
- measurements at more places in one cavity,
- measurements with larger slit height (or free flow depth).

To be able to predict the erosion for armouring design:
- measurements with different armour elements (e.g. size, form or stacking),
- measurements in armour layers below a free surface flow,
- measurements under different turbulence conditions (e.g. in wake flow or the flow behind a sill or pier).
Wave Kinematics on Breakwater Heads and Stability of Armour Layers 
under Multidirectional Waves

Yoshiharu Matsumi ¹, Akira Kimura ² and Kenichi Ohno ³

Abstract

This study complements the wave kinematical investigation on the performance of rubble mound breakwater under uni and multidirectional waves. The measurements of wave kinematics over the head and trunk sections were undertaken to achieve an improved understanding of the influence of wave directionality on the stability of armour layers. The directionality and magnitude of velocity vectors over the head and trunk sections under 3D waves were assessed by comparing them with the measurements under 2D waves. The sensitive zones of the initial damage in the head and trunk were evaluated by linking the velocity measurements with the stability formulas for armour stone movement.

Introduction

Recently there have been studies published, which have examined breakwater stability under uni and multidirectional waves. Unfortunately those studies still may not have established trends for whether or not the influence of wave directionality in multidirectional seas leads to more loads on the breakwater. The staple reason of limited understanding is that the characteristics of the structure such as the slope, the type of armour layer and the breakwater geometry may contribute to different types of breakwater damage. Therefore, a better approach to achieving a comprehensive understanding of the influence of multidirectional waves on breakwater stability is to make the kinematics of the various multidirectional waves over the breakwater, which are concerned in the damage, clear.

In our previous experimental study (1996), the spatial characteristics in correlation of the magnitude of measured velocity vectors over the head were

¹ Associate Professor, D. Eng., Dept. of Social Systems Eng., Tottori University, Tottori 680-8552, Japan. 
² M. ASCE, Professor, D. Eng., Dept. of Social Systems Eng., Tottori University 
³ Graduate Student, M. Eng., Dept. of Social Systems Eng., Tottori University
investigated. In the case of multidirectional waves, the correlation in the middle and back head was very poor regardless of the mean direction of waves and peak periods. From those results, possibility of oblique wave attacking directly the heads due to the directional spread in multidirectional seas could be supported. When relating the initial damage in the head and trunk sections to those oblique waves in the multidirectional seas, those direct wave attacks may lead to higher loads on the armour stones at some local position in the head and trunk. Namely, the location of the sensitive zones where the initial damage occurred under multidirectional waves is deemed to be stronger than the case of unidirectional waves.

The main objective of the present study is to compare wave kinematics under the effect of uni and multidirectional waves in terms of measured magnitudes and directions of velocity vectors over the breakwater. Furthermore, the direct unexpected oblique wave attacks, which are associated with the directional spread of multidirectional waves may cause more damage to the armour layers at some local position in the breakwater. Therefore, the difference in the sensitive damage zones under 2D and 3D waves is also evaluated by linking the velocity measurements with the stability formula for armour stone movement on the slope, which was proposed by authors (1996).

**Experimental Setup**

**Layout of breakwater model**

Physical model tests were carried out, at the Tottori University, in the multidirectional wave basin that had a length of 14m and a width of 8.4m. Figure 1 shows a plan view of the experimental setup. A fourteen-segment snake generator is located along one of the 8.4m sides of the basin. Expanded polystyrene absorbers with permeability, capable of limiting wave reflections to 20% for most frequencies of interest, are installed along the two sides of the basin. The slope of 1:5 and 1:30 is placed on the side opposite the wave generator, in order to ensure an efficient dissipation of wave energy.

The layout of the breakwater model had to be designed carefully to ensure homogeneous sea states on the breakwater. For this purpose, the numerical model (Isaacson; 1992) which was based on the diffraction theory and used the boundary integral equation was adopted in this study. This model can predict the water surface elevation and kinematics of the sea states prevailing at different locations in the basin. A sample output resulting from this numerical model is shown in Figure 2. It illustrates the spatial distribution of wave heights under a multidirectional sea state (mean angle of incidence ($\alpha$); $\alpha=0^\circ$) in the basin without the breakwater model in place. The expected wave heights presented in this figure were normalized with respect to the target wave height. The useful test area, over which the sea state is homogeneous, is limited by a triangular boundary. According to this figure, the best location for the model would be close to the paddle. However, since this wave basin was not yet equipped with active absorption, in order to minimize re-reflections from
the paddles, the model was placed with its longitudinal axis rotated 20° with respect to the paddles, as shown in Figure 1.

![Figure 1 Plan view of the experimental setup.](image1)

![Figure 2 Spatial distribution of wave heights in the basin without the model.](image2)

**Breakwater model**

Figure 3 shows both plan and profile views of the breakwater model adopted in this study. The three dimensional rubble-mound breakwater consisted of two outer layers of armour stones and a relatively porous core, and was built with a slope of 1:2. Its height was 50cm and it performed as a non-overtopping structure in a water depth of 30cm, which was adopted in this experiment. Since the purpose of this study was to investigate the wave velocity field over the head and trunk sections without any damage, the whole surface of the breakwater was covered with a hard nylon mesh in order to restrain the armour stones. The reflection characteristics of the breakwater were estimated under unidirectional waves of normal incidence in the preliminary experiments. The resulting reflection coefficient was about 25%.

The characteristics of the armour and core stones used in this study are presented in Table 1. The weight of armour stones, $W_{30}$, was 42 gf, this value was 1.5 times the weight estimated by Van der Meer's formula (1987) with damage
parameter $S=2$ against the targeted significant wave height, $H_m=6\text{cm}$, and peak wave period, $T_p=1.4\text{s}$. The gradations of the armour stones were meticulously checked and the resulting $D_{95}/D_{15}$ ratio for the armour was 1.1.

**Layout of current meters and wave gauges**

The velocity field over the head and trunk sections was measured using 6 bi-axial electromagnetic current meters at 124 different locations indicated by dots in Figure 4. The measuring points in the head sections were located at $10^\circ$ intervals from the top of front head in a clockwise direction ($\theta p$). In the trunk section, these points are located at 10cm intervals. The water surface elevations of the sea states in the proximity of the model were measured using 8 wave gauges at 8 different locations indicated by circles in Figure 4.

![Figure 4 Measuring points of velocity components over the breakwater.](image)
Test series

Table 2 indicates the characteristics of the incident waves adopted in these experiments. The spectra were the JONSWAP type with two different peak periods (Tp=1.0s, 1.4s). The peak enhancement factor (γ) was chosen to be equal to 3.3. The multidirectional waves were simulated by using the well-known Single Summation Method. For the directional spreading function, the Mitsuyasu-type (1975) was chosen, the spreading parameter (s) was given by the following form (Goda 1985):

\[
s = \begin{cases} 
S_{\text{max}} \cdot (f/f_p)^s & : f \leq f_p \\
S_{\text{max}} \cdot (f/f_p)^{-2.5} & : f > f_p
\end{cases}
\]

Here \( f_p \) denotes the frequency at the spectral peak. Values of \( S_{\text{max}} = 5 \) and \( S_{\text{max}} = \infty \) were applied to simulate multi and unidirectional waves respectively. In order to assess the influence of obliqueness, two different mean angles of incidence \( \alpha = 0^\circ \) and \( \alpha = -15^\circ \) were used, ensuring at the same time homogeneity of the sea state at the head and trunk sections.

In order to minimize statistical variability associated with short wave record lengths, a recycling period (\( T_R \)) of 20 minutes in model scale was used in the synthesis. This storm duration corresponded to about 1400 waves when \( T_p=1.0s \) and about 1000 for \( T_p=1.4s \). The ratios of diameter of the head (\( D_L \)) over wave length and length of trunk (\( T_L \)) over wave length are indicated in Table 2. In each test series, the sea states were pre-calibrated in the basin without the structure in position, while keeping all wave gauges in place. The water depth was 30cm uniformity.

Directional Distribution of Velocity Vectors over the Head

This study has discussed the velocity vectors, which pass a magnitude above the highest 1/10 of those magnitudes evaluated from time series data of the velocity measurements. Because, the armour stones of breakwater may be strongly prone to move under conditions of faster flow velocities.

Figures 5(a)-(d) show examples of the distribution of the relative
frequencies in directionality of the individual velocity vectors in the time series data of the measurements at four difference positions in the head section for uni ($S_{max} = \infty$) and multidirectional waves ($S_{max} = 5$) under normal incidence. Line of 180-0 in every figure is normal to the trunk, bold solid lines (ex. line 60-240 in figure (a)) indicate a line tangent to the horizontal curve of the head at four positions respectively, as shown in figure (e).

(a) $\theta_p=30^\circ$

(b) $\theta_p=70^\circ$

(c) $\theta_p=100^\circ$

(d) $\theta_p=160^\circ$

(c)

Waves

Uni Normal  ($S_{max}=\infty$)

Multi Normal  ($S_{max}=5$)

Figure 5 Distribution of directionality of velocity vectors over the head.
From these figures, the directionality of the velocity vectors under 3D waves is wider than that under 2D waves due to the directional spreading of waves. In figures (a) and (b), the characteristics of the velocity field from the front head section to the top of middle head section are mainly dominated by flow of the runup and rundown of waves on the slope. The center of middle section as seen in figure (c), demonstrates the flow towards down-slope of the head. And the prevailing direction of velocity vectors under 3D waves is different from that of 2D waves. This phenomenon may be generated by reflected waves, which are generated by the oblique wave attacks due to directional spread of 3D waves. In the back head section of figure (d), the flow towards the rear surface of breakwater only exists under both 3D and 2D waves. The difference in the direction of velocity vectors over the head section under 2D and 3D waves remarkably occurs in middle head section by the directional spread of 3D waves. Therefore, in the next section, the influence of this difference on the stability of head and trunk is investigated by linking the stability formulas for armour stones with the measurements of velocity over the breakwater.

**Stability of Armour Stones in Head and Trunk**

In this section, the sensitive zones of the initial damage in the head and trunk sections will be evaluated by linking the velocity measurements with the stability formulas for armour stone movement. These formulas have been derived by taking account of tangential slope of the breakwater with respect to the direction of velocity vectors.

(a) Case of Head  
(b) Case of Trunk

Figure 6 Attacking velocity and hydrodynamics forces on armour stone in head and trunk.
Critical velocity for stability of armour stones in head and trunk

In Figure 6(a), the armour sphere (A) is placed on the head with the horizontal angle ($\beta$) for the velocity vector ($V_r$) with horizontal angle ($\theta$). By assuming the shape of the head is a circular cone, the curve of intersection between the vertical plane and the cone becomes a hyperbola. In this study, the both drag and lift forces were considered as hydrodynamic forces acting on the armour stones. Then, the equilibrium equations between the armour weight and the hydrodynamic forces can be derived by balancing the moment about point O in these figures:

(a) Case of Head

$$\left(1 - \frac{\rho}{\rho_s}\right) W [\cos a_t + f \sin a_u \{1 + \cos(a_t - a_u)\}] = F_D \left(\sin a_t + \frac{b}{r}\right) + F_L \cos a_t$$

(1)

(b) Case of Trunk

$$\left(1 - \frac{\rho}{\rho_s}\right) W [\cos \gamma + 2f \sin \gamma] = F_D \left(-\sin \gamma + \frac{b}{r}\right) + F_L \cos \gamma$$

(2)

where $W$ and $r$ are weight and diameter of armour stone, $\rho_s$ and $\rho$ are unit weight of stone and water, $F_D$ and $F_L$ are drag and lift forces, $f$ is friction coefficient between stones, $b$ is distance between the center of stone and drag force acting point. The parameters $a_u$ and $a_t$ in Eq. (1) are respectively the angle of elevation of armour sphere (A) from (C), and (B) from (A) as shown in Figure 6(a). The parameter $\gamma$ in Eq. (2) is the angle of slope of the trunk section against the attacking velocity vector as shown in Figure 6(b). In this study, the drag and lift forces are described by the following formulas, respectively:

$$F_D = m' \rho \pi r^2 V_r^2$$

(3)

$$F_L = \frac{1}{2} \varepsilon C_L \rho \pi r^2 V_r^2$$

(4)

where $m'$ and $C_L$ are drag and lift coefficients respectively, $\varepsilon$ is sheltering coefficient of armour stone against the velocity. In Eqs. (1)-(4), $f$, $m'$, $C_L$, $\varepsilon$ and $b$ are unknown parameters, $a_u$, $a_t$ and $\gamma$ can be derived from tangential slope of the breakwater with respect to the velocity vector. Assuming that $a_t$ is equal to $a_u$ for simplicity in this study, they are given by following equation after the simple mathematical analysis.

$$a_t = a_u = \tan^{-1}\left\{\frac{1}{2} \cos(\beta - \theta) \right\}$$

(5)
\[ \gamma = \tan^{-1}\left(\frac{1}{2}\cos \theta \right) \]  

(6)

Finally, the critical velocities \( V_{rcH}, V_{rcT} \) for armour stone movement in the head and trunk sections are respectively expressed as:

\[ \frac{V^2_{rcH}}{gr} = \frac{3 \rho}{4 \rho_s} \left[ m' \left\{ \frac{\cos(\beta - \theta)}{2} + b \sqrt{1 + \left( \frac{\cos(\beta - \theta)}{2} \right)^2} \right\} + \frac{\epsilon C_L}{2} \right] \right] \]  

(7)

\[ \frac{V^2_{rcT}}{gr} = \frac{3 \rho}{4 \rho_s} \left[ m' \left\{ -\frac{\cos \theta}{2} + b \sqrt{1 + \left( \frac{\cos \theta}{2} \right)^2} \right\} + \frac{\epsilon C_L}{2} \right] \]  

(8)

When the tangential slope with respect to attacking velocity vector becomes positive, in Eqs. (7) and (8), the plus and minus sign before the friction coefficient are replaced by minus and plus sign, respectively. The unknown parameters \( m', C_L, b, f \) and \( \epsilon \) in Eqs. (7) and (8) were considered as \( m'=1, C_L=0.5, b=0.5r, f=0.4 \) and \( \epsilon=0.4 \) for simplicity in this paper.

Influence of wave directionality on sensitive zones for damage

In order to investigate the influence of the aforementioned difference in the directional spread of the velocity vectors under 2D and 3D waves on the stability of breakwater head and trunk, the spatial occurrence frequencies for armour stone movement in the head and trunk sections are estimated by linking Eqs. (7), (8) and the velocity vectors which have been measured at 124 points shown in Figure 4.

Figures 7(a) and (b) show the spatial distribution of the calculated occurrence frequencies for armour stone movement in the head and trunk sections under normal 3D and 2D waves conditions, where \( T_p=1.4s \) and \( H_{m0}=6cm \). \( R \) is the distance in the radial direction from the center of head as shown in Figure 4. In these figures, the contour lines of relative occurrence frequencies which are normalized with respect to the total number of velocities measured for 20 minutes, are indicated with interval every 0.004.
Figure 7 Spatial distributions of occurrence frequencies for armour stone movements.

It can be found that the sensitive zones for armour stone movement in the head section appear typically at three locations; the front, middle and back head sections, respectively. There is obviously a difference between the values of both occurrence frequencies under 3D and 2D waves. Namely, under unidirectional waves (Figure 7(b)), a more sensitive zone for armour stone movement appears in the back head section. Under unidirectional waves attack, it could be observed in the damage tests (Matsumi et al, 1994) that the damage in the back head section was caused to plunge of the strong current with the high velocities generated by the refraction, shoaling and diffraction processes. On the other hand, under multidirectional waves (Figure 7(a)), the middle section is more sensitive parts for the initial damage. The reason for this phenomenon may be the oblique waves directly attacking that section due to the directional spread associated with the multidirectional seas, which have been mentioned in the direction of velocity vectors (Figure 5(c)). For the trunk
section, the sensitive zone for armour stone movements under 2D waves appears at the whole section. In the case of 3D waves, the existence of the oblique waves has resulted in remarkable spot sensitive zone.

Under oblique incidence, the sensitive zones for armour stone movement in the case of 2D waves were shifted to the rear direction of breakwater with near angle of incidence. In the case of 3D waves, there is no difference between the locations of sensitive zones under normal and oblique incidence, as shown in Figure 8. The reasons for it are unclear, but are possibly due to the wide directional spreading value \( S_{\text{max}}=5 \) adopted in this study.

Figure 8 Spatial distributions of occurrence frequencies for armour stone movements under oblique 3D waves \((S_{\text{max}}=5, T_p=1.4\text{s}, H_m=6\text{cm}, \alpha=-15^\circ)\).

In order to investigate the reliability of these calculations, initial damage tests of armour stones in the head and trunk sections were carried out under the same incident wave conditions as those in the velocity measuring tests. It can be presumed that the repeatability in the damage tests is not good, because the interlocking force of individual stones placed on the breakwater model may be different in every testing case. Then, in this study, the damage tests under the same wave condition were repeated five times. The resulting initial damage zones where the second armour layer was clearly exposed due to the displacement of the first armour layer under 3D and 2D waves attack are shown in Figures 9(a) and 9(b), respectively. The damage areas shown in these figures indicate parts where the initial damage in the same position on the breakwater occurred more than three times in five tests. By comparing these initial damage patterns with the spatial distributions of occurrence frequencies for armour stone movements shown in Figure 7, it can be seen that the calculated results of the sensitive zones for damage of stones in the head and trunk sections are fairly close to the experimental locations.
Magnitude of velocities over head

Figures 10(a) and 10(b) show the spatial distribution of occurrence frequencies for velocities ($V_r$) beyond the critical velocity ($V_{Crit}$) at the head section. The contour lines of relative occurrence frequencies are normalized with respect to the total number of velocities measured in 20 minutes.

In the case of 3D waves (Figure 10(a)), the maximum magnitude of velocities acting on the middle head section becomes nearly 3.5 times the value of critical velocity. This phenomenon may be pointed out to depend on the direct oblique wave attacks, which are associated with the directional spread of 3D waves. On the other hand, in the case of 2D waves, the high velocities with higher occurrence frequencies than those of 3D waves appear especially in the back head section. It has been observed in the damage tests that the reason for it depends on plunge of the strong current generated by refraction, shoaling and diffraction processes on the front and middle head sections.

Conclusion

The prevailing velocity vectors in the middle head section under 3D waves flow towards the down-slop of the head. This occurrence may be generated by the reflected waves which are produced by the oblique waves directly attacking the front head section.

The presented equations of the critical velocity for armour stone movement in the head and trunk sections could satisfactorily explain the initial damage zones in the damage tests. The middle head section under 3D waves is the most sensitive zone for the initial damage. Under 2D waves, a more sensitive zone appears in back head section. For the trunk section, the sensitive zone for the initial damage under 2D
waves appears at the whole section. In the case of 3D waves, the sensitive damage zones become spot patterns because of the existence of the oblique waves.

The maximum magnitude of velocities acting on the middle head section under 3D waves becomes nearly 3.5 times the value of critical velocity for armour stone movement. In the case of 2D waves, the high velocities with higher occurrence frequencies than those of 3D waves appear in the back head section due to plunge of the strong current generated on the front and middle head sections.

Further numerical analysis of wave kinematics over the heads and trunks as a continuation of this study is expected to make the weight of stable armour units under 3D waves clear.

"A STATISTICAL TOOL FOR BREAKWATER DESIGN"

Rodolfo Silva¹, Georges Govaere² & Francisco Martin³

Abstract

This article presents a methodology for the design of breakwater dikes which includes wave estimation, evaluation of the runup at the dike, calculation of the dynamic and pseudohydrostatic forces operating on the crown wall and finally the estimation of the stability of the armour units in the main layer.

The methodology presented is a development of existing experience in the evaluation of the effects produced by regular or monochromatic waves on structures (stability of pieces, induced forces and flow on the slope). This experience is extended to irregular or spectral waves via statistical distribution of waves, taking account of parameters such as root mean square or significant wave height, mean or peak period and water depth.

The application of the methodology described here has given satisfactory results compared with those of other methodologies and experimental data from various researchers.

INTRODUCTION

The function of a breakwater is to provide a sheltered area, to allow certain port activities on the quay and/or to protect against sediment transport in the coastal area. Breakwaters have an outer layer that has to be stable under the wave action, it is constructed with armour units of either natural or artificial material. A core provides the support for the
main layer. In between, there are several layers, forming a transition between the core and main layer. It is common practice, for economic or functional reasons, to construct a crown wall that reduces the extension of the main layer, the most expensive part of the dike.

Wave estimation is perhaps the most important calculation in the design of breakwaters. It is very easy to arrive at erroneous conclusions which can result in badly designed structures. The best way to determine the sea state is undoubtedly through measurements made in situ, preferably over a period of years. However this is not always possible due to the high cost of measuring equipment, its maintenance and operation as well as lack of time.

Where this information is unavailable it is possible to estimate parameters such as root mean square or significant height and its associate mean period by different means. Green (1994) compared different theoretical distributions with several of wave series. His conclusion was that Tayfun's statistical distribution for wave heights best describes the different states of the sea.

Figure 1 shows an example of best fit for different distributions of wave heights to waves corresponding to a TMA spectrum in shallow waters. As can be seen, the Tayfun's distribution offers the best fit.

Figure 1. Probability of exceedance of irregular wave against three statistical distributions.

ESTIMATION OF RUNUP

As regards the geometric design of coastal protection structures, such as mound breakwaters, the estimation of runup is particularly important in determining the crest elevation for structures allowing overtopping and those which do not.
Based on experimental results of his own and other researchers, Losada et al (1981) developed a mathematical model to estimate runup. The original method, which only be applied to regular waves, is given by

\[ Ru = H \left[ Au \left( 1 - e^{-\text{I}_{Ir}} \right) \right] \]  

(1)

where \( \text{I}_{Ir} \) is the Iribarren number defined as,

\[ \text{I}_{Ir} = \frac{\tan \alpha}{\sqrt{H / L_0}} \]  

(2)

\( H \) is the wave height
\( L_0 \) is the wave length in deep water
\( \alpha \) is the slope angle

The coefficients \( Au \) and \( Bu \) depend on the type of material of which the main layer of the dike is made.

Ahrens (1988) proposes another formula for the estimation of runup

\[ \frac{Ru}{H} = \frac{a \text{I}_{Ir}}{1 + b \text{I}_{Ir}} \]  

(3)

where the coefficients \( a \) and \( b \) are obtained by a regression analysis.

Through a last square method the values of \( Au \) and \( Bu \) corresponding to various materials have been found. Table 1 gives the values found for two types of breakwater, firstly homogeneous in which there is no core, and then one with two armour units on its main layer and an impermeable core. Van der Meer (1988) defined a “porosity parameter \( P \)”, that for the case of a homogeneous rubble mound breakwater corresponds to value of 0.6, and for the case of a rubble mound breakwater with two pieces in its main layer and impermeable core, \( P = 0.1 \).

Table 1 Au and Bu for different homogeneous breakwaters and breakwaters with impermeable core. * Compiled by Losada (1991)
In figures 2 and 3 the linear relation between the Au and Bu parameters versus the porosity of the main layer of the dike can be seen. In order to find the runup produced by a dike the parameters for that type of main layer material are evaluated and Losada’s exponential model is applied. If the core of the dike is neither homogeneous nor impermeable the values of Au and Bu can be estimated through an interpolation of the two extreme cases.

For homogenous dikes, the Au and Bu coefficients can be found through

$$Au = -4.706 \cdot n + 3.293$$ (4)
For dikes with impermeable core, the $Au$ and $Bu$ coefficients can be found through

$$Au = -3.825 \cdot n + 3.344$$  \hspace{1cm} (6)$$
$$Bu = -1.179 \cdot n + 0.081$$  \hspace{1cm} (7)

where $n$ is the porosity.

Applying the formulas of Losada et al. (1981) and Ahrens (1988), the results obtained are practically the same. This can be seen in figure 4, which shows $Ru/H$ against $Ir$ for the case of a homogeneous dike composed of rip rap. Based on these characteristics, the parameters $a$ and $b$ of the Ahrens formula for different main layers was evaluated using the previous values of $Au$ and $Bu$. These results are shown in figures 5 and 6. The latter gives the relation $a/b$ against the porosity of the main layer. The relation shows a linear tendency between parameters $a/b$ and $b$ versus porosity.

![Ru/H versus Ir for Losada et al. (1981) and Ahrens (1988) formulas Ir for the case of a homogeneous dike composed of rip rap.](image)

In order to obtain the parameters $a$ and $b$ the following equations are used:

For homogeneous dikes

$$a = b \cdot (-5.5589 \cdot n + 3.7954)$$  \hspace{1cm} (8)$$
$$b = 3.9753 \cdot n - 0.6774$$  \hspace{1cm} (9)

For dikes with impermeable core

$$a = b \cdot (-3.6922 \cdot n + 3.5785)$$  \hspace{1cm} (10)$$
$$b = 1.3971 \cdot n + 0.0501$$  \hspace{1cm} (11)
Ahrens coefficient $b$

To extrapolate the results of regular wave criteria to irregular wave criteria Silva et al. (1997b) and Govaere (1997) proposed a method in which the distribution of runup is considered as the same type as that of the wave height. The wave height distribution presented by Tayfun (1981) was used, a probability distribution which takes into account wave period, root mean square wave height and local water depth at the toe of the breakwater among other parameters.

The methodology is as follows:

- Depending on the mechanical characteristics of the breakwater and the formula selected, Losada et al (1981) or Ahrens (1988), $Au$ and $Bu$ (figures 2 and 3) or $a$ and $b$ (figures 5 and 6) are chosen.
An $Ru_{rms}$, representative of the mean characteristics of the flow, is evaluated, using the formula of Losada et al (1981)

$$Ru_{rms} = H_{rms}[Au(1-e^{-\alpha_{rms}})]$$

or using Ahrens (1988) formula

$$Ru = H_{rms} \frac{a \ tau_{rms}}{1 + b \ tau_{rms}}$$

where,

$$\tau_{rms} = \frac{\tan \alpha}{\sqrt{H_{rms} / L_{inert}}}$$

$$L_{inert} = \frac{gT^2}{2\pi}$$

$$H_{rms} = \left[ \frac{1}{N} \sum_{i=1}^{N} H_i \right]^{1/2} = \sqrt{8m_c}$$

$\bar{T}$ is the mean period

Tayfun’s statistical distribution function (1981), modified to generate a runup distribution, is applied:

$$p(\xi, N) = \xi \int_{0}^{\pi} u J_{\alpha}^{N} \left( \frac{u}{N^{1/2}} \right) J_{\alpha}(\xi u) \, du \quad 0 \leq \xi \leq N^{1/2}$$

$$p(\xi, N) = \xi \left[ 1 - \frac{4}{\pi} \cos^{-1} \left( \frac{N^{1/2}}{\xi} \right) \right] \int_{\pi}^{\frac{\pi}{2}} u J_{\alpha}^{N} \left( \frac{u}{N^{1/2}} \right) J_{\alpha}(\xi u) \, du \quad N^{1/2} \leq \xi \leq (2N)^{1/2}$$

where $N$ is the parameter defined by Tayfun as:

$$N = \left( \frac{\pi}{7\sqrt{2}} \frac{\tanh(k_o h)}{k_o \sqrt{2m_o}} \right)$$

and $\xi = Ru / Ru_{rms}$.
Using this methodology it is possible to evaluate the runup for all types of main layers and for different core porosities under irregular wave attack and for whatever probability of exceedance.

Figure 7 shows a comparison of this methodology with that of van der Meer (1988), which was developed for irregular wave criteria and gives very good results but unfortunately can be applied to very few cases. As can be seen, the proposed method gives good results for whatever probability of exceedance.

![Figure 7](image)

**Figure 7** Comparison of $\frac{R_u}{H_s}$ versus Iribarren's parameter with the suggested method (•••) and van der Meer (1988) formula (-----) for different probabilities of exceedance.

**CROWN WALL DESIGN**

A conventional breakwater is generally composed of two structures which are very different in their behaviour and response to wave action, figure 8. First, there is the body of the breakwater composed of a core of loose material protected by a series of layers of larger pieces. The second is a structure embedded into the top of the former, usually a crown wall of concrete, where services are installed. Being made of loose materials the body of the breakwater is more easily deformed and the damage is ductile in nature; generally taking place over a period of time, after storms. On the other hand, the crown wall is a rigid structure; damage here is of a fragile nature; usually the result of the action of just one sufficiently large wave.

There are numerous methods to calculate the forces acting upon a crown wall, all of which are based on laboratory experiments. Martin et al. (1995) proposed a model which separates the pressures of dynamic origin from those of pseudohydrostatic origin, since these pressure are presented at different times. Figure 9 shows the forces affecting a crown wall according to this method.
Martin's method was originally developed under regular wave criteria. The extension to the case of irregular wave criteria was made by Silva et al. (1997a) and can be summarised as follows:

**Dynamic pressure**

The law of dynamic pressures, $P_d$, on the breakwater can be evaluated as:

\[
P_d = \beta \rho g S \quad \text{for} \quad A_c < z < A_c + S \]

\[
P_d' = \lambda P_d = \lambda \beta \rho g S \quad \text{for the crown wall foundation} \quad < z < A_c
\]

With the runup, $R_u$, for the probability of exceedance chosen, equation (12) or (13), the parameters $\alpha$ and $\lambda$ are calculated from the following expressions:

\[
\beta = 2 R_u / H \cos^2 \alpha \cos \theta
\]

where,

\[
S = H (1 - A_c / R_u)
\]

\[
\lambda = 0.8 e^{(-0.9B/L_{\text{med}})}
\]

$\theta$ is the angle of incidence
Pseudohydrostatic pressure

Martin et al. (1995) proved that the law of pseudohydrostatic pressure is linear and proportional to $\mu pg$, where $\mu$ is a factor of 1 or less, shown by them.

$$P_h(z) = \mu pg (S+A_c)$$  \hspace{1cm} (25)

Comparison of the suggested method was made with measurements of Burcharth et al. (1995) and experiments carried out by Pedersen (1996). The proposed method gives very good results and has the advantage that it can be applied to a wide variety of crown walls of different configurations. More details can be seen in Silva et al. (1997a) and Martin et al. (1995).

ARMOUR STABILITY

Nowadays the methodologies most used to evaluate the stability of the main layer of a dike are those of Hudson (Shore Protection Manual, SPM (1984), the formula of Losada et al. (1979) and the van der Meer formulas (1988). The first two were developed under regular wave criteria and numerous investigations have been carried out with the idea of extrapolating these formulas to irregular wave criteria, such as that of van der Meer (1988).

After some experimental work in a laboratory, Jensen et al. (1996), suggested that when using formulas of SPM (1984) the wave height $H_{250}$ be taken (the mean of the 250 highest waves in a sea state) to obtain the same result as with irregular wave. Vidal et al. (1995) suggest using $H_{100}$ (the mean of the 100 highest waves in a sea state) when Losada’s formula is used. Using the $H_n$ concept is better than that of a probability of exceedance or of $H_{1/n}$, in that using the mean of a given number of large waves implicitly takes into account the length of the storm.

![Figure 10. Example of wave height probability of exceedance.](image-url)
Where the wave height distribution is unknown Tayfun's formula (1981) can be applied, and results as presented in figure 10 are obtained. The minimum probability of exceedance given for a sea state defined by N waves is 1/N. $H_n$ would be the mean wave height found within the probability of exceedance n/N and N, as follows,

$$H_n = \frac{N}{n-1} \int_{u_n}^{H} dH$$

(26)

Normally, using Hudson's formula with the $K_D$ parameter presented in the SPM (1984) gives very conservative armour sizes, as if the uses $H_{100}$ and $H_{250}$. The number of stability, $N_s$, used in Hudson's formula and the function of stability $\Psi$ used in the Losada's formula are related by the relation $N_s = 1/\Psi$.

Figures 10 and 11 compare the methods of van der Meer (1988), Losada et al. (1979) using $H_{100}$, as suggested by Vidal et al. (1995), and SPM (1984) using $H_{250}$, again as suggested by Vidal et al. (1995) versus van der Meer's experimental results (1988). A sea state of 1000 and 3000 individual waves, respectively was considered for levels of damage, S, between 1.5 and 2.5, mass density of the rock $\rho_s = 2650$ kg/m$^3$, mass density of the water $\rho_w = 1025$ kg/m$^3$. The rest of the parameters are presented in table 2. In the first case, 1000 waves, the root mean square errors are: van der Meer (0.0031), Losada (0.0029) and SPM (0.0039), and for the second case, 3000 waves, the root mean square errors are: Van der Meer (0.0061), Losada (0.0075) SPM (0.0064).

Table 2. Parameters used to evaluate figures 10 and 11, for each method.

The extension of Losada et al (1979) to irregular wave criteria and van der Meer method take into account the wave period effect, Losada's formula in the calculation of the stability function $\Psi$ and van der Meer's in the calculation of the stability $N_s$. Both methods produce results of similar dispersion. The SPM method however does not take into account the wave period, even so the root mean square error is similar to those of Losada and van der Meer.

Figure 11. SPM (1984), Losada et al. (1979) and van der Meer (1988) methods versus experimental data of van der Meer (1988) for dimensionless weight of the main layer.
CONCLUSIONS

The statistical distribution for wave height presented by Tayfun (1981) correctly represents different sea states, having the advantage of considering wave breaking in shallow waters.

The method of Losada et al. (1981) and Ahrens (1988) can be used to estimate runup for regular waves for whatever type of armour unit used in the main layer of a dike and for different porosities of the core. The extension to the case of irregular wave criteria via the Tayfun distribution is simple and gives very good results.

Crown wall design using the methodology for irregular wave criteria given by Silva et al. (1997a) gives good results and is easy to apply.

If it is used the wave height of $H_{250}$ is used, as suggested by Jensen et al. (1996), in Hudson's formula, or the wave height of $H_{100}$ as suggested by Vidal et al. (1995), in Losada's formula for the evaluation of the weight of the pieces in the main layer, almost the same results as for the van der Meer's formula.

For shallow waters, using the Tayfun distribution along with the stability function given by Losada et al. (1979) gives a significant reduction of the weight of pieces in the main layer related to those results given by the van der Meer (1988) formula.

The methodology described in this article has given very good results and presents a tremendous advantage in being applicable to many cases, which is not true of the formulas conceived under the irregular wave criteria.

COST COMPARISON OF BREAKWATER TYPES

W.H. Tutuarima¹ and K. d'Angremond¹

Abstract

A cost comparison have been made between various types of breakwaters for a fictitious situation in waterdepths to a local maximum of -15 m and an adopted sea climate. The comparison is based on optimal total project costs, being the sum of costs of construction and capitalized damage during the service period. For these selected conditions the caisson breakwater and the rubble mound type provided with a single concrete armour layer appear most attractive. Composite type of breakwaters seem advantageous for water depths approximately below -20 m.

Introduction

It is remarkable that caisson breakwaters are widely found in coastal areas of Japan and Italy and far less elsewhere. Conventional rubble mound breakwaters, provided occasionally with concrete armour top layers, are far more numerous in western industrial countries. It may be questioned whether the selected type may also result from a rational design approach.

The aim of this paper is to provide a brief review of various types of breakwater which are most fit for a location on the basis of economical considerations with regard to the type of harbour, the site conditions and the service time of the construction.

Approach

For a fixed layout the costs of following breakwaters are compared:
* Conventional rubble mound breakwater
* Bermbreakwater
* Rubble mound b.w. + toplayer of concrete units: Cubes, Tetrapods and Accropods
* Caissons breakwater
* Composite breakwater

¹ Delft University of Technology, Faculty of Civil Engineering and Geosciences, P.O.Box 5048, 2600 GA Delft, The Netherlands
The conventional rubble mound breakwater and the bermbreakwater had previously been compared for a fictitious layout by Hauer (et al, 1995). The same conditions have been used for caisson and composite breakwaters (Schols, 1997) and for conventional breakwaters provided with concrete armour units (Schepers, 1998). In all cases similar site conditions are applied. Costs taken into account are construction costs and capitalized maintenance during the lifetime of the construction.

**Layout and site conditions**

There are two breakwaters in the adopted layout: a northern mole of 1 km and a southern of 3 km length. Both are subdivided in sections with a specific average depth (figure 1). In all solutions the shallow sections in the breaker zone (approx. -6.0 m) are designed as conventional breakwaters. Therefore cost comparisons are due to differences in the deeper sections. The depth at the northern head is at -10 m, at the southern head at -15 m. Depth contours of the sandy seabed, $D_{50} = 200$ micron, are parallel to the coast, sloping 1:100 down to deep water.

Wave climate at deepwater ($H_{\infty}$) and setup of waterlevels ($h$) above MSL are expressed in terms of probability of exceedance of these values (figure 2). The storm duration is set at 6 hours. For the deep water conditions the mean wave period $T_z$ is related to $H_{\infty}$ according (Allersma and Massie, 1973):

$$T_z = 3.94 \times H_{\infty}^{0.376}$$  \hspace{1cm} (1)

The wave direction is perpendicular to the coastline. In view of the shallow area near the coastline the maximum significant waveheight $H_s$ is limited by the local waterdepth $h$ according to $H_s/h = 0.55$. The tidal amplitude is 1.0 m.
Figure 2 Wave and sea climate

Two yield curves A and B of the quarry are adopted (figure 3), which are similar to ordinary existing curves. The more gentle curve A is applied to the conventional breakwater (without concrete armour units) and to the caisson types, curve B to the breakwater types with concrete armour toplayers.

Figure 3 Quarry yield curves

**Stability requirements**

Design calculations for the rubble mound breakwater, including the stability of the concrete armour units, are based on methods developed by Van der Meer (1993), applied in the program Breakwat. The design of the caisson type of breakwaters are
mainly based on the method of Goda (1985). In all cases crest levels are high enough so as to achieve a transmitted wave height $H_T < 0.5$ m. Cross sections of the various types of breakwaters from the main layout section (II) are given in figure 4 to figure 8.

Rubble mound breakwaters

* Conventional breakwater
For each section of the layout the slopes have been varied so as to achieve optimum total costs given the quarry yield curve A as boundary condition. With the resulting slope 1:3.5 costs of repair are rather low but construction costs increased. The cross section is drawn in figure 4. Heaviest armour gradation is 8-15 tons. The efficiency of quarry production was just 24%.

![Figure 4: Conventional breakwater, optimal design section II](image)

* Bermbreakwater
In order to limit costs of damage the bermbreakwater had been designed rather conservatively using the arbitrary selected return period of 500 years for $H_T$ to size the rocks of the berm. Optimization of the waveheight in view of berm stability and the littoral transport by wave action had not been carried out. The cross section is drawn on figure 5. The quarry efficiency was 78%.

* Conventional breakwater + armour units: Cubes, Tetrapods or Accropods
The design method is similar to the conventional type. By replacing the heavy armour rock (8-15 tons, curve B) by concrete armour units (tetrapods, cubes and accropods), the design may be subject to potential cost savings in rock supply. Moreover much effort was given to optimize the quarry efficiency (64%); part of the heavy rocks were crashed for use as armour in the shallow parts of the layout (bedlevels -3 to -6 m). Though the applied steeper slopes (1:1.5 to 1:4/3) will require higher crest levels to match tranquility in the port basin, rock volumes needed were remarkably reduced. On figure 6 the cross section of the accropod is drawn.
Caisson breakwater and composite breakwater

Again the same layout and climate conditions (figure 2) have been used to analyse an optimum design of the two types vertical breakwaters. In both cases the concrete caissons are filled with sand. Minimum freeboard is set by transmission requirements. By variation of the freeboard total costs of material could be reduced. Increasing freeboards may contribute to more structural mass from the caisson above design waterlevel and increase stability to sliding and reduction of the required width of the structure so as to avoid risks of tilting. By limited sailing distances for rock transport (< 150 km) construction costs of the composite breakwater appear lower than of the caisson type. Fragmentation curve A is used for the substructures of rubble mound. Overproduction could be reduced by crushing production of too large rocks down to required grades. Rock production efficiencies are for caisson type 64% and composite type 68%.
Cost calculations

The aim is to base the design on minimum total project costs (TPC), i.e. the lowest sum of costs of construction (CC) and the capitalized costs of damage during the lifetime of the construction. The costs of damage are the sum of direct costs of repair (DC) and indirect costs (IC) due to consequential losses (e.g. loss of port operations) multiplied with the present worth factor (pwf). The consequential losses are related to the amount of industrial investments in the port area. The rate of interest used is 4% and the currency is the Dutch guilder (DGL, 1997).

\[
TPC = CC + pwf^* (DC + IC)
\]  

(2)

Direct costs of repair are related to the yearly risk of damage due to wave action. The method is illustrated for concrete armour units in figure 9 following the damage ranges of \(N_{\text{ad}}\) of Van der Meer (1993).
Figure 9 Risk of damage to concrete armour units

**Characteristic volumes per m' breakwater**

To illustrate characteristics differences in volumes of material applied in the various types, typical volumes for the main layout section II are mentioned in table 1. The remarkable low volume of concrete in the Accropod solution is due to the applied single unit armour layer, as recommended by the supplier. Also clear are the relative high amount of rock of the bernbreakwater and the reduced rock volumes in the types with concrete armour units, when compared with the conventional breakwater, as the result of steeper slopes applied.

Table 2 List of basic costs

Results

Total project costs have been calculated with increasing return periods of design wave heights (25, 50, etc. years). Clearly these costs decrease with increasing level of design wave heights, due to the rapidly decreasing sum of capitalized direct and indirect damage costs and the relatively small increase of construction costs. Table 3 illustrates the results for the concrete cubes solution. In this case the optimum is reached at a design $H_s = 5.4 \text{ m}$, return period 500 years.
The indirect damage costs resulting from the level of investments and the economical value of harbour operations appear to have a great influence on the optimum return period of $H_v$. Reduction thereof will allow for smaller design values. Similar results have been attained with other designs.

Moreover, in the points of optimum return periods for lowest total project costs, the capitalized damage costs are minimal and a clear distinction can be made between the various designs on the bases of the construction costs in those points. The results thereof are summarized in table 4.

Table 4 Construction costs of breakwater types

The high cost level of the conventional type is mainly due to inevitable overproduction of lighter quarry material (quarry efficiency 24%). Costs can be reduced drastically if these volumes can be utilized elsewhere. Although higher volumes are involved, the bermbreakwater yields lower cost levels, mainly due to a higher efficiency (78%). However with increasing transport distances, the savings due to the bermbreakwater decrease (Hauer et al. 1995).
The use of concrete units so as to replace heavy armour rocks over e.g. 10 tons have limited advantages to the costs when unit weights and volumes involved are close to the yield curve of the quarry. However, remarkable savings are reached with a single unit layer of Accropods; this might be the result of a single heavy rock layer as well, provided properly placed. The influence of transport costs of rock will decrease in that case.

The caisson breakwater appears more favourable than the composite type. For deeper bedlevels (> 15 m) this may be the opposite due to higher rock volumes required for the base structure.

Most favourable solutions for the fictitious layout and conditions are the accropode and the caisson breakwater. However transport costs and unit concrete costs may change the results. Larger transport distances may reduce the difference and may even result in an advantage for the caisson solution.

**Increased waterdepths**

For average coastal conditions some interesting results are found with varying water depths. Though expected, it is remarkable that as from water depths larger than 8 to 10 m the caisson types of breakwaters already seem to have cost savings compared to the rubble mound breakwater types, obviously due to increasing volumes of rocks at the base. However, with depths increasing to more than 20 m the composite breakwater appears to be a more cost saving solution, as the increasing heights of the caissons alone require additional widths. The study has been extended to foundation depths of 30 m (Schols, 1997), indicative values are mentioned in table 5.

</tbody>
</table>

Table 5 Indicative range of favourable breakwater type

However, for real situations specific site conditions may alter the results drastically. Construction costs depend strongly on the rate of down time due to wave climate and tidal height conditions, if offshore located breakwaters are considered. Production of accurate placing of heavy concrete armour units from floating crane barges, may vary quite differently from the speed of placing caissons in full height or as composite type, in the presence of ocean swell and local wind waves. Moreover, the feasibility of a caisson solution depends largely on the stability of the foundation, and in particular the sensitivity of the subsoil to liquefaction.
Conclusions

For conditions similar to the case following can be concluded:
- The rubblemound breakwater + Accropod toplayer is most attractive, due to less rock volumes (steeper slopes) and the application of a single unit toplayer.
- The caisson breakwater appears to be a good alternative and may even become favourable if costs of required rock transport for a conventional type are increased.
- The high costlevel of the conventional type is mainly due to inevitable overproduction of lighter quarry material. In cases lower design wave heights are applicable, lighter quarry material and higher level of quarry efficiency will reduce related construction costs.
- Although large volumes of rocks are required, the bermbreakwater yields lower costlevels, mainly due to higher efficiency of quarry production.
- In case high wave heights require heavy armour units, a conventional rubble mound breakwater provided with a toplayer of concrete elements will soon become favourable. A stable single unit toplayer (armour) may increase this advantage.
- Caisson types of breakwater seem to become advantageous with waterdepths exceeding approx. 10 m. For composite breakwaters the advantage may start at waterdepths exceeding 20 m.

Abstract

Following an old Italian tradition of prototype measurements of wave pressures at vertical breakwaters (Franco, 1994), a new twin recording station was set up and operated in 1992-1994 at Porto Torres (Sardinia, Italy) industrial harbour breakwater. In the framework of the MAST3-PROVERBS project an extensive analysis of the available data has been carried out.

Within the same project 2D model tests have also been performed in order to investigate the relation between pressure distribution and overall forces on and under both plain and perforated (multichamber) caissons. The results have been compared with the available design formulae like Goda’s (1985). Statistical distributions of the horizontal and uplift forces for both structure types have also been derived. The scope of the study has been to assess the reliability of the present design methods and to outline a more physically based approach especially for the perforated structure type.

Introduction

The prototype structure is a vertical composite breakwater subjected to nonbreaking wave conditions. Two caissons (20.5x13.9 m), one with plain (solid) wall and one perforated, 62 m apart, based at -15 m on rubble footing in 20 m water depth, were instrumented with ultrasonic wave gauges and pressure sensors along the caisson’s base, on the vertical face and also in the internal chambers as described by De Girolamo et al. (1995). The operating time of the instrumentation was 1992-1994, in which 10 significant storms (2≤Hₚ≤3.5 m, 6≤Tₚ≤9.2 s) have been recorded. A directional wave gauge has been installed 700 m away from the breakwater at the same depth (20 m). Water levels at the wall, front and uplift pressures have been recorded with a sampling frequency of 20 Hz, except for deep sensors (2 Hz).

Experimental conditions identical to prototype have been reproduced in the ENEL random wave flume (but just 2D homogeneous wave field) where the model caisson was equipped with the same number of pressure transducers as in the prototype (Fig. 1) and also with a dynamometer for simultaneous recording of global forces and pressures. The same wave frequency spectra were reproduced in the lab according to the prototype water levels recorded at the wall. Some synthetic Jonswap spectra have been simulated as well.

Prototype data

Parameters describing the loading signal shape of the most severe events of all recorded storms, together with all the other data relative to wave measurements, are collected in a database compiled according to MAST3/PROVERBS notations and confirming the single-peak shape for the pulsating (non-breaking) wave conditions. A further statistical analysis of wave loads proved a good fitting with 2-parameters Weibull statistical distribution for both front and uplift forces on plain caisson and for uplift forces on perforated caisson. With regards to perforated caisson, the trapezoidal integration method cannot be applied, because of geometrical complexity, to calculate horizontal forces from pressure measurements: the Kriebel (1992) method was used instead, and it has proven to give approximation of +/−20% in laboratory, not much bigger than values obtained from statistical analysis of front and back pressures.

Out of the ten storms recorded in field (Franco, 1996) the three largest ones in terms of significant wave height were chosen. A transfer function between the incident spectral densities and the ones measured at the wall was applied and spectra reproduction was good enough to allow a consistent comparison of pressure

measurements. Details on the sea storms parameters are given in de Gerloni (1997 et al.).

**Uplift pressure model and scale effects**

Both plain and perforated caissons and their foundation were accurately reproduced in the lab with a geometric reduction scale of 1/20. The tests were carried out in a 43 m long wave flume equipped with a wedge type generator and with a system of porous walls and lateral channels intended to absorb reflected waves. The rubble foundation grain size simulation was studied in a particular set of tests with a simplified superstructure. In order to ensure the test repeatability, the rubble base set up in the flume was accurately controlled and the rubble foundation material was deposited by means of the so-called “pluvial deposition” method, which ensures the maximum density of the deposited material (Pedroni et al., 1992). A 5 mm thick sheet of tender and waterproof rubber mousse, with holes for six pressure transducers, was applied on the caisson bottom in order to avoid the water to find preferential paths between the caisson bottom and the top layer of the rubble foundation (see Fig. 2).

![Fig. 2 Model set-up for rubble foundation material tests.](image)

A sensitivity analysis has been conducted on the scale effect of the grain size distribution of the rubble mound foundation in terms of uplift pressures. Three grain size curves of the rubble mound foundation with different density and gradation have been tested (cores A, B, C). Limestone rock was used with diameter $D_{10}$ varying from 1.8 to 20 mm and diameter $D_{50}$ varying from 3 to 23 mm. The average grain size has been scaled with respect with the Froude number. Further details are given in de Gerloni et al. (1997). Prototype and model data were analysed in terms of time-sequences values and statistical parameters associated to pressure waves, obtained after zero-down-crossing analysis. A first comparison with prototype data was done by looking at comparable run-up time sequences in the model and prototype (Fig. 3).
Such comparison doesn’t take into account the influence of runup history previous to the selected sequences, which has been proven to be negligible. A strong difference between prototype and model wave uplift pressure on the caisson base (the latter being twice as large) is apparent especially at the seaward edge (Fig. 4 right), but when approaching the harbour edge wave effects get smaller and they cannot be distinguished from the “noise”. It is also shown that the grain size has little influence.

Also the triangular pressure diagram recorded in the model at the moment of maximum uplift force (Fig. 5) appears not to be affected by the model grain size, or conversely the prototype is characterized by a non uniform transversal transmissivity which may be explained by cyclic tilting loading at the edges, as reported by Van Hoven (1997). In fact, neither Le Mehaute (1965) theory (suggesting a grain size scale from 1/16 to 1/11, close to core C scale 1/10) nor Jensen & Klinting’s (1983) studies (suggesting a scale 1/18 close to core B scale 1/20) seem able to justify the differences found. Similar uniform diagram shapes are observed in the troughs of pressure waves, too. Alike conditions had also been noticed in previous prototype measurements at Molo Cornigliano of Genoa Harbour, in 1975 (possibly with the foundation silted up on the harbour side), in small and large-scale model tests (Marchi et al., 1975; Kortenhaus et al., 1994) and in prototype measurements at Dieppe caisson (ULH Group, 1998).
In order to verify directly the actual conditions of the caisson foundation at Porto Torres a scubadiving inspection was carried out by the first author in October 1997. Observation was made along some 150 m of breakwater at the instrumented sections in the transition trunk between plain and perforated caissons on both sides. The outer apron slabs at toe were found to be placed very carefully/regularly one to each other with no more than 2 cm distance from caisson toe. No sand or fine material was observed at toe either sides. Gravel and small stones were found beneath the armour slabs. Info from construction divers confirms that the rubble foundation top was levelled with some 20 cm of gravel before accurate and smooth caisson placement.

The actual non-triangular shape of the uplift pressure diagram can be also explained by the obliquity and shortcrestedness of the real incident waves (recorded storm waves showed a mean attack angle up to 30° to the normal to the breakwater axis). As shown by Franco et al. (1996) after a systematic 3D model study on plain and perforated caissons, the uplift pressure diagrams under 3D waves can have a concavity that shifts the resultant towards the seaward toe (increasing the overturning moment) and the total uplift force is generally overestimated by Goda. This is also consistent with storm 1 records where the Goda design formula describes the triangular model diagram but overestimates uplift pressure values especially near the seaward edge.

**Horizontal loads on plain walls**

With the same method as for uplift pressures, the horizontal pressure time-series on the vertical wall have been compared between prototype and model for specific time intervals in which runup levels were in satisfactory agreement. In Fig. 7 (left) two different prototype time intervals having the same peak elevation and one model time interval in good agreement with them are plotted; the corresponding model and prototype (seq. a) time sequences of front pressure at -2.90 m M.S.L. during storm 1 are shown in Fig. 6 (right) and all the pressure data recorded at each sampling time in the model are compared with those in the prototype in Fig. 7. They show that with similar runup sequences, model pressures are on average larger than the prototype ones (≈+50% in wave troughs, ≈+20% in wave crests).
Fig. 6 Model compared with two prototype water levels (left) and model compared with prototype pressure time series (right).

Fig. 7 Model and prototype pressure measurements under similar wave runup crests (left) and troughs (right).

The overall actions on the model and prototype caissons at comparable runup sequences are plotted in Fig 8: differences are evident in both pressure gradients (uplift pressures and around the peak of the front pressure diagram) and in absolute values; under wave crests the differences are reduced.

Fig. 8 Uplift and horizontal pressure diagrams under wave crests (left) and wave troughs (right) as in Fig. 6 for the plain wall caisson.
The pressure diagrams proposed by Goda formula are compared in Fig. 9 with the corresponding model and field measurements at the different instants of maximum horizontal and uplift force: Goda method is further "conservative" because it assumes simultaneously the max values of horizontal and uplift forces.

Both model and prototype pressure data were integrated with linear interpolation over the vertical face and along the bottom; crests extracted with the zero-down crossing method are well fitted by the 2-parameters Weibull distribution (Fig. 10). Prototype shape parameter (\( \alpha \)) relative to horizontal forces \( F_h \) is well reproduced in the model but the corresponding scale parameter (\( \beta \)) is in the average 72% smaller, which means that the \( F_h \) distribution is the same but shifted towards higher values in the model; \( F_u \) distributions have both different shape and scale parameters.

Statistical estimates of horizontal and uplift forces (\( P=95\%, 98\%, 99\%, 99.6\%, 99.85\%, 99.9\% \)) have been compared with the corresponding model ones and also with the extreme estimates (\( P=99.85\% \)) according to the Goda method. Forces calculated with Goda formula are on average higher than the corresponding estimated ones, especially prototype \( F_h \) (Fig. 11). The lab force data are, on the average, 35%
and 40% larger than those of the prototype respectively for \( F_h \) and \( F_u \) as shown in Fig. 12.

**Fig. 11** Comparison of estimates of \( F_h \) (left) and \( F_u \) (right) forces from 99.85 % Weibull estimates and Goda formula.

**Fig. 12** Extreme horizontal (left) and uplift (right) forces: model and prototype.

**Horizontal loads on perforated wall**

In the same way as for the plain caisson, the perforated wall caisson was instrumented with pressure transducers on the bottom slab and on each vertical wall, and also with a dynamometer for global horizontal forces measurements. In order to investigate the pressures on the internal walls, the tests were repeated by turning backwards the pressure transducers placed on the perforated walls (Fig. 13).
Fig. 13 Setup of perforated caisson model with pressure transducers turned backwards

The model pressure data, recorded in the external and internal walls, have been integrated over the vertical face using the Kriebel (1992) and the Canel (1995) method. Both results exhibit non negligible discrepancies when compared with the lab dynamometer data (Fig. 14). This may be explained both by the intrinsic overestimate of the Goda distribution also on plain walls (up to 20%) and by the lack of knowledge about the true pressure distribution on the perforated walls.

Fig. 14 Comparison between lab data, Goda and Kriebel estimates.

The model test results, in terms of statistical distributions, also indicate that the perforated caissons can be subjected to larger horizontal loads than the plain ones when extreme waves attack the structure (Fig. 15 left). This appears different when
looking at the negative forces (Fig. 15 right) for which the perforated caisson behaves efficiently and more consistently in the load reduction.

A simple formula was looked for to calculate wave forces on perforated caissons as an improvement of Canel's (1995) one that is a modified version of Goda formula itself. By Canel method the hydrodynamic load due to an incoming wave of height $H$ on a partially reflecting structure is estimated by the Goda model with a suitably corrected design wave

$$
\left( \left( \frac{1 + Cr}{2} \right) \right)^H
$$

in which $Cr$ is the expected reflection coefficient. This approach was suggested by the observation of Goda model that establishes a linear relation between the hydrodynamic effects of waves and their height in most hydraulic situations. Values of $Cr$ around 0.5 were measured in the flume for the specific caisson with wall porosity of 0.31.

In order to give an input as general as possible to that formula, a simple modification of the design wave height involving only the dimensionless parameter $B/L$ (where $B$ is the chamber width and $L$ the wavelength), instead of the reflection coefficient $Cr$ was found. The total horizontal force $F_h$ by Goda model was worked out and compared with the corresponding measured values for each available perforated structure data set, coming from different experimental set-ups (University of Le Havre ULH, Leichtweiss Inst. Braunschweig LWI, as reported in MASTIII-PROVERBS 2nd Overall Project Workshop). Fig. 16 shows the comparison of the experimental data with the corresponding Goda values; as expected all the data are below the matching line.

The difference in percentage
with respect to the Goda calculation resulted on average equal to 30% for ENEL and PM/DH 3D random wave tests (Franco et al., 1996) and 24% for ULH regular wave tests.

A reduction coefficient was calculated for each experimental datum in order to make the measured and calculated force coincident. Fig. 17 shows the coefficient trend as a function of the dimensionless parameter B/L. A linear model to describe the relationship between the reduction coefficient of the Goda’s $H_{\text{max}}$ and B/L parameter was found. The equation of the fitted model is:

$$\text{reduction coefficient} = 1 + a \times (\frac{B}{L})$$

where:

- $a = -1.43$
- $\sigma_a = 0.08$
- $R^2 = 0.52$

Fig. 16 Comparison between measured vs calculated forces

Fig. 17 Reduction coefficient trend as a function of the dimensionless B/L parameter
The reflection \((C_r)\) and the reduction coefficient \([1+C_r/2]\) trends are shown in Fig. 18 as a function of the dimensionless parameter \(B/L\). The linear model adopted for the reduction coefficient is therefore conservative for a total chamber width \(B\) less than about a quarter of wave length, while it gives lower wave heights (and then forces) for greater values (though the more \(B/L\) increases, taking \(B\) constant, the less becomes the force).

For such analysis both field and lab data were used, but in the prototype caisson the actual total horizontal force is unknown while in the lab the total horizontal force have been measured.

Conclusions

The behaviour of caisson type breakwaters is generally less severe than predicted by the Goda method both with respect to the horizontal and vertical loads. The real uplift pressure distribution is not triangular as conventionally assumed, but a trapezoidal diagram is more reasonable. With respect to the perforated caissons, the global forces are not well described by the standard design methods. The overall performance of this structure types is effective in the reduction of water levels and negative forces, but they can show an opposite tendency for the horizontal forces at the highest wave crests. A new simplified formula for the preliminary design of multichamber perforated caissons is also proposed.

Wave Impacts on Caisson Breakwaters situated in Multidirectionally Breaking Seas

Frigaard, P., Burcharth, H. F. & Kofoed, J. P.

1. Abstract

The paper concerns horizontal wave forces on caisson breakwaters in multidirectional breaking seas. It is based on model tests performed in a 3D wave tank at Hydraulics and Coastal Engineering Laboratory, Aalborg University. The measured horizontal wave forces are compared to the Goda force. Good agreement with the Goda formula is found for waves not breaking directly on the structure, while increasing degree of breaking on the structure results in forces of up to 50% higher than the Goda force. Furthermore, the reduction of the horizontal wave force on long structures due to the non full correlation of the wave pressure along the structure is investigated. A formula for the force reduction factor based on cross correlation coefficients is given as a function of the mean wave direction and the wave spreading.

2. Introduction

In the design of caisson breakwaters it is common to use the rather simplified but well documented (Goda, 1974), equation for calculation of the wave forces. Alternatively, equations from (Takahashi et al., 1994), (Allsop & Vicinanza, 1996), deals with effects from impulsive forces. However, these models do not at the same time take into account both wave impacts and wave directionality.

The effects of wave breaking and impact forces on vertical structures have been investigated by several researchers in the past. However, the research on impact loading has mainly been based on 2D breaking waves, (Takahashi et al., 1994), (Oumeraci et al., 1995), (Allsop & Vicinanza, 1996), (McKenna & Allsop, 1998).

1959
Attention has also been addressed to the effects of wave obliquity and multidirectionality on the wave loads on vertical caisson breakwaters situated in non breaking seas. Battjes (1982) gave a theoretical description of effects of short-crestedness on wave loads on long structures. Within the joint European (MAST-LIP-TAW) research project, a 3D model investigation was carried out at Delft Hydraulics to assess these effects. The results have been published by several researchers, among them Franco et al. (1995).

Few researchers (Grønbech et al., 1997), (Calabrese & Allsop, 1998), described the effect of obliquity on wave load. These studies included effects from impact forces.

So far, little attention has been paid to the effects of wave obliquity and multidirectionality on the reduction in the wave loads on long caisson breakwaters placed in deep water breaking seas. To assess these effects, a physical model study has been carried out (Hydraulics and Coastal Engineering Laboratory, Aalborg University, 1997 and 1998).

In addition ongoing research will in the near future focus further on this topic. Late autumn 1998 a joint European TMS research project entitled Coherence of impact pressures at vertical wall in multidirectional seas lead by Prof. Alberto Lamberti, University of Bologna, Italy, will be performed at HR Wallingford.

3. Experimental setup

The physical model tests were carried out in the 3D wave basin. A caisson breakwater model constructed in plywood was used in the tests. The model was placed on a one layer smooth foundation constructed in concrete. The idea of this foundation was to provoke wave breaking in front of the caisson or even to introduce wave breaking on the caisson. The cross section and a plan view of one of the models are seen in Figure 1.

The size of the model did not refer to any particular prototype structure, however, a Froude scaling of 1:20 - 1:25 seems appropriate for this type of structures.

Two different crest freeboards corresponding to dimensionless crest freeboards in the range 1.17 - 1.90 were applied in the tests.

Two different model layouts were used, obliquity of the model relative to the wave paddles where 15° and 30°, respectively. The reason for these two model layouts was the fact that model influence given by the layouts should be extracted.

To assess the effects of wave obliquity and multidirectionality of the waves, the wave induced pressures were measured on a 2.4 m wide test section, giving the opportunity to study these effects on a single vertical element of the test section as well as on the total width of the test section.

To eliminate the disturbance from wave diffraction at the two ends of the model, the model were extended beyond the test section.
Preliminary to the tests a numerical study was performed in order to evaluate the diffraction effect from the two ends of the caisson. A consequence of this study was a non-symmetrical placing of the test section in the whole structure, see Figure 1. Even though much effort during planning and model changes were done trying to minimize effects from diffraction it must be concluded that variations in the order of +/- 5% of the incident wave height along the structure within the test section could be expected in a test. Consideration of this variation is rather important for the analysis of lateral force distribution.

In order to control the incident waves the basin were equipped with a full 3D active absorption system, see (Hald & Frigaard, 1997).

As the main objective of the study was to assess the effect of wave obliquity and multidirectionality in breaking seas, the changes on test conditions were mainly the incident mean direction of the waves and the directional spreading of the waves. The wave parameters are summarized in table 1.
Wave spectrum | JONSWAP, $\gamma = 3.3$
---|---
Peak period $T_p$ | 1.2 sec
Significant wave height $H_s$ | 0.14 - 0.18 m
Crest freeboard $R_c$ | 0.21 and 0.27
Water depth near caisson $h$ | 0.3 m
Mean wave direction $\theta$ | $0^\circ$ to $48^\circ$
Spreading of waves | Cosine squared, $\sigma = 0^\circ - 25^\circ$

Table 1 - Wave parameters.

To obtain an adequately statistically validity of the test results, rather long time series were performed with no test series having less than 1800 waves, and on certain occasions up to 2500 waves.

### 4. Wave analysis

Wave height is the most important parameter in the description of the wave forces. Due to high amount of reflection from the caisson and thereby the relatively confused sea, high priority were given to calculation of the incident wave height.

Wave elevations were measured by a wave gauges array consisting of 7 wave gauges located on deep water, see Figure 1. Using the Bayesian Directional Method, see Hashimoto & Kobune (1988), the wave field were separated into incident and reflected wave fields. Mean wave directions, spreading of the waves, significant wave heights and reflection coefficients at deep water were calculated from this incident wave field.

As the waves approached the more shallow water near the caisson they shoaled, refracted and started to break. Therefore, deep water wave parameters could not describe the waves sufficient in shallow water near the structure. Due to the wave reflection wave breaking and the rapid chances in the sea state shallow water wave parameters like wave direction, spreading of energy and wave height could not be calculated with high accuracy. Therefore, the front of the caissons was equipped with up to 4 wave gauges.

Using measured reflection coefficients of approximately 95% an estimate of the shallow water significant wave height were calculated from $H_s = 4/1.95 \sqrt{m_0}$, with $m_0 =$ total amount of energy.

Mean wave directions and energy spreading of the waves referred to in the following were all calculated from the deep water incident wave field.
5. Statistical distribution of forces

The forces in the sections were determined by integrating the measured pressures over the height of the model. In Figure 2, a time series of measured pressures in eight different levels and corresponding integrated horizontal force are shown. The pressures were sampled at 800 Hz. In order to compare the results of the tests with the prediction formula of Goda and to compare the results of tests with different wave heights, the measured forces were expressed in terms of the statistical force parameter $F_{1/250}$ which is average of the force peaks occurring with a probability less than 0.4%. Wave heights input into the Goda formula were measured at the structure exactly where the forces were measured.

In the design of the model layout for non braking and breaking conditions approximately 0% of the waves and 8% of the waves were assumed to break on the ramp or at the caisson, respectively. Figure 2 show that some impulsive loading from the breaking waves were measured but only some deviations relative to pulsating forces were seen.
Figure 3 – Example of statistical distribution of horizontal force peaks.

McKenna & Allsop (1998), stated that the statistical distribution of the pulsating force peaks may be described well by the Weibull distribution, and that a change in the gradient of the Weibull plot indicates the onset of impulsive wave impacts.

Figure 3 show that this deviation happened for force peaks with a probability of exceedence $P$ less than approximately 3 - 4 % which corresponds rather well to the observed number of waves breaking near the caisson or at the caisson.

Figure 4 show that measured forces corresponds very well to forces predicted by the Goda equation. As long as the waves were non breaking this was the case for all tests no matter wave direction and wave spreading. Other researchers, (Franco et al. 1995) and (Grønbech et al., 1997), found poorly agreement between measurements and the Goda force. They reported deviations up to 20 %. This is because they calculated the Goda force from the deep water parameters where the present study uses shallow water wave parameters.
The measured force for the breaking waves deviate approximately 50% from the forces predicted by the formula of Goda. Apparently, the Goda formula underestimates the forces from the breaking waves. Though, here it must be remembered that the test conditions for the breaking waves present somewhat the most severe possible sea condition, which in practice is the upper limit for the number of breaking waves. Such conditions were never meant to be covered by the Goda formula. Goda (1984), described how to avoid such a condition in the design.

Figure 5 - Measured forces compared to the Goda force for different degrees of wave breaking on the caisson.

Allsop et al. (1996), also found that the Goda equation underestimated impact loadings from breaking waves and they demonstrated very good correlation with the equation originally proposed by Allsop & Vicinanza (1996):

$$\frac{F_{1250}}{\left(\rho \omega^2 g h^2\right)} = 15 \left(\frac{H_s}{g}\right)^{3.134} \text{ for } 0.35 < \frac{H_s}{h} < 0.6$$

(1)

In the present study relatively good agreement to the Allsop & Vicinanza equation were found but the equation seemed to overestimate the measured forces. For the test cases the Allsop & Vicinanza equation estimate forces approximately double the estimates from the Goda equation.

Figure 5 shows that force ratio as a function of the number of waves breaking on the caisson. From plots like the one shown in Figure 3 it is possible to find the number of waves breaking on the caisson.

The performed tests were divided in three groups, non breaking waves, moderate breaking waves and breaking waves, respectively. In Figure 5 all force ratios are plotted relative to the average number of waves breaking on the structure in the whole group of wave conditions. A clear trend described by the following equation is found.

$$\frac{F_{1250}}{F_{Goda}} = 0.6 + 25n$$

(2)
6. Lateral distribution of forces

The horizontal wave load over a length of caisson will be reduced relative to forces measured in one section due to the non full correlation of the wave pressures along the structure.

By measuring the vertical distributions in nine sections spaced by 0.3 m and one section 0.1 m wide, the lateral distribution of the horizontal forces was studied. This is important due to the unknown correlation between the lateral distribution of the horizontal pressure and the lateral distribution of the horizontal force. The wave pressures were measured by a set of pressure transducers placed in the test section as shown below.

Figure 6 indicates 10 sections with 8 - 9 pressure transducers in each section. Never the less due to a restriction of 50 available pressure transducers only measurements in four sections were done simultaneously.

![Pressure transducer placement](image)

Figure 6 - Pressure transducer placement. Measures in meter.

From simultaneous measurements of force time series in different sections the reduction factor $r_F$ can be calculated (actually $r_F$ describes the non reduction in the force). Given a structure with length $l_S$ the reduction factor is traditionally calculated as:

$$r_F(l_S, P) = \frac{\int_0^{l_S} F(x,t) \, dx}{l_S \cdot F_P(t)}$$

Notice that the reduction factor might be depending on the probability level $P$ for the calculation.

Calabrese & Allsop (1997) and Burchart (1998), calculated force reduction coefficients simply by doing statistical analysis of lateral integrated force time series, and then take $r_F$ as the ratio between $F_{1/250}$ from the lateral integrated force time series and $F_{1/250}$ from the force times series measured in one section.

Though, such a method for calculating the force reduction will be influenced by diffraction patterns along the structure leading to too low reduction factors, which is unsafe. Furthermore, it is impossible to perform tests with high spatial resolution, so results will be based on a coarse resolution. Generally this effect will result in too high reduction factors. It is not possible assess these effects.
In the present study the spatial correlation coefficient used as the basis for calculation of the force reduction factor is calculated as:

$$\rho(x_1 - x_2) = \frac{1}{\sigma_F^2} \sum_{i=1}^{\Gamma} F(x = x_1, t_i) F(x = x_2, t_i) \Delta t$$

Here $\Gamma$ is the part of the time series that the spatial correlation coefficient is based on ($\Gamma$ can consist of disconnected parts of the time series). $x_i$ and $x_2$ are coordinates of the sections where the time series are measured along the structure. $\sigma_F^2$ is the variance of the $\Gamma$ part of the time series.

The advantages of using the cross correlation coefficients are that diffraction effects are removed from the measurements, and it is possible to get a very high spatial resolution by repeating the tests with different distances between the sections. Results will not be affected by smaller changes in the seastates.

Figure 7 - Spatial correlation coefficients and fitted spatial correlation function $\rho_1 = \rho_1(kx \sin(\theta))$ based on all data points in the time series.

Figure 8 - Spatial correlation coefficients and fitted spatial correlation function $\rho_2 = \rho_2(kx \sin(\theta))$ based on all force peaks in the time series.
Spatial correlation coefficients between the measured integrated pressures in sections with varying lateral distance have been calculated in three different ways, see Figure 7 - 9.

First spatial correlation function \( \rho_1 \) were calculated from the whole of the forces, i.e. using all data points. Second spatial correlation function \( \rho_2 \) were calculated from the parts of the force time series were the peaks of the forces were situated. Finally, the third spatial correlation function \( \rho_3 \) were calculated only from the parts of the force time series were the highest peaks (peaks with a probability of occurrence lower than 0.4 %) were situated. \( k \) is the wave number based on the peak period of the waves at shallow water.

It is obvious that the calculated spatial correlation coefficients show increasingly scatter when they are calculated from fewer data points. Also the figures indicates that the spatial correlation for the highest forces is lower than the spatial correlation for the whole time series. This means that the reduction factor for the highest peaks is lower than the reduction factors for the whole time series.

The reduction coefficients for the design forces were calculated using the spatial correlation function \( \rho_3 \):

\[
r_F = \frac{1}{I_S} \int_{-\frac{L}{2}}^{\frac{L}{2}} \int_{-\frac{L}{2}}^{\frac{L}{2}} \rho_3(x, \xi) \, dx \, d\xi
\]

(5)

It is assumed that the force peak will hit anywhere along the caisson with even probability. This means that the caisson in the calculation is placed randomly relative to the spatial correlation function.
Figure 10 - Reduction factors for the horizontal wave loads.

Figure 10 show calculated reduction factors based on spatial correlation functions (eqn. (4)) compared to reduction factors based on a traditional method of calculation (eqn. (3)). For low values of the dimensionless structure length $kl_s \sin(\theta)$ it is seen that a traditional calculation will underestimate the reduction factor where as for high values of the dimensionless structure length the traditional calculation will overestimate the reduction factor.

The calculated reduction factors can be described by the following equation:

$$r_F = \frac{1}{1 + a(kl_s \sin(\theta))^2}$$

\[ \text{for } \sigma = 18^\circ, a = 1.0 \quad \text{for } \theta > 5^\circ \]
\[ \text{for } \sigma = 25^\circ, a = 1.8 \quad \text{for } \theta > 5^\circ \]  

7. Conclusion

Regarding the effect of wave breaking on vertical caisson breakwaters, an increase compared to non-breaking waves and the predictions by the Goda formula of the wave forces was seen. It was found that the ratio of the waves breaking on the caisson controls the amplification of the force relative to the Goda force.

Because no full correlation exists between measured horizontal forces in sections with varying lateral distance, a force reduction for wide caisson sections are found. It has been shown that force reduction coefficients must be based on measured cross correlation coefficients. Expressions for reduction factors as function of wave angle and wave spreading are given.

Prototype Measurements of the Dynamic Response of Caisson Breakwaters

Alberto LAMBERTI¹ and Luca MARTINELLI¹

Abstract

Prototype tests, aiming to describe the dynamics of caisson breakwater oscillations, were carried out at Genoa Voltri and at Brindisi Punta Riso. The rigid body natural frequencies and modes of oscillation of the caissons were evaluated as well as the rate of damping. The effect of the longitudinal array structure, never tested in physical models, was found extremely relevant; the Mass Spring Dash-pot model for an isolated caisson of Oumeraci & Kortenhaus (1994) was then conveniently updated in order to represent an array structure, showing finally good agreement with the recorded signals.

1. Introduction

When vertical breakwaters are subject to breaking waves, the plane front wall is hit by impulsive pressure loading, which, provided the wall resists the load, will accelerate the caisson causing its oscillation. In these conditions only part of the applied load will be transferred to the foundation and may cause failure, normally by displacing the caisson (Franco, 1994).

Several models were proposed in literature in order to simulate the caisson dynamics: Petrashen (1956), Loginov (1958), Hayashi (1965), Benassai (1975), Smirnov & Moroz (1983), Marinski & Oumeraci (1992), Goda (1994), Oumaraci & Kortenhaus (1994). The last two provide calibrations based on physical models that do not consider the effects of the longitudinal structure of the breakwater. Prototype measurements were carried out only by Muraki (1966), who identified a single system eigenfrequency (=0.2 Hz) but apparently the identified oscillations were not coherent with the wave force that was generating them.

Given the overall lack of knowledge of the response of a vertical caisson subjected to impulsive waves, the EU has financed a project, PROVERBS, with the aim of providing information and tools to allow the design of vertical breakwaters with a desired probability of failure, accounting for the mentioned dynamic behaviour. University of Bologna, within the project, was charged of exciting artificially some prototype caissons and measuring their dynamic response, in order to verify existing models of caisson dynamics and to check errors in the estimate of soil parameters.

In this paper the prototype tests and analysis will be briefly described (chapter 2); the analysis of the movements of the excited caisson showed the presence of natural modes of oscillation that could not be interpreted through the simple models present in literature (chapter 3), based on the dynamic description of an isolated caisson. The analysis of movements of the caissons adjacent to the excited ones suggested that these dynamic models should be adapted in order to represent the caisson array structure (chapter 4). In particular the model by Oumeraci & Kortenhaus (1994) was updated and calibrated, resulting suitable for the simulation of all the observed modes of oscillation (chapter 5).

2. Description of the tests

The prototype tests were performed in Genoa Voltri and Brindisi, during 1997. The tests were carried out hitting a vertical breakwater with a sac and/or with a tug-boat in order to produce a significant dynamic response.

The sac, half filled with sand and weighting 2 tons, see Fig. 1, could fall completely free from a height of 5 m (or partially slowed down from a greater height) and it hit the caisson in proximity of the harbour edge, i.e. with a strong eccentricity. One accelerometer was installed on a “buoy” right into the sac on the sand surface, in order to give information on the applied force.

Fig. 2 shows the excitation due to a tug boat displacing 100 tons and hitting a caisson in Genoa Voltri (a 500 tons tug boat was used in Brindisi). The speed before the contact was close to 0.3 m/sec, varying on the occasions, and the impact force lasting about 0.5 sec for the smaller tug (1.0 sec for the bigger one) was evaluated by one accelerometer fixed on the tug-boat in the longitudinal direction.

The accelerations of the excited caisson and of the two adjacent ones were measured by 15 accelerometers placed as shown in Fig. 3. 9 accelerometers are placed on the central caissons, 1 describing the movements in the longitudinal direction and 8 describing the movements in the perpendicular plane. The adjacent caissons were monitored with 3 accelerometers each. In total, seven groups of three adjacent caissons were monitored, belonging to three vertical breakwaters (main breakwater in Voltri, western lee breakwater in Voltri and main breakwater in Brindisi, see Fig. 4) similar in shape but different in size (3 10' kg, 1 10' kg and 2 10' kg respectively). The joints between adjacent caissons are wide (5-10 cm) only for the case of the main breakwater in Genoa, but in all cases the superstructure has joints at the ends of each caissons. The rubble mound height vary from 2 m to 15 m for the different cases, and the foundation has a first layer of clayey-silty sand over a more fine material and rock below. A detailed description of the hydrodynamic conditions, caisson geometry, structural and foundation aspects are given in Lamberti et al (1998) and Lamberti & Archetti (1998).

In order to reduce the high frequency vibrations produced by sharp impacts, and thus avoid amplifier saturation, the accelerometers of the central caisson were fixed on a concrete cubes acting as mechanical filters. Since vibrations are greatly reduced passing from the central excited caissons to the adjacent ones, only the instruments placed on the central caissons needed to be mechanically filtered.
The filter (See Fig. 5) is formed by a concrete cube (side of 20 cm) glued to the superstructure through 4 round rubber disks. The response of this filter to an impulse is shown in Fig. 6. Note that the natural frequency of oscillation (=20 Hz) is out of the range of interest ([1−8] Hz) and that the damping is rather strong.

Fig. 5 The accelerometers of the central caissons were fixed on a concrete cube.

Fig. 6 The concrete block was excited by a hammer, and this is the response of one of the accelerometers fixed on the block. The eigenfrequency of the mechanical filter is about 20 Hz and the damping is high: amplitude is halved in one cycle.
3. Analysis of tests results relative to the hit caisson

The analysis started with the quantitative definition of the original applied force signal. For the sand sac exciting case the accelerometer direction was controlled fixing the accelerometer to a round and flat disk inserted into the sac, that could ‘float’ over the sand. The sac is not rigid and the average acceleration could not be measured; the signal was used for the evaluation of the length of the impact and for the force-response synchronisation. The force history was then defined assuming an anelastic behaviour, knowing the sac weight, the velocity before the impact and its duration. For the tug-boat excitation, the acceleration during the contact is actually proportional to the real applied force (a 10% hydraulic added mass was considered).

All the 16 channel registrations of the same type (same caisson, same kind of excitation) were cut 2 seconds before the impact and 8 seconds after it, analysed in the frequency domain and bandpass filtered (in Tab. 1 the range for the different tests is given), and pasted into a unique sequence in order to have data in a single file. Furthermore, phase averaged signals were created averaging each channel for the same kind of excitation. The records were synchronised maximising the cross correlation.

The interpretation scheme at the base of the analysis is that caissons can be considered as rigid bodies. Oumeraci & Kortenhaus (1994) described a Mass, Spring and Dash-pot (MSD) model where contributions to mass, stiffness and damping are due to rubble mound and foundation and to seawater. Such a system has three natural oscillation modes (see Fig. 7):

1. the sway mode \((m_1)\): an almost horizontal translation (or rotation around a low centre);
2. the roll mode \((m_2)\): a rotation around a higher centre;
3. the heave mode \((m_3)\): an almost vertical translation.

In order to describe caisson movements a reference system was defined, the origin being in proximity of the instrumentation in order to reduce the overall error; components are:

1. sway, or harbour directed translation \((\xi_0)\),
2. heave, or vertical translation \((\eta_0)\),
3. roll, or rotation around a longitudinal axis \((\theta)\).

The choice of the pole ‘\(O\)’ (points of which displacements \(\xi_0\) and \(\eta_0\) are given) is arbitrary and the relation between any other pole position \((x_c, y_c)\) and its displacement is trivial (see Fig. 8):

\[
\begin{align*}
\xi &= \xi_0 + \theta \eta_0 \\
\eta &= \eta_0 - \xi_0 \theta \\
\theta &= \theta_0
\end{align*}
\]

(1)

The rigid body movements of the central caisson were extracted combining the eight horizontal and vertical accelerations of the central caissons with a best fit procedure: the sway signal is approximately obtained by averaging the four original horizontal signals; the heave is approximately the average of the vertical signals and the roll is similar to the difference between the upper and lower horizontal and vertical accelerations divided by the respective distance of the instruments.

A similar procedure was applied to the adjacent caissons, whose rigid movements have been averaged over the two caissons.

The following analysis consisted in assessing the Power Spectral Density of the responses and the Transfer Functions between force and response, both for phase averaged signal and sequence of tests. The
power peaks coherent with the force for each signal were then evaluated, see Fig. 9 for instance. Since the force showed a rather flat spectrum in correspondence of peaks of the signals, their frequencies were interpreted as the natural frequencies of oscillation.

Signals were then band-pass filtered around the natural frequency.

Vibrations are only partially filtered out from the rigid body signal, they are finally recognised comparing the single and fitted rigid body signals in the appropriate frequency range.

The damping of the natural oscillations was assessed measuring, for each mode, the rate of amplitude decrease of the phase averaged signals after the impact. Similarly, comparing for each mode the acceleration amplitude and phase of the central and adjacent caissons, the amount of energy that travels along the breakwater was evaluated.

The upper graph of Fig. 10 shows the acceleration at quay level (precisely the phase averaged sway signal) induced in Brindisi by the tug-boat. It is possible to note immediately the presence of two different harmonics. The harmonics are presented in the lower graph of the same figure, and they are obtained bandpass filtering the signal around [0.5-1.8 Hz] and [1.8-6 Hz] (e.g. around the frequency peaks observed in the roll and sway signals, see Tab. 1).

The sum of this two harmonics reproduces almost exactly the original signal (almost undistinguished dotted line in upper graph). The same two harmonics are present in the 'roll signal' describing two rigid body rotations, i.e. two modes.

The rotation centre can be assessed band-pass filtering the average signal around the rigid mode frequencies and evaluating the ratio between sway and roll, and/or, for the central caissons, evaluating the acceleration directions at the four corners.

The power of the horizontal acceleration at any point can be easily evaluated combining sway and roll signals: the power of the horizontal acceleration is minimum if the pole is placed at the height of the rotation centre (Eq.1 governs the affect of changing the reference system).

Fig. 11 shows the relative power of the horizontal acceleration at different heights for the two different frequency bands: it is clear that the minimum of the curve, i.e. the position of the rotation centre, is placed below the caisson base.

Similar results are found for the cases of Voltri: this means that two modes have two low rotation centres, in total disagreement with the assumed mathematical model described in Fig. 7, according to which the higher frequency mode (present in the sway
and roll signal) should have a high rotation centre.

Fig. 12 represents, maybe more clearly, the same effect: within the frequency range of the 2nd observed frequency, the corners of the caissons move in the directions shown by the two graphs, obtained plotting the horizontal vs vertical acceleration. The rotation centre is located at the intersection of the two radii orthogonal to the displacement or acceleration: evidently a rotation around a very low centre is taking place.

**Fig. 11** The horizontal acceleration power (divided by its minimum value) in the two frequency bands (see Fig. 10) is presented as function of the distance from quay level. The minimum value of the acceleration power is considered as a good estimation of the height of the rotation centre. The rotation centre is placed well below the caisson base (caisson height = 21.7 m).

**Fig. 12** The accelerations of the corners of the caissons describe a rotation around a very low centre. The graphs are obtained plotting the horizontal vs vertical acceleration in the higher frequency band [1.8-6 Hz], which according to the single caisson model is instead associated to a mode with a high rotation centre.
The natural periods of oscillation were assessed as well as the associated rigid movements: for the almost horizontal oscillation, which are rotations around low centres, the actual depth below the base of rotation centre (R.C.) could be identified comparing the sway and the roll signal. Superstructure vibrations (v) are present only in case of sharp impacts and if the band of frequency, given in the rightmost column, is large enough. Non accurate data are given in square brackets.

</table>

Tab 1 summarises the results of the analysis: the identified frequencies and modes. Two natural frequencies of oscillation were identified in the sway and roll signals plus one in the heave signal (see Fig. 9). The two modes recognised in the roll and sway signals represent rotations around low centres.

Even disregarding the position of the rotation centres, a 3 DOF model for isolated caisson could not be calibrated interpreting the observed oscillations as modes \( m_1 \) and \( m_2 \); the ratio between the measured eigenfrequencies was lower than foreseen by the model for any value of rotational and horizontal stiffness. Also using the model of the foundation suggested by Goda (1994), it was impossible to obtain a calibration without assuming an unrealistic anisotropy of the foundation.

In conclusion the test analysis pointed out three main modes, two of which are rotations around low centres (two \( m_1 \) modes, in disagreement with the system described in Fig. 7) and one is a vertical displacement (\( m_3 \)).

4. Effect of adjacent caissons and interpretation of the identified modes of oscillation

The oscillation amplitudes of the caissons adjacent to the central one were almost one third compared the central one and significantly delayed; a large amount of energy is then subtracted from the central caisson by waves propagating along the breakwater. The effect of this wave can not be completely described by the considered single caisson model.

Comparing the horizontal oscillation of the central and adjacent caissons in a single frequency band (see Fig. 13), it was possible to observe that the oscillations were almost in phase in the frequency band [0.5-1.8 Hz] (around 1st observed frequency) and almost in opposition of phase in the frequency band [1.8-6 Hz] (around 2nd observed frequency).
A possible interpretation of the two identified sway modes involves then the longitudinal dimension: the 1st observed mode is given by a movement of all the caisson in phase, the 2nd observed mode is given by an alternate movement of these.

Fig. 13 Horizontal accelerations induced by the tug at Brindisi on the central and adjacent caissons: the oscillations are almost in phase in the frequency band around the 1st observed frequency (upper graph) and nearly in opposition of phase in the frequency band around the 2nd observed frequency (lower graph).

Fig. 14 7 Hz lowpass filtered heave for central and adjacent caissons. The frequency peak in the heave signal describes in phase movements of the central and adjacent caisson. Any other combination of vertical modes was not identified, probably due to the high environmental noise.

The MSD model was then modified considering an array of caissons, formed by several MSD modules connected one another by spring and dash-pot elements. The added stiffness was estimated as a fraction of the stiffness between caisson and foundation, and the proportionality coefficient was calibrated so that the adjacent caisson accelerations fit the actually measured ones. Damping coefficients were not calibrated directly, since the model describes damping effects directly on the uncoupled modes.

Since the system is symmetric and it was excited symmetrically, only the symmetric movements were considered in the model.

A boundary condition must be inserted if the represented array of caissons is shorter than the actual one. If it is assumed that the last caisson is fixed and the stiffness between the end caissons and the adjacent ones (K_L) is equal to the stiffness between any two other caissons (K_A), the system results more stiff than it actually is; the opposite case is found if the last caissons are supposed to be free to move, i.e. K_L=0. The assumed lateral condition was then a compromise, consisting of a reduction of the last stiffness coefficient to 50 % of the others (K_L/K_A=0.5). The effect of this assumption is reduced if
more caissons are considered, and for an array of 7 caissons the two limit cases do not affect significantly the acceleration of the central caisson.

Let’s consider, for simplicity, a model of just three caissons: the output is not totally satisfactory, but it is possible to highlight the most important characteristics. The system has 6 DOF (three movements of the central caisson and three symmetrical movements of the two adjacent ones) and thus 6 eigenmodes. Fig. 16 shows that two of these eigenmodes are actually formed by rotations around low centres; one is due to all the caisson moving together and the other to a movement in opposition of phase. The observed natural oscillations (Tab. 1) can be interpreted along this line.

When the adjacent caissons move in phase with the central caisson (superscript +), the geodynamic added mass is reasonably bigger than in case of a movement in opposition of phase (superscript -), since in the second case part of the foundation between adjacent caissons is resting (not moving). This effect explains different heights of the ‘m1’ rotation centres (see Fig. 11). Such difference is less important for the case of Voltri, where the longitudinal dimension of the caisson is bigger (the caisson length is 30.1 m in Voltri, 21.0 m, in Brindisi). A small mixed term in the geodynamic added mass matrix was considered (only 1/3 of the geodynamic added mass is considered for an opposition of phase) in all the simulations.

**Kinematic of the system with 6 DOF**

Fig. 16 If the two adjacent caissons are considered in the dynamic system, each eigenmode described in Fig. 7 appears twice: the mode due to all the caisson moving together (superscript +) and the mode due to a movement of the caissons in opposition of phase (superscript -).

In heave oscillations just one frequency peak was clearly identifiable, which was apparently associated to an ‘in phase’ motions of the caissons (see Fig. 14) and it was thus interpreted as mode m3+. Mode m2+ and of type ‘m3’ were not identified, probably due to the low signal/noise. In the next chapter Tab. 2 shows that modes ‘m2’ are almost not excited by the tug, while for the falling sac excitation case in Fig. 22 a comparison between simulated and measured PSD of the roll signals is presented, showing that computed ‘m2’ frequency peaks in the range 3.9-7.9 Hz could be hidden by the environmental noise.
5. Numerical simulations and calibration of the final model

The final simulations were performed considering a 12 DOF model presenting an array of 7 caissons.

The horizontal, vertical and rotational stiffness between caisson and foundation depend on the shear modulus G, and, secondarily, on the Poisson coefficient (=0.4). G was evaluated assuming $E_o=320$ MPa (Young modulus for average pressure = 100 kPa);

$$E \propto \sqrt{\frac{1+2K_v}{3}},$$

vertical pressure $\sigma_v=350$ kPa, coefficient of lateral confinement $K_v=1$.

The horizontal and rotational stiffness between central and adjacent caisson ($K_A$) was calibrated (in a preliminary way) as 40% of the stiffness between caissons and foundation ($K_C$) given by the elastic homogeneous half space theory. For vertical oscillations, the stiffness of the link with the adjacent caissons was calibrated as 60% of the stiffness with the foundation.

Fig. 17 shows the simulation of the horizontal acceleration at quay level for the case of Voltri (W2). The exciting force due to the tug boat is presented in the upper graph. The simulation is compared with phase averaged sway signal of the central caisson. Also the recorded rotational oscillations were found to be well simulated.

**Fig. 17** Simulation of horizontal acceleration at quay level for the case of Voltri, induced by the tug-boat excitation.
Comparison between the model and experimental transfer function between such acceleration and the applied force, presented in Fig. 18, is extremely relevant. The first peak of the TF is placed at 1.4 Hz and it is relative to a sway mode of all the caissons in phase ($m_{1}^{++}$). The last peak is placed at 2.7 Hz and is relative to a sway mode of the caissons in opposition of phase ($m_{1}^{-}$). Since the model represent 7 caissons (the central one plus 3 couples) there are in total 4 sway modes, which are modes $m_{1}^{+++}$, $m_{1}^{++}$, and the two modes $m_{1}^{++}$ and $m_{1}^{-}$ with intermediate eigenfrequency (1.9 Hz and 2.4 Hz, in the simulation). The horizontal force applied by the tug does not excite the four heave modes, and also the four rocking ones are weakly excited. The tug-boat impact excited only the rotations around low centres mainly for two reasons:
1. the point where the force is applied is very close to the rocking centre and
2. the length of the impact is not short compared to all $m_{2}$ eigenfrequencies.

Tab. 2 shows the relative power of the excited modes (in terms of rotations).

Tab. 2 Computed eigenmodes for Voltri main breakwater, excited by the tug boat. The damping coefficients (reduction of the oscillation equal to 40% per cycle) were globally calibrated on the basis of the transfer function. The vertical positions of the computed rotation centres, R.C., are given.

In prototype, the breakwater is formed by many caissons and thus many modes are placed between mode $m_{1}^{++}$ and $m_{1}^{+++}$, i.e. a continuum spectrum of modes is present.

The vertical oscillations induced by the sand sac impacts are not perfectly simulated (see Fig. 19) probably because the applied force, as explained in chapter 3, was reconstructed and since the impact is not really impulsive (the impact lasts about 15 sec), the time history has some importance. The simulated response could reproduce only the first cycles of the recorded acceleration oscillation. Since the impact strongly excites superstructure vibrations, identified at 10-15 Hz, the rigid body oscillations in Fig. 19 were assessed by filtering below 10 Hz the recorded signal.

In the records of the vertical accelerometers 9 and 15 placed in the adjacent caissons (the position is shown in Fig. 3) there is much less noise. Since the main
breakwater caissons in Voltri have large longitudinal joints, the superstructure vibrations excited in the central caissons do not pass to the adjacent ones. The low-pass filtering at 10 Hz is then not necessary for these signals (presented in Fig. 20); they are similar between them for symmetry reasons and they describe the vertical acceleration of the seaward corner of the adjacent caissons. Such acceleration was simulated and presented in Fig. 21.

Comparing Fig. 20 and Fig. 21, it can be seen that the first three oscillations are very well defined with regard to maximum values and wavelengths, while a 4 Hz component seems to be unsufficiently damped in the model (a constant damping was applied to every vertical mode, resulting in a reduction of the oscillations of 47% per cycle)

Tab. 3 shows how the sand sac impact excite the various simulated modes in terms of displacements. In general the 'all in phase' and the 'alternate' motions are the most excited modes in terms of accelerations, the former more than the latter.

Note that all the modes are excited, even the 'm2' modes that were not identified.

Fig. 22 presents PSD of the simulated roll induced by the sand sac excitation, compared to the recorded case: at 2.5 Hz an experimental peak is present, much higher than the simulated one, which might be effect of the vertical oscillation motion having almost the same frequency that was not perfectly identified by the combination of signals that described the rigid body 'roll', or it could be induced by resonance between the two modes with same frequency. Above 10 Hz a lot of energy is present, relative to
superstructure vibration. It is evident that in between the electronic noise can hide the peaks of the simulated signal.

Tab. 3 The falling sand sac eccentric impact excites not only the heave modes but also the rocking and sway modes. The relative power of each mode is given below (for a meaningful comparison, the rotational oscillations were multiplied by the lever arm of the force, i.e. the eccentricity of the falling sac). The applied reduction per cycle was globally calibrated as 47% for the vertical modes, 40% for the rotational modes.

6. Conclusions

Due to the interaction of all the breakwater caissons, the eigenmodes of caisson system are many. The most excited modes in case of a horizontal force applied at the sea-level (as for the tug-boat or a breaker hitting the breakwater) are all sway oscillations (rotational oscillations around centres placed below the caissons base). The relative eigenfrequencies were measured for the cases of both Genoa Voltri and Brindisi breakwaters and shown in Tab. 1: they are in the range 1.3-3.6 Hz.

The heave and rocking oscillations (vertical oscillations and rotation around high centres) were excited only by the falling sand sac load, which induced also high vibration of the superstructure; consequently much more noise was present in the records. The most excited heave mode (apparently the 'all in phase' mode) had frequency around 2.5 Hz.
Unfortunately the rocking modes were not identified with certainty, probably due to the high noise present: Fig. 22 shows that the noise is higher than the model simulated signal.

The superstructure vibrations of the analysed caissons were assessed and found in the range 10-15 Hz.

A MSD model combined to an elastic half space foundation model (Oumeraci and Kortenhaus) can describe the system dynamics only if the movements of at least three adjacent caissons are represented. A very good description (see Fig. 17) of the system dynamics was obtained simulating the movements of an array of 7 caissons. The calibrated parameters were 5: the foundation stiffness for isolated caissons, the stiffness between central and adjacent caisson (40% of the stiffness with foundation for modes ‘m1’ and 60% for modes ‘m3’) and the damping of the ‘m1’ and ‘m3’ modes (reduction per cycle of 40% and 47%, respectively).

The calibration of the foundation stiffness was obtained considering the relation between the Young modulus and the confining stress (the assumed Poisson coefficient being 0.4 and not yet better investigated). The calibration for both Brindisi and Genoa Voltri suggested a Young modulus of 320 MPa relative to a nominal average pressure of 100 kPa.

Experimental and FEM Simulation of the Dynamic Response of a Caisson Wall Against Breaking Wave Impulsive Pressures

Shigeo Takahashi 1, Muneo Tsuda 2, Kojiro Suzuki 3, and Ken-ichiro Shimosako 4

Abstract

After presenting a summary of field survey-observed damage incurred over the past 20 years by caisson walls of Japanese breakwaters, this study describes a series of model experiments and three-dimensional FEM simulations performed to evaluate the dynamic response of a caisson wall subjected to breaking wave impulsive pressure. The important roles played by "elastic" and "inertia" soil pressures are subsequently clarified, and good agreement is obtained between measured and calculated results. The proposed calculation method, which applies the Goda pressure formulae in conjunction with the impulsive pressure coefficient $\alpha_i$, is expected to provide a practical design method against impulsive pressures.

1. INTRODUCTION

Caisson walls seldom fail even when acted upon by impulsive wave pressures that are large relative to normal design wave pressures, i.e., the strain in the wall is reduced by the static and dynamic response of the filling soil and water contained within the caisson chambers. While these responses tend to stabilize a caisson, they have not yet been specifically considered in the design evaluation process. Moreover, if the impulsive pressures are quite large and act at very high frequency, a caisson breakwater can suffer failure (Tanimoto et al., 1975).

Such effects led to the present study whose main objective is to establish a design method against wave pressures, especially impulsive ones, such that wave action failures can be prevented. We consider a caisson wall containing filling sand in the caisson chambers, and focus our attention on its dynamic response, which includes both "inertia" and "elastic" effects, against impulsive wave pressure.

After conducting a field survey of Japanese breakwaters—to determine damage

that has occurred in caisson walls over the past 20 years—a box-shape model caisson was used to perform a series of experiments in which soil pressures and wall strain were measured, i.e., impulsive pressures were applied after filling the model caisson with sand and water or only with water. We also carried out three-dimensional FEM calculations to simulate the strains generated by impulsive wave pressures, and then compared measured and calculated results such that the applicability of the simulations could be evaluated. Finally, the employed FEM simulation is used to investigate the failure of caisson walls of a prototype built at Mutsu-Ogawara Port.

2. CAISSON WALL FAILURES

Current Design Method of Caisson Wall against Wave Actions

Figure 1 shows a diagram of a breakwater caisson, i.e., a large, reinforced concrete box in which chambers separated by inner walls are filled with sand and water. The outer and inner walls have a thickness of 40–60 and 20–30 cm, respectively. The caisson’s front wall is designed against wave pressures, static soil pressure of filling sand, and static water pressure (Fig. 2). The wave pressure distribution at the wave crest is determined by the Goda pressure formulae (Goda, 1974), while that of the wave trough by the relation \(0.5 w \rho H\).

Caisson Wall Failures in Japan

Table 1 presents a summary of field survey-observed damages incurred over the past 20 years by caisson walls of Japanese breakwaters (Hattori et al., 1984; Miyai et al., 1993), where 12 cases due to impulsive wave pressure are indicated. Although failures at fishery ports are not included, the number of failures is still quite small relative to the total number of caissons in Japanese ports (> 16,000). Table 2 summarizes the main reasons for caisson wall failures, with each reason being discussed next using a typical case.

Udono Port Case

Photo 1 shows a caisson wall failure at Udono Port, being damage caused by impulsive breaking wave pressures produced due to the presence of a high, large rubble mound foundation. Note that four caissons slid and one suffered caisson wall damage. Such failures seldom occur nowadays because the generation of impulsive pressure due to this type of rubble mound is common knowledge among breakwater design engineers. In this particular failure, the mound was not originally high, but due to substantial movement of a sandbed situated near the breakwater, the water depth in front of the breakwater increased such that the relative height of the mound became high.

Mutsu-Ogawara Port Case

Impulsive pressures can also be generated when caisson walls are not sufficiently covered by concrete blocks. This situation especially applies to horizontally composite type breakwaters, where the caisson is covered by concrete blocks that dissipate wave energy. Unfortunately, the covering can sometimes become insufficient due to settlement or scattering of the blocks, or it might be insufficient at
the transition part from the horizontally composite type to ordinary composite type.

Photo 2 shows damage to a breakwater at Mutsu-Ogawara Port following a severe storm equivalent to its design conditions (Hitachi, 1994). Caisson No. 7 was nearly destroyed by impulsive pressures from waves breaking on concrete blocks which were scattered and settled.

Figure 3 shows the breakwater's plane view and cross section. While the upper part of caisson No. 7 was completely destroyed, caisson No. 8 moved only 0.4 m and its wall was not damaged. As caisson No. 8 was designed to be located at the transition part, such impulsive pressures were considered in the design. Caisson No. 7 was covered sufficiently by blocks, but due to scattering the transition part was extended such that it reached caisson No. 7. In fact, it had a wall thickness of 70 cm compared to that of No. 7 which was only 45 cm. As will be discussed later, a thicker wall led to differences in resulting damage.

Photo 2 Damaged caisson No. 7.

Fig. 3 Plain view and cross section of the breakwater.
Collision with Concrete Blocks

Photo 3 shows a horizontally composite type breakwater whose caisson wall suffered damage due to concrete blocks colliding with it. When a breakwater is located in rough seas, the blocks are usually large and can hit the wall making holes due to shear failure of the wall. Since impulsive breaking wave pressures are typically responsible for producing damage, here we focus our attention on this type of failure and do not consider in detail those due to collisions with concrete blocks.

3. MODEL EXPERIMENTS

Experimental Setup

Figure 4 shows a cross section of the box-shape model caisson and locations of instrumentation for measuring pressure, strain, and acceleration. The walls are made from acrylic plates, with the front wall having a thickness of either 10 or 15 mm. Regular waves were applied. The shallow water concrete blocks situated directly in front of the caisson generated wave breaking such that impulsive wave pressures impact the front wall. Note that in order to clearly see the effect of soil pressures due to wall acceleration and the resultant wall deformation, we deliberately used a single
caisson model in which the width of the wall is quite long compared to that of a standard caisson.

The natural frequency of the model caisson wall was measured to be 38.5 Hz in air but only 6.3 Hz in water with filling sand present; values that are nearly the same as theoretical ones. The reduction in frequency is due to the added mass effect of water and sand surrounding the wall.

**Elastic Soil Pressure and Inertia Soil Pressure**

We consider two types of internal soil pressure:

1. Elastic soil pressure due to soil acceleration and
2. Inertia soil pressure due to soil deflection.

The former is mainly discussed based on experiments using non-breaking waves, while the latter using impulsive breaking waves. Static soil pressure, *i.e.*, earth pressure at rest, is also considered.

**Caisson Wall Strain Against Non-Breaking Waves**

Figure 5 shows the strain and internal soil pressure generated in a sand-filled caisson when a non-breaking wave hits the front wall. Since the internal soil pressure is nearly proportional to wall displacement, we term this as "elastic" soil pressure.

The wave pressure and elastic soil pressure are compared in Fig. 6, where the elastic soil pressure shows a peak value ≈ 70% of the standing wave pressure. This elastic soil pressure assuredly reduces the strain significantly, and therefore resultant pressure *(p−q)* acting on the wall is greatly reduced.

![Fig. 5 Caisson wall strain due to non-breaking waves.](image)

![Fig. 6 Soil pressure vs. wave pressure.](image)
Dynamic Response of Caisson Wall Against Impulsive Breaking Waves

Figure 7 shows the soil pressure $q$, strain $\varepsilon$, and acceleration $\alpha$ after a wave with impulsive pressure $p$ impacts the front wall. The resultant pressure acting on the wall $(p-q)$ is also shown. Acceleration data indicates that the wall vibrates strongly, and that the soil pressure due to the "added mass effect" is proportional to acceleration. We term the internal soil pressure due to the added mass effect as "inertia" soil pressure, $q_{sp}$. The dynamic response of the front wall and associated pressures can be described using two phases (Fig. 7), namely, phases I and II represented in Fig. 8. In phase I, $p$ shows a positive peak coinciding with positive peaks in $\alpha$ and $q$; and, due to $q_{sp}$, $(p-q)$ and accordingly $\varepsilon$ show no peak. In Phase II, $\varepsilon$ and $(p-q)$ contrastively show nearly coincident peaks while $\alpha$ shows a negative peak. Note that even though $q$ is reduced below its peak value, $\varepsilon$ and $(p-q)$ nevertheless increase due to the negative inertia soil pressure. However, due to the coincidently acting positive elastic soil pressure, $(p-q)$ decreases. In other words, in this case the dynamic response of the caisson wall reduces the peak in $\varepsilon$ by about 50%.

Figure 9 shows the peaks of impulsive wave pressure and inertia soil pressure in Phase 1, and Fig. 10 shows the peaks of wave pressure and wall strain. The inertia soil pressure is 70 - 90% of the impact wave pressure, which indicates that the strain at Phase I is greatly reduced due to soil pressure, making the strain at Phase II more...
significant. By comparing the peak strains for the sand-filled and water-filled caissons due to the soil pressure the peak strain is reduced 40 – 80%.

Fig. 9 Impulsive pressure vs. inertia soil pressure.

4. FEM SIMULATION

FEM Model

Figure 11 shows the mesh system used to carry out time-dependent, three-dimensional FEM numerical calculations simulating the dynamic response of a caisson wall.

Experiments vs. Calculations

Figure 12 compares measured and calculated profiles of \( p, \alpha q, \) and \( \varepsilon \) where the apparent good agreement between them indicates that employed FEM simulation is suitable for approximating the caisson’s dynamic response.

Fig. 10 Impulsive pressure vs. wall strain.

Fig. 11 Mesh system used for FEM simulation.

Fig. 12 Measured vs. calculated results.
Dynamic Response of a Prototype Caisson Wall

Figure 13 shows simulated profiles for a prototype caisson (height, 15.5 m; chamber width, 4.125 m; wall thickness, 60 cm) located at Mutsu-Ogawara Port, where results are indicated for an input wave pressure profile with an impact duration \( \tau \) of 0.01 or 0.06 s. At \( \tau = 0.01 \) s, the inertia effect is the same as that of the model caisson, *i.e.*, it delays the peak in wall displacement and reduces its value by about 30%. At \( \tau = 0.06 \) s, however, the wall displacement peak almost coincides with the peak in wave pressure, with its peak value being the same as the static value. In other words, the effect of the inertia soil pressure is limited only when the impact duration is short.

It should be noted, however, that wall deformation \( \delta_{st} \) includes the effect of elastic soil pressure, which is about one third of input wave pressure; and therefore the resultant wall deformation is in turn reduced by one third.

Figure 14 shows the effect of \( \tau \) on the inertia effect for a wall with filling sand and water, *i.e.*, the caisson's internal soil pressure, displacement, and deflection.
which are all non-dimensionalized by static values. As can be seen, the reduction in deflection, namely strain, due to the inertia effect appears when the duration of impact is much less than the wall's natural period (20 Hz).

The natural frequency of the wall in air is 40 Hz, whereas in water it is 20 Hz for a sand-filled caisson, being slightly higher than standard frequencies because the considered wall thickness of 60 cm is slightly larger than the standard value. These results indicate that the reduction in strain due to the dynamic response, especially that due to the inertia effect, appears when $\tau$ is short, i.e., around 40 ms.

**Rubble Mound Stiffness and Dynamic Response**

The above simulation considered a relatively stiff rubble mound foundation that is lower and wider than standard ones. Therefore, to determine if rubble mound stiffness affects the dynamic response, the value of stiffness was reduced to 1/10th the original value. Figure 15 compares the simulations, where it should be noted that no marked differences appear during the duration of impact, which results clearly indicate that the dynamic response effect of the caisson wall is not affected by the rubble mound foundation.

![Graphs and Diagrams](image-url)

*Fig. 15 Effect of stiffness of rubble mound on dynamic response.*
Bending Moment

Figure 16 shows the horizontal and vertical bending moments of the caisson wall with $\tau = 0.06$ s, where the sand filling markedly reduces both bending moments by $\approx 30\%$. Also shown are corresponding profiles calculated using the conventional design method in which a reinforced concrete plate is fixed along three edges and no filling sand is considered. Note that the horizontal moment is overestimated and the vertical moment underestimated, especially around S.W.L where huge impulsive wave pressure are present.

Figure 17 shows the effect of wall thickness and partition distance on wall compressive stress due to bending moment, where these results clarify that increasing wall thickness is much more effective than decreasing partition distance.

![Fig. 16 Effect of filling sand on bending moment.](image1)

![Fig. 17 Effect of wall thickness and partition distance on wall compressive stress.](image2)
Mutsu-Ogawara Case

Table 3 summarizes the results of applying our 3D, time-dependent FEM model to simulate the actual effects of a strong, 1991 winter storm on the No. 7 (damaged) and adjoining No. 8 (undamaged) caissons of the Mutsu-Ogawara breakwater. From previous work (Takahashi et al., 1994), if we apply the modified Goda formulae (Goda, 1974) assuming an impulsive pressure coefficient of $a$, then the predicted value of the impulsive wave pressure impacting the breakwater would be about $2.8 \omega H$, i.e., since maximum incident wave height during the storm was 14.88 m, the breakwater was hit by an impulsive pressure of 500 kN/m$^2$.

As indicated, the 45-cm-thick wall of the No. 7 caisson was subjected to a bending moment of 315 kNm, which is much higher than the allowable value of 240 kNm. On the other hand, the 70-cm-thick wall of the No. 8 caisson was subjected to a resultant bending moment of 421 kNm, which is much lower than the allowable bending moment of 540 kNm. Such correspondence with field survey observations points towards the suitability of using our model to establish a practical design method against impulsive pressures.

- Impulsive wave pressure coefficient : $\alpha = 1.10$
- Maximum wave pressure : $p = 2.8\omega H$

5. CONCLUSIONS

Main results are summarized as follows:
1) Although failures of caisson walls rarely occur, they are possible if the impulsive pressure is quite large and the thickness of the caisson wall is insufficient.
2) Model experiments successfully demonstrated the dynamic response of the caisson wall against impulsive breaking wave pressures.
3) Based on measured and calculated results showing good agreement, the employed 3D, time-dependent FEM model is considered to effectively simulate the dynamic response of a wall of a sand/water-filled caisson.
4) Internal soil pressures, namely, elastic and inertia soil pressures, play important roles in reducing the strain in a caisson wall, i.e., the strain in the caisson wall due to the elastic soil pressure is dependent on wall stiffness and can reduce the bending moment by as much as 30%.
5) Wall strain due to the inertia effect appears when the impact duration time of
impulsive pressure is shorter than the natural period of the wall, \textit{i.e.}, around 40 ms.

6) The wall's dynamic response is not affected by the stiffness of the rubble mound foundation.

7) Our simulation model is expected to provide a good foundation for continued analysis of caisson wall failures such that a practical design method can be effectively established against impulsive pressures. The ultimate design method will be based on applying the Goda pressure formulae (Goda, 1974) in conjunction with the impulsive pressure coefficient $\alpha_g$ (Takahashi \textit{et al.}, 1994).

Wave Transmission at Submerged Rubblemound Breakwaters

Stuart R. Seabrook\textsuperscript{1} and Kevin R. Hall\textsuperscript{2}

\textbf{Abstract}

Submerged rubblemound breakwaters are becoming more popular as a potential alternative to coastal protection measures where a moderate degree of energy transmission is acceptable. Such situations include areas where vegetative shore protection is existing or proposed or in the event that an existing shore protection structure has become damaged or under designed and a method is needed to reduce the incident wave energy. Although there have been previous investigations on the performance of submerged rubblemound breakwaters, there are only a few design equations available to the design engineer. Those available are based on a limited range of input design variables and as a result are insufficient in some cases.

Physical model studies were performed at the Queen's University Coastal Engineering Research Laboratory (QUCERL) in Kingston, Canada to assess the performance of submerged rubblemound breakwaters under a wide range of design conditions in two-dimensional (2-D) and three-dimensional (3-D) settings. The tests include a number of wide crested structures to provide data where previous investigations have not. The results show that the relative submergence, incident wave height and structure crest width are the most important design variables.

A number of potential design equations were evaluated by statistical analysis methods. The proposed design equation fits the 2-D test data well and provides moderate agreement with the 3-D test results. Although physical testing is suggested for all design applications due to the complexity of site specific considerations, the proposed equation does provide a good preliminary design tool for submerged rubblemound breakwaters.

1.0 Introduction

Submerged rubblemound breakwaters are simply rubblemound structures constructed with a crest elevation below the local water level. Although they are well suited to situations where minimal visual intrusion is desired and where it is desirable to maintain a moderate degree of energy transfer between the shoreline and the offshore region for environmental reasons, their performance is sensitive to water level changes and it is not practical to expect transmission coefficients as low as those achievable with conventional surface piercing structures. However, there are benefits associated with the potentially smaller material requirements for stable submerged structures and the ability to rehabilitate existing structures by simply reducing the incident wave conditions with a submerged breakwater.

Numerous physical and numerical investigations have been performed for various submerged structure configurations and materials. In general, the physical processes at submerged rubblemound breakwaters can be defined for three regions in the vicinity of the structure as indicated in Figure 1. Relevant nomenclature is also indicated.

In Region 1, the incident wave shoals on the rising face of the breakwater, considerable non-linear wave transformations take place as bound waves are developed (Beji and Battjes, 1993) and some wave breaking is initiated. A portion of the incident energy is also reflected from the front breakwater face. Wave breaking continues into Region 2 where significant non-linear interactions occur between the various wave phases. Harmonic generation occurs as energy is transferred from the fundamental wave frequency to higher harmonic frequencies (Driscoll, Dalrymple and Grilli, 1993). Some wave energy is also dissipated on the breakwater crest through friction and air entrainment as well as within the breakwater structure. In Region 3, the free and bound transmitted waves dissociate as they travel into the deeper water. This generally results in a broadening energy spectra as the various wave components travel with their own celerity.

Numerical modeling efforts have met with some success in representing the transformation of weakly non-linear incident waves (Ohyama and Nadaoka, 1993; Driscoll, Dalrymple and Grilli, 1993; Beji and Battjes, 1994; Losada, Silva and Losada, 1996). Although all models are reported to reflect some of the physical modeling data well, none of the approaches can fully model the breaking and non-linear decomposition process on a theoretical basis. Therefore, given the uncertainties associated with the present state-of-the-art in numerical modeling, it may be most appropriate for the design engineer to consider more general design equations based on physical modeling results.
Relatively few design equations have been developed to date for submerged rubble mound breakwaters. Those available have been developed by Seelig (1980) for surface piercing and submerged permeable breakwaters, by Ahrens (1987) for reef-type breakwaters and by Van der Meer (1991) for low crested and submerged rubble mound structures. Seelig’s equation was developed with very little submerged breakwater data and Ahren’s equation is not directly applicable to conventional submerged rubble mound breakwaters given the reshaping nature of reef breakwaters. Van der Meer’s equation was developed from a considerable volume of test data from a number of authors but some variables were not varied to a large degree; a limited variation in crest width was perhaps the most important shortcoming of this research. As a result, none of the existing equations are sufficient for application over a wide range of design conditions.

The objectives of the research presented in this paper are therefore as follows:

1. To test a sufficiently wide range of submerged breakwater geometries, ensuring a broad range of crest widths, under a relatively large range of incident wave conditions in a 2-D setting to assess the validity of the existing design equations.
2. To extend and modify the existing design equations as necessary to provide some physical basis for the dimensionless parameters utilized.
3. To perform 3-D testing for a number of conditions similar to those tested in the 2-D apparatus to assess the validity of the proposed equations for application in more realistic 3-D environments.
2.0 Experimental Setup

The majority of the physical tests were 2-D in nature and were performed in a 1 meter wave flume at QUCERL. These test results provided the data for development of the proposed design equations. Subsequent 3-D testing was carried out in the wave basin at QUCERL using a smaller set of test variables. The results of these tests were used in the evaluation of alternative design equations.

2-D Testing

The testing setup for the 2-D tests is shown in Figure 2. The wave flume is 47.0 m long, 1.2 m deep and 1.0 m wide and is equipped with a flapper type wave generator. A plywood beach was constructed in the flume, upon which the test breakwaters were constructed. The beach permits testing of the submerged breakwaters in relatively large incident waves. The submerged breakwater cross section consisted of a core of relatively course core material ($D_{50c} = 0.017 \text{ m}$) and two layers of primary armour ($D_{50a} = 0.059 \text{ m}$). A second armour size ($D_{50b} = 0.037 \text{ m}$) was used in some tests. The armour size was determined such that the breakwater remained stable during testing. The stone size required for the most severe testing condition was determined using the stability equation of Vidal et al. (1993). The stone size recommended for the “total slope” section was used for the entire breakwater.

Incident and transmitted waves were measured by two wave probe arrays, located in front and rear of the breakwater respectively. The probes were capacitive type water level gauges, sampling the water surface at 20 Hz. Reflection from the rear wall of the wave flume was minimized using a 1:10 beach of rubberized hair in front of a porous matrix of concrete blocks.

In total, approximately 800 tests were performed with irregular waves. A number of tests were also performed with regular waves in order to confirm the presence of physical phenomenon observed by previous authors. The testing program involved 13 submerged breakwater geometries tested under 5 different water levels with a number of incident
wave characteristics.

All irregular wave spectra tested were Jonswap with $\alpha = 0.0081$ and $\gamma = 3.3$. The signals were generated using the National Research Council of Canada’s (NRC), GEDAP wave generation and analysis package. Given the physical characteristics of the flume and the mechanical response of the paddle to the input signal, the generated wave spectral characteristics may vary from the target characteristics by 5% to 10%. A summary of the irregular wave characteristics tested is provided in Table 1.

3-D Testing

The wave basin at QUCERL is approximately 30 m by 25 m by 1.2 m deep and is equipped with a piston-type wave paddle 10.5 m long. All dimensions for the 3-D tests were scaled at 0.63 times those of the 2-D tests and the submerged breakwater structure was constructed on the floor of the basin. A concrete beach was constructed behind the breakwater and covered with sand to minimize the reflection and provide a qualitative assessment of beach development. A subset of testing parameters was used in the 3-D tests, with 3 breakwater geometries and 3 water depths, all tested at incident angles of 90° and 60°. The general testing configuration is shown in Figure 3 below.

Figure 3: 3-D Testing Configurations
The submerged breakwaters used in the 3-D tests were constructed using a relatively fine core material \((D_{50c} = 0.004 \text{ m})\) and the smallest armour tested in the flume \((D_{50a} = 0.037 \text{ m})\). The wave signals were generated from Jonswap spectra. Because the breakwater for the 3-D tests was not constructed on an elevated platform, it was not possible to generate waves as large as those used in the 2-D tests. A summary of the irregular wave characteristics used in the 3-D tests is provided in Table 4.

*Note: Wave characteristics are approximate - those measured in basin may vary to some degree.

Water level probes were placed throughout the area behind the submerged breakwater, and one probe was located near the paddle to provide an indication of the incident wave height. Two velocity probes were also moved throughout the area behind the submerged breakwater to provide a qualitative indication of the general velocity patterns. The locations of the various probes are shown in Figure 3 above.

**Data Sampling and Analysis**

Sampling for each test was performed at 20 Hz over a period of 100 waves. Full reflection analysis was undertaken for the 2-D data to separate the incident and reflected spectra. The reflection analysis was performed using a least squares analysis of 3 probes of the 5 probe array (Mansard and Funke, 1987). The incident wave characteristics at probe arrays 1 and 2 were used to define the transmission coefficient \(K_t\), such that:

\[
K_t = \frac{H_i}{H_s}
\]

where \(H_i\) and \(H_s\) are the incident \(H_{m0}\) values at probe arrays 2 and 1 respectively.

The significant wave height \((H_s)\) at individual probes was used to define the transmission coefficient for the 3-D tests. The incident wave was defined by Probe 5 and the transmission coefficient was computed at various locations behind the submerged breakwater. Although the use of \(H_s\) instead of \(H_{m0}\) to define \(K_t\) is not consistent with the analysis of the 2-D data, it reduces the effect of energy that has leaked into the testing area or been reflected into the lee of the breakwater, on the characteristic wave height estimate.

The transmission coefficient values were analyzed with respect to the various incident wave and structure characteristics. This analysis involved a simple graphical trend analysis of the data, followed by a comprehensive statistical analysis of alternative design equations relating \(K_t\) to the most important design variables. The trend analysis was conducted with
dimensional and dimensionless variables considered to be important to the transmission process. The most important dimensionless variables were ascertained by dimensional analysis of the transmission process.

It is generally accepted that the transmitted wave at a submerged breakwater is a function of a number of variables.

\[ H_t = f(\rho, g, \nu, D_{50a}, n, H_i, L, \theta, B, h_i, h) \]  

(2)

where \( \rho, g \) and \( \mu \) are density, gravitational acceleration and dynamic fluid viscosity respectively and the other variables are defined in Figure 1. A dimensionless form of this expression can be developed using \( \rho, g \) and \( H_i \) as basic or repeating variables such that:

\[ K_t = \frac{H_i}{H_t} \phi \left( \frac{\rho H_i \sqrt{g}}{\mu}, \frac{D_{50a}}{H_i}, n, \frac{L}{H_i}, \frac{d_r}{H_i}, \theta, \frac{B}{H_i}, \frac{h_i}{H_i}, \frac{h}{H_i} \right) \]  

(3)

These basic dimensionless variables were used to develop alternative dimensionless variables which are more relevant to the physical processes affecting transmission at submerged breakwaters. Dimensional and statistical analysis of these relevant variables was undertaken to develop a design equation for transmission at submerged rubblemound breakwaters.

3.0 Results

The observations made during testing were generally consistent with observations noted from previous investigations. The incident wave spectra were broadened with a shift of energy to higher frequencies as the waves passed the breakwater and there was evidence of harmonic generation and subsequent dispersion as individual waves passed over the structure. The most obvious process affecting \( K_t \) was wave breaking. Inspection of the general trends defined by the 2-D test data indicate that \( K_t \) is most sensitive to the depth of submergence \( d_s \), the incident wave height \( H_i \) and the crest width \( B \). To a lesser degree, \( K_t \) is influenced by the period of the incident wave \( (T_p) \), the breakwater armour dimensions \( (D_{50a}) \) and the breakwater slopes \( (\theta) \).

Typical trends observed during the 2-D tests are summarized in Figures 4 through 8. It is evident that the transmission increases with increased \( d_s \), increased \( H_i \) and increased \( B \). It is also shown that a small increase in \( K_t \) is observed with increasing \( T_p \), increasing \( D_{50a} \) an steeper slopes (increasing \( \tan(\theta) \)).
Submerged Breakwater Transmission

$K_t$ vs $d_s$ ($B=0.6$ m, $T_p \sim 2.0$ s)

Effect of $d_s$ and $H_s$ on $K_t$

Submerged Breakwater Transmission

$K_t$ vs $B$ ($d_s=0.05$ m, $H_s \sim 0.10$ m)

Effect of $B$ and $T_p$ on $K_t$

Submerged Breakwater Transmission

$K_t$ vs Slope ($d_s=0.05$ m, $H_s \sim 0.10$ m)

Effect of $\theta$ and $T_p$ on $K_t$

Submerged Breakwater Transmission

$K_t$ vs $D_{50}$ ($d_s=0.05$ m, $H_s \sim 0.10$ m)

Effect of $D_{50}$ and $T_p$ on $K_t$
Three dimensional test data showed similar trends in general but the scatter in the data was much more evident. The transmission coefficients were generally higher in the 3-D tests: this is attributed to a number of factors including diffraction of wave energy into the lee of the breakwater and reflection of wave energy from the testing apparatus. The results show that the relative submergence is the most influential factor under low submergence conditions while crest width is important under higher submergence conditions.

The effects of submergence depth, incident wave height and crest width are shown in Figure 9. This figure is based on the transmission coefficient immediately behind the midpoint of the breakwater with incident waves perpendicular to the structure.

![3-D Testing: Submerged Breakwaters](Image)

Figure 9: Typical 3-D Testing Results

The predicted values of the transmission coefficient for the 2-D test variables were generated using van der Meer's Equation for submerged and low crested breakwaters and Ahren's Equation for reef breakwaters, and are shown in Figures 10 and 11.

![Test Data vs. Ahrens' Equation](Image)

![Test Data vs. van der Meer's Equation](Image)

Figure 10: Predicted $K_t$ - Ahrens' Eqn.  
Figure 11: Predicted $K_t$ - Van der Meer's Eqn.
The results show that these equations are not suitable to represent transmission for structures tested in this study, particularly when the crest width is large. The inability of the existing design equations to predict suitable transmission coefficients for the tested conditions indicates that there is a need for an improved design equation.

4.0 Development of an Improved Design Equation

Previous investigations have indicated that $d_i/H_{m0i}$ is the most important dimensionless variable affecting transmission. This observation was supported by these tests. Numerous dimensionless variables considered, including variables discussed in previous authors works. Only those found to be significant in defining the transmission process are discussed here.

Dimensionless variables representing wave breaking, overtopping, frictional losses and internal flow losses were found to be important in defining the transmission process. These variables are discussed below.

i. The wave breaking process is considered to be represented by the dimensionless variable $d_i/H_{m0i}$ (relative submergence). The relationship between $K_t$ and $d_i/H_{m0i}$ for all of the 2-D test data is shown in Figure 12. The effect of relative submergence is very evident when $d_i/H_{m0i}$ is small. This is expected since the majority of waves are breaking and under breaking wave conditions, the unbroken wave (transmitted) has been found to be closely related to the water depth ($d_i$). Given the scatter, there are obviously other factors playing an important role in the process as well.

As the relative submergence increases, its influence is reduced substantially. This is expected as the relative portion of the incident waves which would break is reduced as the submergence depth increases.
The effect of overtopping is expected to be relatively important in defining the transmission coefficient at submerged breakwaters, especially under wave breaking conditions. As the relative submergence approaches zero, transmission at the submerged breakwater was observed to become a function of the potential for overtopping as well as transmission through the breakwater structure, in particular, the large armour crest material.

Typically, overtopping rates are a function of the wave steepness and structure geometry. A dimensionless form of the structure crest width and the local wave height \( \frac{H_{m0}}{B} \) was found to be representative of the overtopping effect.

As the wave passes over the breakwater, some energy is lost to frictional dissipation on the surface of the structure. The dimensionless variable representing this process was loosely based on the empirical Darcy-Weisbach expression for head loss. This requires the assumption that the flow velocity can be represented by the velocity of a gravity wave and results in the dimensionless variable \( \frac{d_{e}H_{m0}/BD_{s0}}{} \).

Flow within the breakwater structure will also result in some energy loss as a wave travels over a submerged breakwater. Given the relatively high porosity of the armour layer, the effect of the wavelength on the fluid velocity, the effect of submergence depth on the portion of flow within the armour layer and the effect of the crest width on the overall drag losses, the dimensionless variable selected to represent drag losses was \( \frac{Bd_{f}/LD_{s0}}{} \).

On the basis of these dimensionless variables, statistical fitting was used to develop a suitable design equation. A number of alternative equations were considered in an effort to develop a design equation which provided:

- a good statistical fit \( (R^2) \),
- a normal distribution of residuals,
- predictions which are well bounded (ie. \( 0.0 < K_r < 1.0 \)),
- physically relevant variables with a minimum number of fitted parameters

Through trial and error, a finalized form of the design equation was developed such that these criteria were generally satisfied for the 2-D test data.

\[
K_r = 1 - (e^{-0.06(d_{e}H_{m0}/H_{L})} - 0.047(\frac{Bd_{f}}{L D_{s0}}) - 0.067(\frac{d_{e}H_{m0}}{BD_{s0}}))
\]

The proposed equation fits the 2-D test data well, resulting in an \( R^2 \) value of 0.914. Given the uncertainty associated with the fitting of statistical parameters, all of the parameters of the proposed design equation were adjusted to their upper or lower 95% confidence.
interval values such the change in predicted $K_t$ value was maximized. The results, as shown in Figure 13 show that the prediction is not very sensitive to these changes and as a result, the prediction is relatively robust in its relation to the physical variables affecting the transmission phenomenon.

![Proposed $K_t$ Equation Sensitivity to Parameters (95 % C.I.)](image1)

Figure 13: Sensitivity to Parameter Estimates

Although the proposed equation does not fit the 3-D data as well, the prediction is still relatively good at low to moderate transmission coefficients (Figure 14).

![Fit of Equation for 3-D Test Data Est. $K_t$ vs Obs. $K_t$ Behind Breakwater](image2)

Figure 14: Observed vs Predicted $K_t$ - 3-D Tests

5.0 Conclusions

Based on an extensive set of 2-D and 3-D tests of wave transmission at submerged breakwaters, a number of conclusions can be drawn.

i. The transmission coefficient at submerged breakwaters is most sensitive to the
relative submergence \((d/H)\).

ii. The relative crest width is another very important factor which has not been adequately accounted for in previous design equations.

iii. An improved design equation for transmission at submerged breakwaters would be:

\[
K_t = 1 - (e^{-0.68 \frac{d_s}{H_i} - 1.09 \frac{H_i}{B_d}}) + 0.047\left(\frac{B}{L D_{50}}\right) - 0.067\left(\frac{d_s}{B D_{50}}\right)
\]  

iv. The proposed equation represents the comprehensive set of test data well \((R^2=0.914)\) and is robust in its relation to the physical variables which significantly affect the transmission process.

v. The equation is well bounded over the range of test data, which is considered to be representative of typical design conditions. The equation does, however, become unbounded when \(B\) becomes very large or very small due to the size of the 3rd and 4th terms. Therefore, it is recommended that caution be used when applying the equation outside of the following variable ranges.

\[
0 \leq \frac{B d_s}{L D_{50}} \leq 7.08
\]

\[
0 \leq \frac{d_s H_i}{B D_{50}} \leq 2.14
\]

VERTICAL CIRCULATION INDUCED BY A SUBMERGED BREAKWATER

Sánchez-Arcilla, A.¹, Rivero, F.², Gironella, X.³, Vergés, D.³ and Tomé, M.³

Introduction: The concept of submerged breakwaters

Submerged breakwaters are structures whose crest height is below the main water level. From a hydrodynamic standpoint this type of structures show significant differences in behaviour with respect to the emerged ones. As an illustration (figure 1), it is well known that the wave height field in the lee of a structure is significantly different for emerged or submerged breakwaters or even the way it varies with the wave height to free-board, H to F, ratio. Also from a hydrodynamic standpoint, the enhanced mass flux over the submerged breakwater may lead to erosion on the lee-side instead of the conventional accretion and resulting tombolo formation.

From a morphodynamic standpoint, submerged breakwaters induce lower profile mobilities in addition to helping building a perched beach. In general terms, since a submerged structure exerts a smaller barrier effect, the morphodynamic impact should also be smaller (see for some additional discussion the papers by Van de Graaf and Sánchez-Arcilla and others dealing with the results of the DYNBEACH research project as presented in the Coastal Dynamics 95 and 97 conferences).

Finally, this type of submerged structures are normally associated to smaller impacts (e.g. smaller visual impacts, smaller ecological impacts associated to an enhanced water renovation which is essential for a tideless sea as the Mediterranean, etc.)

To understand and model the hydrodynamic behaviour of submerged breakwaters a 3D nearshore circulation model (see e.g. (Svendsen and Putrevu, 1994), (Sánchez-Arcilla et al, 1992),etc) is required in combination with a wave

2014
propagation model able to deal with depth induced breaking and the geometry and porosity of the submerged breakwater. There is nowadays a number of nearshore circulation models, featuring relatively sophisticated "effects" such as the transition zone (Nairn et al, 1990) (Dally and Brown, 1995) the full matrix of wave induced shear stresses \( \langle u_i u_j \rangle \) (Rivero and Sánchez-Arcilla, 1993, 1996) or the mixing associated to vertical dispersion of the current -UV-terms (see e.g. Svendsen et Putrevu, 1994)-. However, these models cannot fully reproduce the experimentally observed hydrodynamic behaviour over a submerged breakwater. Some of the observational (Okayasu, 1989) (Rivero et al, 1997) features which these models cannot reproduce are: i) The mean water level gradient above the submerged breakwater, ii) The recirculation cell over the front slope of the submerged breakwater, and iii) The wave current interaction in front and above the submerged breakwater.

Figure 1. The differences in the vertically averaged circulation field induced by breaking waves in the presence of a shore parallel breakwater depending on whether it is an emerged or a submerged structure

The aim of this paper is to present the on-going development of a 2DV circulation model and a phase-averaged wave model to better understand the hydrodynamic behaviour of a submerged structure. The experimental information derived from previous research projects and the plans for a new set of mobile-bed tests with a submerged breakwater will also be presented.
Numerical modelling: the waves and currents around a submerged breakwater

i) THE WAVES

The wave model developed for the submerged breakwater case is an energetics one, based on the following equation:

\[
\nabla \left[ \left( C_g + U \right) \frac{E}{\sigma} \right] + \frac{D_b}{\sigma} + \frac{D_f}{\sigma} + \frac{D_p}{\sigma} = 0
\]

(1)

which states the conservation of wave action (due to the existence of strong currents above and in front of the submerged breakwater) considering the rates of "action loss" due to wave breaking, \( D_b \) (occurring on the up-slope of the submerged breakwater) bottom friction, \( D_f \) (because of the drag exerted by the submerged breakwater main armour units) and porous flow, \( D_p \) (due to the permeable flow inside the submerged breakwater).

The \( D_b \) term is evaluated using the (Battjes and Janssen, 1978) formulation for irregular wave tests and the (Dally et al, 1985) formulation for regular waves. Even though these formulae are intended for purely depth-induced breaking, all parameters are set to standard values. The maximum wave-height, \( H_m \), in (Battjes and Janssen '78) is calculated using (Tomé, 1997):

\[
H_m = \frac{2\pi Y_d}{k} \text{tanh} \frac{\gamma_s k h_b}{2\pi Y_d}
\]

(2)

where \( Y_d, Y_s \) are the deep and shallow water breaker indexes, to account for breaking waves of different frequencies (i.e. different \( h/L \) ratios).

The \( D_f \) term is evaluated according to (see e.g. Tolman, 1992)

\[
D_f = \frac{2\rho}{3\pi} f_w U_{arb}^3
\]

(3)

This term, although expected to be important above the submerged breakwater section, has not been analysed in any detail in this work. The friction coefficient used is a standard wave friction factor (see e.g. (Nielsen, 1992)).

The loss of energy (action) due to the existence of a permeable submerged breakwater is evaluated using (Sawaragi et Deguchi, 1992):

\[
D_p = \frac{D}{4} \beta_p C_g H^2
\]

(4)

where \( \beta_p \) corresponds to the imaginary part of the wave number and is a function (see (Sawaragi and Deguchi, 1992)) of:
with $d_{\text{porous}}$ the thickness of the porous layer (the lab tests described in next section use an impermeable core) and $K_p$ the permeability of such a layer.

The introduction of reflection in the proposed phased-averaged model - given essentially by equation (1) plus the corresponding dispersion relationship, including the current Doppler-shift - is accomplished using "external" linear superposition.

$$ \eta = \text{Re} \left( a \cdot e^{i(\alpha - \Delta \theta)} + R \cdot a \cdot e^{i\theta} \right) $$

where Re means "real part", $ae^{i(\alpha - \Delta \theta)}$ is the incident (regular) wave train, and $\Delta \theta$ is the phase lag between incident and reflected waves due to their travel above a bottom with variable slope (figure 2):

$$ \Delta \theta = 2 \int_0^x K dx $$

This expression coincides, for a plane sloping bottom, with the ones proposed by other authors (see e.g. (Méndez, 1997), (Sutherland and O’Donoghue, 1998)).

The reflection coefficient $R$ is written in terms of a modulus and a phase (the former expressing the ratio between reflected and incident wave heights and the latter the uncertainty about the exact point where reflection starts.)

Within this framework it is relatively straightforward, although cumbersome, to derive other wave properties such as (Méndez, 1997):

$$ U = \text{Re} \left[ -\frac{g}{w} \alpha \cdot f(z) e^{i(\alpha - \Delta \theta)} + \text{Re} e^{i\theta} \right] $$

$$ M_f = E \frac{K}{w} (1 - R R^*) $$

$$ S_{xx} = E \left( 1 + R_R^2 + R_f^2 \right) \left( 2 \cdot n - \frac{1}{2} \right) - R_R \cdot \cos \Delta \theta + R_f \cdot \sen \Delta \theta $$

where $n = \frac{1}{2} \left( 1 + \frac{2 \cdot k \cdot h}{\senh (2 \cdot k \cdot h)} \right)$

and where $M_f$ is the wave-induced mass flux and $R^*$ is the complex conjugate of $R$ (all other variables having their usual meaning in this context).
ii) THE DEPTH-AVERAGED CURRENTS

The mean water level variations, $\langle \eta(x) \rangle$, are derived from the vertically-averaged x-momentum equation:

$$\frac{\partial}{\partial x} \left( \int_{-h}^{0} u^2 \, dz \right) + \frac{\partial S_{xx}}{\partial x} + \rho g \left( h + \langle \eta \rangle \right) \frac{\partial \langle \eta \rangle}{\partial x} = \langle \tau_x \rangle - \langle \tau_b \rangle \tag{11}$$

Where $U = I + \alpha$, $\eta_{cr}$ is the crest level and the rest of variables are as usual in surf zone analyses. The $S_{xx}$ term has two contributions: $S_{xx} = S_{xx}^w$, waves + $S_{xx}^\alpha$, roller (see e.g. (Tomé, 1997)).

The conventional approach to evaluate $\langle \eta \rangle$ in beach surf-zones is to neglect the convective term $(u^2)$ and the $\tau_x$ and $\tau_b$ so that the x-momentum equation becomes:

$$\frac{\partial S_{xx}}{\partial x} + \rho g \left( h + \langle \eta \rangle \right) \frac{\partial \langle \eta \rangle}{\partial x} = 0 \tag{12}$$

However, in front and above the submerged breakwater, according to the (laboratory) experimental evidence the $u^2$ terms cannot be neglected, since $U$ is large near the submerged breakwater and the $\frac{\partial}{\partial x}$ of $u$ is also large. This term is thus
retained, assuming a uniform undertow distribution below \( \langle \eta \rangle \) and a 1DV local mass balance (i.e. the mass flux above \( \langle \eta \rangle \) cancels the undertow). With this, the convective term can be evaluated as:

\[
\langle \int_0^{\eta_{cr}} \rho u^2 dz \rangle = \int_{\eta_0}^{\langle \eta \rangle} \rho U^2 dz + \int_{\langle \eta \rangle}^{\eta_{cr}} \rho u^2 dz = \frac{Mf^2}{\rho (h + \langle \eta \rangle)} + aMf^2
\]

with \( a = \frac{64}{3\pi \rho H} \)

iii) SOME RESULTS

A sample of the wave and mean water level results so obtained is shown in figure 3 for regular waves. The wave-height variation appearing in figure 3a) shows the oscillatory behaviour typically associated to the superposition of an incident and a reflected wave. The \( \langle \eta \rangle \) variation with \( x \) follows reasonably the experimental results although under-estimating the set-up in the downward slope of the submerged breakwater.

The results “without” reflection appear in figure 4 and show that the model without reflected waves is not able to predict the spatial oscillations of H in front of the submerged breakwater.

The mean water level predictions, although comparable, also tend to improve “with” reflection in the sense that an enhanced set-up is predicted (by the “full” model) in the downward slope.

The effects of the convective term (figure 5) affect basically the \( \langle \eta \rangle \) predictions. The introduction of the \( u^2 \) term allows a deeper “trough” in \( \langle \eta \rangle \) right at the beginning of the submerged breakwater crest just as it appears in the observations. The increased set-up right after the submerged breakwater is however not fully reproduced.

The same trends in results are obtained for irregular waves although in this case the H and \( \langle \eta \rangle \) predictions are far better than the \( Q_b \) results. It should be, however, remarked that the fraction of breaking waves (determined visually from video recording of the experiments) is being used far beyond its intended original applicability. The overall agreement between observations and predictions for H and \( \langle \eta \rangle \) is however satisfactory.
Figure 3. Sample results of the wave-height field and associated MWL for the "full" model presented in section 2 and the geometry depicted in the figure.

Figure 4. Same results as in figure 3 but without the reflection mechanism for the wave model (dashed line).

Figure 5. Same results as in figure 3 but without the convection terms in the \( \langle \eta \rangle \) equation (dashed line).
iv) SOME REMARKS ON THE 2DV CURRENT FIELD

The 2DV current problem is being solved with the corresponding mass and momentum equations, using $\sigma$-co-ordinates so as to have the same vertical resolution for all water depths (i.e. well in front of the submerged breakwater or right above it).

The preliminary obtained results are based on the following x-momentum equation:

$$ u \frac{\partial u}{\partial x} + w \frac{\partial w}{\partial z} + \frac{1}{\rho} \frac{\partial P}{\partial x} = - \frac{\partial}{\partial x} \langle u^2 \rangle - \frac{\partial}{\partial z} \langle uw \rangle + \frac{\partial}{\partial z} \left( \nu_r \frac{\partial u}{\partial z} \right) $$

(14)

where the pressure is evaluated by

$$ P = \rho g (\eta - z) - \rho \langle \tilde{w}^2 \rangle $$

(15)

and the x-derivative mixing term has been neglected (due to the expected greater vertical variations in flow properties).

The obtained results show a relatively high sensitivity to the bottom and mean water level boundary conditions, given by the corresponding shear stresses at $\langle \eta \rangle$ (associated essentially to the wave decay due to breaking, see e.g. (Sánchez-Arcilla et al., 1992), (Sánchez-Arcilla et al., 1994) ) and at $z_h$ (associated to the experienced bed friction due to the drag exerted by the submerged breakwater plus the flow inside of it). These preliminary results appear also to be quite sensitive to the $\langle \tilde{u}, \tilde{u} \rangle$ wave shear stresses, in the sense that the resulting circulation field could feature or not a recirculation cell in front of the structure.

Because of this, the focus here will be exclusively on the evaluation of the wave stresses for the case of a sloping bottom with a submerged structure.

In general, the wave shear stresses, for the x-momentum equation, $WSS_x$, are given by:

$$ WSS_x = - \frac{\partial}{\partial x} \langle \tilde{u}^2 \rangle - \frac{\partial}{\partial z} \langle \tilde{u} \tilde{w} \rangle $$

(16)

There will be a non-zero contribution to $WSS_x$ whenever there is a spatial variation of the wave-height field. For the case of a sloping-bottom with a submerged structure there are two physical origins for these $H$ variations:

a) The shoaling/breaking processes, for which

$$ \frac{\partial \langle \tilde{u} \tilde{w} \rangle}{\partial z} = \langle \tilde{u} \tilde{\delta} \rangle - \frac{1}{2} \left[ \frac{\partial}{\partial x} \left( \langle \tilde{u}^2 \rangle - \langle \tilde{w}^2 \rangle \right) \right] = \frac{1}{2} \left[ \frac{\partial}{\partial x} \left( \langle \tilde{u}^2 \rangle - \langle \tilde{w}^2 \rangle \right) \right] $$

(17)
according to (Rivero and Sánchez-Arcilla, 1995) and assuming that the oscillating motion has no vorticity, \( \vec{\omega} \) (even for the breaking wave case).

With this, the resulting shear stresses, \( WSS_{SB} \), are given by:

\[
WSS_{SB} = -\frac{1}{2} \frac{\partial}{\partial x} \left( \frac{H gT^2}{L} \right) \left( \frac{ch(2kz)}{ch^2(kh)} \right)
\]  

(18)

The order of magnitude of \( WSS_{SB} \) is \(-0.1\) m/sec\(^2\) for shoaling waves and +0.1 m/s\(^2\) or greater for breaking waves (governed by a saturation law of the type \( H_b = \gamma h \)). For more details see (Vergés and Sánchez-Arcilla, 1998).

b) The reflection processes for which (assuming a horizontal bottom), the corresponding shear stresses, \( WSSI_R \), are given by:

\[
WSSI_R = -\frac{kH^2w^2}{4} \frac{\sin 2kx}{sh^2(kh)}
\]  

(19)

This term turns out to be, thus, a function of 2kx which represents the phase-lag between reflected and incident waves (Vergés and Sánchez-Arcilla, 1998). It is due to the fact that the correlations between incident and reflected wave velocities need not be necessarily 0:

\[
\langle \vec{\omega}_i \vec{u}_r \rangle \neq 0 \neq \langle \vec{u}_i \vec{\omega}_r \rangle
\]  

(20)

The order of magnitude of the modulus of this term is around 0.5 m/s\(^2\).

The \( WSS_x \) term for the general case of sloping bottom with submerged breakwater can therefore be written as (Vergés and Sánchez-Arcilla, 1998):

\[
WSS_x = (1 + K_R^2)WSS_{SB} + K_RWSSI_R
\]  

(21)

where \( K_R = \frac{H_R}{H_I} \) is the reflection coefficient.

Model testing: The fixed and mobile bed experiments.

i) RIGID-BED TESTS

A set of hydrodynamic tests to analyse the submerged breakwater hydrodynamic performance and “impact” have been performed in a number of recent research projects carried out at the LIM/UPC. The tests, which are now beginning to be fully processed, cover a range of \( H/L_0 \) (wave steepnesses) and \( F/H \) (relative freeboard) values (figure 6). For most of the tests twelve “verticals” were obtained (figure 7). Each vertical was instrumented with 5 electromagnetic currentmeters and 6 pressure sensors.
The preliminary results show transmission coefficients, \( K_T \), in close agreement with state of art predictions (see e.g. (Van der Meer, 1990)). The dependence of \( K_T \) on \( F/L_0 \) (freeboard over the deep-water wavelength) rather than on \( F/H_{in} \) (as is usual in the state of art) allows improved predictions and a “clearer” variation with the wave steepness \( H/L_0 \) (figure 8). From this type of analysis it is
possible to derive engineering formulae for the design of submerged breakwaters such as:

\[ K_T = K_T(I_r)_{F=0} + f(I_r)\frac{F}{L_0} \]  

(22)

This expression shows that \( K_T \) starts-for \( F=0 \)- with a value (a function of Irribaren's parameter) for submerged breakwaters reaching the mean water level, and then \( K_T \) increases linearly with \( F/L_0 \), the slope being also a function of Irribaren's parameter, \( I_r \). The same type of analysis can be applied to e.g. the reflection coefficient or, in general, the hydrodynamic behaviour of the structure.

The observed circulation fields also display the expected features (e.g. a strong return flow over the crest of the structure, enhanced with respect to a real submerged breakwater since in the flume there must be 1DV mass flux compensation) plus some less "obvious" characteristics, such as the vortex in the up-ward slope of the structure.

**ii) MOBILE BED TESTS**

The mobile bed tests will be carried out as part of the MAST-III SCARCOST project whose main aim is, in this context, to analyse the hydrodynamic behaviour of the submerged breakwater and, in particular, the scouring in front of it.
The tests, scheduled for the 2nd term of 1999, will "repeat" the geometry, wave and "free-board" conditions tested for a rigid bed. This will allow to concentrate on the hydrodynamics in front of the structure and the associated bed evolution (figure 9). The observations include, as shown in the figure, free-surface elevations in front and over the structure, the current field in front and on the upward slope and pore pressures in the sand in front of the submerged breakwater. A PIV system, recently implemented in the CIEM flume of the LIM/UPC, will also be used to record the spatial velocity field in front of the structure and, in particular, in the vicinity of the scouring section.

Each of the mobile bed tests will have a minimum of 15,000 waves so as to allow for a "reasonable" development of the scouring in front of the structure (see e.g. (Herbich et al, 1984)).

The expected results will allow a characterisation of scouring as a function of hydrodynamic conditions and also the derivation of practical recommendations for the design of submerged breakwaters.

Conclusions: what has been done and remains to be done.

The following conclusions must be considered as on-going remarks since a large part of the experimental work is still to be processed and parts of it (mobile bed tests) even to be done. The numerical simulations are in a similar position since the adaptation of existing models for the submerged breakwater case is still very much under development.
Within this frame, the main on-going conclusions are the following:

i) The hydrodynamic performance of submerged breakwaters is quite sensitive to the design parameters. This requires careful selection and analysis since otherwise the submerged breakwater may not behave as expected (e.g. it could hardly affect the incoming waves) or even have contrary effects (e.g. enhanced erosion in the lee-area due to enhanced mass flux over the structure).

ii) The wave modelling with the submerged breakwater geometry appears to require a reflection coefficient "modulus" (to account for the decrease in $H_r$) and a reflection coefficient "phase" (to account for the exact origin of reflection). The same (i.e. real and imaginary parts) happens with the wave number, whose imaginary part is required to account for the energy loss in the porous (granular) layer.

iii) The current modelling appears to require the convective terms for the accurate predictions of set-up variations and the full "wave" stresses (due to the sloping bottom and the co-existence of incident and reflected wave fields) for the correct simulation of the current pattern.

Acknowledgements.

The authors would like to acknowledge the Spanish CICYT for sponsoring part of the rigid bed tests. The SCARCOST (Mast III) project partly supports the mobile bed tests and the COAST-3D (Mast IIII) project partly supports the theoretical development for the wave modelling. The authors also want to acknowledge the discussions and exchange of ideas with researchers from the Escuela de Caminos de Santander and, in particular, Drs. I. Losada and F. Mendez.

References

Abstract

The results are presented of 2DH numerical modelling of morphological effects of submerged breakwaters. In particular, segmented configurations are focussed upon, since segmented submerged breakwaters induce interesting and important current circulations in the horizontal plane.

In a previous study, a module that calculates a phase-averaged stationary wave field was used to compute wave forces. These forces were next used to calculate current patterns. In the present study, waves are introduced via a harmonic boundary condition in a phase-resolving module, based on the nonlinear shallow water equations. The advantage of this approach is that the current patterns are directly calculated, the disadvantage is that it requires more computation time.

The first results of morphodynamic computations with submerged breakwaters, in intra-wave mode, are promising. The most important mechanisms are reproduced rather well. Some of the shortcomings of the previous model study with a stationary wave model have been overcome. However, a lot of fine tuning still needs to be done.

1. Introduction

Submerged breakwaters are detached, mostly shore parallel, structures with their crest below water level. Their purpose is twofold. Firstly, submerged breakwaters 'filter' waves, by causing larger waves to break and leaving smaller waves more or less undisturbed. Secondly, they block offshore transport of sediment.

In Italy, submerged breakwaters have been used at various locations (Lamberti and Mancinelli, 1996; Tomasicchio, 1996). Their economic and aesthetic (Liberatore, 1992; Ozaki and Mitushashi, 1993) advantages compared to emerging breakwaters make submerged breakwaters an attractive tool for coastal management.

However, specially in case of the segmented configuration, one should be prepared for large sediment losses through the gaps due to concentrated offshore flow (Browder et al., 1996). A special (and expensive?) design of the structure may solve
this problem (Nobuoka et al., 1996). In any case, extensive numerical and physical modelling are recommended for a proper implementation (Smith et al., 1995).

2. Basin experiments

At the Laboratory of Fluid Mechanics of Delft University of Technology, small scale 3D basin experiments with segmented submerged breakwaters were carried out (De Later, 1996; Van der Biezen et al., 1996). Aim of the experiments was to obtain a data-base for numerical modelling studies. A movable bed was used to include morphological effects of the structures. The measurements focussed on morphology rather than on hydrodynamics. Apart from Delft University of Technology, five other universities participated in this research project, which was funded by the Human Capital and Mobility Programme of the EU.

At the Hydraulic and Maritime Research Centre in Cork, Ireland, hydrodynamic parameters were measured in similar tests with a fixed bottom (Murphy et al., 1996). Apart from these basin tests, flume experiments were carried out as well by other universities. Detailed information on the project is included in the Test Definition Report (Høgedal et al., 1994).

2.1 Experimental setup

In the wave basin (length = 28 m, width = 14 m, depth = 0.60 m), three series of test were carried out: one series without structures, one series with three separate breakwaters of 6 m length each (two gaps of 3 m in between) and one with two breakwater segments of 12 m and 6 m length with only one gap of 3 m in between. In each series three different wave heights were generated: 0.08 m, 0.10 m and 0.12 m. The generated wave field was regular and normal incident to the beach, with a wave period of 1.55 s. The initial beach slope for each test was 1:15. Figure 1 shows a plan view of the wave basin for the configuration with three submerged breakwaters (all measures in meters).

Figure 1. Plan view of the wave basin with three submerged breakwater segments.
All experiments were conducted with a rubble mound breakwater with an impermeable core and 2:3 slopes on both sides. The armour layer of the prototype breakwater consisted of two layers of rock stones, $D_{50} = 0.812$ m. The crest width was chosen as $3D_{50}$ and the thickness of the armour layer as $2D_{50}$. The water depth at the seaward toe of the breakwater equals 6 m and the breakwater submergence equals 1.5 m.

Scaling the prototype breakwater with a 1:15 ratio yields the measures given in Figure 2. The submergence of the breakwater crest is constant for all tests.

![Figure 2. Submerged breakwater design](image)

The structure is placed on a concrete slope. The profile landward of the structure consists of sediment with a grain size $D_{50}$ of 95μm.

### 2.2 Measured parameters

The experiments lasted 7:30 h each, interrupted by several profile measurements. The first profile measurement is at $t = 0:00$ h, the initial profile. The next measurements are at $t = 0:30$ h, $t = 1:30$ h, $t = 3:30$ h and, finally, at $t = 7:30$ h. During the profile measurements the wave generator was stopped.

Apart from the profile height, velocities in the horizontal plane and free surface elevations were measured. The time series were taken at different cross-sections. For more details, reference is made to Van der Biezen et al. (1996).

### 2.3 Measurement results

The measurement results presented here only intend to illustrate the measurement data used for the numerical study. For each measured parameter a short explanation is given.

Figure 3 shows two examples of measured wave heights, for a generated wave height of 0.12 m. The left plot shows wave height measurements for an experiment without submerged breakwaters, and the right plot shows measurements in a cross-section with a submerged breakwater.

Free surface elevation was measured at four cross-shore locations. From the time series, an average wave height was calculated using the standard deviation of all samples. Although the hydrodynamic measurements are not detailed, the influence of the submerged structure on the wave heights is clearly visible.
Current velocities in the horizontal plane were measured at several cross-shore locations. Figure 4 shows depth averaged currents, averaged in time over the first 1:30 h of the experiment to obtain the overall current pattern. The waves propagate top-down in this figure.

The velocity measurements show offshore directed currents towards and through the gaps between the breakwater segments. This leads to significant sediment losses, as illustrated by Figure 5 which shows the bathymetry of the basin with three breakwater segments after 7:30 h of wave action.

Figure 3. Measured wave heights with and without a submerged breakwater

Figure 4. Measured currents, magnitude and direction

Figure 5. Measured bathymetry after 7:30 h of wave action
3. 2DH Morphological Modelling, phase averaged

In 1997, a first attempt was made to reproduce the experiments with a numerical model (Schaap 1997, Torrini 1997, Van der Biezen et al. 1997). The package used for this study was Delft3D, developed by Delft Hydraulics. Delft3D consists of several modules, which can be combined so that it suits the case of interest. Only a few aspects of this previous study are mentioned, more details can be found in the given references.

3.1 The model system

Without going into detail (details on Delft3D can be found in the Manual, 1996) the combination of modules applied in this first study is given in Figure 6.

![Figure 6. Model system including a wave field module](image)

The computation starts with the calculation of the stationary wave field (module 1) for the given boundary conditions and initial bathymetry. Wave diffraction, which is not included in this module, is represented by directional spreading. Relevant output of module 1 (e.g. wave forces) is written to a communication file. Secondly, the currents are calculated by module 2, which needs information from the communication file. The current field is again written to the communication file. Module 2 takes most of the computation time.

Next the morphological procedure can be run. Module 3 calculates a velocity field from the discharge data in the communication file, with a correction of the total flux velocity for the mass flux by waves. Sediment transports are calculated using the Bijker formula with wave effect. Module 4 updates the bathymetry and adds the new bathymetry to the communication file.

From a stability consideration, the allowed morphological timestep can be determined. Several morphological timesteps can be processed (sequence of modules 3 and 4) without the need to update the current field (and to run module 1 and 2). In this case new velocities corresponding to the updated bottom are calculated from the last discharge data using a continuity relation.

3.2 Waves

The Delft3D-wave module calculates a stationary wave field, which includes wave heights, setup, energy dissipation etc. Figure 7 shows the calculated wave setup for a two-breakwater-segments case. Setup behind the structures is a consequence of energy dissipation by friction and by wave breaking. The resulting setup gradients,
together with the level increase due to mass transport of water over the breakwater crests, are the driving mechanisms for the return flow through the gaps as illustrated in Figure 8.

3.3 Currents

The wave forces in the communication file are used to calculate currents. The measured horizontal current pattern, see Figure 4, appears to be well reproduced by the pattern calculated by module 2, see Figure 8. Waves propagate top down; the circulation cells with offshore directed flow through the gaps are clearly present.

3.4 Morphology

The calculated morphologic changes are, to some extent, in accordance with the measurements. The sediment loss through the gaps between the breakwater segments is well reproduced. However, there are also large discrepancies.
Figure 9 gives the calculated bottom after 3:30 h (approximately half of the experiment duration) which shows large local scour at the waterline and at the landward toe of the structure.

![Figure 9. Calculated bathymetry after 3:30 h wave action](image)

The local scour landward of the submerged breakwater follows from a peak in energy dissipation calculated by the wave module. In the experiments, energy was dissipated over a longer distance by spilling breakers. Furthermore, the wave module was not specifically developed to handle a regular wave field.

The unrealistic (computed) scour at the waterline is due to the inability of the model to change ‘dry’ grid points into ‘wet’ gridpoints. Since the initial slope is quite steep, this shortcoming has important consequences.

4. 2DH Morphological Modelling, phase resolving

Since the above shortcomings are related to the use of the wave module, and since the experiments are carried out with regular waves, it was decided to try the harmonic boundary option in the flow module for wave generation instead of the wave module. Normally, this option is used to introduce the tide in a simulation.

Delft3D-flow solves the non-linear shallow water (NSW) equations. This implies, amongst others, that a hydrostatic pressure is assumed, which is correct in case of tidal waves. In case of short waves this is usually not so, since vertical accelerations in the water column disturb the hydrostatic pressure.

The waves generated in the basin, however, approximate shallow water waves to a large extent. In the deepest part of the wave basin, the wave celerity that follows from the linear wave theory (with hyperbolic functions) equals 1.99 m/s. The shallow water wave celerity, calculated by the model, equals 2.36 m/s which is only 19% too high. This percentage will even be less in the area of interest, near the structures.

An alternative to the nonlinear shallow water equations, solved in this study, are the Boussinesq equations which can be applied to a larger part of the coastal region. An advanced model based on these equations is discussed by Madsen et al. (1997). In the present study, however, a NSW approach was chosen for the reason that sediment transports and morphology needed to be included.
4.1 The model system

The model system as described in section 3.1 is now changed, since the wave module will not be used during computation. The new model system is given in Figure 10.

Figure 10. Model system without wave module

In the sections below, the output of each module will be discussed according to their computational sequence during a model run.

4.2 Waves

The simulation starts with the calculation of the wave propagation in the basin (with initial bathymetry) induced by a harmonic boundary condition. In contrast with the previous study, the output does not consist of one stationary wave field. Instead, for each grid point now a time series containing water levels and current data is written to the communication file.

Consequently, the flow in the basin is not calculated separately, like in the previous study, but follows directly from the time-averaged velocity fields stored in the communication file. The same holds for the setup (time averaged water levels).

The calculation of wave propagation is continued until any start-up effects have disappeared. Figure 11 gives an example of calculated water levels in a particular cross-section at different time steps just after the start of a simulation.

Figure 11. Calculated water levels for different time steps
The influence of the submerged breakwater on the wave height is clearly visible in Figure 11. It is remarked that this approach also includes wave reflection, wave diffraction and, most important, wave runup. Wave runup is responsible for erosion of the dry beach.

The front of the waves tends to become steeper during their propagation towards the breakwaters. To ensure that the wave, once it reaches the structure, has a proper shape, the incoming wave at the boundary was modified to anticipate for the steepening of the wave front. Furthermore, a discharge boundary instead of a water level boundary was chosen since it corresponds more to the motion of the wave paddles.

The parameters used for calibration are the horizontal viscosity and the roughness length. The viscosity was found to be smaller than the default value and the roughness length needed to be enlarged: \( \nu_H = 0.01 \text{ m}^2/\text{s} \) and \( k_s = 0.5 \text{ m} \), where \( k_s \) is the Nikuradse roughness length used in White Colebrook's friction formulation. Specially \( k_s \) is large, to obtain enough wave decay. Figure 12 shows some calibration results for a section with and a section without a submerged breakwater.

![Figure 12. Measured and calculated wave heights](image)

Figure 12 shows that the measured wave heights are reproduced quite well; the calibration parameters are somewhat out of range, though. Some wave height variation seewards of the submerged structure can be seen. This is due to reflection of wave energy. The calculated wave set-up shows the presence of interfering waves, both in cross-shore and in longshore direction, see Figure 13. The waves propagate from left to right in this figure and two submerged breakwater segments are present.

![Figure 13. Wave setup [m] calculated from water level time series](image)
Figure 13 also shows a wave setup landwards of the submerged breakwaters, which is in accordance with the output of the wave module in the previous study, see Figure 7 in section 3.2.

4.3 Currents

As mentioned before, the net current pattern as well as the setup can be obtained by averaging respectively the velocity and water level time series over a number of wave periods. The resulting net current pattern looks similar to Figure 8.

4.4 Transports

The sediment transports are computed from discharge fields, stored in the communication file. With use of the bathymetry, first time varying velocity fields are computed from which time varying sediment transports can be calculated. To obtain the net sediment transports, again a time average over a number of wave periods is taken.

The Bijker sediment transport formula is used to calculate sediment transports from the velocity components. However, since the wave module is not used, no wave effect could be included. This reduces the Bijker transport formula to a combination of the Kalinske-Frijlink formula for bed load transport, the Rouse-Einstein expression for the sediment concentration distribution and the Einstein expression for the suspended sediment transport. Since this combined formula is applied within the wave periods (intra-wave), the wave effect is more or less included via the individual discharge fields.

An example of an intra-wave sediment transport field is given in Figure 14.

![Figure 14. An individual intra-wave sediment transport field](image)

The waves propagate top-down in this figure. Large onshore sediment transports can be seen at the lee side of the structures and offshore transports through the gaps. Other sediment transport fields show a similar pattern.
4.5 Morphology

As mentioned before, one of the advantages of the present NSW approach is the calculation of wave runup. This opens a way to include erosion near and above the waterline.

The transport module uses a parameter that influences the downslope transport by gravity. A higher parameter value yields a smoother profile. Also, a high value increases the transport of sediment from dry to wet grid points near the water line, because at the water line steep slopes tend to occur. As soon as the begin and end grid point of a local slope are both wet, downslope sediment transport takes place. For one cross-section, the profile development including the calculated behaviour near the waterline is given in Figure 15.

![Figure 15. Calculated profile development](image)

With the adjusted parameter for downslope sediment transport, full morphologic runs were made. Since the required computation time is large, only the first 3:30 h of the total duration of the experiments was computed. The runs presented here all have an initial wave height of 0.12 m.

Figure 16 shows the calculated erosion and accretion during a 3:30 h simulation with two submerged breakwaters.

![Figure 16. Calculated erosion and sedimentation after 3:30 h](image)
In this figure, erosion is negative and accretion is positive. The figure shows erosion at the waterline and at the landward toe of the submerged breakwaters. Accretion occurs in the area between the structures and the waterline, because of the 'flattening' of the initial profile which is quite steep (1:15). Furthermore, sediment is deposited seawards of the gaps.

Figure 17 shows a 3D image of the calculated bathymetry after 3.5 h wave action with two submerged breakwaters.

Figure 17. Calculated bathymetry after 3.5 h for two submerged breakwaters

Figure 18a. Comparison for a section with submerged breakwater
Specially at the waterline and at the landward toe of the structure, the shallow water approach seems to be more accurate.

5. Conclusions and Recommendations

From the above presented numerical study on segmented submerged breakwaters, the following conclusions can be drawn:

- Numerical modelling of submerged breakwaters describing waves with the non-linear shallow water equations yields promising results. The calculation time, however, increases compared to simulations which use a stationary wave field.
- The measured wave height decay over a submerged breakwater is predicted well when using the shallow water approach, although somewhat unusual values have to be used for bottom roughness and horizontal viscosity.
- When modelling morphology around submerged breakwaters, it is of importance to describe the erosion near the water line correctly. The study shows that the intra-wave approach is more accurate on this aspect. However, both approaches require further study.

The shallow water assumption opens new possibilities regarding morphological modelling of submerged breakwaters. The present research has been a pilot study into this field. A lot of fine tuning still needs to be done. Other sediment transport formulas should be tried, and the description of the transport processes near the water line needs more attention. Furthermore, extra measurement data bases would be useful for calibration purposes.

WAVE PRESSURE DISTRIBUTION ON PERMEABLE VERTICAL WALLS

Hendrik Bergmann\textsuperscript{1}, Hocine Oumeraci\textsuperscript{2}

Abstract

The pressure distribution at permeable vertical walls is investigated within a comprehensive large-scale test programme considering experiments with a variation of wave parameters and structure porosities. Monochromatic non breaking and slightly breaking waves on such structures are examined and results are compared to the GODA formula for impermeable vertical walls and a modified GODA method which has been developed here for permeable walls. Two parameters involving the structure porosity are introduced to account for the nonlinear processes at permeable walls. Using these parameters new prediction formulae have been derived for the pressure distribution at the wall.

1. Introduction

The advantages of permeable vertical wave barriers are obvious in terms of wave damping performance, reduction of wave reflection, overtopping and forces. Wave damping is of fundamental importance for the protection of harbours and marinas. Rubble mound structures can be used if there are no limitations in space and in case of shallow water depth, otherwise vertical structures may be favoured. However, impermeable vertical structures result in considerable wave reflection which can cause navigation problems in harbour entrances for smaller vessels. Therefore, it might be advisable to use perforated structures which allow to better control wave transmission and reflection. In this case reliable information on wave loads and pressure distribution on the permeable wall is needed for stability analysis and design.

The most widely used pressure formulae for the design of coastal structures with vertical walls under breaking and non breaking wave conditions are the GODA

\textsuperscript{1} Dipl.-Ing., Research Assistant, Leichtweiss-Institut, TU Braunschweig, Beethovenstr. 51a, 38106 Braunschweig, Germany, e-mail: h.bergmann@tu-bs.de

\textsuperscript{2} Prof. Dr.-Ing., University Professor, Managing Director of Leichtweiss-Institut, TU Braunschweig
However, these formulae do not account for a wall porosity so that reduction coefficients can only be estimated by engineering experience or obtained from hydraulic model tests. Therefore, the hydraulic performance and the pressure distribution of single permeable vertical walls was investigated within a comprehensive large-scale test programme. The extension of the existing formulae in terms of structure permeability was performed considering experiments in intermediate water depth with different wave conditions and structure porosities. For this paper only non breaking and slightly breaking waves on such structures were examined and results are compared to the GODA method for impermeable walls. Two dimensionless parameters involving the structure porosity were introduced to account for the nonlinear processes at permeable walls.

2. Experimental Set-up and Test Conditions

The tests were conducted in the Large Wave Flume (GWK) of the Coastal Research Centre, a joint institution of the University of Hannover and the Technical University of Braunschweig. The flume has a length of 320m, a width of 5m and a depth of 7m (Fig. 1). A sand beach with a slope of 1:6 was installed about 220m from the wave paddle for the dissipation of transmitted wave energy. The vertical permeable wall, made of horizontal steel bars was located about 100m from the wave paddle.

![Cross Section of the Large Wave Flume (GWK) with Positions of Permeable Wall and Wave Gauges.](image)

The incident waves, wave transmission and wave reflection were analyzed by wave gauges which were grouped in three harps (one in the far field, one in front and one behind the structure) with 4 wave gauges each. Additional wave gauges were installed to measure the water surface elevation and the water level gradient directly at the permeable wall.

The tests were carried out with regular waves ($H=0.5\text{-}1.5m$ and $T=4.5\text{-}12s$), random waves ($H_s=0.5\text{-}1.25m$, $T_p=4.5\text{-}12s$), solitary waves ($H=0.5\text{-}1.0m$) and transient wave packets. The water depth was kept constant ($d=4.0m$) in the test phase with permeable walls but was varied between 3.25 and 4.75m for the impermeable wall tests ($P=0\%$). Due to the structure height of approximately 6m, overtopping is negligible.

The structure porosity $P=s/e$, with gap spacing $s$ and distance $e$ between two ad-
Figure 2: Definition of Structure Porosity $P = s/e$.

Figure 3: Locations of Pressure Transducers and Load Cells for a Permeable Wall with Porosity $P=26.5\%$.

In order to analyze the resulting wave loads pressure transducers of type NATEC SCHULTHEISS PDCR 830 were installed at 10 positions at the front and rear side of the structure. Fig. 3 shows the front view of the wall (porosity $P=26.5\%$) with locations of the pressure transducers over the structure height. The resultant pressures were calculated by adding the two pressure components on both sides of the wall elements which were equipped with pressure cells (Fig. 4). Data were recorded at 200Hz logging frequency.
3. Experimental Results and Discussion

The hydrodynamic pressure distribution under wave attack at the front of a vertical impermeable structure can be described by the water surface elevation $\eta^*$ above still water level, the pressure $p_1$ at still water level (SWL) and the pressure $p_2$ at the toe of the structure (GODA, 1985). For the vertical walls tested in the GWK (2D-case, normal incidence of waves, no berm) the equations for the characteristic values (Fig. 5) described by GODA can be simplified to:

\[ \eta^* = 1.5 \cdot H_i \]  
\[ p_1 = \alpha_1 \cdot \rho \cdot g \cdot H_i \]
with $\alpha_1 = 0.6 + 0.5 \cdot \left( \frac{(4\pi d/L)}{\sinh(4\pi d/L)} \right)^2$ \hspace{1cm} (3)

\[ p_2 = \frac{1}{\cosh(2\pi d/L)} \cdot p_1 \] \hspace{1cm} (4)

The tests considered in this paper were run with monochromatic waves. The wave height $H_i$ describes the mean incident wave height and $L$ is the local wave length at the structure.

Fig. 6 shows the measured pressure heads at the front and at the rear side for different structure porosities. Results are shown exemplarily for an incident wave height of $H_i=0.80m$ and a wave period of $T=8s$ for all porosities investigated. In addition, the calculated pressures (Eq. (1) - Eq. (4)) on an impermeable wall are also plotted. The graph represents a) the pressure distribution acting simultaneously on the front face of the wall and on the rear side of the wall (left side) and b) the resultant pressures (right side) for the time step where the maximum total force on the structure occurred (wave crest). The total horizontal force was obtained by integration of measured resultant pressures over the structure height for every time step.

Figure 6: Simultaneous Pressure Distribution on Front and Back Side (a) and Resulting Pressure Distribution (b).

Generally, all measurements show a similar profile compared to the GODA distribution, but the influence of the wall porosity is obvious. At the structure front
face higher pressures $p_1$ are observed for low structure porosities ($P=11\%$), whereas on the rear side of the structure the higher pressures occur for large values of structure porosity ($P=40.5\%$). Due to the reduction of pressure at the structure face and the increase of pressure at the rear side of the structure the resulting pressure values are even more reduced when compared to the calculated pressures for an impermeable wall (Fig. 6, right). Hence, in the case of a permeable wall the resulting pressure values $p_{1,res}$ and $p_{2,res}$ are the governing pressures for the calculation of the total loading of the structure. The resulting pressure values are calculated as described above (see also Fig. 4) and used for further analysis. In addition it is apparent from Fig. 6 that the wave run-up at the structure is overestimated by Eq. (1). In the following the aforementioned characteristic values will be discussed in terms of the porosity of the wall.

### 3.1 Maximum Surface Elevation at Structure Front $\eta^*$

The linear relationship between run-up height and wave height (Eq. (1)) is not appropriate for the description of the physical processes at the structure face. In fact, ratios $\eta^*/H_i$ measured in the Large Wave Flume varied between 0.56 and 1.32 for $P=40.5\%$ to $P=0.0\%$, respectively. The maximum wave run-up at the structure front ($\eta^*$) is governed by the influence of shallow water depth (function of $d/L$) and the reflection properties of the structure which is directly related to the reflection coefficient $C_r$ and the structure porosity $P$. The influence of the structure porosity $P$ is considered by the reduction parameter $\Psi_e$. The surface elevation at the structure face can be determined as:

$$\eta^* = \Psi_e \cdot \left[2 - \tanh\left(\frac{4\pi d}{L}\right)\right] \cdot H_i$$

where the reduction parameter $\Psi_e$ is defined as a function of the wall porosity $P$:

$$\Psi_e = \left(1 - 0.5 \cdot \sqrt{P}\right)$$

The correlation between measured and calculated $\eta^*$-values is relatively good, although the wave run-up at the structure is slightly overestimated for small waves but underestimated for large waves (Fig. 7). This nonlinear process in terms of the wave height and the influence of the reduction parameter $\Psi_e$ will be discussed more thoroughly under Section 3.2.2.

### 3.2 Pressure Distribution at Structure

In Fig. 8 all measured resultant pressure values $p_{1,res}$ (at SWL) under different wave conditions (regular waves) are shown in comparison with results using the GO-DA formula for impermeable walls. The influence of the structure porosity is significant, resulting in twice the $p_{1,res}$-values for the porous wall with a porosity $P=11\%$ as
compared to a wall with porosity $P=40.5\%$. The GODA formula overestimates the measured pressure values, mainly due to the influence of structure porosity.

It is also seen from Fig. 8 that the results for the impermeable wall tested in the GWK are not well predicted by the GODA formula. The measured pressures at SWL are underestimated, particularly for the longer waves (i.e. no. 11 - 17).
Applying a linear correction factor which accounts for the structure porosity of the permeable wall did not show satisfactory results. Smaller pressures $p_{1,\text{res}}$ are described accurately with this linear correction method while higher pressures are underestimated.

Hence, a correction procedure accounting for the load reduction due to porosity for vertical breakwaters in the GODA method has to consider nonlinear effects due to shallow water conditions and large wave heights. Consequently, the extension of the existing formulae has to be performed in two successive steps:

1. Modification of the GODA formula (Eqs. (2) and (3)) to predict the measured pressures in the reference case (impermeable wall).
2. Introduction of reduction factors considering the porosity of the structure.

3.2.1 Modification of the $\alpha_1$-Value in the GODA Formula for the Impermeable Case

The normalised pressure $p_1$ at still water level in the simplified GODA formula (Eq. (2)) is controlled by $\alpha_1$ which accounts for the maximum surface elevation at the structure

$$\alpha_1 = \frac{p_1}{\rho \cdot g \cdot H} = 0.6 + 0.5 \cdot \left( \frac{(4\pi d/L)}{\sinh(4\pi d/L)} \right)^2 \quad (7)$$

Plotting $\alpha_1$ as calculated by Eq.(7) over the relative water depth $d/L$, it becomes apparent that Eq.(7) does not represent the measured normalized pressures (Fig. 9).

![Figure 9: Normalized Pressure at SWL vs. the Relative Water Depth d/L.](image-url)
Increasing the second coefficient for calculating $\alpha_l$ from 0.5 to 0.9 allows a much better prediction of the data measured at the impermeable wall. This result seems to be acceptable as a first attempt to consider the influence of shallow water depth (tests performed in the region of shallow water to intermediate water depth, $0.04 < d/L < 0.5$, see Fig. 9). This modification has to be considered for the calculation of the resultant pressure at the structure toe $p_{2,\text{res}}$ which is described in Section 3.2.3.

### 3.2.2 Reduction Factors for Resultant Pressure at Still Water Level (SWL)

Moreover, besides modifying the GODA formula in terms of prediction of maximum pressures at impermeable structures the next step is to consider the force reduction due to the structure porosity. The reduction factors $\Psi_p$ is introduced which describes the influence of the surface elevation at the rear side of the structure. The whole set of extended formulae regarding to maximum resultant pressure at SWL ($p_{1,\text{res}}$) are given as follows:

$$p_{1,\text{res}} = \rho \cdot g \cdot H^*$$  \hspace{1cm} (8)

with

$$H^* = \alpha_i^* \cdot \Psi_e \cdot \Psi_p \cdot H_i$$  \hspace{1cm} (9)

The resultant pressure head $p_{1,\text{res}}$ is controlled by the pressure gradient at the structure which is affected by the following factors

- the modified $\alpha_l$-value in the GODA formula

$$\alpha_i^* = 0.6 + 0.9 \cdot \left(\frac{(4\pi d/L)}{\sinh(4\pi d/L)}\right)^2$$  \hspace{1cm} (10)

- reduction of wave run-up due to structure porosity ($\Psi_e$, Eq. (6))

- reduction of resulting pressure due to surface elevation at the back side of the structure

$$\Psi_p = \left(1 - \sqrt{P}\right)^a$$ \hspace{1cm} with \hspace{0.5cm} $a = \sqrt{\frac{1}{6} \frac{d}{H_i}}$  \hspace{1cm} (11)

The coefficient $\Psi_e$ (Eq. (6)) is dependent on the structural porosity and describes the influence of the permeability on the wave run-up at the structure face. $\Psi_p$ estimates the decrease in resulting pressure due to surface elevation at the back side of the structure (see also Fig. 6). $\Psi_p$ is strongly influenced by the transmission of wave energy through the structure gaps which depends on the flow resistance induced by the velocity in the apertures. The schematic flow pattern is illustrated in Fig. 10. High waves and thus large horizontal velocity components increase the flow resistance due to large velocities in the structure gaps. Hence, for large wave heights the transmission of wave energy through the structure openings is much more limited compared...
to small wave heights. The parameter $\Psi_p$ describes therefore a kind of "dynamic porosity" of the structure. The expected influence of the wave period on wave transmission and flow resistance could not confirmed by the data.

![Diagram](image)

Figure 10: Flow Resistance for Small- (left) and Large Wave Heights (right), Induced by the Velocity Gradients in the Structure Gaps.

In Fig. 11 the product of the two coefficients $\Psi_e$ and $\Psi_p$ is shown as a function of the wave height $H_j$ for various structure porosities. For an impermeable wall no reduction of pressure values results from the equations given ($\Psi_e \cdot \Psi_p = 1$). In this case only the modification of the $\alpha_t$-value should be considered for the prediction of the maximum resulting pressures at still water level. The reduction factors decrease significantly with increasing structure porosity which is even more relevant for smaller wave heights $H_i$.

### 3.2.3 Reduction Factors for the Resultant Pressure at the Structure Toe

Compared to impermeable walls, the pressure reduction at the structure toe is larger for permeable structures. This is due to the almost constant pressure over the water depth on the rear side of the structure (see Fig. 6). The main influencing parameter is the "dynamic porosity" ($\Psi_p$) which is therefore included in the depth dependent term of the GODA formula (see Eq.(4)). This will decrease the pressure $p_{2,\text{res}}$ at the structure toe. Additionally, a further reduction factor (85%) was necessary to fit the measured data (Eq.(12)). The following relation for $p_{2,\text{res}}$ was found:
\[ P_{2,\text{res}} = 0.85 \cdot \frac{1}{\cosh \left( \frac{2\pi d}{L} \frac{1}{\Psi_p} \right)} \cdot P_{1,\text{res}} \]  

Taking into account the modified \( \alpha_1^* \) value and the reduction coefficients \( \Psi_e \) and \( \Psi_p \) the comparison of measured and calculated characteristic resulting pressure values \( P_{1,\text{res}} \) and \( P_{2,\text{res}} \) is shown in Fig. 12 and Fig. 13, respectively.

The results confirm the proposed formulae for the prediction of characteristic pressure values at permeable walls for maximum horizontal forces under wave crests.

### 3.3 Relation between Wave Elevation and Pressure Distribution at Permeable Walls

For the impermeable wall the wave elevation at the structure front \( \eta^* \) should result in the same value as the wave height \( H^* \) used for the calculation of resultant pressures. This is more or less verified by the data (Fig. 14, \( P=0\% \)). For permeable vertical walls the ratio \( \frac{H^*}{\eta^*} \) is influenced by the surface elevation at the rear side of the structure and can be described by a factor \( (1-\sqrt{P})^{0.5} \).
Figure 12: Measured and Calculated Resultant Pressures $p_{1,\text{res}}$ at SWL Considering the Nonlinear Influence of the Structure Porosity.

Figure 13: Measured and Calculated Resultant Pressures $p_{2,\text{res}}$ at Structure Toe Considering the Nonlinear Influence of the Structure Porosity.
The elevation of the nonlinear wave crest is described for the wave run-up by Eq. (5) and for the pressure distribution by Eq. (10). This should be done in a more consistent way by one equation. As a first attempt the resultant pressures on permeable walls should be calculated by the modified formulae (Eq. (6) - (12)). The elevation above still water level $\eta^*$ estimated by Eq. (5) can be used as the upper limit of pressure integration for the calculation of horizontal forces.

It will be the objective of further studies to relate the resultant pressures directly to the nonlinear wave elevation at the structure front.

4. Conclusions and Future Work

For the design of permeable structures reliable information on wave loads and pressure distribution is needed. The influence of the incident wave height $H_i$, described by the "dynamic porosity" has to be considered for the analysis of wave damping processes at the porous wall. The resultant pressure distribution at vertical wave screens under non breaking and slightly breaking waves is dominantly governed by:

- the non-linear wave profile (section 3.2.1)
- reduction of wave run-up due to "structural porosity" (section 3.2.2)
- reduction of resulting pressure due to "dynamic porosity" (section 3.2.2)
The nonlinear extension of the GODA formulae for calculating the resultant pressure distribution at permeable vertical walls as proposed in this paper gives accurate results for wall porosities between 0% and 40.5%, as compared to data obtained from hydraulic model tests in the Large Wave Flume (GWK) of the Coastal Research Centre, Germany.

The future work will resolve the following main objectives:

- Pressure distribution under wave troughs
- Wave spectra (random conditions at front and rear side of the structure!)
- Chamber systems (combinations of different permeable walls followed by an impermeable wall).

IMPACT LOADINGS ON VERTICAL WALLS IN DIRECTIONAL SEAS

N.W.H. Allsop & M. Calabrese *

ABSTRACT

Recent research under PROVERBS has demonstrated that wave impact loads can cause damage or failure of caisson or blockwork breakwaters. Research studies of wave loadings, pulsating or impact, have generally used only 2-dimensional wave flume experiments, and so most design methods are strongly biased towards 2-d.

This paper describes results from 3-dimensional wave basin tests by Universities of Naples, Sheffield, and HR Wallingford in the UK Coastal Research Facility (CRF). The aim of the study was to quantify effects on wave pressures or forces of oblique or short-crested wave conditions on simple vertical or composite breakwaters.

This analysis has focussed particularly on wave impact loadings as earlier 2-d tests at Wallingford showed them to be potentially severe for some combinations of foundation level and relative wave conditions. New reduction factors are presented.

1. INTRODUCTION

Hydro-dynamic wave loads constitute the main design loading for overall stability of a vertical breakwater. Many wave loads are slow-acting or pulsating, but wave impact loads can be very intense. Research in the UK with support from the EU MAST project PROVERBS has demonstrated that wave impact loads, despite their short durations, can cause failure of caisson or blockwork breakwaters.

Design wave forces on caisson breakwaters and related structures are usually derived as quasi-static loads using methods by Goda (1985) which calculate equivalent loads for sliding. Recent studies on failures of vertical breakwaters by Oumeraci et al.

2056
(1995) Allsop & Vicinanza (1996), Allsop et al (1996a, b) and others have demonstrated that damage or failure can be caused by wave impacts. These may be triggered by particular combinations of waves and water levels, bed slope, berm and wall geometries, some of which have been identified in studies by Allsop et al. (1996b), Allsop & Vicinanza (1996) or Calabrese et al. (1996).

Most studies of wave loadings, pulsating or impact, have used 2-dimensional (2-d) wave flume experiments as it has been assumed that long-crested normal wave attack is most damaging. Design methods are therefore strongly biased towards 2-d wave attack, and relatively little information is available on 3-dimensional effects. There are however strong reasons to review this, and to investigate the stability of such structures under 3-d wave conditions:

a) Real waves are highly irregular in space and time, so along particular lengths of wall, the instantaneous widths of wave fronts are often relatively short.
b) Main breakwaters are often orientated oblique to the largest waves so that the worst wave forces act over only a short length of the structure at any one time.
c) Wave impact pressures are limited spatially, even under long-crested waves, but reduction of effective force with length of element has not been quantified.

Methods to evaluate wave forces under oblique and/or short-crested waves have been suggested by the empirical methods of Goda (1985) or theoretical methods of Battjes (1982). Battjes' method estimates wave force reduction coefficients in relation to: angle of attack, $\beta$; directional dispersion index, $n$; and relative length of caisson or wall element $L_c/L$, where the element length is $L_c$ and wavelength is $L$. Experiments by Franco et al. (1996), measured effects of long- and short-crested waves with $\beta \leq 60^\circ$ and standard deviation of spreading $\leq 30^\circ$, but did not record impact loads.

In contrast, important objectives of the studies summarised here, were to:

a) Identify conditions which lead to impulsive loads on vertical breakwaters under oblique or short-crested waves;
b) Evaluate the influence of wave obliquity, $\beta$, and of directional dispersion, $n$, on the intensity of the wave load;
c) Assess the influence of multi-directionality on the distribution of loads along the wall under pulsating and impact wave conditions.

Figure 1  Test set-up in CRF
2 EXPERIMENTAL STUDY

2.1 Test facilities
These experiments were conducted in the UK Coastal Research Facility (CRF), a large wave and current basin 54m by 27m equipped with 72 paddles to give oblique long-crested or short-crested waves. The model caisson sections were placed in a line in the basin, parallel to the paddles, and on a 1:20 bed slope, see Figure 1.

Oblique or short-crested random waves were produced by adjusting the wave paddle control signals. Absorbing beaches behind the structures reduced wave reflections, and extension walls reduced diffraction distortions. Four different breakwater types were tested: Structure 0 was a simple vertical wall and Structures 1-3 were composite walls with mounds of different geometry. The structures were closely based on those tested by Allsop et al (1996) and McKenna (1997), and used the same measurement caisson, but fitted with eighteen pressure transducers in 3 vertical rows, see Figure 2.

![Figure 2](image)

**Figure 2** Test caisson and pressure transducers

Most tests were run for 500 waves, but some were repeated for 2000 waves. For Structures 1-3, three different relative height / depth of rock armoured berm in front of the caisson were studied. Test conditions for Structure 0 covered the range tabulated below, but restrictions on basin availability limited tests for other structures:

</tbody>
</table>

2.2. Test Programme
Tests on each structure were conducted in three phases:
a) long-crested waves with $\beta = 0^\circ$;
b) long-crested oblique waves with $\beta = 15^\circ, 30^\circ$ and $45^\circ$;
c) short-crested waves, $\beta = 0^\circ$ and directional dispersion index of $n = 2$ or $n = 6$. 

2.3 Pressure Signal Analysis

Pressures were summed by trapezium rule to give horizontal forces on each column, $F_h$ at each timestep (at 400 Hz). The time signal of pressures at static water level was divided into "events" using parameter and threshold definitions developed within PROVERBS, and analysis methods by Calabrese et al (1997) and Allsop et al (1996). Forces and moments were calculated at each timestep. Fictional pressures or forces on imaginary column "a" were interpolated between columns 1 and 2.

Maximum wave forces on each column ("1", "a", "2", "3") were found for each event. Individual column forces were considered as representative of wave loads, $F_h(0)$, acting on an infinitesimal segment, $L_c=\delta l$, of the wall. To simulate longer caissons, average wave forces were calculated for combinations of columns ("2+3"; "1+a+2"; "a+2+3"; "1+a+2+3") giving wave loads, $F_h(n)$, for each caisson length, $L_c$:

<table>
<thead>
<tr>
<th>$F_h (n)$</th>
<th>Caisson length, $L_c$ (m)</th>
<th>Adjacent column combinations</th>
</tr>
</thead>
<tbody>
<tr>
<td>$F_h (0)$</td>
<td>$\delta l$</td>
<td>1; 2, or 3</td>
</tr>
<tr>
<td>$F_h (1)$</td>
<td>0.260</td>
<td>2+3</td>
</tr>
<tr>
<td>$F_h (2)$</td>
<td>0.520</td>
<td>1+a+2; or a+2+3</td>
</tr>
<tr>
<td>$F_h (3)$</td>
<td>0.780</td>
<td>1+a+2+3</td>
</tr>
</tbody>
</table>

For each caisson length, forces, $F_h(n)$, were ranked in magnitude and the average of the 1/250 highest forces, $F_{h1/250}(n)$, was evaluated. For the overall analysis of forces, values of $F_{h1/250}(n)$ for $n=0$, 1, or 2 were calculated by averaging across the columns used. This average has been used in the analysis below, except when relative peak to average values are discussed in section 3.2.

3. RESULTS

3.1 Occurrence of impacts

The aim of the initial analysis was to identify conditions which lead to impulsive loads and to evaluate their occurrence $P_i$. Work by Allsop et al (1996) and McKenna (1997), distinguished between "pulsating" and "impact" loadings using probability distributions of wave forces. Individual forces were ranked and plotted on Weibull axes, and any significant departure above the Weibull line was taken as indicating an impact. The probability level at which forces started to diverge from the Weibull line gave percentage of impacts $P_i$ (%) for each column of transducers.
This paper generally discusses average values of $P_i$ across three columns. Evaluations of $P_i$ were checked by evaluating impacts from video recordings of the experiments.

Simple vertical wall

Impacts under long-crested normal waves were compared with results from 2-d tests by Allsop et al (1996) with only slight variation. The onset of impacts was reached at about $H_s/h_s = 0.35$ in both experiments for long-crested waves at $\beta=0^\circ$. For short-crested waves at $\beta=0^\circ$, $P_i$ again showed no changes in comparison with long-crested waves. Again, impacts begin at conditions close to $H_s/h_s = 0.35$, although there are some indications in Figure 3 that impacts do not increase as rapidly with increasing $H_s/h_s$ in short-crested waves as for long-crested waves.

For oblique long-crested waves, $\beta = 15^\circ$, $30^\circ$ and $45^\circ$, there were much fewer impacts than for normal long-crested waves, Figure 4. For larger waves, $H_s/h_s > 0.35$, impacts were less frequent with oblique waves than for normal attack, $\beta=0^\circ$.

These tests were in intermediate depths: $0.05 \leq h_s/L_{pi} \leq 0.18$. Conditions which gave impacts fell in $0.03 \leq s_p \leq 0.06$.

Figure 4 Effect of oblique wave attack on impacts

Figure 5 Effect of $H_s/d$ on $P_i$, high mound

Lower steepnesses, $s_p = 0.02$, showed no impacts.
Composite walls, low and high mounds
Addition of even a small rock berm or slope in front of a simple wall has been shown to increase substantially the number and severity of impacts. In the previous 2-d study, Allsop et al (1996) argued that the onset of impacting for low mounds, 0.3<h_b/h_s<0.6, occurred at H_s/h_s = 0.35, but that P_i increases rapidly at higher values of H_s/h_s. Results from long-crested waves at β=0° from these tests support the earlier conclusions, but suggest that impacts for low mounds might start to occur at lower relative wave heights than suggested previously, perhaps H_s/h_s ≤ 0.30.

The 2-d tests by Allsop et al (1996) showed that impacts increase further with high mounds, 0.6<h_b/h_s<0.9. Impacts start at smaller values of H_s/h_s, and become much more frequent with increasing relative wave height. Tests on high mound composite walls in the CRF at β=0° substantially confirmed this, with impacts starting at values of H_s/h_s as low as 0.25. These are shown against H_s/h_s in Figure 5. Whilst there are substantially fewer results than in the 2-d tests, and the general trend is very similar, it may be noted that the % of impacts in the 3-d tests all fall below the outer limit of the results for the 2-d tests. This confirms the expectation that, even when using nominally perpendicular and long-crested waves, inherent perturbations and instabilities are likely to develop, and these will reduce the level of wave impacts from those predicted from 2-d wave flume tests.

Figure 6  Dimensionless wave force for vertical walls, normal wave attack

L_c=\delta_l.

Forces for long-crested normal waves in Figure 6 have been non-dimensionalised as F_{h1250}/\rho g h_s^2, and plotted against relative wave height H_s/h_s. Summary results from the 3-d tests by Franco et al (1996), are included, for which H_s/h_s = 0.20. These forces are very similar to those measured here for the lower values of H_s/h_s, where there are no impacts, only pulsating loads. Comparisons with Goda predictions show relatively good agreement over the pulsating zone, but use of Goda's method seems
inappropriate in the impact zone \(0.35 < H_s/h_s < 0.55\) where Goda's method would not be expected to match the measured wave loads.

The simple prediction line by Allsop & Vicinanza (1996) in Figure 6 indicates an upper limit, with a few results above the line. This may be due to the greater possibility of extreme loads under impacting conditions, particularly when sampled by more than one column of transducers, and illustrates the essential variability of impact loads, even under similar hydrodynamic and geometric conditions.

For short-crested waves, values of \(F_{h1250}/\rho g h_s^2\) are again plotted against relative wave height \(H_s/h_s\) in Figure 7. The results appear to show no significant change in local force for the range of conditions tested, dispersion index \(n = 2\) or \(6\), compared with loads generated by long-crested waves of the same height.

The influences of oblique long-crested waves on forces on any narrow strip of the caisson are more significant in Figure 8. Over the pulsating zone, \(H_s/h_s \leq 0.35\), forces are very similar to those for normal approach, even though the component of force perpendicular to the caisson might have been expected to reduce. In the impact region however, wave loadings diminish considerably under oblique attack.
3.3 Variability of forces
With these data, it is possible to estimate variations of peak force by comparing results from the 3 columns of transducers. Values of $F_h$, including the "Goda" force ($F_{h1250}$) can be calculated using three alternative methods, giving successively less averaged values:

a) from the average force calculated at each timestep across all three columns;

b) from peak forces on each column, averaged event by event, but not necessarily at the same point in time;

c) from peak forces on any individual column, irrespective of event or timestep.

Most analysis has been based on averages by methods a) or b). These are necessarily smaller than the peak values calculated using method c). Some estimates of increase in "local" force may therefore be derived from comparison of these values, plotted as dimensionless forces in Figure 9a)-c).

These comparisons show consistent increases in $F_{h1250}$, with reduced averaging, methods a) –
c). Allsop & Vicinanza's simple formula gives a reasonable representation of forces averaged over typical caisson widths of 10-20m, but under-estimates the "local" force over a single narrow strip, even for normal and long-crested wave attack.

Peak values in c) have been compared with average forces in a) as $F_{h(peak)}/F_{h(ave)}$ plotted against $H_s/h_s$ in Figure 10. Values of $F_{h(peak)}/F_{h(ave)}$ reached 1.2-1.3 for normal long-crested attack. Under long-crested oblique attack, most results were much lower, not exceeding $F_{h(peak)}/F_{h(ave)} = 1.15$, but with a single test giving 1.4. Under short-crested waves the ratio $F_{h(peak)}/F_{h(ave)}$ never exceeded 1.15, suggesting that peak forces are unlikely to exceed those analysed in this research by any substantial margin, except under conditions of normal attack.

3.4 Effect of caisson length

Battjes (1982) argued that oblique or short-crested wave attack on caisson of length $L_c$ will give further reductions in effective force relative to normal and/or long-crested attack, and relative to loads on a narrow strip (modelled here as a single column of transducers).

These reductions are illustrated in Figures 11 and 12 where Battjes methods give prediction curves of the decay coefficient, $C_{Fh}$ in relation to relative caisson length, $L_c/L_{op}$. These curves, show that these theoretical considerations predict only small reductions in effective force over caisson lengths around 10-25m, the largest caisson constructed to date.
being a single example in Japan of 100m long. In contrast waves of $T_p=7-15\text{s}$ would cover wave lengths of $L_{op}=80-350\text{m}$.

Battjes methods were developed for simple vertical walls, so the comparisons here are based on tests with Structure 0, the simple vertical wall. The first results considered here are therefore for normal, long-crested waves in Figure 13. Results from these tests have been combined with results from Franco et al (1996), which show little decay over caisson lengths $L_c/L_{op}$ up to 0.4. Measurements from the CRF however show up to 10% decay, ie $C_{Fh}$ down to 0.9 for non-impact conditions for relative caisson lengths up to $L_c/L_{op}=0.15$. Wave impact conditions ($H_s/h_s>0.35$), however, gave substantially greater reductions in the effective force, even over short caisson lengths, $0.005 <L_c/L_{op}<0.2$. A simple regression line gives the reduction factor $C_{Fh}$ in terms of relative caisson length with a coefficient $B = 1.35$ for long-crested waves and $\beta = 0^\circ$:

$$C_{Fh} = 1 - B \left( \frac{L_c}{L_{op}} \right)$$

Figure 13  Force decay for long-crested / normal waves

Under slightly oblique attack, $\beta = 15^\circ$, forces in Figure 14 for non-impact conditions show more significant reductions than for $\beta = 0^\circ$, but there is only slightly greater change for impact conditions. The same simple form of regression line gives $C_{Fh}$ in terms of $L_c/L_{op}$: for $\beta = 15^\circ$, yielding $B = 1.70$:

$$C_{Fh} = 1 - B \left( \frac{L_c}{L_{op}} \right)$$

Figure 14  Force decay for long-crested waves and oblique attack, $\beta = 15^\circ$
At greater obliquities, the force reduction is more marked for pulsating conditions. Measurements at $\beta = 30^\circ$ in Figure 15 also show slightly greater reduction for impacts.

Effects of short-crested waves in Figure 16 show no significant effect of spreading between $n=2$ and $n=6$. The regression for $\beta = 0^\circ$ gives $B = 1.56$, steeper than for long-crested waves at $\beta = 0^\circ$, but less severe than for long-crested waves and $\beta = 15^\circ$.

These results suggest that Battjes' model may be used to give conservative predictions in the pulsating zone, but that force reductions under impacts are much more significant than predicted by linear methods. Calculations of the mean decay function on $F_h$ for impacting conditions can be summarised by the simple equation relating decay to relative caisson width, $L_c/L_{op}$, given in equation (1) where coefficient $B$ is defined for each test case below.

4. CONCLUSIONS

Initial conclusions from these studies may be summarised:

a) There is good agreement between results from 2-d tests in 1994 with 1:50 approach bed slope, and results from tests with normal long-crested waves in the CRF with 1:20 approach bed slope.

b) Impacts on composite walls follow trends identified previously at Wallingford. There are however indications that impacts might start at slightly lower relative wave heights, perhaps $H_s/h_r \leq 0.30$. The data also suggest that higher levels of impacts for some configurations may be reduced under 3-d conditions, even if only normal wave attack is used.

c) Under oblique long-crested waves, the occurrence of wave impacts on vertical walls are substantially reduced at $\beta=15^\circ$, $30^\circ$ and $45^\circ$. This is repeated for high mounds at $\beta=15^\circ$, $30^\circ$ and $45^\circ$, and low mounds for $\beta=30^\circ$ and $45^\circ$.

d) Effects of short-crested waves of dispersion index 2 or more do not appear to vary significantly with increased spreading.

e) Under oblique or short-crested waves, the variation of peak forces relative to those averaged over a short length equivalent to a single caisson of about 20m are relatively small, not exceeding a ratio of 1.2.

f) The variation of peak force on a single narrow strip under normal wave attack is more substantial, with peak forces up to 1.3 times greater than the average.

g) Battjes’ method for estimating the decay of average force with longer caissons gives very small reductions for most practical caisson lengths. The tests with pulsating conditions show that Battjes’ predictions are generally conservative.

h) For impact conditions, average forces reduce significantly with caisson length, giving reductions of 25% or so over relative caisson lengths of only 0.2.

i) A simple reduction factor for $F_h$ under impacting conditions as a function of $L_c/L_{op}$ has been developed. Values of a coefficient $B$ have been presented here in Table 1 for long-crested waves at different obliquities, and for short-crested waves.

The results of these studies also suggest the following initial conclusions on spatial correlation of impact forces under oblique / short-crested waves:

j) For heavy impacts ($F_{\text{impact}}/F_{\text{Goda}} \gg 2.5$), and small obliquity or spreading: - assume a typical coherence length $\leq L/16$;

k) For light impacts ($F_{\text{impact}}/F_{\text{Goda}} < 2$), normal wave attack ($\beta = 0^\circ$) and little spreading: - assume a typical coherence length $\leq L/4$;

ACKNOWLEDGEMENTS

This paper is based on studies by the Department of Hydraulic and Environmental Engineering of University of Naples, the Coastal Group of HR Wallingford, and Department of Civil Engineering of University of Sheffield. Tests and analysis were supported by the Construction Sponsorship Directorate of the UK Department of Environment under contract CI 39/5/96, and by the EU’s MAST project PROVERBS under MAS3-CT95-0041.
Additional support was given by the "Programme for International Exchange of Researchers" of University of Naples Federico II, with further funding for visiting researchers at Wallingford from the National Council for Research in Italy, CNR, and by University of Sheffield and HR Wallingford.

The authors gratefully acknowledge assistance in testing at Wallingford by Adrian Channel, Rob Jones, Diego Vicinanza, and Alberto Bracci-Laudiero; and in processing data by Lawrence Banyard, Kirsty McConnell, and Rob Jones.

WAVE FORCES ON A VERTICAL WAVE BARRIER

David Kriebel\textsuperscript{1}, Charles Sollitt\textsuperscript{2}, and William Gerken\textsuperscript{3}

Abstract

This paper presents a comparison of measured and predicted wave forces on a vertical wave barrier, defined here as a thin impermeable vertical wall extending from above the water surface down to near mid-depth. Theoretical wave loads are computed using the eigenfunction expansion method. Measured wave loads are obtained from two sets of laboratory experiments, one conducted at the U.S. Naval Academy and the other conducted at the Oregon State University in a large wave flume. Results of this study suggest that the eigenfunction theory can predict wave loads to within 10\% to 20\% accuracy for a wide range of wave conditions, water depths, and wave barrier drafts.

Introduction

Existing methods of predicting forces on vertical wave barriers, as contained in the Army Corps of Engineers \textit{Shore Protection Manual} (1984) or the Naval Facilities Engineering Command \textit{Design Manual} 26.2 (1982), appear to be overly-conservative. Both design manuals adopt the Sainflou or Miche-Rungren solutions for wave forces on a full-depth vertical wall, and then modify these with an \textit{ad hoc} reduction factor to account for the limited draft of the wave barrier. Both manuals also state that the maximum wave force should be computed under the assumption that a wave crest occurs on one side of the wall while a wave trough occurs on the other side. In general, however, neither assumption is valid; and, as a result, predicted wave loads may far exceed actual wave loads for a typical wave barrier.

In the present paper, a more rigorous method of computing wave loading on a wave barrier, based on the eigenfunction expansion theory, will be reviewed. Results of this theory will then be compared to measured wave forces obtained from two recent laboratory experiments. The experimental portion of this study is itself unique in that tests were conducted independently at two different scales in two different laboratories, with small-scale tests conducted at the U.S. Naval Academy and large-scale tests conducted at the Oregon State University.

Background

An illustration of a vertical wave barrier is shown in Figure 1. The wave barrier consists of a thin impermeable vertical wall with a draft or penetration, \( w \), in water of depth \( d \). The wave field consists of incident waves with height \( H_i \), transmitted waves of height \( H_t = K_t H_i \), and reflected waves of height \( H_r = K_r H_i \), where \( K_t \) and \( K_r \) are the transmission and reflection coefficients. As waves interact with the barrier, each side of the barrier experiences fluctuating dynamic pressures and, because these pressures differ on the up-wave and down-wave sides, the barrier experiences time-varying wave forces.

![Figure 1. Definition sketch of wave interaction with a vertical wave barrier.](image)

It does not appear, however, that these wave forces have been widely studied. For design purposes, the most widely used method of computing wave loads on a wave barrier is that outlined in the Army Corps of Engineers Shore Protection Manual (SPM) and in the Navy Design Manual 26.2 (DM26.2). However, as noted above, this procedure has been adapted from experience with wave loading on full-depth vertical walls; and, to the authors' knowledge, it has never been verified against measured wave loads on a partial-depth vertical wave barrier. From discussions with design engineers, it appears that the procedure outlined in the SPM or in DM26.2 is overly conservative, and one goal of the present study is to evaluate the predictive skill of this method.

---

4 Based on discussions at a Wave Barrier Design workshop, held by Peratrovich, Nottingham & Drage, Inc. in Seattle, Washington, on April 24-25, 1995
A second goal of this study is to evaluate a more rigorous method of estimating the wave loads on wave barriers. Two theoretical methods have been proposed for computing the linear or first-order wave forces on these structures: (1) the boundary integral equation method of Liu and Abbaspour (1982) and (2) the eigenfunction expansion method of Losada, Losada, and Roldan (1992). With these theories, the interaction of the incident waves with the barrier is determined based on a solution of the appropriate boundary value problem for linear waves. The wave force per unit length on the barrier, \( f \), is then computed as

\[
f = \int_{-w}^{0} (P_{dp} - P_{dn}) \, dz
\]

where \( P_{dp} \) and \( P_{dn} \) are the dynamic pressures on either side of the wave barrier as obtained from the theoretical solution. In this paper, we compute these pressures using the eigenfunction theory. For given incident waves, this theory determines the reflected and transmitted progressive waves, as well as the evanescent wave modes, all of which contribute to the pressures on the face of the barrier. To date, however, the eigenfunction theory has not been widely accepted for design; and, it is the goal of the present paper is to evaluate its validity relative to the design methods now adopted in the SPM or in DM26.2.

**Description of Experiments**

Laboratory measurements of wave forces on vertical wave barriers were conducted independently in two facilities at two different scales. In the summer of 1996, a series of experiments were conducted at the Naval Academy Hydromechanics Laboratory (NAHL) using regular waves in a wave tank 37 m long and 1.5 m deep. In the summer of 1997, experiments were conducted at the Oregon State University (OSU), using both regular and irregular waves, in a wave tank which is 104 m long. The water depth in the OSU tests was fixed at 3.0 m so that tests could be conducted at twice the scale used in the NAHL tests. In each set of tests, four values of the wave barrier draft, \( w \), were tested, producing four values of the dimensionless draft, \( w/d \), of 0.4, 0.5, 0.6, and 0.7.

In both tanks, an extensive set of regular waves were tested with a wide range of relative depths, ranging from near shallow conditions, with \( d/L \) of about 0.10, to deep water conditions, with \( d/L \) exceeding 0.50. For each relative depth, two values of wave steepness were tested, with target values 1/40 and 1/30. In the OSU tests, irregular waves were also used. These were generated from target JONSWAP spectra, most with peak enhancement factors of 3.3. Peak wave periods were in the range of 2 to 6 seconds and were selected to produce a range of relative depths, \( d/L_p \) (where \( L_p \) is the wavelength associated with the peak period) similar to regular wave values. Zero-moment significant wave heights, \( H_{mo} \), were in the range of 0.3 to 0.7 m and were similarly selected to produce values of the spectral steepness, \( H_{mo}/L_p \), similar to the steepness used for regular wave tests.
One difference between the two test programs involved the way that forces were measured. In the NAHL tests, a rigid frame was installed across the 2.4 m tank width and the wave barrier was attached to this frame in three sections. The two outer sections, each 1.05m wide, were rigidly attached to the supporting frame and forces on these sections were not measured. The center section, 0.30m wide, was then attached to two modular force gages (one near the top and one near the bottom) which were, in turn, attached to the supporting frame. The center section was separated from the outer sections by gaps 1 to 2 mm in width, thus permitting the wave load on the center panel to be isolated and measured. In the OSU tests, in contrast, the wave barrier was constructed as a single rectangular panel that spanned the entire 3.3 m tank width. This panel was attached to the side walls at four points (top and bottom on each side of the tank) by load beams that were instrumented with strain gages.

For regular waves, the forces analyzed in this paper are based on an average of force amplitudes in the positive (down-wave) and negative (up-wave) directions. Most wave heights were small enough that mean forces on the wave barrier were small and difficult to resolve. The force amplitudes were, however, sometimes skewed so that the amplitude in one direction (either the up- or down-wave direction) was somewhat larger than that in the opposing direction. These amplitudes typically differed by only a few percent and, as a result, the two force amplitudes could be averaged with little loss of information. For irregular waves, the significant force amplitude was determined from the force spectrum. In this case, the zero-moment of the spectrum, \( m_0 \), was determined, and the significant force amplitude was determined as \( F_{nw} = 2^* \langle m_0 \rangle^{1/2} \). It is noted that the factor of two is used here, instead of four, in order to determine the force amplitude.

**Evaluation of SPM and DM26.2 Design Method**

One of the primary goals of the experiments was to provide data that could be used to evaluate the existing design practice as summarized in the SPM or DM26.2. Figure 2 presents results of this evaluation in which measured wave loads from the laboratory tests are compared to those predicted using the SPM approach. Figure 2a shows the results in dimensional form (force per unit width across the tank) while Figure 2b shows the same results in dimensionless form. In this case, the measured and predicted wave loads are normalized by the force associated with a linear wave on a full depth vertical wall as

\[
F_o = \rho g H_i \frac{1}{k} \frac{\sinh kd}{\cosh kd}
\]  

(2)

In Figure 2a, it is apparent that the wave loads predicted using the SPM or DM26.2 procedure are generally more than twice as large as those that were measured. In some case, predicted forces were three or four times as large as those measured. The scales of the two test series are also apparent as the OSU data extends the range of measured values to forces that are about eight times as large as those measured in the NAHL tests. When the same data are plotted in dimensionless form, it is apparent that the NAHL and OSU
data follow the same trends and cover nearly the same dimensionless range of conditions. It is still clear, however, that the predicted values are generally more than twice as large as those measured. Some predicted forces are more than 2.5 times $F_o$ while none of the measured forces exceeded $F_o$.

Figure 2. Comparison of measured forces to forces predicted using SPM or DM26.2 design method, for regular waves.
Review of Eigenfunction Theory

In order to obtain more accurate theoretical predictions of the wave forces, the
eigenfunction expansion theory of Losada et al. (1992) and Abul Azm (1993) was
implemented. Kriebel and Bollmann (1996) applied this method to the prediction of wave
transmission past vertical wave barriers and their solution is repeated here.

The eigenfunction theory involves solution of the velocity potentials on the up-wave (incident wave)
and down-wave (transmitted wave) sides of the wave barrier. These up-wave and down-wave solutions must then be appropriately matched at the location of the
wave barrier \(x=0\). Following Losada et al. (1992), these potentials can be selected to
automatically satisfy the requirement that the velocities must be matched at all elevations
below the barrier at \(x=0\). As a result, the velocity potentials must have a spatial
dependence (in \(x\) and \(z\)) given by

\[
\Phi_{up} = Z_1 e^{ik_x x - \alpha x} + \sum_{n=1}^{N} R_n Z_n e^{-ik_x x - \alpha x} \quad \Phi_{dn} = Z_1 e^{ik_x x + \alpha x} - \sum_{n=1}^{N} R_n Z_n e^{ik_x x + \alpha x}
\]  

(3)

where \(R_n\) are complex coefficients describing the dimensionless amplitude and phase of the
progressive \((n=1)\) and evanescent \((n>1)\) wave modes and where other terms are defined
below. In this form, the first term in each velocity potential is the incident progressive
wave mode while the terms in the summation includes both the scattered progressive wave
\((n=1)\), and the evanescent wave modes \((n>1)\).

The functions \(Z_n\) in equation (3) describe the depth-dependence of the wave modes
and are given by

\[
Z_n = -i \frac{g H_i}{2 \sigma} \frac{\cosh k_n \sigma (d+z)}{\cosh k_n d}
\]  

(4)

The wavenumbers \(k_n\) are given by the solution of the dispersion equation

\[
\sigma^2 = g k_n \tanh k_n d
\]  

(5)

where the first root is the linear progressive wavenumber, \(k_1 = k\), and where there are then
an infinite set of imaginary roots for \(n>1\).

The solution for the complex amplitudes \(R_n\) must satisfy two additional physical
requirements: (a) the horizontal velocities must be zero on both sides of the barrier in the
upper region where \(-w<z<0\), and (b) the dynamic pressures must match in the gap below
the barrier where \(-d<z<-w\). As a result, two sets of matrix equations are obtained as follows.
The first boundary condition, in the upper region, is satisfied by setting the horizontal velocities \((u=\partial \Phi/\partial x)\) equal to zero at the barrier \((x=0)\), by multiplying by the orthogonal eigenfunctions, and by depth integrating over the immersed length of the wall \((-w<z<0)\), giving

\[
\sum_{n=1}^{N} R_n k_n Y_{nm} = k_1 Y_{1m}
\]

where the function \(Y_{nm}\) is the same as that defined by Losada et al. (1992)

\[
Y_{nm} = \int_{-w}^{0} Z_n Z_m \, dz
\]

The second boundary condition in the lower region involves matching dynamic pressures or, equivalently, matching the up and down-wave potentials from equation (3) under the wall \((x=0)\). As shown by Losada et al. (1992), this yields a second set of matrix equations for the unknown amplitudes \(R_n\) as

\[
2 \sum_{n=1}^{N} R_n X_{nm} = 0
\]

where \(X_{nm}\) is given by

\[
X_{nm} = \int_{-d}^{-w} Z_n Z_m \, dz
\]

The unknowns \(R_n\) can be readily obtained by solving a single set of equations which result by adding the two matrices in equations (6) and (8) as

\[
\sum_{n=1}^{N} R_n (2X_{nm} + k_n Y_{nm}) = k_1 Y_{1m}
\]

Once the solution is obtained for the unknowns \(R_n\), the wave forces on the wave barrier may be determined from equation (1). Based on linear wave theory, the dynamic pressures are related to the velocity potentials as \(p = i \rho \sigma \Phi\), and the linear wave force per unit width (at \(x=0)\) is given by

\[
F = i \rho \sigma \int_{-w}^{0} (\Phi_{up} - \Phi_{dn}) \, dz = 2 i \rho \sigma \sum_{n=1}^{N} R_n \int_{-w}^{0} Z_n \, dz
\]

Substitution of equation (4) gives the following expression for forces on a vertical wave barrier
\[ F = \rho g H_i \sum_{n=1}^{N} \frac{R_n}{k_n} \frac{\sinh k_n d - \sinh k_n (d-w)}{\cosh k_n d} \] (12)

For a full-depth wall \((w = d)\) with perfect reflection, \(R_1 = 1\), and all other values of \(R_n = 0\) for \(n > 1\), such that equation (12) gives the force associated with linear standing waves, denoted \(F_o\), in equation (2). This value provides a convenient normalizing parameter for the forces on a partial-depth wave barrier, and experimental results can be compared to theory on the basis of the ratio, \(F/F_o\).

**Comparison of Theory and Data**

**Regular Waves**

Forces computed using equation (12) are compared to selected results of the regular wave tests in Figure 3 for values of \(d/L = 0.12\) to 0.50. As may be seen in these comparisons, the predicted loads essentially agree with the measured values for each relative depth and for each of the four values of wall penetration, \(w/d\), tested. In the top of Figure 3, for relatively shallow water depths, the agreement is particularly good. For deeper water depths, at the bottom of Figure 3, there is more scatter in the data and the eigenfunction solution tends to form an upper bound to the data. In all cases, measured and predicted wave loads range from about 20% to 90% of the value \(F_o\) associated with a linear wave reflecting from a full-depth vertical wall.

A summary of all of the regular wave results obtained in this study is shown in Figure 4 where the measured force (dimensionless) is compared to that predicted from the eigenfunction theory. From this comparison, it is clear that the eigenfunction theory predicts the force amplitude to within about 10% to 20% for all cases tested. The eigenfunction solution forms nearly an upper bound to the data and, on average, it tends to overestimate the measured wave loads by just a few percent.

In comparison to the SPM or DM26.2 methods discussed earlier, the eigenfunction solution is clearly superior. It can be shown that the eigenfunction method provides improved predictive capabilities for two reasons. First, it more accurately models the vertical distribution of pressure on the wall without ad hoc reduction factors, especially near the base of the wall where the pressures on the two sides of the wall must match. Second, it correctly models the phase shifts between incident, reflected, and transmitted waves, and between the various evanescent wave components. While the SPM and DM26.2 method assumes a 180° phase shift in the water levels across the wall, observations show that the phase shift is closer to 90° under most conditions. While not shown here, measured values of the phase shift are well-predicted by the eigenfunction theory.
Figures 3. Comparisons of measured and predicted wave forces for regular waves, for selected values of relative depth $d/L$. 
Figure 4. Comparison of measured wave loads to those predicted by the eigenfunction theory, for all regular wave tests.

Irregular Waves

Selected results of tests using irregular waves are shown in Figure 5. In these comparisons, the measured data consist of the zero-moment or significant force amplitude, derived from the force spectrum as described earlier. The predicted wave loads are determined as follows. Starting with a JONSWAP wave energy spectrum, equation (12) is used to compute a transfer function between wave amplitude and force amplitude at each frequency in the spectrum. The squared value of this transfer function is then multiplied by the JONSWAP wave spectrum at each frequency to obtain the force spectrum. The significant force amplitude is then derived as two times the square-root of the area under the force spectrum. Both the measured and predicted significant force amplitudes are then normalized by the force on a full depth vertical wall as computed from the zero-moment significant wave height, $H_{mo}$, as

$$F_o = \rho g H_{mo} \frac{1}{k_p} \frac{\sinh k_p d}{\cosh k_p d}$$

where $k_p$ is the wavenumber associated with the wave period at the peak of the spectrum.
Figures 5. Comparisons of measured and predicted wave forces for irregular waves, for selected values of relative depth $d/L_p$. 
Results in Figure 5 suggest that the eigenfunction solution, applied on a frequency-by-frequency basis in the frequency domain, can provide very robust predictions of wave loads across a wide range of relative water depths. Figure 6 presents a comparison of the measured and predicted significant force amplitudes for all of the irregular wave tests conducted at OSU. As may be seen, the predictions appear to be even more accurate for random waves than for regular waves, as all but five points are predicted to within a 10% error.

Figure 6. Comparison of measured wave loads to those predicted by the eigenfunction theory, for all irregular wave tests.

Summary and Conclusion

Results presented in this paper indicate that for a wide range of relative water depths, and for wave barrier drafts near mid-depth, the eigenfunction expansion theory is capable of predicting wave loads to within 10% to 20%, with somewhat more accurate predictions for irregular waves than for regular waves. This is considerably more accurate than the predictions obtained from the SPM or DM26.2, which were often more than twice as larger as the measured wave loads.
It is interesting to contrast these findings to those of Kriebel and Bollmann (1996) who found that the eigenfunction theory generally over-predicted wave transmission by a larger percentage. They found that viscous dissipation in a large vortex at the base of the wall acts to reduce the size of the transmitted wave from that predicted by the eigenfunction theory. This is of little concern for the prediction of wave forces, however, because of the nearly 90° phase shift found between water levels across the wave barrier. Wave forces are maximum at the time when the incident and reflected waves form a partial standing wave crest (or trough) on the up-wave side of the barrier, but when the water level on the down-wave side is near the still water level. At this instant, the magnitude of the transmitted wave is of little consequence.

Finally, it is noted that the eigenfunction solution presented here is consistent with linear wave theory with pressures only integrated up to the still water level. Inclusion of pressures above the still water level, up to the instantaneous wave crest, did not improve the solution but tended to cause the eigenfunction solution to over-predict by a larger margin. As a result, it may be inferred that dynamic pressures predicted by the eigenfunction theory below the still water level must be somewhat larger than those that would be measured if a wave barrier were instrumented with pressure transducers. This could be the subject of future research.

STATISTICAL DISTRIBUTION OF HORIZONTAL WAVE FORCES ON VERTICAL BREAKWATERS

Janice McKENNA\textsuperscript{1} and William ALLSOP\textsuperscript{2}

ABSTRACT

This paper discusses the statistical distribution of wave impact forces on vertical wall structures. It describes new analysis carried out based on the distribution type to identify the parameter combinations that lead to wave impacts.

Comprehensive 2-dimensional random wave model tests were carried out to measure wave pressures on a range of structure types. Initial analysis of these tests showed that the Weibull distribution could be used to describe non-breaking wave forces.

For some structural configurations however the wave forces were found to give a poor fit with the Weibull distribution. These data had been excluded from the initial analysis. The new analysis described in this paper has resulted in a revised parameter map to summarise the risk of wave impact, derived from the full data set and based on the distribution type.

1. INTRODUCTION

Vertical wall structures were widely used in the UK as seawalls and breakwaters before rubble mound breakwaters and rip-rap revetments gained popularity in the 1900's. In Japan and Italy, caissons continue to be favoured for breakwater construction. A thorough understanding of the relationship between wave forces on vertical walls and overall structure geometry is necessary to enable the design of a suitable, cost-effective structure, with an acceptably low risk of failure. It is also desirable to minimise the risk of severe exposure to large breaking wave impact forces, so that future maintenance costs are not unduly high.

Vertical walls in the marine environment are subjected to highly variable wave loads, yet existing design methods are deterministic. The main design method for caissons, developed by Goda (1974, 1985), provides a good estimate of non-breaking wave forces (McKenna, 1997). For wave impacts however, the predicted forces using Goda's

method are 'effective' values, damped by the response of the structure and foundation, rather than actual impact loads. These wave impact loads were previously thought to be unimportant for the stability of massive structures such as caissons, but Oumeraci et al (1995) have shown that repeated wave impacts can cause incremental displacements.

It is necessary to recognise the wide variation in force type and magnitude, and to incorporate a measure of their probability of occurrence, in order to develop improved design methods. Work within MAST III-PROVERBS has been directed towards this aim.

Identification of a suitable statistical distribution for wave forces on vertical wall structures is particularly important for the development of probabilistic design tools. Previous work on the statistics of wave forces has concentrated on establishing the extreme distribution of a series of (theoretically) regular waves, see for instance Kirkgoz (1995), but these results cannot be applied to real (random) seas.

The Weibull distribution can be used to describe pulsating wave forces measured in model tests on caisson breakwaters using random waves. Allsop et al (1996a) have shown that the onset of wave impacts can be defined as a change in gradient of the probability plot where wave forces start to increase rapidly above those predicted by the simple Weibull distribution.

The design load for many structures will however be due to wave impact forces rather than non-breaking waves. It is therefore important to be able to establish the statistical distribution of wave impact forces, and to know the relative proportions of pulsating and impact forces for a given structural configuration.

2. MODEL TESTS

Comprehensive parametric model tests were conducted in a random wave flume at HR Wallingford during 1994. These tests were designed to investigate the influence of structure geometry on wave pressures and forces, using random waves. Over 200 tests were carried out in all, to explore the effects of varying the following parameters:

a) Significant offshore and inshore wave heights, $H_{s0}$ and $H_{si}$;
b) Water depth in front of structure, $h_s$; and crest freeboard $R_c$;
c) Wave steepness, $s_{m0}$, and peak wavelength at structure toe, $L_p$;
d) Water depth over mound in front of wall, $d$; and berm height, $h_b$;
e) Berm width, $B_t$;
f) Front slope of mound, $\alpha$;
g) Depth of embedment of caisson into mound, $h_c$-

The caisson was instrumented with 8 pressure transducers on the front face and 4 on the underside as shown in Figure 1. Pressure data were acquired on all transducers simultaneously at 400Hz for 500 waves in each test. These tests have been described previously by Allsop et al (1996b).
3. DATA ANALYSIS

A data analysis program was developed to carry out the initial analysis of the pressure data acquired from these model tests. The pressure data were spatially integrated at each time-step to give horizontal and uplift force time histories. In order to study the statistics of the data set, information regarding the force maxima was required for each wave event. An event was defined from the beginning of each rapid pressure rise on the transducer at still water level, and the analysis program was configured to search for the required information within each 'event'.

As horizontal and uplift pressure and force maxima do not necessarily occur at the same time, a number of output files were written, so that each phenomenon could be studied separately.

The next stage of the data analysis was to rank the pressure and force maxima contained in the output files in order of magnitude to enable their statistics to be explored. This paper concentrates on the results of the further analysis of the horizontal forces.

4. STATISTICS OF WAVE FORCES

Wave impact forces on coastal structures are extremely variable, and are therefore better described by their statistics than by any single deterministic value. In selecting an appropriate statistical distribution for wave forces, it is an advantage to maintain any association between wave heights and wave forces. If a narrow band process is assumed, wave heights can be approximated by the Rayleigh distribution, which is a special form of the more generic 3-parameter Weibull distribution.
Analysis of the pressure data from these model tests by Allsop et al (1996a,b) showed that the Weibull distribution could be used to give a good description of wave forces from non-breaking waves (referred to here as pulsating wave forces), as shown in Figure 2. It was also found that the onset of wave impacts could be defined by a change in the gradient of the Weibull plot, where the wave forces start increasing more rapidly with non-exceedance level, Figure 3.

Figure 2  Weibull distribution of pulsating wave forces

Figure 3  Transition from pulsating forces to impact forces
This method of estimating the percentage of impacts was applied to each test, and was found to give good agreement with observations from the flume testing and with analytical considerations of the physical processes involved. This analysis led to the development of a parameter map, Allsop et al (1996a,b) that could be used to estimate the risk of wave impacts on a particular structure.

Further analysis by McKenna (1997) revealed that the Weibull distribution could also be used to describe wave impact forces in some instances, Figure 4. It was also noted that for other cases the percentage of impacts could be difficult to determine, as the change in the gradient of the distribution was not distinct. These cases were selected for further investigation, and it was found that the data points plotted as a gradual curve on Weibull axes, rather than a straight line with a sharp change in gradient, Figure 5.

The structural configurations corresponding to these curved distributions were investigated and a common link was found in the relationship between the offshore wave conditions and the local water depth at the structure. Limiting values of $H_{1/3}/h_s = 0.425$ and $L_{mo}/h_s = 17$ were identified, beyond which wave forces no longer fit the Weibull distribution, Figure 6. The distortion of the distribution is caused by shallow water wave transformations. The smallest waves reach the structure relatively unchanged, but there is a gradual increase in the amount of modification of the wave shape as the wave heights and lengths increase. The incident wave height distribution was found to be non-Rayleigh for these cases, Figure 7.

**Figure 4**  
Weibull Distribution of horizontal wave impact forces
Figure 5  Non-Weibull distribution

Figure 6  Parameter ranges for Weibull distributed forces
Attempts to analyse the full data set by Allsop et al. (1996b) had highlighted the need to separate the data into regions of similar response characteristics. The dimensionless parameters that influenced wave forces were identified as:

- Relative mound height, $h_b/h_s$;
- Relative wave height, $H_s/d$;
- Relative berm length, $B_{eq}/L_{pi}$.

The effects of these parameters were summarised in the parameter map presented by Allsop et al. (1996a,b). The derivation of that parameter map had concentrated on a central core of data, where the water depth over the rubble mound berm, $d$, was greater than twice the significant inshore waveheight, $H_i$. Cases where the water level was close to or below the top of the rubble mound were excluded.

Potential weaknesses had been recognised in that derivation, both in excluding a set of data from the analysis, and in using the dimensionless parameter $H_s/d$, which tends to infinity as the water depth over the rubble mound tends to zero. It was concluded that, if possible, this parameter should not be used in further work to extend the parameter map to include the full data set.

The approach used in this further work to include the full data set in the parameter map considered the effects of the non-Weibull distributed forces, and included additional parameters to describe the effects of transformation from the offshore wave climate to the inshore wave climate. The dimensionless parameters used in the new parameter map (Figure 8) are:

- Relative offshore wave height, $H_{so}/h_s$;
- Relative offshore wave length, $L_{mo}/h_s$;
Vertical and Composite Breakwater Structures

Figure 8  Parameter map showing critical parameter ranges for wave impacts on vertical and composite breakwaters
• Relative inshore wave height, $H_s^i/h_s$;
• Relative berm height, $h_b/h_s$;
• Relative berm length, $B_{eq}/L_p$.

The significance of each of these parameters, and their contribution to the description of the overall physical processes are described below.

5.1 **Degree of Wave Breaking ($H_s^i/h_s$ and $L_{mo}/h_s$)**

In order to represent the effects of structural geometry properly, it is first necessary to identify those tests where the seabed causes wave breaking on the approach to the structure. These tests must be identified at the beginning of the analysis, as they would distort any conclusions about the overall response to the structure itself. These tests were easily identified by the curved distribution of data when plotted on Weibull axes, as described previously.

Further work is required to identify the parameter influences in cases for which the data are not Weibull distributed. A suitable statistical distribution must be established for these tests and the response to the structure geometry may then be identified from this new analysis.

It is not possible at this stage to speculate on effects of individual parameters in these cases, but it is certain that structures in shallow water are at risk of exposure to breaking wave forces. The overall level of forces on the structure may however be low, as the incident waves may be substantially broken (and aerated) before reaching the structure. Blackmore and Hewson (1984) have shown that wave forces due to highly aerated waves are significantly lower than corresponding 'deep water' waves.

Configurations that fall into this category should be treated as though they will be subjected to high impact forces, and designed accordingly, until further work has been carried out in this region of the parameter map. This is particularly important for structures in areas with high tidal ranges.

5.2 **Wave regime at structure ($H_s/h_s$)**

The most significant parameter affecting the onset of wave impacts for Weibull distributed data was found to be the relative incident wave height, $H_s^i/h_s$. This parameter represents the likelihood of wave breaking at the toe of the structure, before any significant interaction with the structure has taken place. The critical value of $H_s^i/h_s$ to cause the onset of impacts was investigated by plotting the percentage of impacts, $P_i\%$, for each test against $H_s^i/h_s$.

Initial investigations using Weibull distributed data from structures 0, 1, and 2 suggested that if the value of $H_s^i/h_s$ was less than a critical value of 0.2, there would be no wave breaking, and the resulting forces would therefore be pulsating, see Figure 9.

Extension of this analysis to include all structures showed that impacts did occur for some configurations where $H_s^i/h_s < 0.2$ (Figure 10), but that all these structures had very high rubble mounds in comparison to the local water depth. This effect is described in section 5.3. The limit of $H_s^i/h_s = 0.2$ was therefore accepted as the impact indicator for
vertical wall structures and structures with low rubble mounds. A second limit of $H_{si}/h_{s} = 0.3$ was identified as the point beyond which some impacts were recorded in all tests, also illustrated in Figure 10.

Figure 9  Variation in percentage of impacts with $H_{si}/h_{s}$ (structures 0, 1 and 2)

Figure 10  Variation in percentage of impacts with $H_{si}/h_{s}$ (all structures)
In the zone between these limits, i.e., $0.2 < H_{si}/h_s < 0.3$, a mixture of pulsating and impact conditions was observed. In this region, the occurrence of wave impact forces was later found to be dependent on the relative berm length, $B_{eq}/L_{pi}$, as described in section 5.4.

The effects of relative incident wave height, $H_{si}/h_s$, may be summarised as follows:

- $H_{si}/h_s < 0.2$: pulsating wave forces except for structures with high mounds and long berms;
- $0.2 < H_{si}/h_s < 0.3$: pulsating wave forces except for structures with long berms;
- $H_{si}/h_s > 0.3$: high probability of impacts on all structure types.

### 5.3 Height of rubble mound berm ($h_b/h_s$)

The relative height of the rubble mound berm was found to be significant in cases where $H_{si}/h_s < 0.2$, i.e., the relative incident wave height was low. In this region, no impacts were observed for cases where $h_b/h_s < 0.7$, defined here as 'low mounds', as shown in Figure 11. A mixture of pulsating and impact forces was observed in tests on structures with $h_b/h_s \geq 0.7$, defined here as 'high mounds'. The relative berm length, $B_{eq}/L_{pi}$, was found to be important in these cases, as described in section 5.4.

![Figure 11](image-url) **Figure 11** Influence of relative berm height, $h_b/h_s$ (structures with small relative incident wave height)

The relative berm height, $h_b/h_s$, is a much less significant parameter than the relative incident wave height, $H_{si}/h_s$. It plays an important role however in causing impacts for those configurations with small values of $H_{si}/h_s$, and may therefore be particularly important for structures in areas with high tidal ranges. The parameter $h_b/h_s$ describes the effect of a small water depth on top of the rubble mound on the breaking process, identified as important by Allsop et al. (1996a,b). The relative berm height replaces $H_{sa}/d$ to describe this effect. It is a much more stable parameter, as it tends to infinity only if
the water depth at the toe of the structure is zero, and may therefore be used over the range of practical structures.

The effect of $h_b/h_s$ is markedly less significant than the effect of $H_s/h_s$ over the parameter ranges considered here. It is however an important part of the overall physical processes involved, and further investigations concentrated in the region $H_s/h_s < 0.2$ with various berm configurations may well uncover potentially damaging cases related to the berm height. In addition, further work covering the whole region of the parameter space might indicate that $h_b/h_s$ is important in other instances, for example when combined with the relative berm length.

5.4 Length of rubble mound berm ($B_{eq}/L_{pi}$)

The relative berm length, $B_{eq}/L_{pi}$, was found to be important in the regions $H_s/h_s < 0.2$ and $0.2 < H_s/h_s < 0.3$ (small and intermediate relative wave heights).

A mixture of impacting and non-impacting cases occurred for high mounds ($h_b/h_s > 0.7$) in the region $H_s/h_s < 0.2$, as stated previously in 5.2. Configurations with relative berm lengths, $B_{eq}/L_{pi}$, of at least 0.25 were found to experience wave impacts, as shown in Figure 12.

In the region $0.2 < H_s/h_s < 0.3$, a similar analysis showed that impacts occurred in those tests with relative berm lengths, $B_{eq}/L_{pi} \geq 0.14$ as shown in Figure 13.

![Figure 12](image)

Figure 12  Influence of relative berm length $B_{eq}/L_{pi}$ (Structures with high mounds and small relative incident wave height)
6. CONCLUSIONS

Random wave forces on vertical walls may be described well by the Weibull distribution, both in the pulsating and impact zones. In these cases, the onset of impacts can be identified by a sharp change in the gradient of the probability plot.

If significant shallow water wave transformations have occurred, the resulting wave forces plot as a curve on Weibull axes. Critical values of relative offshore wave height and wave length have been identified, to determine whether the Weibull distribution may be used to describe wave forces.

The parameter map presented by Allsop et al (1996a,b) has been improved following new analysis and the identification of non-Weibull distributed data.

A revised parameter map for determining the risk of wave impacts is presented, which includes data for structures where the water depth over the rubble mound berm is small.

NEURAL NETWORK MODELLING OF FORCES ON VERTICAL STRUCTURES

Marcel R.A. van Gent¹ and Henk F.P. van den Boogaard¹

ABSTRACT: For the design of vertical breakwaters, reliable predictions of the horizontal forces are required. Through physical modelling useful predictions can be made but, due to the very complex interaction between waves and structures, the derivation of reliable empirical relations based on such tests can still be rather difficult. Here, based on a large data-set from physical model tests, use is made of Neural Network modelling to predict horizontal forces on vertical structures. In addition, a method is developed to estimate the reliability-intervals around the predictions. The resulting tool is a complementary design-tool for predicting forces on vertical breakwaters and also a suitable tool for application in probabilistic design methods.

1. INTRODUCTION

Horizontal forces on the upright seaward section of vertical structures often form the most important wave load. Due to the complexity of the phenomena, it is difficult to describe the effects of all relevant parameters in design formulae. For such processes in which the interrelationship of parameters is unclear while sufficient experimental data are available, Neural Network (NN) modelling may be a suitable alternative. Mase et al. (1995) showed that this technique is valuable for the stability analysis of rubble-mound breakwaters. Here, an NN is developed for predicting wave forces on vertical structures where nine different parameters are considered important as the main factors that determine the total horizontal force. First the parameters that were used to determine the horizontal forces are discussed.

¹) WL | DELFT HYDRAULICS, P.O. Box 177, 2600 MH Delft, The Netherlands.
Then the actual development of the NN is described, followed by a comparison with traditional design formulae. In addition, a method to assess the reliability of the NN-predictions is presented. More detailed information concerning this paper can be found in Van Gent and Van den Boogaard (1998).

2. NEURAL NETWORK MODELLING

2.1 PARAMETERS INVOLVED IN FORCE PREDICTION

The total horizontal force on a vertical breakwater is the result of the interaction between the wave field, the foreshore and the structure itself. Here perpendicular wave attack is considered. In order to describe the wave field two parameters are applied: The significant wave height in deep water ($H_s$) and the corresponding peak wave period ($T_p$). The effect of the foreshore is described by the slope of the foreshore ($\tan \theta$) and the water depth in front of the structure ($h_s$). The structure is characterised by the height of the vertical wall below and above the water level ($h'$ and $R_c$), the water depth above the rubble-mound foundation ($d$), the width of the berm ($B_b$) and the shape of the superstructure ($\varphi$). Figure 1 shows the nine parameters on which the NN was based.

![Fig. 1 Parameters used for NN-modelling of horizontal forces on vertical structures.](image)

In particular, the crest shape factor ($\varphi$) was introduced to account for the differences in crest shapes of the structure, such as inclined or curved crests. Measured forces obtained under similar wave conditions and similar structures but with different crest shapes (vertical and non-vertical) were compared by computing the ratio of the corresponding horizontal forces. The average of the computed ratios was taken as the crest shape factor for that shape. The values were in the range from 0.8 to 1.0 (1.0 corresponds to a vertical crest). This approach was adopted in view of the fact that wave overtopping was not significant in those tests where the crest elements differ considerably from a simple rectangular caisson.
2.2 DESCRIPTION OF DATA-SET

Data on total horizontal forces on vertical structures are collected from physical-model tests performed at several laboratories. The applied measurement techniques and analysis methods differ from institute to institute. Based on published data the parameter corresponding to the total horizontal force that is exceeded by 99.6% of the waves has been derived. For some cases this parameter was not directly measured but has been obtained by interpolating between for instance the 99% and 99.8% values. For one data-set an extrapolation has been applied by using a Weibull-fit through the 90%, 95% and 98% values; the fit gave good predictions of the measured 99%-values and therefore has been applied to predict the corresponding 99.6% values. Nevertheless, inaccuracies may have been introduced by these interpolations and extrapolations.

The data is described in detail in the following publications: Van der Meer and Juhl (1992), Allsop et al (1996), Kortenhaus and Oumeraci (1997) and Madrigal and Wei (1997). In total 612 data-patterns have been used: 68 from DELFT HYDRAULICS (The Netherlands), 59 from DHI (Denmark), 97 from CEDEX (Spain), 215 from HR Wallingford (UK) and 173 from Leightweiss Institute (Germany).

As will be discussed, an analysis concerning the consistency of the data-set has been performed. It occurred that some data-sets, especially the relatively large data-sets, show significant variations in output for data-patterns with similar input-patterns. The inconsistencies in the data-set do not necessarily lead to incorrect predictions by the NN if these measurement errors can be considered as a random white noise, i.e. no 'systematic errors'.

One of the sources of inconsistencies in the data-set is that the data includes several types of wave forces. The data-set contains conditions that lead to pulsating wave forces but also conditions that lead to impact forces. Especially tests leading to impacts with a relatively low number of waves lead to relatively weak repeatability and therefore input-patterns with a less reliable output. However, if conditions are divided into classes of ‘pulsating forces’, ‘impact forces’ and ‘transitional’ according to the diagram by Kortenhaus and Oumeraci (1997), 244 patterns are identified as ‘pulsating forces’, 362 as ‘impact forces’ and 12 as ‘transitional’. Inconsistencies such as large differences between output for similar input-patterns are not restricted to one of these classes (inconsistencies occur for ‘impact forces’ and for ‘pulsating forces’).
The accuracy of the NN-modelling depends strongly on the quality of the data-set. Therefore, for this application it is even of greater importance that a method is available to quantify the reliability of the NN-output. The consequence of the applied method is that the accuracy of the NN predictions can be further improved if more reliable data-patterns become available.

2.3 NEURAL NETWORK TRAINING

General

Here, NN-modelling will be briefly discussed. For a more detailed but still general introduction a well written review on NN included in ACM (1994) is recommended, as well as the book of Beale and Jackson (1990). For further details on the technical background, examples, and applications the book of Haykin (1994) is very suitable.

NN can be seen as a sophisticated data-oriented modelling technique to find relations between input- and output-patterns without using process-knowledge. Here, the applied input-pattern is \([H_s, T_p, \tan\theta, h_s, h', R_c, d, \varphi, B_b]\) and the output is a single parameter \([F_{h-99.9\%}]\). For the preparation of an NN model a sufficiently large set of input-output patterns is required.

The configuration of an NN-model can vary. The NN is organised in the form of layers and within each layer there are one or more processing elements called 'neurons'. The first layer is the input layer and the number of neurons in this layer is equal to the number of input-parameters. The last layer is the output layer and the number of neurons in this layer is equal to the number of output parameters. The layers between the input and output layer are the so-called 'hidden layers'. Here, a configuration with only one hidden layer is chosen and information goes from the input-layer, via the hidden layer, to the output-layer ('feed-forward' configuration). Figure 2 shows an example of such a configuration.

Each neuron receives inputs from all neurons of the preceding layer via the connectivities. To each connectivity a weight is assigned. The total input of a neuron then consists of a weighted sum of the outputs of the preceding layer. The output of the neuron is generated using a ‘non-linear activation function’ with a sigmoid shaped form. This procedure is followed for each neuron; the output neuron generates the final prediction of the NN.
Before the NN can be used the weight-factors need to be calibrated for which a part of the data-set is used (here: a ‘training-set’ of 500 of the 612 tests). This is the so-called ‘training’ of the NN using some ‘learning’ procedure. After that the NN need to be validated by using the remaining part of the data-set (here: a ‘testing-set’ of 112 of the 612 tests).

**Training and testing**

The calibration of the weight-factors is performed by using data for which both the input and the output are fed to the NN. Starting with an initial guess for the weights the procedure is that the inputs of this ‘training-set’ are fed to the NN and the NN’s outputs are compared to the observed outputs (measured output). On the basis of the differences between both, the weights are adjusted in such a way that in the next step when the inputs are again fed to the NN, a better prediction is found. This procedure is repeated until no further improvements can be made. This iterative adjustment of the weights is called ‘training’ of the NN and usually this is done by minimisation of some cost function (or error function) that quantifies the differences of predicted outputs and the desired output (measured), often called ‘targets’. A common form of cost function is a superposition of the squared differences. For the minimisation of the cost function, gradient based methods turn out to be most efficient and for the computation of gradient the well known ‘error back propagation rule’ is used. Here, for calibration the root-mean-square error is defined as:
An important step in the NN-modelling is to find the optimal number of neurons in the hidden layer. By increasing the number of hidden neurons the differences between the NN-output and the desired output (measured) of the data used for calibration will decrease because more hidden neurons lead to more degrees of freedom (more weight-factors). However, there is a certain optimum because at a certain number of hidden neurons, the NN also starts to model 'noisy fluctuations' in the data-set which is unfavourable for the accuracy of the real predictions. At that moment the NN-model is 'overtrained'. To prevent such an overtraining of the NN not all available data is used for training; a part is reserved for verification. In this partition the 'training-set' and 'testing-set' must be equivalent in statistical sense (i.e. representative for the whole data-set). The optimal number of neurons can be found by training the NN for a range of numbers of neurons in the hidden layer and each time comparing the NN's performance (root-mean square error) on the training and testing-set. Figure 3 shows the performance of NN with various numbers of hidden neurons. More neurons lead to a better performance of the NN for the data used for training but at some stage the predictions of the remaining data (testing-set) become worse. This is an indication that at this stage, NNs with more hidden neurons are not suitable for generalisation and do not provide optimal predictions. This is shown in Figure 3 and in this case a configuration with 8 hidden neurons was chosen as the optimal NN.

\[
RMS_{\text{train}} = \sqrt{\frac{1}{N_{\text{train}}} \sum_{n=1}^{N_{\text{train}}} \left( F_{\text{NN}}^{\text{test}}(H-0.4\%)_n - (F_{H-0.4\%})_n \right)^2}
\] (1)
Application

The aim of the NN is to be applied both for small-scale tests and for prototype situations. Here the basic data-set is based on small-scale tests, however. Therefore a treatment to predict correct prototype situations needs to be included. If for a certain input-pattern \([H, T_p, \tan \theta, h, h', R_c, d, \varphi, B_b]\) a prediction is required, this input-pattern is scaled by using the Froude-scaling law to an input-pattern with a wave height on which the NN is trained (here all patterns are scaled to a wave height of \(H=0.1 \text{ m}\)). This also reduces the number input-parameters for the actual NN-configuration from 9 to 8 (here the configuration 8-8-1 is used which means 8 input parameters, 8 hidden neuron and 1 output parameter). The prediction by the NN \(F_{99.9}\) is then again scaled back to the actual wave height. This procedure where physical knowledge is incorporated in the NN, allows for predictions on different scales. However, this also introduces overpredictions for situations with wave impacts where the Froude-scaling law is not strictly valid.

Using the above described scaling of the data, the data-set can be statistically summarised as shown in Table 1. It must be taken into account that the input components of data-set are not uniformly distributed within the ranges of the parameters given in Table 1. This non-uniformity cannot be recognised from the univariate statistics of Table 1 and a more advanced approach must be followed to obtain an 'accurate' description of the input domain. This, as well as a method to obtain reliability-intervals for NN-predictions of the forces, will be addressed in the following section.

Table 1: Statistical parameters of the scaled input-patterns of the data-set used for calibration/training.
Fig. 4 Comparison of measured and predicted (NN) horizontal forces.
Fig. 5 Comparison of measured and predicted (Goda) horizontal forces.
Fig. 6 Data-points with similar input but large differences in measured properties.
Fig. 7 Comparison of measured and predicted (NN) horizontal forces (2 data-sets).
Fig. 8 Comparison of measured and predicted (Goda) horizontal forces (2 data-sets).
Comparison with Goda-method

Figure 4 shows a comparison between the measured horizontal forces and the predictions by the NN for all 612 data-patterns. Figure 5 shows a comparison between the same measured forces and the well-known Goda-method (Goda, 1985). For this data-set the scatter is large for both prediction methods. For this data-set the NN-output shows a better agreement than the Goda-method. The large scatter is not due to the prediction methods but mainly the result of inconsistencies in the data-set (see also Van Gent and Van den Boogaard, 1998).

In Figure 6 some data-patterns from Figure 4 which have the same, or nearly the same, input-pattern are connected with lines. This figure shows that for nearly identical input-patterns considerable deviations are observed in the measured output. For such input-patterns the NN-output shows nearly the same output, however this is consistent in contrast to the measured data which show rather large inconsistencies. Since the accuracy of the NN-predictions depends largely on the quality of the data-set, the observed inconsistencies in the data-set induce the necessity for information concerning the reliability of the NN-predictions. Although the NN is developed with data of all five data-sources, two data-sources do not show these inconsistencies. For those two data-sets Figure 7 and Figure 8 show the same comparison between measured data and predictions by the NN-tool and the Goda-method. The comparison between measured and by the NN-tool predicted forces shows a good agreement. For a relatively large part of the data-set, the Goda-method underpredicts the forces. The comparisons indicates that the NN-tool can serve as a complementary design-tool. In the following section, a method to quantify the reliability of the predictions is discussed.

3. RELIABILITY INTERVALS

Here, a tool is described to obtain reliability-intervals for the horizontal force predictions of the NN. Since the NN is calibrated with a data-set that does not uniformly cover all possible situations, the NN in fact interpolates between certain measured data-patterns or extrapolates from a region with measured data-patterns. The NN-tool, like other ‘fit-procedures’ is more suitable for interpolation than for extrapolation. The tool to quantify the reliability is based on information of the distribution of the data-set, hereafter the training-set, over the range of the parameter-domain covered by the measured parameter combinations. It is noted that the here developed approach is quite general and is not restricted to the NN-
modelling of forces on vertical breakwaters (more details can be found in Van Gent and Van den Boogaard, 1998).

Three steps are distinguished in this approach: First it is studied how the input-parameters of the training-set are distributed over their domain; then a method is developed to decide whether or not a prediction by the NN can be accepted or not, and finally a method to quantify the reliability of an NN-prediction is described.

In the first step the parameter-domain spanned by the input-patterns of the training-set is determined by means of a probability density function (PDF) \( f(j) \). In particular the PDF can be used to determine which parts of the input parameter-domain are densely represented by the training-set (and where the NN will generate the most accurate predictions) and which parts are sparse, or even absent (and where the NN is used for extrapolation rather than interpolation).

Following the approach suggested by Van den Boogaard et al (1993) a very suitable and accurate way to find an estimate of the PDF \( f(j) \) is to place a basis function \( \varphi(j) \) at every input-pattern of the training-set and then take the superposition of all these basis functions. In this way the basis function \( \varphi(j) \) spreads each point over its neighbourhood and for this reason \( \varphi(j) \) is called a Point Spread Function (PSF). Often a (multivariate) Gaussian profile is chosen for the PSF and a copy of this Gaussian functions is centred at each input-pattern. Gaussian functions have (multivariate) ellipsoids as iso-lines and the form of these ellipsoids (i.e. the directions and lengths of the principal axes) is uniquely determined by the covariance matrix within the formula of a Gaussian function. For the PSF \( \varphi(j) \) this covariance matrix \( \Sigma_p \) cannot be chosen arbitrarily but must be derived from the \( N \) input-patterns within the training-set. This is done in such a way that the superposition of all the Gaussian Point Spread Functions provides the most accurate estimate of the PDF \( f(j) \). From the derivation of this 'optimal' covariance function it also follows that the PSF \( \varphi(j) \) is centred at 0. All this leads to:

\[
\varphi(\tilde{x}) = \frac{1}{N} \sum_{n=1}^{N} \varphi(\tilde{x} - \tilde{X}_n) \quad \text{with} \quad \varphi(\tilde{\xi}) = \frac{1}{(\sqrt{2\pi})^D \sqrt{|\Sigma_p|}} \exp\left[-\frac{1}{2} \tilde{\xi}^T \Sigma_p^{-1} \tilde{\xi}\right]
\]

where \( D \) is the number of input-parameters (dimensions), \( N \) is the number of input-patterns, \( \Sigma_p \) is a covariance matrix, \( \tilde{X}_n \) denotes the n-th input-pattern, and \( \tilde{x} \) is the vector of the input-pattern for which the prediction by the NN is required. This provides the density-function for a certain input-pattern for which the NN is applied. If this density-function exceeds a certain minimal threshold value \( \delta \), one can say that
the input-pattern is close to input-patterns of the training-set, and thus the NN can provide a relatively accurate result. The remaining problems are first to define a proper threshold-value $\delta$ for which the prediction of the NN can still be accepted and secondly, if a prediction can be made, to quantify the reliability of the predictions.

To illustrate the above described technique Figure 9 shows the principle for data with two parameters $(x,y)$ only. The basic-data (i.e. the training-set) is non-uniformly spread over the parameter-domain. For predictions within the range of the basic-data (Data-point 1), a relatively reliable prediction will be obtained. For a prediction outside the range of the basic data the predictions are based on extrapolation and will be less reliable. When extrapolating in a direction with basic-data, a relatively reliable extrapolation might still be obtained (Data-point 3). For extrapolations in a direction with low spread, the reliability of the extrapolation (and thus the prediction of the NN) will be unreliable (Data-point 2) (ellipsoids in Figure 9 denote iso-lines of the PSF $\varphi(\cdot)$ centred at the measured input-patterns; the PDF $f(\cdot)$ is the superposition of these PSFs and provides the density of the input data-set).

To obtain a proper threshold-value $\delta$ for which a prediction by the NN can be accepted, a 'level of significance $\alpha'$ is introduced. Then the PSF $\varphi(\cdot)$ is used to define an ellipsoid (forming an iso-line of the PSF) that is placed around the input-pattern $\bar{x}$ for which an NN-prediction is required. The 'radius' of this ellipsoid is $R_\alpha$ and it depends on the significance level $\alpha$. $R_\alpha$ is such that the volume of the ellipsoid is a fraction $\beta:=1-\alpha$ of the total volume of the PSF. It can be shown that for a given $\alpha$ this radius must satisfy the equation $\gamma(\frac{\alpha D}{2}, \frac{\alpha R_\alpha^2}{2}) = \beta$ where $\gamma(\cdot, \cdot)$ is the incomplete gamma-function. The relation between the threshold-value $\delta$ and the radius $R_\alpha$ is then as follows:
\[ \delta = \varphi (\xi_a) = \frac{1}{N (\sqrt{2\pi})^d \cdot \sqrt{\Sigma_p}} \exp \left[ -\frac{1}{2} R_a^2 \right] \] (3)

Then all input-patterns \( \tilde{x}_n \) of the training-set are selected that are within the ellipsoid of the radius \( R_a \) around the new input \( \bar{x} \). These patterns of the training-set are used to derive the 95% reliability interval for the NN's prediction of the total horizontal force for the new input \( \bar{x} \). The number of the so selected input-patterns depends on the value that is chosen for the significance level \( \alpha \). From a sensitivity analysis a value \( \alpha = 0.05 \) turned out to be very suitable in practice. If no input-patterns of the training-set are within the ellipsoid, the corresponding NN-prediction will be considered as unreliable and no reliability-interval is defined. If a number of \( K \) input-patterns (with \( K \geq 1 \)) of the training-set are within the ellipsoid, the reliability-interval around the prediction for the new input-pattern \( \bar{x} \) is determined based on the measured outputs \( T_k (F_{0.95 \text{th}}) \) belonging to the input-patterns \( \tilde{x}_n \) within the ellipsoid. The mean and variance of the outputs of \( T_k \) can be estimated by:

\[
\langle T_k \rangle = \frac{1}{K} \sum_{k=1}^{K} T_k , \quad \sigma_{(T)}^2 = \frac{1}{K \cdot (K - 1)} \sum_{k=1}^{K} \left( T_k - \langle T \rangle \right)^2
\] (4)

Assuming that the mean of the \( K \) outputs satisfy a Gaussian distribution, the 95%-reliability-interval is:

\[
\left( \langle T_k \rangle - 1.96 \cdot \sigma_{(T)} , \langle T_k \rangle + 1.96 \cdot \sigma_{(T)} \right)
\] (5)

The mean of the outputs \( \langle T_k \rangle \) is in general not equal to the prediction by the NN. The reliability-interval however, is considered as a useful measure for the reliability of the prediction. Therefore, for the final reliability-interval around a prediction by the NN, i.e. \( \text{NN}(\bar{x}) \), the following measure is used:

\[
\left( \text{NN}(\bar{x}) - 1.96 \cdot \sigma_{(T)} , \text{NN}(\bar{x}) + 1.96 \cdot \sigma_{(T)} \right)
\] (6)

Inaccurate test-results that are used for training the NN, such as those with observed inconsistencies leading to the relatively large scatter (Figure 4), affect the prediction of the NN but this also leads to a wider reliability-interval around the prediction. This justifies that also these tests are used for the NN; the user of the NN-tool is given a prediction but in regions with relatively unreliable basic-data, this prediction will involve a wider reliability-interval.
As an example of the above described approach the predictions by the NN-tool are shown in the left graph of Figure 10 (as in Figure 7) while the right graph shows the upper limits and the lower limits of the 95%-reliability-intervals for these predictions. This approach which yields insight in the accuracy of the predictions prevents application of the NN for situations where no basic-data is available (significant extrapolation) and also provides a measure for the reliability of the predictions for situations where sufficient tests in the applied data-set are available.

4. CONCLUSIONS

The presented results show that Neural Network modelling can well be used for the prediction of horizontal forces on vertical structures. A tool has been developed to obtain a reliability-interval for the Neural Network predictions. Still, the accuracy of the Neural Network is largely determined by the quality of the data-set. It has been shown that the differences between the Neural Network predictions and the measured values are to a large extent caused by inconsistencies in the data-set. For the data-sets that show none of the observed inconsistencies the comparison between the NN-output and the measured forces is good and the agreement is such that the tool can be used as a complementary design tool. For the present data-set the predictions by the NN-tool show a better comparison with the measured data than the Goda-method.
ACKNOWLEDGEMENTS

This study was co-sponsored by the Commission of the European Communities within the framework of the MAST-PROVERBS project (contract MAS3-CT95-0041). Mr. M.D. Sánchez (IHE/DELT HYDRAULICS) is acknowledged for his preliminary study which led to valuable insight in applications of NN-modelling for the present subject.

Abstract

When calculating the stability of a breakwater foundation information on the pore pressures directly underneath the caisson in the bedding layer and in the sand layer is needed. In this paper easy to handle calculation techniques are presented to derive the pore pressures underneath the caisson. A quasi-stationary calculation technique has been verified for the situation of a caisson breakwater, by a hindcast of laboratory tests. The differences between the quasi-stationary calculations and the laboratory measurements appear to be small and can be explained by non-stationary effects. The pore pressure distribution in real cases may considerably deviate from the traditionally assumed triangular distribution, due to several effects. Non-stationary effects are only relevant if the rubble is relatively fine and wave impact occurs. The pore pressures in the sand layer have been studied by centrifuge tests. Two types of pore pressure development can be distinguished, the instantaneous pore pressures, which follow the wave action at sea and the residual pore pressures, which gradually develop under repetition of loading. The residual pore pressures may lead to liquefaction if silt or fine sand is present in the subsoil.

Introduction

In the past many vertical breakwaters have been built. Several have been collapsed or suffered severe damage, see [Oumeraci, 1994]. When judging the stability of the foundation of a vertical breakwater the strength of the subsoil is important. Until recently only little was known about the strength of the vertical breakwater foundation and the strength development during wave attack. In this paper a study on the influence of the pore pressures on the strength of the rubble mound and the subsoil is presented.

¹Delft Geotechnics, Stieltjesweg 2 P.O. Box 69 2600 AB DELFT, The Netherlands
²Norwegian Geotechnical Institute, P.O. Box 3930 Ullevaal Hageby N-0806 OSLO, Norway
In the following only vertical, caisson breakwaters are considered. The results, however, can also be applied to block walls. The caissons are assumed to be placed on a rubble mound. Underneath the rubble the original subsoil is present. Pore pressures in the subsoil will only be explicitly predicted if the subsoil consists of sandy material.

The water pressures in the rubble and in the subsoil, in the following referred to as pore pressures, are fluctuating by the wave action at sea. The pore pressures fluctuate around an average pressure level, corresponding to mean sea level. The wave-induced deviations in pore pressures are referred to as excess pore pressures. So the actual pore pressures are a summation of the average pore pressures and the excess pore pressures. In this paper only the excess pore pressures will be discussed. The resultant of these pressures along the caisson bottom is referred to as uplift force.

The total stress in the rubble and the subsoil consists of two components the pore pressure and the effective stress. When the total stress remains constant and the pore pressure increases as a result of wave action the normal effective stress decreases and the shear resistance, being the product of normal effective stress and the tangent of the friction angle, decreases proportionally.

Three main failure modes of a caisson foundation can be distinguished:

- Sliding over the foundation
- Bearing capacity failure of the rubble
- Bearing capacity failure of the subsoil

The three failure modes are depicted in figure 1. In reality a number of combinations of the above mentioned failure modes can be observed. In all the failure modes the pore pressures play an important role. They determine the uplift force relevant for the first mode, the reduction of the shear resistance in the mound, relevant for the second mode and the reduction of the shear resistance in the subsoil relevant for the last mode.

![Figure 1 Failure modes](image-url)
Pore pressures in rubble

Linear pressure distribution

Traditionally, the pore pressures along the caisson bottom are estimated by a triangular shaped distribution. The water pressure at the front edge of the caisson bottom can be calculated by an analytical equation, e.g. the Goda formula. Since at the harbour side of the caisson no wave action is assumed to be present, the excess pore pressures at the harbour side toe of the rubble are negligible. Linear interpolation between the two points leads to the previous mentioned triangular shaped water pressure distribution underneath the caisson bottom.

Validation of a stationary numerical model

The linear pressure distribution is valid for a homogeneous bedding layer with a constant small thickness. When considering other cases a more sophisticated model is needed. In soil mechanics laminar flow models are used to simulate a stationary ground water flow situation. These models are based on Darcy's law in combination of the continuity equation. When applying these equations, only the permeability and the layout of the rubble and subsoil need to prescribed. This limited amount of information makes these models easy to be used.

These models however imply a number of restrictions.

- Stationary flow: the non-stationary effects will be discussed below
- Laminar flow: in coarse rubble the flow will usually be turbulent, however, corrections can be made by an adaptation of the permeability distribution.
- Incompressible water: this not a serious restriction for this situation.

The validity of the application of such a model (MSEEP) for calculating the pore pressure development in the rubble layer underneath a caisson is studied with a hindcast of large-scale laboratory tests.

The laboratory tests have been carried in the large wave flume of Hannover, see [Kortenhaus et al, 1994]. In this wave flume a test caisson has been constructed. The caisson height was about 2.76 m and the caisson width 3.0 m. The caisson was placed on a rubble mound with a thickness underneath the caisson of 0.60 m, a height at the front of 1.02 m and 0.77 m at the backside. Below the mound and separated by a geotextile a sand layer with a thickness of about 2 m was present. This sand layer was placed on the concrete floor of the flume.

The water pressures have been measured at several locations in the model. Directly underneath the caisson 6 rows of pore pressure transducers were located. The first row on top of the rubble, directly below the caisson bottom. The next row in the middle of the rubble layer. The following rows were located in the sand layer.

Four water pressure transducers have been placed in the front slope of the rubble. The readings of these transducers are used to determine the boundary conditions for the numerical model calculations. The pressures measured underneath the caisson are used to validate the calculation results.
A large number of waves have been applied on the test model. Two regular waves have been selected for this hindcast. First a smooth non-breaking wave, $H = 0.7 \text{ m}$ and $T_p = 6.5 \text{ s}$, has been selected, secondly a breaking wave including wave impacts, $H = 0.9 \text{ m}$ and $T_p = 3.5 \text{ s}$. Despite differences in wave characteristics, the maximum wave induced pressures in the rubble at the front of the caisson were nearly equal for both waves.

For the validation of the quasi-stationary calculation technique four moments in time have been selected from the continuously measured time-series. The moments are indicated by the water level at the front of the caisson:

- wave crest
- falling water level, passing still water level
- wave trough
- rising water level, passing still water level

The exact moments in time are selected from the reading of the pore pressure transducer, closest to the caisson front.

Figure 2  Comparison between the measured and calculated pore pressures
In figure 2 the validation results for the breaking wave are presented for each of the four conditions. From these graphs the following can be notified:

- Differences between the measured and calculated pore pressures in the rubble are found to be negligible for wave trough conditions.
- Differences are found for the situation at which the water level at the front passes still water level. For the rising water level more difference is found then for the falling water level.
- For the wave crest differences up to 20 % are found.

The calculations of the non-breaking wave show similar tendencies. Except that the differences for the wave crest are negligible, like for the wave trough.

Non-stationary effects can explain the differences between the measured and calculated pore pressures for the rising and the falling water level. When the water level passes still water level, the acceleration of the water flow reaches it's peak value and the time-depending effects of inertia and elastic storage become important.

The differences in pore pressures found for the wave crest with its temporarily high peak forces during the wave impact can also be explained by non-stationary effects, as will be discussed below.

In the scale model a homogeneous rubble layer with constant thickness has been applied. Consequently, an almost triangular shaped distribution is found for the wave crest as well as for the wave trough.

Stationary model applied in practice

No triangular pressure distribution is found, however, if the grainsize distribution of the rubble is non-homogeneous. When at one side of the caisson finer material is used more flow resistance and larger pore pressure gradients are found in the region of the finer material. An example is presented in figure 3. That such a pore pressure distribution may be realistic was demonstrated by measurements underneath the Porto Torres breakwater [Franco, 1996].

Not only the deviation in grainsize distribution leads to a deviation of the triangular shaped pore pressure distribution underneath the caisson. Other causes for deviation from the linear distribution may be:

- All kinds of natural activities, like animals or plants, may block the pores in the rubble. This leads to a gradual reduction of the permeability of the rubble.
- The presence of impermeable, tightly placed apron slabs in front of the breakwater.
- Flow concentration around the edges in combination with the effect of turbulence, especially with high mounds.
- When the caisson bottom does not connect perfectly to the top of the rubble some space is present larger then the average pore volume.
Non-stationary effects

The quasi-stationary calculations approximate the actual pressures until a certain level of accuracy. For a more accurate approximation of the pressures the non-stationary effects need to be included.

In this study it is assumed that the non-stationary effects can simply be added to the results of the quasi-stationary calculations. Furthermore the non-stationary effects are split into two different components. First the effect of the (pressure) wave passing the caisson foundation is studied. For this situation the caisson is assumed to be completely fixed. This is referred to as the direct component. The second component is the indirect component. For this situation the movement of the caisson is studied independently from the wave action at sea. The water level at the front of the caisson is assumed at still water level. The excess pore pressures underneath the caisson are caused by the rocking and uplift motions of the caisson. Both components are presented in figure 4. In the following it is assumed that these phenomena can be studied individually from each other and that superposition of these components is allowed.

The non-stationary effects will be discussed for the situation of wave crest with wave impact, as this is the most relevant situation for the stability of the foundation.

Direct component

The first approximation of the direct component is a quasi-stationary pore pressure distribution, as can be found from the numerical calculations. According to this approximation all pore pressure-time curves in the bedding layer would have the
same shape as the pressure-time curve at the front of the caisson and the variations would also be simultaneous. All pressures need only be reduced with a factor, which is constant for each location and can be found from quasi-stationary calculations or, even more simplified, with a linear distribution, as proposed by Goda and many others.

Inertia and elastic compressibility, however, influence the direct component during wave impacts with short duration: the pressure wave induced at the seaside needs some time to pass through the bedding layer. The combination of inertia, elastic compressibility in the two phases (soil skeleton and water, which is compressible due to small air bubbles) makes analytical solutions rather complicated. Before trying to find such analytical solution, two approximations of the direct component are presented:

- Approximation for one-phase material: "acoustical wave"
- Approximation without inertia: "elastic storage”.

Both approximations will be studied in the next sections in order to find formulations for the relevant corrections to the quasi-stationary approach.

**Acoustical wave in direct component**

The propagation of the wave impact pressure variation through the rubble mound can be described as an acoustical wave if inertia and compression of the rubble-water mixture are modelled and

![Figure 4 Distinction between direct and indirect component](image)

if the mixture can be considered as a one-phase material. Last condition is met either if both phases move together ("no drainage"), as occurs with fine grained material, or if the water phase moves alone, hardly hindered by the rubble ("complete drainage"), as occurs with very coarse rubble.
Equations for both cases have been developed [MAST III / PROVERBS 1999] in order to quantify the influence on the uplift force during wave crest. This influence depends on the duration of the wave impact, the width of the caisson and the stiffness of the rubble skeleton and pore water. A maximum increase of the uplift force of 30%, of the static situation, may only occur if the duration and stiffness are very small, where as the width is very large. Otherwise, the influence is negligible.

Elastic storage in direct component

According to the assumption used for the "acoustical wave", no energy loss, thus no damping occurs with the acoustical wave transmitted through the mound. For the completely undrained case it is assumed that the pore pressure variation at the seaside is transferred from the water to the skeleton without relative movement of the water through the skeleton. For the completely drained case, it is assumed that the fluid moves freely through the skeleton, without any stress transfer ("friction") to the skeleton. Both extremes are rather unlikely with the grainsizes usually applied in a mound.

There will be some relative movement of the water with respect to the skeleton together with friction and, consequently, energy loss. This effect in combination with the compression of the water, but without inertia, can be modelled with the one dimensional storage equation for elastic compression of the pore water.

The solutions of this equation yield an equation for the characteristic length for elastic storage, \( L_{es} \), a function of impact duration, pore water stiffness and permeability of the rubble, [MAST III/ PROVERBS, 1999]. This characteristic length should be compared with the caisson width, \( B_c \). The characteristic length can be determined with equation 1.

\[
L_{es} = \sqrt{\frac{TC_v}{\pi}}
\]

Where,

\[
c_v = \frac{k \times K_w}{n \gamma_w}
\]

\( T \) = wave period  
\( c_v \) = consolidation coefficient  
\( k \) = permeability  
\( K_w \) = compressibility of the pore water  
\( n \) = porosity  
\( \gamma_w \) = unit weight of water

The progress is now largely determined by the parameter \( L_{es} \). If \( L_{es} \gg B_c \) the elastic storage is not relevant and the pore pressure distribution may be quasi-stationary. With \( L_{es} < B_c \), the uplift force, \( F_{u,\text{max}} \), will be reduced, as illustrated in figure 4.
Indirect component

The effect of the indirect component can be found by considering the case where the "external" forces, together with caisson inertia, cause uplift and rotation of the caisson, whereas the pressure heads at both outer ends of the caisson remain equal to the mean sea level, defined to be zero. (right hand side of figure 4).

The "external" forces are \( F_f \) and \( F_u \). Where \( F_u \) is the resultant of the excess pore pressures along the caisson floor. In this case, however, these pore pressures are not considered explicitly. The pore pressures found below, are those which should be added to the quasi-stationary pore pressures to find the final value of \( F_u \).

![Diagram showing influence of elastic storage on uplift force](image)

Figure 5 Influence of elastic storage on uplift force

Uplift causes an increase in pore volume; rotation causes an increase and a decrease in pore volume. Uplift and rotation together cause a change in pore volume, which is linearly distributed in x-direction, as illustrated at the right hand part of figure 4. The mass balance requires a flow velocity \( q \), which will vary more or less parabolically in x-direction. This flow causes friction resistance, which is compensated by a pressure head gradient to meet the impulse balance. With the given zero pressure head at both ends of the caisson, a pore pressure decrease where the caisson rises and an increase where it descends.

An analytical equation has been developed to estimate the influence of the indirect effect [MAST III/ PROVERBS, 1999], i.e. the reduction of the uplift force during wave crest. Relevant parameters appear to be the impact duration, the caisson width, the skeleton stiffness and the permeability. The reduction appears to be significant for short impact duration, large caisson width, small skeleton stiffness and low permeability. Usually this is not the case.

By extended Finite Element calculations the effects of direct and indirect component have been studied separately, in the framework of the hindcast of the above mentioned large-scale tests in Hannover. For the calculations in which the caisson
was completely fixed the calculated pore pressures did not differ from the pore pressures calculated for the free moving caisson. From these results the indirect component is considered of minor importance during these tests.

Pore pressures in the sandy subsoil

The influence of the wave action on the pore pressure development is among other things studied by centrifuge tests [van der Poel and de Groot, 1998]. These tests were carried out in the centrifuge of Delft Geotechnics in Delft. For these tests the 13 m (prototype) wide caisson was directly placed on the sand layer. The model was enclosed by a gravel layer, which covered the sandy subsoil. A lay-out of the prototype caisson is presented in figure 6. The figure shows two displacement meters on top of the model. Below the caisson pore pressure transducers were placed. First a row is placed in the caisson floor. Secondly a row of pore pressure transducers was placed at 2,70 m, prototype measures, below the bottom of the caisson.

A typical reading of the transducer indicated in figure 6 by a circle is presented in figure 7. From this figure two types of pore pressure development can be distinguished.

First type is the instantaneous pore pressures. These pore pressures follow the wave action at sea directly. This type of pore pressure development can be distinguished from the reading by the sharp high rise peaks.

The instantaneous pore pressures are caused by the deformation of the skeleton of the sand layer. The movements of the caisson cause compression, decompression and shear deformation of the skeleton of the sandy subsoil. At locations where compression occurs the pore volume decreases, leading to an increase of the pore pressures. At locations of decompression and shear deformation the pore volume increases, leading to a decrease of pore pressures. These fluctuations occur rapidly in time. For this reason the instantaneous pore pressures are hardly influenced by drainage effects. Only in a small top layer some drainage influences the pore pressures.

The second type of pore pressure development, the residual pore pressures, can be distinguished from the reading. These pore pressures induce a gradual increase of average pore pressure. Under a repetition of loading, the wave attack, the grains of the sand layer will show a tendency of re-arrangement. For many situations the subsoil will densify or show the tendency of densification. For these conditions the pore volume will decrease. This pore volume decrease leads to extra pore pressures. When by consolidation the excess pore pressures can not be completely drained off during the passage of one wave some residual pore pressures are left leading to an increase of average pore pressures.
When full drainage occurs during a wave train or during a storm, the subsoil will densify and even the residual pore pressures will not remain. This might lead to deformations of the subsoil and to settlements at the surface. Where no drainage occurs the pore pressures will increase. A continuous increase of pore pressures will lead to liquefaction of the sandy subsoil. To judge whether this increase might lead to liquefaction the following rule of thumb is presented. When drainage period $T_{\text{drainage}}$
is smaller than 100 times the wave period $T$ no significant pore pressure can be expected. When drainage period is longer the possibility of liquefaction should be considered. The parameter $T_{\text{drainage}}$ is a function of caisson width $B_c$ and consolidation coefficient of the subsoil $c_v$.

$$\frac{T_{\text{drainage}}}{T} < 100$$

Where

$$T_{\text{drainage}} = \frac{B_c^2}{c_v}$$

### Application to a practical example

The above presented theories and equations have been applied to real existing structures. In this paper the results of the calculations for the breakwater Genoa Voltri, Italy, are presented.

The breakwater is located on a rubble layer with a thickness of up to 15 m. Below this rubble several soil layers can be distinguished. On top there is a silt layer with a thickness of 13 m. Below the silt layer there is a sand layer of 8.5 m of thickness. Underneath the sand layer there is a stiff clay layer with a strongly variable thickness. For the calculations a thickness of 9.5 m is applied. These soil layers are based on a rock foundation. The characteristic soil parameters are presented in table 1.

Table 1 Applied soil parameters

The following wave characteristics are applied

- significant wave height 8.3 m
- design wave height 13.2 m
- wave period 11.5 s

First the influence of the non-stationary effects are considered. For the acoustical wave approach it is found that the influence of these effects on the uplift force are negligible.

For the elastic storage approach $L_{\text{exp}}/B_c$ is found to be equal to 4. From figure 5 it can be seen that for the elastic storage approach the uplift force equals to the stationary found uplift force.
Also the influence of the indirect component of the non-stationary effects appeared to be of minor importance.

From both simulations it can be concluded that the non-stationary effects are not relevant for the Genoa situation. The uplift force during wave crest can be calculated by stationary calculation techniques.

For the pore pressures in the subsoil the possibility of occurrence of liquefaction can be judged according to the equation 2. The results are presented in table 2.

<table>
<thead>
<tr>

<td>50 600</td>
<td>4 360</td>
</tr>
</tbody>
</table>

Table 2      Results of liquefaction judgement

For the sand layer the drainage period is short enough to prevent the occurrence of liquefaction. For the silt layer however it is possible for liquefaction to occur. For designing purposes for this situation a study focussed on liquefaction needs to be carried out.

With this information the stability can be calculated. Applying the stationary pore pressure distribution underneath the caisson in the rubble the factor of safety can be calculated for each of the earlier mentioned failure modes. The following safety factor are found:

- Sliding over the foundation $\mu = 1.73$
- Bearing capacity failure in the rubble $\mu = 1.27$
- Bearing capacity failure of the subsoil $\mu = 1.16$

According to the calculations the bearing capacity failure of the subsoil is the dominant failure mode. Sliding of the caisson over the rubble is found to be unlikely.

Conclusions

Pore pressures influence the stability of breakwater foundation. For preliminary design an easy to handle stationary flow model can be used to calculate the pore pressure underneath the caisson. Uneven distribution of the grain sizes in the rubble, a non-flat seabed and apron slabs may cause a significant deviation from the traditionally assumed triangular pressure distribution. To estimate the importance of non-stationary effects analytical equations and graphs can be used. The residual pore pressures in the sandy subsoil might lead to liquefaction if the drainage period is 100 times smaller then the wave period, which may be the case with silt or fine sand in the subsoil.

Economic Optimal Design of Vertical Breakwaters

H.G. Voortman\textsuperscript{1}, H.K.T. Kuijper\textsuperscript{2}, J.K. Vrijling\textsuperscript{3}

Abstract

In the design of coastal structures, the choice of the safety level for which the structure has to be designed is a major problem. This is also the case for vertical breakwaters. This paper applies the concept of economic optimisation to derive the appropriate safety level and at the same time the optimal geometry. Application to a design case shows that it can be economically optimal not to distribute the acceptable failure probability equally over all failure modes, but rather let one or two failure modes determine the total probability of failure.

Introduction

In Europe the interest in and the importance of vertical breakwaters is growing. A central point is the optimal geometry, e.g a ratio of the width and height of a vertical breakwater in the sense that the total lifetime costs are minimised. For a given safety level it is possible to choose the width and height of the breakwater in such a way that the construction costs are minimised. In practice however one has to determine the optimal level of safety.

In general there are two boundary conditions for the acceptable safety level:
- The individual acceptable risk. The probability accepted by an individual to die in case of collapse of a structure;
- The societal acceptable risk. The probability of occurrence of a certain number of casualties in case of collapse of a structure.

In addition to these limits, it is possible in some cases to derive the optimal probability of failure based on an economic analysis. In the case of a breakwater without amenities the probability of loss of life due to failure is very small, but the economic losses can be severe. Therefore an economical point of view for optimising the structures design is suitable and sufficient.

In this paper the concept of economic optimisation is applied to a fictitious design case of a vertical (caisson) breakwater. The relation between a full probabilistic optimisation procedure and the simpler approach of minimising the construction costs for a given safety level is shown. It is also shown that the system probability of failure of an optimal designed breakwater is largely determined by only

one or two failure modes. Wave transmission imposes a constraint on the caisson height.

Van Dantzig (1956) was the first to apply economic optimisation for the determination of the optimal safety level. He applied the method to derive the optimal height of the dike protecting the central part of the Netherlands. A wide variety of applications is found nowadays, primarily in engineering and economics. However, the only application to vertical breakwaters known to the authors is by Burcharth et al. (1995). In the paper by Burcharth a vertical breakwater is optimised using an objective function which assumes the caisson costs proportional to the caisson weight. The only design variable considered in Burcharth's paper is the caisson width.

In this paper, a more realistic caisson cross-section consisting of a concrete floor and cap and a mixed sand/concrete body is used. The objective function consists of a part that describes the construction costs and a part that describes the expected costs of failure. The construction costs are described as a function of the volumes of sand, concrete and rubble stone in the breakwater cross section. The risk part contains a part that describes damage due to serviceability limit states (SLS) and a part that describes damage due to ultimate limit states (ULS). As design variables the caisson height, the caisson width and the height of the rubble foundation are chosen in order to find the optimal breakwater geometry.

Practical experience shows that very often the system probability of failure of a structure is determined by a single failure mode (weak link). This paper will show that it is economically optimal to have such weak links in the design of a vertical breakwater.

Economic Optimisation

An economic optimal design is defined as the design for which the total lifetime costs are minimal. The total lifetime costs consist of the construction costs and the expected value of the damage costs. In case of a vertical breakwater the total lifetime costs are a function of:

- The vector of design variables \( \bar{x} \)
- Initial costs, not depending on the design variables \( I_0 \);
- Construction costs as a function of the design variables \( I(\bar{x}) \);
- Costs per day in case of serviceability failure \( C_{SLS} \);
- The probability of serviceability failure per day \( P_{f,SLS}(\bar{x}) \)
- Costs per event in case of ultimate limit state failure \( C_{ULS} \);
- The probability of ultimate limit state failure per year \( P_{f,ULS}(\bar{x}) \)
- Maintenance costs for the breakwater per year \( C_{main} \);
- The net interest rate per year \( r^* \);
- The yearly rate of economical growth, expressing growth and development of the harbour \( g \);
- The lifetime of the structure in years \( N \).

In this paper the maintenance costs have been neglected.
The optimal set of design variables is found by minimising the cost function:

\[
I(x) = I_0 + I(x) + \sum_{n=1}^{\infty} \left( \frac{365C_{\text{SLS}}P_{\text{F-SLS}}(\gamma) + C_{\text{ULS}}P_{\text{F-ULS}}(\gamma)}{(1 + r^{-g})^n} \right) \]

Several minimisation procedures have been developed which can be used to minimise function (1) (Press et al, 1990). For the calculation of the failure probabilities also several methods exist (Ditlevsen and Madsen, 1996). Some points to consider in the choice of the algorithms are mentioned in the remainder of this paper.

The Design Case

In this paper, a fictitious design case has been considered. A caisson breakwater has to be designed for a water depth of 25 m with respect to mean sea level (MSL). The subsoil consists of sand. An overview of the conceptual design cross section is given in Figure 1. The exact sizing of all elements in this design cross section will be derived by economic optimisation.

![Figure 1: Overview of breakwater cross section](image)

The total length of the breakwater is assumed to be 6000 meters. The height and width of the caisson as well as the berm height are chosen as design variables. The height of the concrete cap and floor are kept constant. The cap and floor consist of concrete only. The zone between cap and floor consists of filling sand and concrete. In the optimisation procedure the number of walls inside the caisson is unknown. A fixed percentage of concrete of 10% has been used in the weight and cost calculations. The costs of concrete, filling sand and rubble are estimated by practising engineers. An overview is given in Table 1.

<table>
<thead>
<tr>

<td>250</td>
</tr>
<tr>
<td>Filling sand</td>
<td>5</td>
</tr>
<tr>
<td>Rubble</td>
<td>70</td>
</tr>
</tbody>
</table>

Table 1: Overview of material costs

Due to these cost figures and the properties of the breakwater cross section, it is more expensive to increase the width of the caisson then the height of the caisson. Increasing the caisson width results in a larger volume of the concrete cap and floor.
which results in a faster increase of the concrete volume in comparison to an increase of the caisson height.

In case of failure of the breakwater, the damage will consist of structural damage to the breakwater itself and economical damage due to the interruption of harbour processes. In this study for the damage in monetary terms, figures have been used which originate from a similar study for a rubble mound breakwater (Delft University of Technology, 1995).

<table>
<thead>

</tr>
<tr>
<td></td>
<td>Economic damage per event</td>
<td>555,000,000</td>
</tr>
</tbody>
</table>

Table 2: Overview of damage costs

All damage is considered from the viewpoint of the harbour authorities. Economic damage denotes the economic damage due to interruption of harbour operations, loss of port dues, claims and costs of alternative transport. Structural damage consists of a (fixed) part that denotes damage to harbour inventory and a (variable) part denoting the damage to the breakwater itself.

Boundary Conditions and Wave Force Model

The boundary conditions for the breakwater consist of hydraulic boundary conditions (wave height, water levels) as well as of geotechnical boundary conditions (friction angles and densities). An overview of the relevant boundary conditions and the assumed distributions is given below.

Table 3: Overview of boundary conditions

The wave loading on the caisson is calculated by means of the method of Goda (1985) which is extended by Takahashi (1996) to include impact conditions.
Failure Modes

In this study a total of six failure modes have been implemented in the optimisation procedure. These six failure modes are:

- Wave transmission (SLS);
- Sliding of the caisson over the rubble foundation (ULS);
- Exceedance of the maximum allowable eccentricity of the resultant vertical force (ULS). The eccentricity has to be limited to ensure sufficient rotation capacity for the other ULS failure modes to be valid;
- Straight sliding plane through the rubble foundation (ULS);
- Sliding of rubble foundation over the subsoil (ULS);
- Failure of the subsoil (ULS).

Wave transmission effectively describes the functionality of the breakwater. It is included by applying the transmission model of Goda (1969) and providing an acceptable significant wave height in the harbour basin.

The last five failure modes describe different forms of foundation failure. These models are taken from a report written under the European Marine Science and Technology program (de Groot et al, 1996). In the report two sets of "feasibility level models" are given. One set is applicable to caissons placed on low rubble mounds and the other is applicable to caissons placed on high rubble mounds. De Groot provides no clear definition of low and high rubble mounds. Furthermore, in an optimisation process all options are open and therefore the behaviour of all alternatives should be accurately described. Therefore, the set of failure modes in this study consists of the union of the two sets given in de Groot.

Observation of the list of failure modes and the cost function shows that there are two main sources of damage, i.e. damage due to excessive wave transmission and damage due to instability of the caisson. Instability of the caisson is the result of a series system containing all the ULS failure modes mentioned above. In a fault tree, instability of the caisson is described as in Figure 2.

![Figure 2: Fault tree for ultimate limit states](chart)

Several methods are available to provide reliability estimates for this kind of systems of failure modes. The choice of the algorithm is not an arbitrary one, as will be seen later.
Deterministic Optimisation of the Caisson Design

If all input is treated deterministically, it is possible to derive the required width of the caisson as a function of the crest height of the caisson. Since the construction costs are a function of the height and width of the caisson, the construction costs can be minimised for a given design wave height and water depth, resulting in optimal caisson dimensions. Analysis of this case is useful since it is an integral part of the full probabilistic optimisation, as will be shown later. The disadvantage of this procedure is that the optimal design is still dependent on the choice of the (deterministic) design conditions and is therefore in fact still open.

The deterministic optimisation procedure has been applied to a breakwater design according to Figure 1, using design wave heights of $H_s = 3.74$ m for SLS and $H_d = 9.64$ m for ULS. The design variable berm height has been fixed to 6 m. The required caisson width is expressed as a function of the caisson height for each limit state. The construction costs have been calculated for every design alternative, resulting in Figure 3.

![Figure 3: Construction costs as a function of the crest height of the breakwater (berm height 6 m)](image-url)
Subsoil failure requires the largest caisson width in all cases and thus decides
the construction costs. Assuming an acceptable significant wave height behind the
breakwater of 0.50 m, wave transmission imposes a constraint on the crest height.
This constraint is shown in Figure 3 by the vertical line. This shows that the function
of the breakwater (in this case described by wave transmission) is an essential part of
the optimisation of the breakwater design.

**Probabilistic Optimisation and its Relation to Deterministic Optimisation**

In the previous section the optimal breakwater design was determined for
chosen design wave heights. However, also the design wave heights (significant wave
height for SLS and design wave height for ULS) can be made subject to economic
optimisation by specifying them as distribution functions (all other input is still
treated deterministically). This approach can be considered an intermediate step
between the deterministic optimisation of the previous section and the full
probabilistic approach of the next section.

Using the fault tree (figure 2) it is possible to calculate the probability of
caisson instability due to any of the given failure modes. Wave transmission is treated
separately, resulting in an ultimate significant wave height which indicates when
excessive wave transmission occurs. Since in this case the daily and extreme wave
heights are the only random variables, substitution of the ultimate wave heights in
their respective distributions results in estimates of the failure probabilities. The
failure probabilities are used in equation (1) to derive the expected value of the
damage costs. Following this procedure for several caisson height and width
combinations provides the total lifetime costs as a function of the caisson dimensions.
Figure 4 shows a contour plot of the total lifetime costs for a breakwater using a berm
height of 6 m.

![Contour plot of total lifetime costs](image)

**Figure 4: Contour plot of total lifetime costs (random wave height only, costs in $10^6\text{ US \$}**
In the previous section it was shown that for fixed values of the berm height, water depth and design wave heights, it is possible to derive the required caisson width as a function of the caisson height. The result of this deterministic approach is also shown in Figure 4 as the dotted line. The optimal design found in the probabilistic procedure lies exactly on this curve. This shows that minimisation of the construction costs for a fixed probability of failure is included in the probabilistic optimisation procedure. In figure 4 the point “full probabilistic approach” denotes the result of the full probabilistic optimisation, described in the next section.

In the probabilistic procedure, wave transmission causes a sharp increase of the lifetime costs with decreasing crest height, rather than a fixed constraint. This effect is also visible in Figure 4.

A Procedure for Full Probabilistic Optimisation

In the previous section the probability of failure of the breakwater was considered equal to the probability of exceedance of a certain wave height. In practice however the failure probability depends on several parameters which might show random behaviour. Optimising a breakwater design taking into account several uncertainties requires a numerical optimisation procedure, which consists of the following components:

- An algorithm for the minimisation of functions in several dimensions;
- A numerical description of the cost function;
- A procedure for the calculation of the system probability of ULS failure;
- A procedure for the calculation of the probability of SLS failure.

Figure 5 shows a scheme of the co-operation between the main components.

Figure 5: Structure of optimisation process
Minimisation algorithms can with advantage be obtained from several sources (See for instance: Press et al, 1990). The choice of the algorithm should be made with care. In general, algorithms that use derivatives of the function are the most efficient. Application of such an algorithm requires the function to be continuously differentiable. In this case the deterministic optimisation has shown that in most cases the optimal design is found exactly in the intersection point of two failure modes. Therefore, the derivatives can be expected to be discontinuous and the use of them in the minimisation procedure has therefore been avoided. The direction set method developed by Powell and implemented by Press et al (1990) has been used. The minimisation procedure is the central part of the optimisation procedure since it controls all the calls made to the cost function and therefore also all the calls to the probabilistic method.

The numerical description of the objective function is the equivalent of formula (1) expressed in programming language. The cost function needs the failure probabilities as input. To obtain the failure probabilities the procedure makes a call to a probabilistic algorithm and passes all relevant input to this procedure.

Several methods for the calculation of the system probability of failure exist (See for instance: Ditlevsen and Madsen, 1996). For application in an optimisation program the algorithm has to fulfil two requirements:

- The algorithm should provide reliability estimates in a relatively short time;
- The resulting estimates of the failure probabilities have to be stable, meaning that recalculation of the failure probability for the same geometry should yield a result that only differs in the range of numerical inaccuracies.

The first requirement is important because of the large number of reliability calculations that are to be made in the course of the optimisation procedure (typically 100 to 500). A probabilistic procedure that takes long calculation times will slow down the optimisation too much.

The second requirement is necessary because of the co-operation between a minimisation procedure and a probabilistic procedure. Especially Monte Carlo methods provide reliability estimates that slightly vary from calculation to calculation, even for the same dimensions of the breakwater. This variation is inherent to the Monte Carlo method and presents no problem if the reliability estimates are not used in an optimisation procedure. When using Monte Carlo estimates in an optimisation, the slightly varying failure probabilities cause variations of the cost function, which cause convergence problems for the minimisation procedure.

In this paper first order reliability methods have been used to calculate the Ditlevsen bounds of the system probability of failure (Hasofer and Lind, 1974; Ditlevsen, 1979; Hohenbichler, 1983). The upper bound of the failure probability according to Ditlevsen is used in the cost function as the system probability of ULS failure. The probability of serviceability failure is calculated by means of a first order reliability method.
Results of Full Probabilistic Optimisation

The procedure described in the previous section has been used to derive optimal caisson dimensions for several berm heights using all input given in Table 3. The results have been used to determine an overall optimal breakwater cross section, i.e. a breakwater cross section with an optimal berm height, crest height and caisson width. Figure 6 shows the optimal total caisson height and the caisson width for several berm heights. For a berm height of 6 m the optimal width and height are 17.20 m and 23.25 m respectively. This is larger then in the case with only random wave heights due to the added uncertainty in the subsoil properties and the water level (see also figure 4).

Figure 6: Optimal caisson dimensions as a function of the berm height

Figure 7 shows three alternative breakwater designs with different berm heights and corresponding optimal caisson dimensions.

Figure 7: Optimal designs for three berm heights

Both Figure 6 and Figure 7 show that up to a berm height of approximately 6 m there is a strong decrease of the caisson width with increasing berm height. For higher berms this reduction is considerably less.

Figure 8 shows the failure probability per failure mode as well as the overall probability of ULS failure for every calculated alternative.
Figure 8: Overview of failure probabilities for alternative designs

Figure 8 shows that in most cases the system probability of failure is determined by one failure mode only (subsoil failure). In these cases the height is governed by wave transmission, in the way shown in Figure 4. Since there is a clearly dominant failure mode, the system probability of failure can also be accurately calculated by taking the fundamental upper bound of the failure probability instead of the Ditlevsen bound.

Figure 9 gives an overview of total lifetime costs as a function of the berm height. It should be noted that every point denotes the costs of an optimal caisson corresponding to that berm height.
Apparently, the optimal design is found in the vicinity of the point in Figure 6 where the large width reduction due to higher berms is virtually over. This leads to the conclusion that in this case the only (economical) justification of the rubble foundation is a reduction of the loading on the subsoil.

The calculation results lead to the following conclusions regarding the optimal breakwater geometry for the design case:

1. The optimal design consists of a berm with a height of 5.8 m with respect to the sea bottom and a caisson with a total height of 23.5 m (crest height MSL +4.3 m) and a width of 17.5 m;
2. The optimal geometry is decided by wave transmission (SLS) and subsoil failure (ULS);
3. The system probability of ULS failure of the optimal design virtually equals the probability of subsoil failure. This indicates that subsoil failure is a very clear “weak link” in the design;
4. Due to the presence of a weak link, the system probability of failure can be accurately calculated by taking the fundamental upper bound instead of the Ditlevsen bound.

Conclusions

This paper considers the application of economic optimisation to the design of vertical breakwaters. Regarding the procedure itself the following conclusions can be drawn:
• The concept of economic optimisation provides a rational way of supporting the choice of the optimal safety level;
• Minimisation of the construction costs of a breakwater for a given safety level is an integral part of the full probabilistic optimisation procedure.

Regarding the optimal geometry for the design case, the following conclusions are justified:
• The crest height of the optimally designed caisson breakwater is determined by wave transmission;
• The system probability of ULS failure virtually equals the probability of subsoil failure. Subsoil failure is therefore a very clear “weak link” in the optimal design. The optimisation procedure shows that it is not economical to distribute the acceptable probability of failure equally over all failure modes;
• The only (economical) justification of a rubble berm in this case is reduction of the loading of the subsoil, thus decreasing the probability of failure of the structure.

Regarding the implementation of the procedure in programming language, the following points are important:
• Ready-at-hand minimisation algorithms can with advantage be used;
• Minimisation algorithms which use derivatives of the cost function should be avoided;
The probabilistic algorithms to be implemented in the optimisation procedures should provide stable estimates of the failure probabilities, in order to avoid convergence problems of the minimisation algorithm. Stability in this case meaning that a repeated calculation for the same geometry should provide a result for the probability of failure that only differs within the range of numerical accuracy.

Yokosuka, 1996
1. Abstract

The paper presents a new system for implementation of target reliability in caisson breakwater designs by means of partial safety factors. The development of the system is explained, and tables of partial safety factors are presented for important overall stability failure modes related to caisson structures placed on bedding layers and high rubble mound foundations with underlaying sand and clay subsoils.

2. Introduction

Given the stochastic nature of wave loads it is important to deal with the involved uncertainties in a rational way when designing breakwaters. Application of the partial safety factor concept is generally accepted as a rational solution to implementation of safety in designs, and is adopted in many national codes as well as in the EUROCODE. The partial safety factors are in existing codes calibrated against experience with the performance of numerous civil engineering structures in which way it is assured that a conventional structure, such as a house, will obtain the usual safety when designed using the prescribed safety factors. However, the actual safety in terms of probability of a certain damage within a certain span of years is unknown. For breakwaters this seems not to be a suitable concept because extensive experience with existing structures is not available. Moreover, it is decidable to know the actual safety of a design also because rational comparisons of alternative designs have to be performed on the basis of equal safety levels. Reliability analysis, e.g., using a level 2 First Order Reliability Method (FORM), can of course be done for any structure by means of computer programs. However, it is regarded a help to the designers to make a partial safety factor system available which in an easy way makes it possible to design a breakwater to any target reliability level.

Such a system was introduced and developed by the PIANC PTC II Working Group 12 on Rubble Mound Breakwaters (Burcharth 1991 and 1993) and has now been further developed to cover caisson breakwaters by the PIANC PTC II Working Group 28 on Vertical Wall Breakwaters.

The partial safety factor system is developed on the basis of the validity of the Goda (1985) wave load formula. This formula is not valid for design cases where frequent wave breaking directly on the caisson wall takes place. This causes very large short-duration impulsive loads for which design tools are hardly developed. Steep seabed slopes or semi-high rubble slopes in front of the structure can trigger such unfavorable wave conditions. Goda (1985 pp 132-138) provides advice as how to avoid such excessive impact loadings.
The overall procedure in development of the partial safety factor system comprises the following steps:

- Identification of failure modes
- Formulation of limit state equations for the failure modes
- Modelling of uncertainties related to loads (waves), strengths (soils, concrete) and limit state equations
- Selection of format for the partial safety factor system
- Calibration of the partial safety factors
- Verification

3. Failure modes

All possible failure modes must be considered in the design. The present paper deals with the overall stability failure modes illustrated in Fig.1. A more complete discussion of failure modes is given in Burchard (1998).

Fig.1. Important overall stability failure modes.
4. Wave modelling

For calibration of partial safety factors the maximum significant wave height in $T$ years is denoted $H^T_S$ and is modelled by the extreme Weibull distribution function:

$$F_{H^T_S}(h_s) = [1 - e^{a}(-\left(\frac{h_s - H^T_S}{\beta}\right)^\alpha)]^{\lambda T}$$  \hspace{1cm} (1)

Wave data from 4 quite different geographical locations are selected, see table 1 where $h_s$ is the water depth, $N$ is number of samples and $\lambda$ is the number of observations per year.

Table 1. Wave data from different locations fitted to a Weibull distribution. $\beta$, $H^T_S$ and $h_s$ are in meters.

The wave data from Bilbao, Sines and Tripoli correspond to deep water waves while the wave data from Follonica correspond to shallow water waves. In order to model the statistical uncertainty $a$ and $\beta$ are modelled as Normal distributed variables.

The model uncertainty related to the quality of the measured wave data is modelled by a multiplicative stochastic variable $Z_{H_s}$ which is assumed to be normal distributed with expected value 1 and standard deviation $\sigma_{Z_{H_s}}$. Good and poor wave data could be represented by $\sigma_{Z_{H_s}} = 0.05$ and 0.2, corresponding to accelerometer buoy and fetch diagram estimates, respectively.

5. Soil strength modelling

The undrained shear strength of clay is modelled by a log-Gaussian distributed stochastic field $\{c_u(x,z)\}$ where $z$ and $x$ are vertical and horisontal coordinates, respectively. The expected value function $E[c_u(x,z)]$ and the covariance function $Cov[c_u(x_1,z_1),c_u(x_2,z_2)]$ is written

$$E[c_u(x,z)] = E[c_u(z)]$$ \hspace{1cm} (2)

$$Cov[c_u(x_1,z_1),c_u(x_2,z_2)] = Cov[c_u(x_1 - x_2,z_1 - z_2)]$$ \hspace{1cm} (3)

where $(x_1,z_1)$ and $(x_2,z_2)$ are two points in the soil. $E[c_u(x,z)]$ gives the expected value in depth $z$ of the undrained shear strength of clay. $Cov[c_u(x_1,z_1),c_u(x_2,z_2)]$ gives the covariance between $c_u$ at position $(x_1,z_1)$ and $c_u$ at position $(x_2,z_2)$. $Var[c_u(x_1,z_1)] = Cov[c_u(x_1,z_1),c_u(x_1,z_1)]$ is the variance of $c_u$ at position $(x_1,z_1)$.

It is seen that the expected value depends on the depth and the covariance depends on the vertical and horizontal distances. Generally the correlation lengths in horisontal and vertical direction will be different due to the soil stratification.
The mean value function and covariance function are assumed to be modelled by

\[
E[c_u(x, z)] = c_{u0} + c_{u1} z \\
Cov[c_u(x_1, z_1), c_u(x_2, z_2)] = \sigma^2_{c_u} \exp\left(-|\alpha(z_1 - z_2)|\right) \exp\left(-\left(\beta(x_1 - x_2)\right)^2\right)
\]

where \(c_{u0}\) and \(c_{u1}\) model the expected value, \(\sigma^2_{c_u}\) is the standard deviation and \(\alpha\) and \(\beta\) model the correlation.

Since the breakwater foundation is made of friction material and it is assumed that foundation failure modes can develop both in the rubble mound and in sand subsoil, statistical models for the effective friction angle and the angle of dilation are needed for the rubble material and the sand subsoil. These angles are modelled by Lognormal stochastic variables.

6. Estimation of partial safety factors for one failure mode

In code calibration based on first order reliability methods (FORM) it is assumed that the limit state function can be written

\[
g(x, z) = 0 \tag{4}
\]

where \(x = (x_1, \ldots, x_n)\) is a realization of \(X = (X_1, \ldots, X_n)\). External loads (e.g. wave), strength parameters and model uncertainty variables are examples of uncertain quantities. \(z = (z_1, \ldots, z_N)\) are \(N\) design variables which are used to design the actual structure. Realizations \(x\) of \(X\) where \(g(x, z) < 0\) corresponds to failure states, while \(g(x, z) > 0\) corresponds to safe states.

If the number of design variables is \(N = 1\) then the design (modelled by \(z\)) can be determined from the design equation

\[
G(x^c, z, \gamma) \geq 0 \tag{5}
\]

\(x^c = (x^c_1, \ldots, x^c_n)\) are characteristic values corresponding to the stochastic variables \(X\). \(\gamma = (\gamma_1, \ldots, \gamma_m)\) are \(m\) partial safety factors. The partial safety factors \(\gamma\) are usually defined such that \(\gamma_i \geq 1, i = 1, \ldots, m\). In the most simple case \(m = n\).

The design equation is closely connected to the limit state function (4). In most cases the only difference is that the variables \(x\) are exchanged by design values \(x^d\) obtained from the characteristic values \(x^c\) and the partial safety factors \(\gamma\).

The characteristic values are for variable load variables usually the 98 % fractile of the distribution function of the stochastic variables. For the significant wave height the characteristic value \(\tilde{H}_S^{T_L}\) is chosen as the central estimate of the significant wave height which in average is exceeded once every \(T_L\) years. The design values for load variables are then obtained from

\[
x^d_i = x^c_i \gamma_i \tag{6}
\]

The characteristic values are for strength variables usually the 5 % or 50 % fractiles of the distribution function of the stochastic variables. Here the 50 % fractile is
used in order to obtain partial safety factors larger than or equal to 1. The design values are then obtained from

$$x_i^d = \frac{x_i}{\gamma_i}$$  \hspace{1cm} (7)

The limit state / design equations are formulated either as a force balance or, in case of foundation failure modes, as work equations using the upper bound theory of plasticity related to kinematically admissible rupture failures. Figure 2 illustrates two typical cases.

Figure 2. Illustration of failure modes for formulation of limit state design equations.

For sliding failure the limit state function can be written

$$g = (F_G - Z_{Fv} F_U (Z_{Hs} H_D)) f - Z_{FH} F_H (Z_{Hs} H_D)$$  \hspace{1cm} (8)

where

- $F_G$ reduced weight of caisson under water
- $F_U$ wave induced uplift force
- $F_H$ horizontal wave force
- $H_D$ design wave height
- $Z_{Hs}$ model uncertainty related to the significant wave height $H_S$
- $\rho_c$ density of the caisson
- $Z_{FH}$ model uncertainty on horizontal wave load
- $Z_{Fv}$ model uncertainty on vertical wave load
- $f$ friction coefficient

The design equation corresponding to (8) is written

$$G = \frac{1}{\gamma Z} (F_G^c - 0.77 F_U^c) f^c - 0.90 F_H^c$$  \hspace{1cm} (9)

where
\( f^c \) mean of base friction coefficient

\( \gamma_Z \) partial safety factor on \( f^c \)

\( F_G^c \) mean value of reduced weight of caisson under water

\( F_U^c \) and \( F_H^c \) wave induced uplift force and horizontal wave force calculated by Goda formulae using \( \gamma_H \hat{H}_D^T \) as wave height, where \( \gamma_H \) is the partial safety factor and \( \hat{H}_D^T \) is the expected maximum wave height in a storm with \( T_L \)-years return period (often taken as \( 1.8 \hat{H}_S^T \)). The factors \( Z_{F_U} = 0.77 \) and \( Z_{F_H} = 0.90 \) compensates for the bias (safety) implemented in the Goda formulae.

For foundation failure the limit state function can be written

\[
g = (F_S + F_G - Z_{F_U} F_U(Z_{H_S} H_D))\omega_V - Z_{F_H} F_H(Z_{H_S} H_D)\omega_H
\tag{10}
\]

where

\( F_S \) boyancy reduced gravitational force on the sliding soil element

\( \omega_V \) displacement vector, \( \omega_V = \sin(\varphi_d - \theta) / \cos \varphi_d \)

\( \omega_H \) displacement vector, \( \omega_H = \cos(\varphi_d - \theta) / \cos \varphi_d \)

The reduced effective angle of friction is calculated from

\[
\tan \varphi_d' = \frac{\sin \varphi_r' \cos \psi_r}{1 - \sin \varphi_r' \sin \psi_r}
\]

where \( \varphi_r' \) is the effective angle of friction and \( \psi_r \) is the dilation.

The design equation is written

\[
G = (F_S^c + F_G^c - 0.77 F_U^c)\omega_V^c - 0.90 F_H^c \omega_H^c
\tag{11}
\]

where \( F_S^c \) is the mean value of \( F_S \). \( \omega_V^c \) and \( \omega_H^c \) are obtained using the the design value of \( \tan \varphi_d^c \) determined from

\[
\gamma_Z \tan \varphi_d^c = \frac{\sin \varphi_r^c \cos \psi_r^c}{1 - \sin \varphi_r^c \sin \psi_r^c}
\tag{12}
\]

where \( \gamma_Z \) is the partial safety factor on \( \tan \varphi_d^c \).

The application area for the code is described by a number, \( L \) of different typical structures. The partial safety factors \( \gamma \) are calibrated such that the reliability indices corresponding to the \( L \) structures are as close as possible to the target reliability index \( \beta_t = -\Phi^{-1}(P_f^t) \), where \( P_f^t \) is the target probability of failure. This is formulated by the following optimization problem

\[
\min_{\gamma} W(\gamma) = \sum_{j=1}^{L} w_j (\beta_j(\gamma) - \beta_t)^2
\tag{13}
\]
where \( w_j, j = 1, \ldots, L \) are weighting factors \( (\sum_{j=1}^{L} w_j = 1) \) indicating the relative frequency of appearance of the different design situations. \( \beta_j(\gamma) \) is the reliability index for structure no. \( j \).

7. Format for partial safety factors

Partial safety factors are calibrated with the following code entries:

- the design lifetime \( T_L \) (= 20, 50 or 100 years)
- the acceptable probability of failure \( P_f \) (= 0.01, 0.05, 0.10, 0.20 or 0.40) corresponding to the target reliability indices \( \beta_T \) (= 2.33, 1.65, 1.28, 0.84 or 0.25)
- the coefficient of variation \( \sigma'_{Z_{H_S}} = (0.05 \text{ and } 0.20) \).
- Deep or shallow water conditions.
- Hydraulic model test or not.

The partial safety factors are:

- a load partial safety factor \( \gamma_P = 1 \) to be multiplied to the permanent load.
- a load partial safety factor \( \gamma_H \) to be multiplied to \( H_{S_L}^{T_L} \) (the central estimate of the significant wave height which in average is exceeded once every \( T_L \) years). The design wave height is to be taken as a multiplum of \( H_{S_L}^{T_L} \).
- a safety factor \( \gamma_Z \) to be used with friction materials in rubble mound and/or subsoil (tangent to the mean value of the friction angle is divided by \( \gamma_Z \)).
- a safety factor \( \gamma_C \) to be used with the undrained shear strength of clay materials in the subsoil (the mean value of the undrained shear strength is divided by \( \gamma_C \)).

8. Limit state functions and design equations

For calibration of the partial safety factors the parameters for the stochastic variables shown in table 2 are used. The correlation coefficient between \( Z_{F_H} \) and \( Z_{M_H} \) and between \( Z_{F_V} \) and \( Z_{M_V} \) are estimated roughly to 0.9. In table 2 \( D \) denotes a deterministic variable, \( N(\mu, \sigma) \) denotes a normal distribution with expected value \( \mu \) and standard deviation \( \sigma \) and \( LN(\mu, \sigma) \) denotes a lognormal distribution.

The tidal elevation \( \zeta \) is modelled as a stochastic variable with distribution function \( F_\zeta(\zeta) = \frac{1}{\pi} \arccos \left( -\frac{\zeta}{\zeta_0} \right) \) where \( \zeta_0 \) is the maximum tidal height. \( \zeta_0 = 0.75 \text{ m} \) is used.
Table 2. Statistical parameters for calibration of partial safety factors for foundation failure with sand subsoil.

8.1 Horizontal sliding

Equations are given in section 6.

8.2 Scour failure for circular roundheads on sand

The design equation is written, see Sumer et al. (1996) (no rubble foundation):

\[
G = \frac{1}{\gamma Z} \frac{S^c}{B^c} - 0.5 \left( 1 - \exp(-0.175(KC(\gamma_H \tilde{H}_S^{T_r}) - 1)) \right)
\]

where \( s_p \) is the wave steepness and

\[
KC = \frac{U_m T_p}{B_r} \quad \frac{1}{\sinh(2\pi h_s' / L_p)}
\]

where

\[
U_m = \frac{T_p}{T_p} \quad \pi Z_{HS} H_S \quad \frac{1}{\sinh(2\pi h_s' / L_p)}
\]
Figure 3. Foundation failure modes.

\[ T'_p = \sqrt{\frac{Z H_s H_s 2\pi}{s_p g}} \]

and the wave length \( L_p \) is determined from

\[ L_p = g \frac{T^2_p}{2\pi} \tanh(2\pi h_s / L_p) \]
8.3 Hydraulic instability of foundation rubble mound armour layer

The design equation is written, see Madrigal et al. (1995):

\[ G = \frac{1}{\gamma_Z} \Delta^c D_n^c (5.8 \frac{h'}{h_s} - 0.60) N_{o_d}^{0.19} - \gamma_H \hat{H}_S^T \]

8.4 Foundation failure modes

Figure 3 shows the investigated foundation failure modes. The complete sets of design equations can be found in Burcharth (1998) and J.D. Sørensen et al. (1998).

9. Partial Safety Factors

Below is shown the results of the probabilistic calibration of partial safety factors. In deterministic design of the breakwater the following bias values for the forces and moments are to be used:

LATERAL VERSUS LONGITUDINAL ARTIFICIAL REEF SYSTEMS

Yoshimi Goda¹ and Hiroshi Takagi²

Abstract
A new submerged breakwater structure for shore protection is proposed and called the longitudinal reef system. It is efficient in dissipating wave energy by increasing wave heights at the front through wave refraction effect and by enhancing wave breaking. Comparison is made between the new longitudinal reef system and the conventional broad-crested reef system through model experiments and numerical computation. The superiority of the longitudinal system to the conventional system is confirmed through the comparison.

Introduction
Shore-parallel, detached breakwaters have been used in many countries to protect beaches from erosion. As their emerged crests obstruct the aesthetic view of the sea from beach areas, however, they are sometimes rejected by local residents and visitors. Thus, submerged breakwaters with broad crests are developed and built at several coasts around Japan; they are called artificial reefs.

Artificial reefs dissipate incoming wave energy by forcing them to break on top of the crests because of shallow depth there. Energy dissipation could be enhanced if the wave refraction effect is mobilized to increase wave heights before breaking. This can be done by building a number of slender artificial reefs arranged longitudinally as shown in Fig. 1. Goda (1995) named such a system as a longitudinal reef system. The conventional artificial reefs with crests extended alongshore are called the lateral artificial reefs in the present paper.

In the previous paper by Goda (1995), wave transmission characteristics over a longitudinal reef system were presented, based on wave flume tests and numerical computations. The present paper discusses the results of 3-D tests in a wave...

Fig. 1 Sketch of longitudinal artificial reef system.

basin for wave heights and wave-induced currents around both lateral and longitudinal reef systems, and compares their performances by means of numerical computations.

**Models of Longitudinal and Lateral Reef Systems for Tests**

*Volume of Reef Unit*

With the notations listed in Fig. 1, the volume of one unit of reefs is approximately calculated by Eq. 1.

\[ V = \frac{1}{2} [b(a + \pi s/3) + (a + s)B] \]  

(1)

The above equation applies for both lateral and longitudinal reef systems; i.e., the former has the crest width \( a \) greater than the crest length \( B \), while the latter has \( a \) smaller than \( B \).

In the comparison between the lateral and longitudinal reef systems, their construction cost is an important factor together with their hydrodynamic characteristics. As the construction cost is primarily controlled by the total volume of reef units, model reefs of longitudinal and lateral units were built with the same total volume to make a fair comparison of their performance.

*Wave Basin for Model Tests*

An outdoor wave basin with the size of 9.0 m by 13.0 m was employed in the present study. A planar slope with the inclination of 1/20 was built with mortar in a slant angle of 15° to the wave paddles as shown in Fig. 2. The initial section of 0.52 m was made with the inclination of 1/10.

All the tests were carried out with the water depth of 0.30 m in front of the wave paddles. The grid lines of the \( x \) and \( y \) coordinates were drawn on the slope with the interval of 0.5 m with the origin at the upper left corner. The shoreline
was located at the line of \( x = 6.0 \) m. Two wave guide walls were placed at the both sides along the lines of refracted wave propagation; their locations were determined after several trials so as to insure smooth wave propagation along them.

**Model Reef Units**

Three longitudinal reef units were placed in the basin as shown in Fig. 2. The submergence depth was \( h_c = 0.03 \) m, the crest length was \( B = 1.50 \) m, and the crest width was \( a = 0.10 \) m. They were built with crushed stones with the diameters ranging from 30 to 50 mm. The front and rear slopes were 1/2, and the side slope was 1/2.5.

![Diagram of wave basin with longitudinal reefs](image)

**Fig. 2** Wave basin with longitudinal reefs.

These three longitudinal reef units were placed at the location of \( x = 3.0 \) to 4.5 m (crest position) with the separation of 1.0 m between the central axes which were located at \( y = 2.0, 3.0, \) and 4.0 m, respectively.

A lateral reef system was made with two units with \( h_c = 0.03 \) m, \( B = 0.45 \) m, and \( a = 1.00 \) m. Figure 3 provides a sketch of the lateral unit built on a slope of 1/20. The total volumes of the longitudinal and lateral reef systems were about \( 0.127 \) m\(^3\) for both cases. The front line of the crests of two units were placed at the location of \( x = 3.5 \) m, and their central axes were set at the lines of \( y = 2.1 \) and 3.9 m.

![Diagram of sketch of a lateral reef unit](image)

**Fig. 3** Sketch of a lateral reef unit.
Test Waves

Two trains of irregular waves with $H_{1/3} = 7.5$ cm and $T_{1/3} = 1.2$ s and those with $H_{1/3} = 5.5$ cm and $T_{1/3} = 1.6$ s were used in the tests. The offshore incident wave angle was 15°. Wave profiles were recorded with capacitance gauges at the sampling frequency of 20 Hz. The wave records were analyzed by the zero-downcrossing method, and the highest one-third wave height $H_{1/3}$ and period $T_{1/3}$ were computed. The data shown in the present paper refer to the significant wave height and period. Current velocities were measured with bi-axis ultrasonic current meters. Though the instrument could output instantaneous velocity data, only the mean currents averaged over 200 s were utilized for analysis of wave-induced currents.

Numerical Analysis of Wave Heights and Radiation Stresses

Governing Equation

Numerical simulation of wave deformation around the reef was made by using the parabolic equation based on the numerical scheme by Hirakuchi and Maruyama (1986). According to their scheme, the governing equation for the complex amplitude of the velocity potential, $\phi$, is given as follows:

$$
\frac{\partial \phi}{\partial x} = \left\{ i \left( k_x + \frac{k_y^2}{2k_x} \right) - \frac{1}{2k_x c_g} \frac{\partial}{\partial x} (k_x c_g) \right\} \phi + \frac{1}{2k_x c_g} \frac{\partial}{\partial y} \left( c_g \frac{\partial \phi}{\partial y} \right) - f_D^b \phi \quad (2)
$$

where $k_x$ and $k_y$ denotes the wave numbers in the $x$ and $y$ directions, respectively, $c$ the wave celerity, $c_g$ the group velocity, $i$ the imaginary number. The term $f_D^b$ is a function which represents the effect of wave breaking on amplitude attenuation, and it is hereby called the wave attenuation function for brevity.

As the wave amplitude is proportional to the absolute amplitude of velocity potential, its spatial distribution is obtained by solving Eq. 2 with a forward difference scheme. Numerical computation was carried out for an area corresponding to physical model tests shown in Fig. 2: the grid size was set at $\Delta x = \Delta y = 0.10$ m.

Modification of Wave Celerity and Wave Number

Observations of breaking wave fronts running over a submerged mound reveal that the part of wave front on top of the crest moves faster than the neighboring part of wave front on the side slopes, even though the water depth is shallower at the crest than on the side. The increase of wave speed is caused by the fact that the wave celerity is not only governed by the water depth but also affected by the wave amplitude; i.e., a finite amplitude effect. Because the wave refraction by local topography is controlled by the spatial variation of wave celerity, a correct representation of wave celerity is required for appropriate evaluation of wave transformations. The finite amplitude effect on wave celerity was approximated by Goda (1995) as in the following empirical formulation:
The wave celerity by the small amplitude wave theory, $H$ the wave height, and $h$ the local water depth.

The upper expression in the right-hand side of Eq. 3 was formulated in analogy of the phase velocity of the 3rd order Stokes waves. The lower expression was set to make a smooth transition across the boundary of $H = 2h$. The wave numbers $k_x$ and $k_y$ have been adjusted by dividing them with this rate of wave celerity increase. However, the group velocity $c_g$ has been kept the same as that given by the small amplitude wave theory.

**Formulation of Wave Attenuation Function**

The wave attenuation function $f_D'$ was given the following form as discussed by Goda (1995):

$$f_D' = \begin{cases} 
0 & : H < \gamma h \\
\frac{K}{2h} \left[\left(\frac{H}{\gamma h}\right)^2 - 1\right]^{1/2} & : H \geq \gamma h 
\end{cases}$$

(4)

The constant $K$ in Eq. 4 represents the relative rate of wave energy decay by breaking. It was given the value of $K = 0.125$ which yielded best agreement with the results of previous model tests. As for $\gamma$, which is the ratio of wave height to water depth at breaking, the present study sets its value according to the following breaker index by Goda (1974):

$$\gamma = 0.17 \frac{L_0}{h} \left\{ 1 - \exp \left[ -\frac{1.5\pi h}{L_0} (1 + 15 \tan^{4/3} \theta) \right] \right\}$$

(5)

where $L_0$ is the deepwater wavelength and $\theta$ represents the angle of inclination of bottom slope from the horizon. In the present study, the $\tan \theta$ was set at 1/30 throughout the computational area inclusive of the submerged crests of reef systems, for the sake of simplicity.

**Computation of Irregular Wave Heights**

Though the numerical scheme of the parabolic equation has been developed for regular waves, the effect of wave irregularity can be taken into account by superposing the results of regular wave analysis for multiple levels of wave heights but with the same wave period. Individual wave heights are assumed to follow the Rayleigh distribution, and the range of wave height distribution is divided into $N$ segments with the equal probability of appearance. The wave height representing...
each segment is assigned as

\[ H_m = 0.706\left(H_{1/3}\right) \left[\ln \frac{2N}{2m - 1}\right]^{1/2} \]  

where \( N \) is the number of representative wave components and \( m \) is an integer from 1 to \( N \) (\( m = 1 \) yields the largest height and \( m = 30 \) the smallest). In the present study, \( N = 30 \) was employed. The results of the computations of \( N \) components at a given grid point were summed up to calculate the representative heights of irregular waves. By summing up the upper one-third components and multiplying it with the probability of appearance, the significant height \( H_{1/3} \) is obtained, while the summation of the whole components yields the mean height \( \bar{H} \).

**Computation of Radiation Stresses**

For each component of regular waves, the radiation stresses \( S_{xx}, S_{xy}, \) and \( S_{yy} \) are computed at each grid point from the results of wave amplitude and direction. The results of the 30 components are summed up to yield the overall radiation stresses, which provide the steady state input for computation of wave setup and wave-induced currents. As the radiation stress is proportional to the wave energy density, the overall radiation stress in the present study is an energy-averaged one.

**Numerical Analysis of Wave Setup and Wave-Induced Currents**

**Governing Equations**

The wave-induced currents and water level change are simulated by solving the continuity and momentum equations for long waves with the input of radiation stresses computed from the wave deformation analysis. The continuity equation is expressed as

\[ \frac{\partial \zeta}{\partial t} + \frac{\partial U(h + \zeta)}{\partial x} + \frac{\partial V(h + \zeta)}{\partial y} = 0 \]  

where \( \zeta \) denotes the amount of water level change, and \( U \) and \( V \) represent the cross-shore and longshore components of depth-integrated current speeds, respectively. The equations of motions are described as

\[ \frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} + F_x - M_x + R_x + g \frac{\partial \zeta}{\partial x} = 0 \]  

\[ \frac{\partial V}{\partial t} + U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} + F_y - M_y + R_y + g \frac{\partial \zeta}{\partial y} = 0 \]

where \( F \) represents the friction terms, \( M \) the horizontal mixing terms, \( R \) the gradients of radiation stresses, and \( g \) the acceleration of gravity.

The friction terms are evaluated with the friction coefficient \( C_f = 0.01 \) by using the vector-sum velocity of wave-induced currents and orbital velocity at the bottom. The horizontal mixing terms are calculated with the dimensionless
constant \( N = 0.016 \) after Longuet-Higgins (1970).

**Computational Procedures**

The governing equations are solved with the finite difference scheme. The central difference is employed for spatial grids and the forward differences are used for time steps. The grid size is the same as that for wave field, and the time step was set at \( \Delta t = 0.01s \).

Computation starts from the condition of rest with the input of spatially-distributed radiation stresses, which are adjusted to increase gradually to the full magnitude to avoid computational instability. As computation progresses, the changes in water level and wave-induced currents approach to the equilibrium state. In the present study, the computation was stopped when the maximum value, throughout the computation area, of the velocity difference from the preceding time step became equal to 0.001 cm/s or less. Because this condition was quite strict compared with conventional computations of wave-induced currents, one run of computation required 5,000 to 10,000 time steps to yield the final results.

**Examples of Wave-Induced Current Computation**

Figure 4 exhibits the computed results of wave-induced currents around the reef systems for irregular waves with \( H_{1/3} = 7.5 \text{ cm} \) and \( T_{1/3} = 1.2 \text{ s} \) for both the longitudinal and lateral reefs. Strong onshore currents are generated on top of reef units as expected. Rip currents between reef units are stronger for the lateral reef than for the longitudinal reef. Counterclockwise vortices at the left sides of both figures are probably the results of insufficient calibration of side boundary conditions in numerical works.

![Fig. 4 Computed currents around longitudinal and lateral artificial reefs: \( H_{1/3} = 7.5 \text{ cm} \) and \( T_{1/3} = 1.2 \text{ s} \).](image)
Wave Heights and Currents around Longitudinal Reef System

Significant wave heights measured in the physical models are compared with the results of numerical computations in Figs. 5 and 6. The former is for waves $H_{1/3} = 5.5$ cm and $T_{1/3} = 1.6$ s, and the latter is for waves $H_{1/3} = 7.5$ cm and $T_{1/3} = 1.2$ s. The left drawings show the cross-shore variations of wave heights along the line $y = 2.5$ m (middle line between the first and second reef units), while the right drawings depict the longshore variations along the line $x = 4.75$ m (just behind the reef units).

Fig. 5 Comparison of measured and computed wave heights around the longitudinal reef system for waves of $H_{1/3} = 5.5$ cm and $T_{1/3} = 1.6$ s: the cross-shore variation along $y = 2.5$ m in the left and the longshore variation along $x = 4.75$ m in the right.

Fig. 6 Comparison of measured and computed wave heights around the longitudinal reef system for waves of $H_{1/3} = 7.5$ cm and $T_{1/3} = 1.2$ s: the cross-shore variation along $y = 2.5$ m in the left and the longshore variation along $x = 4.75$ m in the right.
Numerical computation generally yields the wave heights almost in agreement with the measurements. Exception is the longshore variation of Fig. 6 in the left drawing, in which numerical computation overpredicts wave heights. Because the local water depth along the line $x = 4.75$ m is $h = 6.25$ cm, the significant wave height by random wave breaking should be about 5.3 cm according to the random wave breaking model by Goda (1975). However, computation predicts the wave height up to 8 cm.

The discrepancy is due to the use of a simple technique of representing irregular waves with segments of wave heights as determined by Eq. 6. Each component of waves is treated as regular waves, and the wave height after breaking eventually becomes $H = \gamma h$ regardless of incident wave heights. The original Rayleigh distribution of wave heights is transformed to have an upper cutoff at $H = \gamma h$. Thus the wave height in very shallow water approaches to the breaker height of regular waves.

Comparison of the measured and computed wave-induced currents are shown in Fig. 7. On top of the reef crests, strong onshore currents were visually observed, but they could not be confirmed by measurements, because the current meter emerged at the troughs of large waves and could not produce reliable records. The current patterns and velocities of measurements and computations are quite similar except for the counterclockwise vortices in the left which are predicted by computation but not observed in the measurements.

**Wave Heights and Currents around Lateral Reef System**

The distributions of wave heights around the lateral reef system are exhibited in Figs. 8 and 9. The cross-shore wave height variations are shown in Fig. 8 for waves with $H_{1/3} = 5.5$ cm and $T_{1/3} = 1.6$ s. The line $y = 3.0$ m at the middle of the two reef units and the line $y = 4.0$ m being off the central axis of the
second unit by 0.1 m were chosen for demonstration and shown in the left and right drawings, respectively. In the area between the reef units, the computed and measured significant wave heights are in good agreement. On top of the reef crest, wave heights decrease rapidly and the computation can simulate the wave decay quite well. However, in the area behind the reef along this section, the computation gives the wave height much higher than the measurement. This height corresponds to the breaker height of regular waves, owing to the use of a simple representation of irregular waves by Eq. 6 as discussed earlier.

Fig. 8 Cross-shore wave height variations around the lateral reef system: \( H_{1/3} = 5.5 \) cm and \( T_{1/3} = 1.6 \) s.

Fig. 9 Longshore wave height variations around the lateral reef system: \( H_{1/3} = 7.5 \) cm and \( T_{1/3} = 1.2 \) s.

The longshore variations of wave heights are shown in Fig. 9 for waves with \( H_{1/3} = 7.5 \) cm and \( T_{1/3} = 1.2 \) s. The line along \( x = 4.0 \) m in the left is located slightly behind the rear tip of the crest, and the line along \( x = 4.5 \) m in the right is located in the area of planar slope. Though computed wave heights exhibit
wider variations than the measured ones, they are approximately in agreement.

The strength of wave-induced currents around the lateral reef system is compared with that of the longitudinal system in Tables 1 and 2. Examples of currents by computation have been shown in Fig. 4. The maximum rip currents through the gap of reef units by model tests and numerical computation are listed in Table 1, and those of the maximum longshore currents are listed in Table 2.

Numerical computation predicts stronger rip currents for lateral reefs and weaker longshore currents for a lateral reef system than for a longitudinal reef system. However, measurements did not record velocities as strong as those by computation, and differences between the two reef systems were not significant. A relatively small number of current measurement points might have been a reason that measurements could not detect the largest velocities around the reef system.

Discussion on Numerical Computation for Artificial Reef System

Figures 4 through 9 provide the basis for judging the accuracy and reliability of the numerical computation method employed in the present analysis. Admittedly it has several shortcomings, such as false current patterns and locally large wave heights in the area sheltered by the reef units.

One problem inherent to the numerical analysis around reef systems is the steep gradients at the front, sides, and rear slopes of reef units. Application of the mild slope equation as well as the parabolic equation to such a bathymetry violates the assumption of gradual variations of the physical quantities involved. Nevertheless, the parabolic equation by Hirakuchi and Maruyama (1986) can predict the wave height distribution relatively well. Wave irregularity has been incorporated simply by summing up the computational results for multiple levels of wave heights.

The merit of the parabolic equation is the fast speed in computation, because the spatial distribution of wave amplitude is directly solved. Computations of various reef layouts are done quickly and a best layout can be selected. A weak point in the present analysis is the difficulty in an appropriate evaluation of the wave decay function $f_D$ which would well behave on top of reef units as well as
in the rear area. The assessment of $f'_D$ needs a calibration with laboratory data. The scale effect is a problem in model tests of artificial reefs, because the water depth at the reef crest is often quite small. Goda and Morinobu (1997) reported that a minimum water depth of 10 cm is required to correctly reproduce the wave breaking phenomenon on a trapezoidal step; a smaller water depth results in a smaller height-to-depth ratio at breaking.

**Comparison of Prototype Lateral and Longitudinal Reef Systems**

As the foregoing discussions were limited to the model reef systems, an examination of prototype structures is presented in the following.

A prototype situation is postulated as shown in Fig. 10. The sea bottom has the gradient of 1/20 from the shoreline to the depth $h = 2$ m, 1/50 from the depth $h = 2$ to 10 m, and 0 beyond 10 m. A lateral artificial reef system of two units ($a = 150$ m and $B = 40$ m) with the gap 50 m (at the crest level) is set at the location of $x = 280$ to 320 m in the water depth from $h = 4.5$ to 3.7 m. For comparison, a longitudinal artificial reef system with seven units ($a = 20$ m and $B = 65$ m) is set at the location of $x = 280$ to 345 m in the water depth from $h = 4.5$ to 3.2 m. The submergence depth is $h_c = 1.5$ m, the front and rear slopes have the gradient of 1/2, and the side slopes has the gradient of 3/10 for both the systems. The approximate volume of the lateral system is 64,000 m$^3$, while the latter is 62,000 m$^3$.

![Fig. 10 Setup of computational area for lateral and longitudinal reef systems.](image)

Figure 11 shows examples of computation of wave height distributions. The incident waves are unidirectional irregular waves with the height $H_{1/3} = 1.0$ and 3.0 m, the period $T_{1/3} = 8$ s, and the incident angle of 15°. The top figures show the wave heights along the front edges of both reef systems ($h = 4.5$ m), the center figures are for those along the middle line of the reefs ($h = 3.5$ m), and the bottom figures correspond to those along the rear edge of the longitudinal reef ($h = 2.5$ m).
As seen in Fig. 11, wave heights behind the longitudinal reef system are found to be lower than those behind the lateral system. Difference is prominent in the case of the small wave height \( H_{1/3} = 1.0 \text{ m} \). It is owing to the acceleration of wave breaking process by increase of wave height owing to the wave refraction effect at the heads of longitudinal reefs. Thus a longitudinal reef system is judged superior to a lateral reef system in the efficiency of energy dissipation when the crest submergence depth is the same.

In construction of prototype structures, a lateral reef system requires a minimum depth of 2 m or so owing to the limitation of the draft of working vessels. On the other hand, a longitudinal reef system can be constructed with the zero crest depth, because the crest width is small and a working vessel can reach out the crane arm to any location on the crest while mooring along the side slopes. Wave damping capacity of a longitudinal reef system can be further enhanced by setting the crest elevation as close to the low water level.

![Computed wave heights around the lateral and longitudinal reef systems](image)

(a) \( H_{1/3} = 1.0 \text{ m}, T_{1/3} = 8\text{ s} \)

(b) \( H_{1/3} = 3.0 \text{ m}, T_{1/3} = 8\text{ s} \)

Fig. 11 Computed wave heights around the lateral and longitudinal reef systems

Conclusions

Major findings in the present studies are summarized as in the following:

1. A numerical scheme based on the parabolic equation for irregular waves demonstrated its capability to simulate the wave height distribution around
the lateral and longitudinal artificial reef systems. The capability was confirmed through comparison with 3-D model test data.

2. Wave-induced currents around the artificial reefs were approximately simulated by numerical computation, though further refinements are needed.

3. The newly-proposed longitudinal reef system has been shown more efficient in dissipating wave energy than the conventional lateral artificial reef system, because of incorporation of wave refraction effect.

4. Strong rip currents between the gap between the lateral units were predicted by computation, but model tests did not yield appreciable differences in current speeds between the longitudinal and lateral reef systems.

Abstract

The concept of a horizontal perforated plate placed in water, with a method for implementing the concept in a real sea as a new type of reef breakwater, is proposed in the present paper. The feasibility and superiority of the proposed breakwater in hydraulic characteristics in comparison with conventional reef breakwaters has been shown by theoretical and experimental study.

1. Introduction

Wave height reduction with reef breakwaters is caused by energy dissipation from waves breaking over the crests of the breakwaters. Mass transport caused by the wave breaking, however, may generate offshore flow at the gaps between two adjacent breakwaters and, hence scouring at the bottoms of the gaps. Also, the massive structural body of the breakwater may interfere with existing currents on the beach. As an alternative breakwater, an impermeable plate placed horizontally in the water does not interfere with currents. However, strong wave forces may be exerted on the plate, causing problems. If perforations are made in the horizontal plate, much wave energy dissipation at the perforations due to flow separation and reduced wave forces may be anticipated. The perforations could also encourage vertical flow with vertical oxygen transport. The region under the perforated plate could become good shelter for aquatic creatures.

The objective of this study is to propose the concept of a horizontal perforated plate placed in water, with a method for implementing the concept in a real sea as a new type of reef breakwater, and to investigate the hydraulic characteristics of the breakwater theoretically and experimentally.

2. Theoretical Study

2-1. A boundary-value analysis

A theoretical study to search for an optimum opening ratio for the plate was performed as a boundary-value problem for small amplitude waves (Kakuno & Zhong 1993). A plate having slits as perforations was considered. To analyze the problem, the whole region was divided into five regions, as shown in Fig.1. In each region except that which holds the plate, a velocity potential which satisfies the boundary conditions at the sea surface and/or the sea bottom was assumed, with unknown coefficients. Evanescent waves which may occur near the plate were neglected. The waves over and under the plate were assumed to have the same wave number because of the continuity of flow through the slits. In the region which holds the slitted plate, a velocity potential for flow through a slitted plate that has been obtained theoretically is assumed (Kakuno & Liu 1993). The unknown coefficients included in each velocity potential can be determined after matching the potentials at the boundaries.

2-2. An Energy Dissipation Model

The effect of the energy dissipation due to flow separation at slits can be included by introducing a complex wave number in the regions over and under the plate. The imaginary part of that wave number can be determined by equating the energy flux difference between plate ends evaluated linearly using the imaginary part to that evaluated using quadratic resistance at the slits. The same value, \( f = 1.5 \), was assigned as for vertical slits (Kakuno & Liu 1993), where \( f \) is the value of the energy dissipation coefficient included in the quadratic resistance.

2-3. Preliminary experiments to verify the theory

To verify the theory, preliminary experiments to measure the reflection and transmission coefficients were performed using a horizontal slitted plate placed in water of constant depth, \( h = 0.3 \text{m} \), in a wave tank 20m long, 0.5m wide, and 0.6m high. The thickness, the width in the direction of wave propagation, the opening ratio, and the submerged depth of the plate were \( b = 6 \text{mm}, B = 60 \text{m}, r = 0.089 \), and \( R = 6 \text{cm} \).
respectively.

Fig. 2 (a) and (b) show comparisons of the theoretical transmission and reflection coefficients, $y_T$ and $y_R$, with laboratory data as a function of $B/L$, where $L$ is the wave length, under the conditions of the wave steepness $H/L=0.01$ and 0.02, where $H$ is the wave height. The agreement between the theoretical results, in which the effect of the energy dissipation is taken into consideration, and the laboratory data is good overall; hence the validity of the theory has been shown.

![Fig.2 Comparison of transmission coefficients between theory and experiment](image)

2-4. Comparison with impermeable horizontal plate

To examine the difference between the perforated horizontal plate and the solid horizontal plate, laboratory data for an impermeable plate (Aoyama et al. 1988) were compared with calculated results for the perforated plate under the same conditions (Fig.3). As shown in the figure, the characteristics of the two types of plate are remarkably different. Lower transmission and reflection may be attained by the perforated plate over a wide range of $B/L$, indicating more effective energy dissipation by the perforated plate.
Fig. 3 Comparison of transmission and reflection coefficients with those of an impermeable horizontal plate

2.5. Optimum opening ratio

Fig. 4 shows calculated results for the perforated plate for a varied opening ratio. As shown in the figure, a smaller ratio leads to less transmission and greater reflection. An opening ratio of $r=0.1$ may be concluded to be the optimum which minimizes transmission and reflection.

Fig. 4 Transmission and reflection coefficients as a function of opening ratio

3. Proposal of a New Type of Reef Breakwater

To implement the concept of the horizontal perforated plate in the sea, concrete units, whose schematic diagram is shown in Fig. 5, were conceived. Each unit is principally composed of a horizontal perforated upper slab which plays a principal role in wave energy dissipation, and columns to support the slab from the bottom. The dimensions and weight of a typical unit in the sea are $3m \times 3m \times 3m$ and $W_a=16tf$, respectively. The opening ratio of a unit will be about $r=0.1$, which was determined to be the optimum in the theoretical study. The units will be placed in a single layer on a rubble mound with a crest depth of 0m - 2m in the sea, as shown in Fig. 6.
Fig. 5 A concrete unit to make up a new type of reef breakwater

4. Experimental Studies

A series of experimental studies was performed using 1/20 scale models of the units in a wave tank 50 m long, 1 m wide, and 1.50 m high, to measure the transmission and reflection coefficients. Experiments to measure water level rise and wave height attenuation over the breakwater, and to examine the stability of the units, were also performed using the same wave tank. The waves were regular in all experiments. The model units were placed on a 15 cm-thick rubble mound on a horizontal floor in the wave tank. The breakwater width tested was primarily $B=2.4\text{m}$, 16 rows of units, but in the experiments to measure the transmission and reflection coefficients, breakwaters with widths $B=1.2\text{m}$, 8 rows of units, and $0.6\text{m}$, 4 rows of units, were also tested. The water depths (crest water depth) tested were $h=30\text{cm}$ ($R=0\text{cm}$), $35\text{cm}$ (5cm), $40\text{cm}$ (10cm), and $45\text{cm}$ (15cm). Fig. 7 shows a picture of waves over the crest of the breakwater model ($B=2.4\text{m}$, $R=0\text{cm}$, $T=3\text{s}$, $H=15.5\text{cm}$).
The experiments to examine the stability of the units were performed by using breakwater models which were placed on a horizontal floor raised from the wave tank floor. The berm widths tested were 30cm and 75cm, with the length from the rubble mound end to the offshore edge of the units, $L_M$, 55cm and 100cm, respectively. Four wave periods within the range from 1.5s to 3.15s were used, and the wave heights were increased till instability was observed, keeping the period constant. Because instability was observed in the row at the very offshore side edge only, modifications were made for the row. One of the modifications was made by using units made of high density material, and the other was made by modifying the cross section of the units. Fig.8 shows a unit with the modified cross section, and Fig.6 shows a breakwater with the units at the offshore edge. It was found that the units with the modified cross section were most stable. This is because that the larger opening in the upper slab may reduce wave forces exerted on a unit. The degree of stability was determined on the basis of the criteria shown in Table 1.

5. Results

5-1. Comparison of transmission coefficient with that of a conventional reef breakwater

Fig.9 (a) and (b) show examples of comparisons of experimental data for the transmission coefficients of the present breakwater with those of a conventional reef breakwater (Uda et al. 1988) as a function of $B/L_0$, where $L_0$ is the deep water wave length, with relative crest depth, $R/H_0'$, as a parameter, where $H_0'$ is the wave height in deep water if the wave is not refracted. In transmission wave records, the effect of bi-frequency components was found to be small, and hence these were not included in the figures. As shown in the figures, the transmission coefficients of the present breakwater are much smaller than those of conventional breakwaters, implying effective energy dissipation over the breakwater. The difference between the two types of breakwaters becomes large when relative crest depth, $R/H_0'$, becomes large, which implies that, at deeper crest depths, effective energy dissipation caused by separation can still be expected in the present breakwater, while breaking waves of large scale may not occur in conventional reef breakwater. A flat water surface with no waves nor any disturbances was observed under the condition $R/H_0' = 0$ and $B/L_0 > 0.75$, shown in Fig.9 (b). The slits were aligned with the direction of wave incidence in all experiments. But the same results were obtained in an experiment in which the slits were changed to be perpendicular to the wave incidence.
The transmission and reflection coefficients were obtained from transmitted and reflected wave heights behind and in front of the model by using Goda's method (Goda et al. 1976). The period and the wave height were varied from 1s to 3s, and from 0.01m to 0.16m, with the wave steepness $H/L = 0.01 - 0.05$.

The water level rise and the wave height attenuation over the breakwater were measured at 13 points over the crest, including the offshore edge and lee edge. Water level fluctuations were recorded for 60s with sampling period 0.04s, from the time that the first wave arrived at the wave gauge at the offshore side. The water level records were then averaged for the duration, excluding the first 20s and the last several waves, to obtain averaged water level rise from the still water surface. The wave heights over the breakwater were determined by using the zero-up crossing method.

**Fig.8 A concrete unit with modified cross section for the offshore side edge**
The reflection coefficients were confirmed to be small. The maximum value obtained was $\gamma_R = 30\%$ when $R=0\,$cm, and the coefficients tended to decrease with increasing crest depth up to $\gamma_R = 10\%$ when $R=15\,$cm.

**Fig. 9** Comparison of transmission coefficients with those of a conventional breakwater

5-2. Water level rise distribution over the breakwater

Fig. 10 shows relative water level rise distribution over the crest of the present breakwater, $\eta/H_0'$, when $R=5\,$cm. As shown in the figure, the water level rise gradually increases as waves propagate over the crest from the offshore side to the lee side, showing the same tendency as with a conventional breakwater, and becoming maximum at the point just before the lee side edge. Smaller $R/H_o'$ tends to be associated with larger $\eta/H_0'$, a trend which can also be seen in conventional reef breakwaters.

**Fig. 10** Water level rise over the present reef breakwater

5-3. Comparison of the water level rise with that of a conventional reef breakwater

As mentioned earlier, water level rise over the crest of the reef breakwater may cause scouring at the gap between two adjacent breakwaters. Hence, scouring characteristics should be investigated and compared with those of conventional
breakwaters. In Fig.11, a comparison of the water level rise at the lee edge of the present breakwater as a function of $R/H_0$ with that of a conventional breakwater is shown. Much smaller water level rises than those from conventional breakwaters, especially for the range $R/H_0<2$, can be seen. In addition, the present breakwater presents no massive body obstructing the flow, so that scouring at the gap between two adjacent breakwaters would not become a problem.

![Fig.11 Comparison of water level rise at the lee side edge with that of a conventional reef breakwater](image)

5-4. Wave height distribution over the breakwater

Fig.12 shows a wave height distribution over the crest of the breakwater. In contrast to conventional reef breakwaters, where wave height dissipates rapidly because of waves breaking over the crest, wave height reduces gradually over the crest because of the energy dissipation due to flow separation.

![Fig.12 Wave height distribution over the breakwater](image)

5-5. Stability

The present unit is characterized by an upper slab with perforations and a large vacant volume underneath. This configuration leads to concern for the stability of the units under severe wave conditions. Also, as mentioned earlier, the units will be placed in a single layer on a rubble mound, so the instability of the units will be caused by a different mechanism from that for conventional reef breakwaters, which
feature sloping units with waves running up and down the slopes. Therefore, characterization of the stability of the present breakwater design should be carried out using a different approach from that for conventional breakwaters.

Experiments to examine the stability showed that waves which were incident upon the breakwater attacked the offshore side edge first, then traveled over the crest, reducing the wave height by energy dissipation. Because of this mechanism, the instability occurred in the row at the very offshore side edge only. Moreover, the instability was observed to be due to incipient motion with large waves, and not due to drag force, which plays a role in conventional breakwaters which have side slopes (see Fig.13).

Fig.13 A large wave at the offshore edge of the breakwater

The experiments showed that the units became unstable as the wave period became longer, and as the crest depth became shallower, as anticipated.

5-6. Required weight of the unit

Assuming that the unstable motion occurring in the row at the very offshore side edge is caused mainly by the inertia force, a theoretical formula with an empirical coefficient to examine the stability of the breakwater in the sea was created. This examination was carried out for a unit with the modified cross section which has a greater opening ratio, shown in Fig.8, than the regular units which will be placed behind the offshore side row.

The concept of the formula was as follows. The inertial component in the wave force exerted on a plate, which has slits as perforations, is expressed as (Kakuno & Liu 1993)

\[ \Delta P = 2\rho C\dot{w} \]
where \( \rho \) is the fluid density, \( C \) is the blockage coefficient determined theoretically and corresponding to the inertial resistance, and \( \dot{w} \) is the acceleration which acts on the plate in the normal direction. Because the wave force of Eq.(1) is per unit area, the force exerted on the upper slab is

\[
F = \Delta P L_B^2
\]

(2)

letting \( L_B \) denote the side length of the upper slab.

The acceleration \( \dot{w} \) in Eq.(1) was assumed to be proportional to the convective term, that is

\[
\dot{w} \propto w \left( \frac{\partial w}{\partial z} \right)
\]

(3)

where \( w \) is the vertical component of water particle velocity passing through the slits. Moreover, it was assumed that \( \partial w / \partial z \) could be evaluated as

\[
\frac{\partial w}{\partial z} \propto \alpha \left( \frac{w}{b} \right)
\]

(4)

where \( b \) is the thickness of the upper plate, and \( \alpha \) is a constant to be determined experimentally. Consequently, the acceleration may be evaluated as

\[
\dot{w} = \alpha \left( \frac{w^2}{b} \right)
\]

(5)

If we substitute the vertical water particle velocity at the depth of the upper slab calculated by the small amplitude theory for \( w \), then the wave force exerted on the plate can be expressed as

\[
F = 2 \rho \alpha \left( \frac{C}{A} \right) \left( \frac{A}{b} \right) \frac{\pi^2 H^2 \sinh^2 k(h - R)}{T^2 \sinh^2 kh} L_B^2
\]

(6)

where \( A \) is half the spacing of adjacent slits of the upper slab. The coefficient \( \alpha \) can be determined using Eq.(6) and the minimum unstable weight of the unit obtained in the experiments. Fig. 14 shows a graph of \( \alpha \) against \( L_M / L_0 \), for various types of breakwater model. As shown in the figure, \( \alpha \) has a strong and unique relationship with \( L_M / L_0 \) regardless of the type of the unit, the type of the berm width, the crest depth, etc. A regression curve which best fits the data, shown as a broken line in the figure, is expressed as

\[
\alpha = 0.078 \left( \frac{L_M}{L_0} \right)^{-1.20}
\]

(7)

For simplicity in the derivation of a design formula for the stability of the units, however, we will use

\[
\alpha = 0.15 \left( \frac{L_M}{L_0} \right)^{-1}
\]

(8)
Instead of Eq. (7), which is shown as a solid line in the figure.

\[ W_w = 0.85 \gamma_w \frac{H^2 \sinh^2 k(h - R)}{L \sinh^2 kh} L_B^2 \]  

(9)

where \( \gamma_w \) is the unit weight of sea water, and the relation \( L_0 = \frac{gT^2}{2\pi} \) was used in the derivation from Eq. (6) to Eq. (9). From the above expression, the required weight in air of the unit with modified cross section can be obtained readily as

\[ W_a = 0.85 \gamma_w \frac{S}{S - 1} \frac{H^2 \sinh^2 k(h - R)}{L \sinh^2 kh} L_B^2 \]  

(10)

where \( S = \frac{\gamma_c}{\gamma_w} \), and \( \gamma_c \) is the unit weight of the unit.

The most significant discrepancy from conventional formulae, for example the Hudson formula, is that the required weight is proportional to the square of the wave height, not to the third power of the wave height, as in conventional formulae. This is mainly because the water particle velocity is assumed to be proportional to the wave height in the present derivation, while it is assumed to be proportional to the square root of the wave height in the conventional formulae. Another reason is that a representative length scale of armor unit is treated as the side length of the upper slab, \( L_B \), in the present derivation, while it is assumed to be proportional to the cube root of the wave height in the conventional formulae.
6. Concluding remarks

The present theoretical and experimental study has shown the feasibility and superiority of the proposed breakwater. The characteristics of the proposed reef breakwater may be summarized as follows:

- invisible
- less transmission and reflection
- does not generate current
- does not interfere with existing currents
- reduced wave forces
- good shelter for aquatic creatures and hence,
- totally environment-friendly breakwater.

Performance of Submerged Active Breakwaters in a Hydraulic Model

K. R. Hall and M.P. Fischer

Abstract

A submerged active breakwater consists of a large buoyant cylinder that is held horizontal beneath the free surface of the water, by a spring and damper restraint system. The cylinder will be forced to oscillate in a certain mode, in response to an incident wave train. If properly "tuned", the cylinder can absorb a considerable fraction of the incident wave energy. Utilization of this concept may provide a number of potential benefits including: 1) a no loss to fish habitat; 2) a depth-independent materials cost; 3) a scheme easily adaptable to long term water level changes (such as those which occur naturally in the Great Lakes and those which are anticipated with sea level rise); and 4) the capability of adequately protecting a coastal area while maintaining boat access and water circulation. Knowledge of these devices however, is currently limited to performance in; 1) regular wave trains of narrow frequency bands, 2) zero angle of incidence between the wave crest and the structure, and 3) waves of small amplitude.

Research evaluating the performance of submerged active breakwaters was performed in a two-dimensional wave flume in the Queen's University Coastal Engineering Research Laboratory (QUCERL). Both single cylinders and multi-cylinders placed in series were evaluated. Transmission coefficients in the range of 0.3 to 0.7 were measured over a broad range of conditions, indicating the possibility of these devices being used in prototype situations to achieve the benefits described above.

INTRODUCTION

In the field of coastal zone protection, with a general trend of global sea level rise, the design and implementation of coastal defense structures is becoming significantly more complex. In response to the detrimental effects of conventional breakwaters, such as elimination of fish habitat and water stagnation, a variety of new breeds of breakwaters are emerging in an effort to meet the new demands and restrictions of coastal protection.

1 Professor, Centre for the Aquatic Environment, Queens University, Kingston, ON, Canada
2 Project Engineer, Aquafor Beech, Kingston, ON, Canada
A submerged active breakwater is one such variety. Consisting primarily of a large circular cylinder, this type of breakwater is designed to remove a large portion of incident wave energy while maintaining fish habitat and remaining fully submerged.

In order to investigate these devices, a series of experiments was performed at the Centre for the Aquatic Environment (CAE), Queen’s University, Canada. The testing program was completed to broaden the existing experimental data base, evaluate the performance of these devices subject to irregular waves, evaluate the influence of the depth of submergence and to examine the performance of a multi-cylinder array of submerged active breakwaters. Specifically, tests were focused on determining the performance of a specific type of submerged active breakwater by examining the effects of wave height, wave period, the degree of randomness of the waves and the depth of submergence. In addition, a significant portion of the testing was aimed at observing the attenuation abilities of a system of two such devices placed in parallel.

BACKGROUND

The type of submerged active breakwater under consideration has been previously studied by Evans et al.2 and Davis.4,5 and was referred to as the “Submerged Cylinder Wave Energy Device” or the “Bristol Cylinder”. Figure 1 shows a typical setup for a submerged active breakwater. Essentially, the device consists of a large buoyant cylinder that is submerged to a desired depth by a system of cables, springs and some damping mechanism. As the on-coming wave motion interacts with the cylinder, it is forced to oscillate, typically in circular orbits in some phase related to that of the water particle orbits. By adjusting the stiffness of the springs and degree of damping in the restraining system, the device can be “tuned” to the incoming wave frequency and wave energy. When this tuning condition is satisfied, the device is capable of absorbing a considerable portion of the incident wave energy. As the cylinder oscillates in a circular orbit beneath the free surface, the damping mechanism absorbs the energy of the waves, causing little or no reflection and in certain cases, virtually eliminating the transmitted wave.

The concept for this type of submerged active breakwater was first studied on a theoretical basis by Evans1 who built on the early work on submerged cylinders by Dean6,
Ursell\textsuperscript{7} and Ogilvie\textsuperscript{8}. From all of the work presented by Evans and Davis, the primary goal of the Bristol Cylinder was the conversion of readily available wave power to usable electrical energy.

Several benefits and drawbacks are immediately apparent; others become more apparent when one considers the previous studies and experiment of Evans\textsuperscript{1}, Evans \textit{et al}\textsuperscript{2} and Davis\textsuperscript{3,4}. Benefits for such devices at the prototype scale include:

- No loss to fish habitat.
- A material cost that is virtually independent of the depth of water.
- A scheme that is potentially adaptable to long-term water level changes, such as those apparent in the Great Lakes and also those anticipated with global sea level rise.
- The adequate protection of a coastal region while maintaining more than sufficient water circulation to prohibit stagnation.
- The suitability for use in conjunction with newer bio-engineered shore protection methods which are capable of withstanding some degree of wave energy.
- The ability to maintain boat access across the breakwater.

Some of the current fundamental shortcomings include the following:

- Previous testing and theory has shown adequate performance of submerged active breakwaters in wave attenuation only for regular waves of small amplitude over narrow frequency bands.
- Progressive wave crests are limited in angle to a direct wave attack, an incident angle of zero degrees.
- Devising a robust spring and damping unit that can be used in a prototype scenario may prove to be a challenging task.

\textit{RESEARCH GOALS}

In an effort to broaden the experimental background of submerged active breakwaters, a few key shortcomings were to be addressed. Initially, since most, if not all published experimental data is based on device performance with regular sinusoidal wave trains, the experiments were to be conducted using random wave signals as well. Developing seas, indicative of Great Lakes conditions, were to be modelled by using Jonswap spectra with a specified significant wave height, $H_s$, and a peak period, $T_p$.

Secondly, a single device in operation produces a typical performance curve that is narrow in bandwidth over which it provides adequate wave attenuation. In an effort to improve the frequency range, two devices, tuned to different conditions, were to be tested in parallel. This was meant to partially validate the "n" cylinder theory presented by Evans \textit{et al}\textsuperscript{3}. This dual-cylinder system was also to be examined under random wave conditions.
The devices would then be reversed in order to observe the potential benefits of having a smaller period-tuned device in front versus behind.

Thirdly, the performance of individual and dual systems is to be examined in four different depths of submergence using irregular wave conditions.

**NUMERICAL MODEL**

A numerical model to be used to provide a comparison between the theoretical efficiency (or ability to reduce the height of the transmitted waves) with experimental data was developed based primarily on the underlying assumptions of irrotational flow around the cylinder and first-order small amplitude wave theory. From an external force balance equating the oscillatory wave forces to the resistive forces of the cylinder, including added mass and hydrodynamic damping terms related to the cylinder motion, and the spring and damper effects, the efficiency can be calculated as,

\[
E = \frac{4\omega^2 db}{\{k - (m + a)\omega^2\}^2 + \omega^2 (b + d)^2}
\]

where \(\omega\) = angular wave frequency \((2\pi/T)\), rads/s, \(d\) = damper constant, Ns/m, \(b\) = hydrodynamic damping, Ns/m, \(k\) = spring constant, N/m, \(m\) = cylinder mass per unit length, N/m, \(a\) = added mass, N/m.

From this relationship, it can be seen that to maximize the efficiency of the system, the spring rate and damper constant must be adjustable such that the following conditions can be met,

\[
d = b \quad \text{and} \quad k = (m + a)\omega^2.
\]

The added mass term, \(a\), is representative of the additional mass of water that is moved in conjunction with the motion of the cylinder. The hydrodynamic damping term, \(b\), can be thought of as the wave-making ability of the cylinder. Curves of the variation of these two parameters with wave number can be found in McIver\(^9\). By using the efficiency equation, we can essentially choose a desirable tuned wave period and then examine the predicted performance of a cylinder over a wide range of frequencies subjected to small amplitude waves. This results in the typical theoretical performance curves shown in Figures 2 and 3 in terms of wave height reduction (transmission coefficient) and energy removal (power absorption efficiency). Since the added mass and hydrodynamic damping terms vary to a large extent with wave frequency and depth of submergence, so do the predicted efficiency curves. Since this paper deals primarily with breakwater transmission, only transmission curves will be discussed.
Additional parameters that affect these curves are the cylinder's specific gravity and the spring and damper rates. Figures 4, 5, 6 and 7 show the variation in cylinder performance as a function of these parameters.
From the experimental work of Davis\textsuperscript{4,5}, it was shown that the numerical model can predict the performance of a single cylinder quite accurately provided the modeller has a good estimate of the spring and damper rates being used.

Further theoretical work carried out by Evans et al\textsuperscript{3} demonstrated mathematically that any number of devices could be used in parallel with no destructive interference. The performance of a system of "n" cylinders could thus be predicted using superposition of the individual performance curves for each cylinder. Since the addition of any device could only cause additional reduction of the transmitted wave, an "n" cylinder system could only be an improvement over an "n-1" cylinder system. The outcome of this work showed that any degree of wave attenuation could be achieved over a wider frequency band by adding additional devices in parallel.

This effect can be seen in Figures 8 and 9 in terms of wave transmission and power absorption efficiency. In addition to this broadened frequency band, the system would be capable of performing satisfactorily in progressively larger waves due to the subsequent attenuation by successive cylinders.
For the dual-cylinder system, Evans et al. expresses the power absorption efficiency as a function of the individual cylinder efficiencies,

\[ E(T) = 1 - [1 - E_1(T)] \cdot [1 - E_2(T)] \]

where \( E \) is shown as a direct function of the incident wave period, \( T \). In addition, assuming the reflection is truly zero, the transmission coefficient of the dual-cylinder system can be expressed as,

\[ K_T = K_{T_1} \cdot K_{T_2} \]

The creation of this "n" cylinder model is restricted by the linear simplification that the transmitted wave is restricted to the fundamental harmonic.

**EXPERIMENTAL SETUP**

Tests were performed in a two-dimensional wave flume in the Queen’s University Coastal Engineering Research Laboratory. The flume is 1.2 m deep and is approximately 50 m long. The water depth was maintained at 86.0 cm for all tests described in this paper. Both regular and irregular waves were utilized in the testing program. In order to determine the performance of a device for all conditions tested, a sweep of wave periods with a constant wave height was performed. Waves of 2.0, 3.0 and 5.0 cm were used with periods of 0.7 s to 2.0 s at 0.1 s intervals. Although this setup allows a conversion to any scale, the anticipated scale of 1:60 would project performance of a 12 m diameter cylinder in 1.2 m, 1.8 m and 3 m waves with periods ranging from 5.4 s to 15.5 s.
Figure 10 shows one of the test cylinders in the dry and in the wave flume. Both cylinders, 1.08 m long with a 10.6 cm (4") radius, were constructed using ABS pipe and symmetrically weighted to give a specific gravity of 0.3. Two 8.0 m long parallel tracks were installed on the flume bottom and equipped with stainless steel, double sealed bearings at the desired anchor points. Two cables at each side, attached at 90° to each other, passed down underneath the bearings and vertically up towards the springs that were located above the water surface.

The springs were automotive leaf springs attached to provide an upward force on the cables. Damping was not added because preliminary tests tended to indicate that there was too much damping already inherent with this cable system.

The wave flume was equipped with ten capacitance wave probes of which eight were sampled during each run. The signals were generated by the GEDAP wave generation and analysis package, developed by the NRC Canadian Hydraulics Center. Sampling was done at 20 Hz. The samples were then analysed by the GEDAP package by zero-crossing analysis and variance spectral density for a number of parameters including incident and transmitted significant wave height, incident and transmitted periods, incident and transmitted wave power and reflection from the device(s). The zero-moment wave height was not used due to the irregular nature of the transmitted spectra.

After the analysis of the wave signal, the efficiency, E, could be expressed as the fraction of the incident wave power absorbed by the cylinder,
\[ E = \frac{P - P - PT}{P} \]  

[6]

where \( P \) is the wave power of the incident (i), reflected (r) and the transmitted (t) components. The power is calculated as per small amplitude wave theory as,

\[ P = \frac{\rho g^2 TH^2}{32\pi} \cdot \frac{\tanh(kd)}{\sinh(2kd)} \cdot \left(1 + \frac{2kd}{\sinh(2kd)}\right) \]  

[7]

where \( P = \) wave power, W/m \( g = \) acceleration by gravity, m/s^2 \( T = \) wave period, s \( H = \) wave height, m \( d = \) water depth, m \( k = \) wave number \((2\pi/L)\), dimensionless.

Note that with this equation, the efficiency could also be determined easily by the measured wave heights thus knowing the values of the reflection coefficient, \( K_R \), and the transmission coefficient, \( K_T \),

\[ E = 1 - K^2 - K_T^2 \]  

[8]

where

\[ K = \frac{H}{H} \quad \text{and} \quad K_T = \frac{H_T}{H} \]  

[9]

since the wave power is a function of \( H \) squared. This efficiency equation could only be used if the transmitted wave was truly locked to the fundamental, since the power is a function of the wave period, \( T \). As will be discussed later, wave scattering to higher harmonics is common and thus expressing \( E \) in terms of \( K_R \) and \( K_T \) alone is invalid.

**RESULTS**

The notation for the devices and systems of devices tested is shown in Table 1. To tune the devices to the desired frequency, the spring and damper rates require adjustment. The intent was to determine a suitable spring rate and then add damping to maximize the efficiency of the devices by the addition of a rubbing strip or “brake” on the cables. This was tested but any addition of frictional damping caused a decrease in the performance.

**Table 1** Device descriptions

Reflection from the cylinders rarely exceeded 5%. Even reflection of up to 10% would cause no more than 1% error in the determination of the efficiency, which is certainly less than the accuracy of the probe sampling and analysis routines combined. The reflection from the cylinders could thus be neglected as well. Measurements of significant wave height and wave power in front and behind the cylinder could therefore directly represent incident and transmitted components.
Regular Wave Results
The results of extensive testing using regular waves are shown in Figures 12, 13, 14, and 15. Device 1 shows trends in good agreement with the theoretical optimum although a certain degree of difference is expected as the optimum is based on infinitely small waves. The shape of the observed curve is quite consistent with the theory, indicating that the inherent damping is close to the required damping. The theoretical drop in efficiency on the other side of the peak cannot be examined due the limitations in wave generation at periods less than 0.7 s. During the higher frequency waves (T<1.1 s), transmission was typically 40% to 70% but increased to 80% to 100% at lower frequencies. The data supports the trend that an increase in incident wave height will generally cause a decrease in efficiency. Device 1 transmission peaked with the attenuation of 2 cm waves at 0.7 s to a $K_T$ of 28%.

![Figure 12. Device 1 transmission in regular waves](image1)

![Figure 13. Device 2 transmission in regular waves](image2)

![Figure 14. System 3 transmission in regular waves](image3)

![Figure 15. System 6 transmission in regular waves](image4)
Experiments with Device 2 were significantly different than the desired optimum. Since the same bearing/cable mechanism was used as with Device 1, inherent damping of was significantly greater than required. This caused skew of the peak to significantly lower wave periods than the desired 1.5 s peak. Despite this problem, Device 2 provided better wave attenuation for 2 cm and 3 cm waves than Device 1 with $K_T$ values typically 10% less. Wave attenuation for Device 2 peaked again at 0.7 s for 2 cm waves with a $K_T$ of 22%. It should be noted that the performance curves show a rather broad frequency band over which they perform satisfactorily. The peaks are broad for two reasons, the first being the low specific gravity of the cylinders tested (see Figure 4) and secondly, the excessive damping inherent in the test setup (see Figure 7).

System 3 performed worse than anticipated. Firstly, with the first cylinder performing satisfactorily, scattering of the 0.8 s to 1.2 s to the second harmonic proved to be of too high a frequency for the second device to provide any attenuation of its own. It actually had a detrimental effect, especially with the smaller waves. Possible reasons for include the fact that the inherent damping and friction in the system did not permit the rear cylinder to oscillate in the typical circular orbit and for the most part, the cylinder did not move. The small wave forces generated by the reduced wave were insufficient to cause any motion. Additionally, the smaller period scattered waves of 0.4 s to 0.6 s are believed to experience additional shoaling and their energy tends to pass primarily over the top of the cylinder. In one case, a transmission of 31% occurred across the first cylinder and 133% across the second which resulted in an overall system transmission of 42%. It’s unfortunate that the wave generator used could not properly generate waves of such high frequencies such that the performance of single devices under very small period waves could be tested. Wave attenuation peaked at 0.7 s with a $K_T$ of 23% for 2 cm waves and tapered off almost linearly at higher periods.

When the position of the cylinders was reversed, the performance of the system improved. For System 6, the greatest attenuation resulted in $K_T$ values of 17% to 18% for wave periods of 0.7 s, 0.8 s and 0.9 s for 3 cm waves. The data tends to approximate the theoretical optimum better with a typical improvement greater than 5% across the entire spectrum. Overall, transmissions of 50% and less were achieved over 0.7 s to 1.2 s for all wave heights tested, providing better results than system 3 and both cylinders individually. Again, the wave attenuation for the larger waves improved significantly while the 2 cm wave attenuation improved to a lesser degree. The main beneficial effect of a dual-cylinder system is that the performance curves of the larger 3 cm and 5 cm waves are significantly improved. No significant widening of the performance curves was achieved primarily due to the lack of difference between the individual devices’ peak periods.

**Irregular Wave Results**

The results with irregular waves are shown in Figures 17, 18, 19 and 20. The response curves are significantly smoother as no standing waves develop. In comparing these results with those of regular tests, observation shows that larger wave heights cause less drop in efficiency than with regular waves, for all devices tested. Wave attenuation of 5 cm waves always improved, for 3 cm waves it usually improved mildly while for 2 cm
performance was rarely improved. All devices tend to perform significantly better at longer periods with irregular waves.

These two latter points are likely due to the nature of a Jonswap spectrum. First, the x-coordinate on the graphs indicates the peak period of the spectrum. With regular waves, the peak period is also equal to the average period. However, with irregular wave spectra, the average period is less than the peak period, such that the overall device performance may reflect response to the average period as opposed to the peak period. Second, we are using the significant wave height as the governing wave height parameter. For regular waves, it is more representative of the average wave height, as opposed to irregular wave signals, where the average wave height is significantly less than the significant wave height. The typical drop in efficiency in 2 cm significant waves can be attributed to this as
well, since the average height of the 2 cm irregular waves was likely insufficient to generate the required oscillatory forces to create ideal movement of the cylinder.

The peak attenuation of Devices 1 and 2 in random seas is quite consistent with the regular wave tests. It can be seen more clearly with this data, that the peak period of Device 2 is approximately 1.0 s whereas the peak of Device 1 may be 0.7 s or less. The only significant difference in performance is for waves of larger periods, where Device 2 causes 5% to 10% more attenuation than Device 1. Device 1 peaked at 0.7 s with 2 cm waves with a $K_T$ of 34%. Device 2 peaked with a $K_T$ of 39% at 0.9 s with 3 cm waves.

The difference in performance based on which device is in front can also be observed easier with the irregular waves. The wave attenuation is up to 15% more for System 6 than System 3. System 3 peaked at 0.7 s with 5 cm waves with a $K_T$ of 32%, while system 6 peaked at 0.7 s with 5 cm waves with a $K_T$ of 23%.

Essentially, the efficiency of these breakwaters was only very slightly worse in random developing seas than in regular sinusoidal waves. The linear theory is also clearly capable of predicting trends in their performance under random waves. This is very beneficial since the numerical model could therefore be used for prototype design with relative confidence that it will perform as intended in random wave conditions.

**SUMMARY**

A variety of very general, conservative conclusions can be drawn from these results.

1. Wave transmission of less than 50% can be obtained by a single breakwater over a relatively large frequency range for waves less than 0.3A, where A represents the radius of the cylinder. This broad frequency envelope can be attributed primarily to the use of cylinders with a low specific gravity.

2. Wave transmission of less than 50% can be obtained by a dual-breakwater system over a slightly larger frequency range for waves less than 0.5A.

3. A general trend exists whereby the efficiency of the breakwater drops when subjected to waves of increasing size.

4. The spring rate and degree of damping are crucial in tuning a cylinder to the intended design conditions. Over-damping tends to broaden the performance curve and drop the theoretical peak efficiency slightly.

5. The numerical model, which predicted this test data satisfactorily, is sufficient to predict trends in the performance of submerged active breakwaters. It also shows that a wider performance envelope can be achieved when placing two devices in parallel, tuned to different wave periods. The test data cannot confirm the widened envelop, but it shows that even with devices tuned to approximately the same peak period, an overall improvement in efficiency can be obtained.

6. The order in which the individual tuned cylinders are placed appears to have some effect on the dual-breakwater system performance curves. Positioning the cylinder tuned to the longer periods in front and shorter periods behind provided better results.
when examining the combined systems. Designing and positioning cylinders with the second device tuned to the second harmonic would likely have some practical advantages. Unfortunately, the numerical model and experimental data cannot fully support this hypothesis at this time.

7. A two-cylinder system can cause wave attenuation of larger waves to a level that may be acceptable relative to the attenuation caused by a single cylinder.

8. Current testing is being performed to observe the effects of varying the depth of submergence on a breakwater with pre-set tuned conditions. A comparison will be made to the numerical model.

WAVE FORCE AND STABILITY OF ARMOR UNITS FOR COMPOSITE BREAKWATERS

Katsutoshi KIMURA*, Yuzo MIZUNO** and Michifumi HAYASHI***

Abstract

The stability of armor units for composite breakwaters was studied by two- and three-dimensional model tests and prototype failure analyses. The wave force on armor blocks was cleared for different relative mound depths and berm widths. The stable weight of armor blocks is proposed in which the block shape factor is used as a parameter. The necessary thickness of foot-protection blocks is formulated as a function of the relative mound depth for the breakwater trunk and head.

Introduction

Rubble mounds for composite breakwaters are usually protected by armor blocks and foot-protection blocks. These blocks are conventionally designed according to the knowledge obtained through past experience. However, due to a recent increase in the construction of breakwaters at deeper locations with a higher design wave height, a number of cases have occurred in which such experience-based methods are no longer effective. In addition, the armor stability for three-dimensional conditions, such as oblique incident waves and wave action around breakwater heads, remains unknown and damage under such conditions has been increasing.

In this study, the stability of armor blocks and foot-protection blocks was...
examined by two- and three-dimensional model tests. From these results, methods to calculate the necessary armor units for composite breakwaters are proposed, and their applicability for practical design is verified by data analyses of previous damage.

Wave forces on armor blocks

A two-dimensional wave flume (24m × 0.8m × 1.0m) was divided into two parts. The horizontal and vertical wave forces acting on the dummy block (48cm × 10cm × 1.46 cm) are measured using load cells. The force distribution is shown in Figure 2.

**Figure 1** Breakwater model for measuring wave forces

**Figure 2** Wave force distribution

\[ F_y = F_{h'/h} \]

\[ F_y = \begin{cases} 1.46 & \text{for } h'/h = 0.25 \\ 1.83 & \text{for } h'/h = 0.50 \\ 2.19 & \text{for } h'/h = 0.75 \end{cases} \]
5cm) were obtained using a load cell (Figure 1). The structural conditions were: water depth $h$ was set at 50 cm and the depth of the mound $h'$ and mound berm width $B_M$ were altered. The wave force experiment was made with regular waves and the wave conditions were altered using three types of wave period, $T$, and a wave height, $H$, of 2 to 14 cm. In addition to the wave forces, the water levels above the dummy block were also measured.

Figure 2 shows the vertical wave force at each location of the mound when the relative mound depth $h'/h$ was 0.25. The wave force reached its maximum at the mound shoulder and decreased as the water depth increased. The wave force at the front of the caisson was slightly smaller compared with that of the shoulder.

Figure 3 shows the vertical wave force acting on the block at various values of relative berm width $B_M/L$ ($L$: wave length for the water depth $h$) and relative mound depth $h'/h$, which was obtained by dividing $t$, or the required thickness of blocks to resist the vertical wave force, by the wave height $H$. The maximum wave force acting on the block was at $h'/h = 0.2$, with the corresponding required block thickness $t/H$ being about 0.2. Under the usual mound conditions of $h'/h = 0.6$ to 0.8, the maximum wave force occurs when $B_M/L$ is at or around 0.1.
Stability Formula for Armor Blocks

The following Hudson's formula gives the stable weight of an armor block,

\[ W = \frac{\gamma_d H_{1/3}^3}{N_s^3(S_r - 1)^3} \]  

(1)

where, \( H_{1/3} \) is the significant wave height needed for designing, \( \gamma_d \) is the unit weight of the block, and \( S_r \) is the relative density of concrete in the sea water. The stability number \( N_s \) was formulated by Tanimoto et.al. (1982) and was extended for armor stones by Kimura et.al. (1994). For armor blocks, the following equations were modified to separate the block shape factor and mound shape conditions of composite breakwaters,

\[ N_s = N_{SO} \cdot \max\{1.0, A \left( \frac{1 - \kappa}{\kappa^{1/2}} \right) \frac{h'}{H_{1/3}} + \exp\left[-0.9 \left( \frac{1 - \kappa}{\kappa^{1/2}} \right)^2 \frac{h'}{H_{1/3}} \right]\} \]  

(2)

where, \( h' \) is the water depth of the mound foundation, \( N_{SO} \) is the standard stability number of each armor unit, and is determined by stability tests for the high mound conditions. The coefficient \( A \) was decided from the results of the stability tests. The non-dimensional flow parameter \( \kappa \) is expressed as,

\[ \kappa = \begin{cases} \frac{4\pi h'/L'}{\sinh 4\pi h'/L'} \cdot \sin^2 kB_M & (B_M/L' < 0.15) \\ \frac{4\pi h'/L'}{\sinh 4\pi h'/L'} \{2 \sin^2 (0.15 \cdot 2\pi) - \sin^2 (2\pi B_M/L')\} & (0.15 < B_M/L' < 0.25) \end{cases} \]  

(3)

where \( L' \) is the wave length of the design significant wave period where the water depth is \( h' \).

Two-dimensional model tests for armor blocks

The stability tests were made for three types of blocks, A, B and C, using irregular waves. The number of waves was 500 and the stability number, \( N_s \), was calculated by using the critical stability weight corresponding to the damage ratio of 1%. The relative mound depth, \( h'/h \), was altered within the range of 0.25 to 0.75. The high
mound condition of \( h'/h = 0.2 \) represents the hardest condition for the stability of the armor block, and the stability number at this time was defined as the critical stability number \( N_{so} \).

Figure 4 shows the motion of blocks together with time-series describing wave forces obtained by load cells when the wave period \( T \) was 1.83 s, wave height \( H \) was 18 cm, \( h'/h \) was 0.6 and \( B_m/L' \) was 0.055. The vertical wave force, \( F_v \), was larger than the horizontal wave force, \( F_H \). Considering the block motion, the peak of the vertical wave force coincided with the time when the block was uplifted. The uplifted block was then rolled by the wave-induced flow. Predominance of the vertical wave force is characteristic of the wave force acting on armor blocks. After the uplift motion, the blocks are overturned by the wave-induced flow. The stability number \( N_S \) was obtained for blocks A, B and C under various structural and wave conditions. The coefficient \( A \) in Eq. (2) was found to be 0.525.

Figure 5 shows the relationship between \( h'/H_{1/3} \) and the dimensionless stability number \( N_S/N_{so} \), when \( \kappa \) is from 0.06 to 0.40. The values of \( N_S/N_{so} \) for blocks A, B
and C are indicated by different marks, but each mark corresponds well with the calculated values (solid line), thus verifying the calculation method. $N_{SO}$ was found to be 2.0 for all blocks used.

**Three-dimensional model tests for armor blocks**

The three-dimensional test was made in a wave basin 33 m wide and 20 m long.
By changing the breakwater alignment, the wave incident angle was altered in four cases to 0, 30, 45 and 60°. The length of the island breakwater was 8.4 m for normal incidence and 7.2 m for oblique incidence. The water depth was set constant at 46.8 cm and the mound depth was altered. Long-crested irregular waves were used for the stability test with a D-block of three weights (66gf, 100gf and 140gf). The mound condition of $h'/h$ was set at 0.5, the wave period $T_{1/3}$ was constant at 1.90s and wave height $H_{1/3}$ was varied in a range of 5 to 25 cm.

Photo 1 shows the movement of blocks under oblique incident conditions of $H_{1/3}=14.4$cm, $T_{1/3}=1.90$s, with $\beta = 30, 45$ and 60°. The damage of armor blocks occurred mostly at the berm of the mound for oblique wave conditions. This compares with normal incident conditions when damage starts from the slope of the mound.

Figure 6 shows the effect of the incident wave angle for a stable block weight for the wave condition of $T_{1/3}=1.90$s and $H_{1/3}=18.0$cm. The stable weight for oblique waves was smaller than that for normal incidence.
Required thickness of foot-protection blocks

The two-dimensional experiments were made to identify the stability of foot-protection blocks using a wave flume (28 m × 0.6 m × 1.0 m) and irregular waves. Water depth \( h \) was constant at 46.8 cm, and three different mound depth \( h' \) were used. The foot-protection blocks used were of a uniform plane shape (10 cm in length × 5 cm in width), with their thickness \( t \) varied between 1.6 cm, 2.4 cm and 3.2 cm. The specific gravity of the block model mortar was adjusted in accordance with the specific gravity of seawater. The foot-protection blocks were laid side by side in two rows, with the longer side facing the upright section.

The three-dimensional experiments were made using the wave basin mentioned previously. The model’s cross section was the same shape as in the two-dimensional experiments. Using four different incident angles \( \beta \) (0, 30, 45 and 60 deg.), the breakwater trunk and head were analyzed for their respective required thicknesses. The breakwater head, in particular, was checked both forward and backward in relation to the direction of the waves.

Table 1 shows the standard dimensions of foot-protection blocks commonly used in Japan. The thickness of foot-protection block \( t \) was formulated as a function of relative mound height.
Figure 7 Necessary thickness for trunk section

\[ \frac{t}{H_{1/3}} = a_f (h'/h)^{-0.787} \quad (h'/h \geq 0.4) \quad (4) \]

Here \( a_f \) is a parameter showing the differences in breakwater trunk and head.

Figure 7 shows the results of the stability test at the breakwater trunk. In this figure, the horizontal axis represents the relative mound depth, \( h'/h \), and the vertical axis represents the thickness of the foot-protection block, \( t \), which was made non-dimensional by the wave height \( H_{1/3} \). The necessary thickness was greater when the period was shorter. By focusing on the condition of the safe side, the necessary thickness was formulated as shown with the dotted line in this figure (\( a_f = 0.18 \)) for the breakwater trunk.

Figure 8 shows the effect of incident wave angles. In the case of oblique wave attack at the breakwater trunk, relative mound depth, \( h'/h \), was limited to 0.5. When the oblique incident angle was within 60 deg, the difference in necessary thickness was smaller compared with the normal incident condition.

Figure 9 shows the results of the experiments on the breakwater head. Unlike
Figure 8 Effect of oblique wave attack

Figure 9 Necessary thickness for head section
the breakwater trunk, the required thickness increased as the wave period increased,
which is due to local flows generated at the breakwater head. From the values on the
safe side of the experiment range, $\alpha_f$ for the breakwater head corresponds to 0.21.
According to Figure 8, which shows the influence of the direction of waves when the
relative mound depth $h'/h = 0.667$ at the breakwater head, the required thickness at the
forward head is maintained at about the same level by the incident angle $\beta$, while at the
backward head the required thickness increases when $\beta$ is 45 deg. or more. This is
because of the rapid flow around the corner and the increasing standing wave height at
the backward head of the island breakwaters.

</table>
Analysis of disaster damage regarding foot-protection blocks

Table 2 summarizing the disasters (1966 to 1991) related to destruction of foot-protection blocks of composite breakwaters in Japan. In 18 cases out of 25, breakwater heads experienced disaster damage, this indicating that breakwater heads suffer more damage than breakwater trunks. The details show that foot-protection blocks on the breakwater trunk experience less displacement. In this case, the damage was limited merely to foot-protection block displacement. In contrast, on the breakwater head, in many cases, foot-protection block displacement is followed by rubble foundation scouring. The incident wave angle $\beta$ in most disasters was within $30^\circ$.

Figure 10 shows a typical example of the disaster condition at the breakwater head in S-Port. The details of the storm wave are assumed to be: $H_{1/3} = 7.0$ m, $T_{1/3} = 13.5$ s, incident wave angle $\beta = 15$ deg. Foot-protection blocks on the harbor side (40 tf) were scattered, and 150 m$^3$ of material at the corner of the rubble mound foundation ($0.2 \sim 0.3$ tf) below the caisson was scoured. When the wave incidence was almost normal, the damage started from the harbor side corner of the head caisson.

In X-Port, the island breakwater tail suffered greatest damage from the $\beta = 66^\circ$ of oblique incident waves (Figure 11). The wave condition was: $H_{1/3} = 5.6$ m, $T_{1/3} = 10.1$ s. The damage was concentrated at the breakwater tail, and the foot-protection blocks (28 tf) were displaced and partly broken by the shock of the displacement. Such damage to the breakwater head was caused by the rapid flow around corners. It corresponds well with the numerical calculation results shown by Kimura et al. (1994) in terms of the flow speed around the mound. The required thickness expected for the foot-protection block to prevent disaster damage in Table 2 is given by Eq.(4).
Figure 12 shows on the axis of the ordinates that the ratio of required thickness of foot-protection blocks used $t_p$ to $t_{cal}$, which contrasts with the relative mound depth $h'/h$ on the axis of the abscissa. Most of the damage to foot-protection blocks occurred under the condition of $t_p/t_{cal} = 1$ on both the breakwater head and trunk, which verifies the adequacy of the calculation method.

Conclusions

The calculation method of the stable weight for composite breakwater armor blocks and the required thickness of foot-protection blocks are discussed. The major conclusions are as follows:

- Armor blocks:
  - A calculation method for the stability number using a block form factor as a parameter is proposed.
  - For oblique incident waves, the weight required for stability is likely to be less than for normal incident waves.
  - The stability number for wide mound berm conditions is formulated.

- Foot-protection blocks:
The required thickness for breakwater head and trunk are formulated by using the ratio of the relative mound depth as a major parameter.

The wave direction effect on the breakwater trunk was found to be small.

The necessary thickness at the breakwater head needs to be increased depending on the wave direction.

The adequacy of the required thickness calculation method was verified from field damage data.

Acknowledgments

We would like to thank Dr. Shigeo Takahashi, Port and Harbour Research Institute, Ministry of Transport, Japan, for his valuable overall suggestions concerning this study. The great contribution of Mr. Takanobu Suzuki of Hokkaido Development Bureau and Mr. Yoshikazu Doi of North Japan Port Consultants is also deeply appreciated.

HYDRAULIC PERFORMANCE OF A HIGH MOUND COMPOSITE BREAKWATER

Muttray, M.\(^1\); Oumeraci H.\(^2\); Shimosako, K.\(^3\); Takahashi, S.\(^4\)

Abstract

The hydraulic performance of an innovative structure based on the concept of a high mound composite breakwater has been investigated in large-scale hydraulic model tests in the Large Wave Flume (GWK) of the Coastal Research Center (FZK), Germany. The experimental results concerning wave breaking, wave transmission and wave reflection are presented.

1 Introduction

The development of effective and economic protective structures (sea walls, breakwaters etc.) still remains one of the main tasks in coastal engineering. Due to increasing requirements (structural integrity, multipurpose use, environmental aspects etc.) the complexity of these structures is also growing. It is therefore necessary i) to better understand the hydraulic processes at, on and inside these structures and, based on this understanding, ii) to develop rational design formulas.

A new type of breakwater called 'high mound composite breakwater' (HMCB) has been developed at the Port and Harbour Research Institute (PHRI), Japan. It will be applied for the protection of artificial islands along the Japanese coast. This new structure appears to be more effective in terms of hydraulic performance and stability than traditional breakwaters.

Within a joint research project between Port and Harbour Research Institute (PHRI), Yokosuka/Japan and Leichtweiß-Institute (LWI) of the Technical University Braunschweig/Germany the wave load on a HMCB has been investigated in

\(^4\)Dr. Engg., Chief of Maritime Structures Lab., Hydraulic Engineering Division, Port and Harbour Research Institute
In a second Japanese-German research project between Civil Engineering Research Institute (CERI), Hokkaido, Japan and LWI wave overtopping and splash on a HMCB has been studied in 1998. This paper is intended to summarize and discuss the main results concerning the hydraulic performance for this new type of breakwater mainly using results from the first project.

(a) Historical Background

A traditional high mound breakwater consists of a rubble foundation which is larger than the foundation of a caisson breakwater but smaller than a normal rubble mound breakwater. A monolithic superstructure which is much smaller than a caisson but larger than the crown wall on a rubble mound breakwater is placed on top of this foundation (Fig. 1).

The high mound breakwater concept is very old (Takahashi, 1997). The Cherbourg breakwater, originally a rubble mound breakwater, was reconstructed in 1830. Its height was increased, a superstructure was placed on top and it became a high mound breakwater (Fig. 1a). The Alderney breakwater, built in 1890, is another example for an early high mound breakwater (Fig. 1b).

The advantages of high mound breakwaters are as follows:

- the volume of the rubble material is smaller than for a traditional rubble mound breakwater.
- all armour units are placed below still water level, therefore a smaller block weight is required than for a rubble mound breakwater.
- the superstructure is much smaller than a traditional caisson breakwater.

Since armour units, mound and superstructure are smaller than for traditional breakwaters the construction is easier and the costs are lower. However, stability problems may arise from breaking wave impact loads on the monolithic superstructure. The waves start breaking on the seaward slope of the rubble foundation and
cause impact loads which may be critical for the stability of the comparatively small superstructure. Consequently, the breakwater development has moved from the high mound towards low mound composite breakwaters which became the standard type of composite breakwater.

(b) Concept of the High Mound Composite Breakwater (HMCB-Concept)

The breaking wave forces on the superstructure have to be controlled to make use of the aforementioned advantages of the HMCB. The new idea consists in a perforated superstructure to decrease breaking wave impact loads and thus the stability without increasing the mass of the superstructure.

The superstructure of the new HMCB consists of a permeable front wall (pillars resulting in a porosity of ca. 28%) and an impermeable back wall. It is placed on a rubble foundation with a relatively flat seaward slope. The height of the rubble foundation is about 50% of the height of the total structure (Fig. 2).

Figure 2: Cross Section of the HMCB Model in the GWK with Measuring Devices

The wave load on a HMCB is qualitatively different for different wave heights. Very small waves, which do not break, will not be critical for the stability of the superstructure. Larger waves which will break close to the superstructure will cause impact loads on the superstructure. However, these impacts are very local at the pillars of the slit front wall and therefore not critical for the stability. Further increasing the wave height will move the breaking point seaward. These very large waves will be already broken when they reach the superstructure and the load will remain almost constant even for increasing wave heights.

The concept behind the HMCB consists in the following two effects:

i. Temporal and spatial separation of the total wave load into 3 components which will occur at different times:
   - wave load on the seaward slope of the rubble foundation;
   - wave load on the slit front wall of the superstructure;
   - wave load on the impermeable back wall of the superstructure.
ii. Reduction of wave load by increasing the amount of dissipated wave energy due to breaking.

The mechanism which is responsible for the wave breaking at this structure will necessarily limit the maximum wave load on the superstructure which can not be exceeded even for very large waves. This is the governing characteristic of the HMCB. The maximum load for a properly designed HMCB is significantly smaller than the maximum load for a low mound vertical breakwater. Therefore, the HMCB might become a promising alternative for conventional breakwaters in shallow water; i.e. a fourth standard type of breakwater besides rubble mound breakwaters, berm breakwaters and low mound caisson breakwaters.

2 Experimental Set-up and Test Procedure

The model in the Large Wave Flume (GWK) of the Coastal Research Center (FZK), a joint institution of the University of Hannover and the Technical University of Braunschweig, Germany consists of a mound and a monolithic superstructure (Fig. 2). The rubble mound which is 1.75 m high and made of coarse rock material (0.5-5 kg) is placed on a sand layer of 1.85 m with a 1:75 foreshore slope. The armour layer on the seaward 1:3 slope is covered by a single layer of Accropodes (40 kg). The toe is protected with rock material (90 kg). The berm is covered with concrete blocks of 300 kg with holes (opening ratio of 10%). The superstructure is divided into 3 instrumented concrete units across the 5 m flume width. Each unit has a width of 1.75 m, a height of 1.63 m and a total weight of 4.6 t. The front side of each unit consists of 3 cylindrical pillars with a diameter of 40 cm and a distance of 56 cm from centerline to centerline (porosity of 28%). The back wall is impermeable. By turning the superstructure the impermeable back wall became a front wall and a traditional high mound breakwater alternative has been tested comparatively.

19 wave gauges have been used to record the wave motion in front of, at, inside and behind the breakwater (Fig. 3). To measure the wave load 18 pressure transducers have been placed in and outside the superstructure. The structural response of the superstructure has also been measured using strain gauges, displacement meters and accelerometers.

![Figure 3: Cross Section of the Breakwater Model in the Large Wave Flume](attachment:image)

A total of 133 tests have been performed with regular and irregular waves (PM spectra with 200 waves/wave train) at 3 different water levels (h = 2.05 m, 2.625 m and 2.875 m in front of the breakwater) and with 3 different wave periods...
(T_p = 3.6 s, 5.0 s and 7.0 s). For each water depth and wave period the wave height has been increased stepwise until the wave load reached a maximum and started decreasing due to wave breaking.

3 Experimental Results

(a) Wave Breaking

Wave breaking is the most relevant hydrodynamic process for a HMCB. The incident waves are expected to break on the seaward slope of the rubble foundation. Only very small waves (H < d_b) will reach the wall without breaking (Fig. 4). These waves will cause only small wave loads and are therefore not critical for the stability of the superstructure. All the larger waves (H > d_b) will break at or in front of the breakwater. To predict breaking wave impact loads on the superstructure it is therefore necessary to know the breaking point:

- for small waves (slightly breaking) the breaking point is close to the superstructure;
- for larger waves the wave breaking becomes more pronounced but at the same time the breaking point moves seawards. Therefore, smaller waves might break against the superstructure whereas larger waves break on the seaward slope or at the toe of the rubble foundation; i.e. they are already broken when they reach the superstructure.

Two critical wave heights at the breakwater toe have been defined to describe the transition from non-breaking to breaking waves (H_{min}) and from breaking to broken waves (H_{max}). For each wave height and water level the first critical wave height H_{min} occurs just when waves start breaking against the superstructure and the second critical wave height H_{max} when the waves are already broken when they reach the superstructure.

The breaking criteria available have essentially been developed either for beaches or for traditional vertical breakwaters. Both can not be used to describe the range of critical wave heights for a HMCB. Therefore, an engineering approach has been developed to predict wave breaking for high mound breakwaters within the range of wave and structural parameters tested.

The critical wave heights H_{min} and H_{max} are influenced by the following parameters which are drawn in Fig. 4: (i) the geometry of the rubble foundation (equivalent berm length B_{eq} and height of the rubble foundation h_b), (ii) the local wave length L and (iii) the water depth (at the toe of the rubble foundation h and on the berm d_b).

To describe the wave breaking process in front of a HMCB three dimensionless parameters have been used:

- relative wave height on the berm H/d_b ("breaking criterion");
• *relative berm length* $B_{eq}/L$ (geometry of the rubble foundation in horizontal direction);

• *relative berm height* $h_b/h$ (geometry of the rubble foundation in vertical direction).

These ratios have been combined in a dimensionless breaker number $I_b$:

$$I_b = \frac{2\pi}{L} \frac{B_{eq}}{h_b} \left( \frac{h}{h_b} \right)^{3/2}$$

An empirical formula has been developed to calculate the critical wave heights $H_{\text{crit}} = H_{\text{min}}$ and $H_{\text{crit}} = H_{\text{max}}$:

$$\frac{H_{\text{crit}}}{d_b} = a + b \cos(c \cdot I_b)$$

where $a$, $b$ and $c$ are empirical coefficients and are to be determined for $H_{\text{min}}$ and $H_{\text{max}}$.

For traditional vertical breakwaters $H_{\text{min}}$ is an important design parameter because larger waves will cause a significant increase of the wave forces (wave impact loads). For a HMCB the critical wave height $H_{\text{max}}$ is a more relevant design parameter because this wave height will cause the maximum load. Larger waves will increase the wave energy dissipation but will not increase the load.

![Figure 5: Typical Time Series of the Pressure Head Measured at the Perforated Front Wall for Slightly Breaking, Breaking and Broken Waves](image)

The breaker types have been identified by three different procedures: (i) visual observation during the tests and analysis of video records, (ii) analysis of time series of pressure measurements at the front wall at SWL (Fig. 5) and (iii) analysis of time series of the total horizontal force on the front wall.
Pressure time series (at SWL) of different breaker types are plotted in Fig. 5. Three typical time series of regular waves (T = 5 s, HHWL) are shown. By increasing the incident wave height the signal is continuously changing from a typical slightly breaking wave to a breaking and broken wave. Even at the slit front wall large impact pressures have been observed. But these high pressures are very local and therefore result in comparatively small forces.

The transition from non breaking to breaking and broken waves with increasing wave height is shown in Fig. 6. The pressure head p/pg measured at the front side of the pillar (perforated front wall) is plotted against the incident wave height H for regular waves of T = 5 s (HHWL). For non-breaking and slightly breaking waves the pressure head increases linearly with the wave height whereas for breaking waves the relationship becomes exponential. For broken waves the pressure head is decreasing in most cases with increasing wave height. In some cases with long waves the pressure head was slightly increasing even for broken waves.

\[ \text{Figure 6: Pressure Head at the Perforated Front Wall vs. Wave Height for Different Breaker Types} \]

It is obvious that errors in the prediction of wave breaking of more than 10% of the incident wave height may result in large uncertainties for the wave load prediction. Thus an accurate method for the load type classification is needed.

The critical wave heights \( H_{\text{min}} \) and \( H_{\text{max}} \) as a function of \( I_b \) are shown in Fig. 7. These wave heights can be determined using the simple approach given by Eq. (2).
Figure 7: Breaking Criterion for the HMCB for Regular Waves:

\[
\frac{H_{\text{min}}}{d_b} = 1.5 + 0.7 \cos(1.75 I_b)
\]

\[
\frac{H_{\text{max}}}{d_b} = 2.5 + 0.9 \cos(1.75 I_b)
\]

(b) Wave Transmission

The wave transmission has been analysed by two wave gauges located behind the breakwater (WG 18 and 19 in Fig. 3). The average wave height measured by these gauges has been used to estimate the transmitted wave height. Due to resonance effects (wave reflection at the 1:6 slope at the end of the wave flume and re-reflection at the rear side of the breakwater) the transmission of regular wave tests was significantly higher than for irregular waves (essentially model effects). Therefore, the irregular wave results should be used for design purposes.
For the transmission analysis the tests have been divided into two groups: (i) "non overtopping" conditions \((H < R_c)\) and (ii) "overtopping" conditions \((H > R_c)\). The relevant parameters for the wave transmission are defined in Fig. 8.

For "non overtopping" cases the following dimensionless parameters were used to describe the wave transmission:

- relative length of the rubble foundation \(l_f/L\) \((l_f = \text{average length of the rubble foundation} = 7.68 \text{ m (1996)} \text{ resp.} 10.18 \text{ m (1998)})\) which is relevant for the wave energy dissipation due to friction inside the foundation;
- wave steepness \(H/L\) which influences the wave breaking process and the subsequent wave energy dissipation;
- relative water depth in front of the breakwater \(h/H\) which may represent the dynamic porosity of the rubble foundation (hydraulic conductivity decreases with increasing wave height).

These parameters have been combined to yield a dimensionless transmission number \(M\):

\[
M = \left(\frac{L}{l_f}\right)^{3/2} \left(\frac{H}{L}\right)^{1/2} \left(\frac{h}{H}\right)^{3/4}
\]  

(4)

Figure 9: Wave Transmission for "Non Overtopping" \((H < R_c)\) and "Overtopping" \((H > R_c)\) Conditions vs. Transmission Number \(M\) for Irregular Waves
The wave transmission $K_t$ for "non overtopping" conditions ($H < R_c$) of impermeable and slit type structure can be described by the following empirical formula:

$$K_t = a M^b$$

regular waves: $a = 0.033$ $b = 2.0$
irregular waves: $a = 0.044$ $b = 1.2$

In Fig. 9 the transmission coefficient $K_t$ for irregular waves is plotted against the transmission number $M$ for both types of superstructure. For "non overtopping" conditions the transmission past the rubble foundation is independent of the geometry of the superstructure. For the slit type superstructure the same transmission has been observed as for the impermeable superstructure. For "overtopping" conditions it was found that wave transmission does not substantially increase due to wave overtopping for irregular waves. Transmission for "overtopping" conditions shows more scatter without any clear tendency for higher values. Therefore, wave transmission should be calculated for "non overtopping" and "overtopping" conditions by Eq. (5).

(c) Wave Reflection

The partial standing wave field in front of the breakwater has to be analysed to determine: (i) the incident wave parameters as input parameters for the wave load of the structure and (ii) the wave reflection and thus the wave energy dissipation at the structure.

The reflection analysis has been performed by two different procedures using wave records of the first 4 wave gauges (WG 1 to 4) which were located about 140 m in front of the breakwater (Fig. 3):

- the 3-gauge-procedure (*Mansard & Funke, 1980*): This standard procedure was used for the analysis of regular and irregular wave tests in the frequency domain;
- a new reflection analysis which has been developed at LWI (*Oumeraci & Muttray, 1997*): This procedure was used for the re-analysis of the regular wave tests in the time domain.

In Fig. 10 the wave reflection at the breakwater is plotted against the surf similarity parameter $\xi$ for both structure types and for regular and irregular waves. The scatter in Fig. 10 shows that $\xi$ is not a very appropriate parameter to describe wave reflection. Therefore, a new reflection number has tentatively been developed.

The wave reflection depends on the wave length $L$, the water depth $h$ and the wave height $H$ at the toe of the breakwater as well as on a number of structural parameters like: steepness and roughness of the seaward slope, porosity of the rubble foundation, height and length of the berm, reflection properties of the superstructure etc.. The reflection performance is also affected by wave overtopping. The following dimensionless parameters which are defined in Fig. 4 were found to be most relevant for wave reflection:
- wave steepness $H/L$ (breaking process and subsequent wave energy dissipation);
- relative berm length $B_{eq}/L$ (horizontal geometry of the foundation);
- relative berm height $h_{b}/h$ (vertical geometry of the foundation).

The wave reflection for regular and irregular waves is qualitatively different for this type of breakwater. The reflection process at the complex front face of the HMCB generates higher harmonic free waves which are propagating slower than the reflected waves. Therefore, only the first waves in the reflected wave train are not disturbed by free waves. The regular wave reflection analysis has been performed for these first waves and does not consider the higher harmonic free waves. The irregular wave reflection analysis has been performed for a complete wave train of about 200 waves and it includes the transfer of wave energy towards higher frequencies. The physical processes in the wave reflection will be described in detail in a forthcoming paper.

Two different reflection numbers are used to describe the wave reflection for regular waves ($R$) and for irregular waves ($R'$) where the former describes a linear reflection process and the latter also covers nonlinear effects. The regular wave reflection is mainly influenced by the wave length $L$ whereas the wave steepness $H/L$ is predominant for the irregular wave reflection.

The wave steepness $H/L$ and the relative berm length $B_{eq}/L$ are combined to yield the regular wave reflection number $R$:

$$R = \frac{H}{L} + \frac{B_{eq}}{L}$$

Figure 10: Wave Reflection for Regular and Irregular Waves vs. Surf Similarity Parameter
\[ R = \left( B_{eq} \frac{2\pi}{L} \right)^2 \frac{1}{\sqrt{H/L}} \]  

(6)

Other structural parameters like slope of the mound, roughness and porosity of the rubble foundation are constant and their influence may be included in empirical coefficients. The relation between reflection number \( R \) and reflection coefficient \( K_r \) can be calculated by the following empirical formula:

\[ K_r = a \tanh^b \left( \frac{R}{c} \right) \]

(7)

slit type wall: \[ a = 0.32 \quad b = 1.5 \quad c = 5.2 \]
impermeable wall: \[ a = 0.45 \quad b = 1.5 \quad c = 4.3 \]

The results of the reflection analysis are plotted in Fig. 11 for regular waves and irregular waves.

The regular wave reflection is increasing with increasing reflection number \( R \). This plot shows significantly less scatter for regular waves than the relation between reflection coefficient \( K_r \) and surf similarity parameter \( \xi \) in Fig. 10. The maximum reflection is about 45% for the impermeable type and about 32% for the slit type.

The reflection coefficients for irregular waves are much larger for small reflection numbers \( (R < 5) \) and are more scattering than those of regular waves (Fig. 11). Therefore, a new reflection number \( R^* \) has been developed for irregular waves.

Figure 11: Reflection Coefficient vs. Regular Wave Reflection Number for Regular and Irregular Waves
waves which takes into account the wave steepness \( H/L \) and the relative berm height \( h_b/h \):
\[
R^* = \left( \frac{h}{h_b} \right)^2 \frac{1}{\sqrt{H/L}}
\]  
(8)

The wave reflection for irregular waves is shown in Fig. 12 against the irregular wave reflection number \( R \). The maximum wave reflection is about 50\% for the impermeable type and 30\% for the slit type. To calculate the reflection coefficient for irregular waves \( R^* \) has to be used together with Eq. (7) and the following coefficients:

- **Impermeable type**: \( a = 0.5 \), \( b = 2.0 \), \( c = 4.5 \)
- **Slit type**: \( a = 0.3 \), \( b = 2.0 \), \( c = 4.5 \)

![Figure 12: Reflection Coefficient vs. Irregular Wave Reflection Number \( R^* \) for Irregular Waves](image)

4 Conclusions

The hydraulic performance of an innovative structure based on the concept of HMCB has been investigated in the Large Wave Flume (GWK), Hannover, Germany using regular and irregular waves. The following key results have been achieved:

- The breaking process has been analysed for regular waves. Two critical wave heights \( H_{\text{min}} \) and \( H_{\text{max}} \) have been defined (Eq. (3)). \( H_{\text{max}} \) is most critical for the stability of the superstructure. An engineering approach has been developed taking
into account the geometry of the front face of the breakwater and the incident wave parameters to predict these critical wave heights.

Wave transmission past the HMCB has been investigated for regular and irregular waves. The main parameters for the wave transmission have been combined in a dimensionless transmission number $M$ (Eq. (4)). Wave overtopping does not contribute significantly to the wave transmission.

Wave reflection has been analysed for regular and irregular waves. The main parameters for the wave reflection were used to build two dimensionless reflection numbers: $R$ describing the linear reflection of regular waves (Eq. (6)) and $R^*$ for nonlinear reflection of irregular waves (Eq. (8)). For a high mound breakwater with an impermeable type superstructure the maximum reflection coefficient is about 50% and significantly smaller than the maximum reflection for a vertical breakwater. The slit type superstructure will reduce the maximum reflection to about 30%.

Future research work is needed to extend the results to the prediction of breaker types under irregular wave conditions. The empirical formulae for the prediction of wave transmission and reflection should be replaced by more general formulae.

5 Acknowledgements

This project has been supported by the Science and Technology Agency of Japan and the 5th Port Construction Bureau of Ministry of Transport (MOT)/Japan. However, without the basic research project 'Design Wave Parameters in Front of Structures with Different Reflection Properties' (OU 1/3-1) founded by the German Research Council (DFG) these results would not have been achieved. Those supports are gratefully acknowledged.

Abstract

The effectiveness of a second perforated barrier seaward of a solid wave barrier in significantly reducing wave reflections and simultaneously improving wave protection is demonstrated in the paper. The indicated optimum seaward wall porosities and overall widths can be readily incorporated into practical structural designs for small craft facilities in relatively sheltered waters with limited wave periods. Results of an extended laboratory testing program and specific application to a recently designed and constructed structure are presented.

Introduction

Wave barriers (screens, curtains or skirts) have been found to offer cost effective and space efficient means of providing wave protection for small craft facilities in sheltered waterways where wave periods are restricted to locally wind generated seas.

The resultant wave reflections from a vertical barrier (as from other structures such as rubble mounds and floating breakwaters) often adversely impact on surrounding areas. Li (1995) demonstrated the significant reductions in wave reflection that may be achieved (for a full depth vertical seawall) by the seaward addition of a second perforated wall.
In this paper, the design and effectiveness of a double wave barrier (with perforated seaward wall) in simultaneously satisfying low wave reflection and transmission requirements has been investigated in scaled laboratory wave flume and basin testing. Under design storm situations such structures experience significant wave overtopping and turbulent energy losses, conditions which are not conducive to analytical nor numerical solution.

Single Vertical Wave Barrier

Kriebel and Bollmann (1996) modified the original power transmission theory of Wiegel (1960) in obtaining an improved yet simple solution for estimating wave transmission for a single vertical wave barrier of the type shown in Figure 1.

![Figure 1. Definition sketch for single vertical wave barrier.](image)

The Kriebel and Bollmann solution for wave transmission \((H_t/H_i)\) is given by,

\[ K_{ts} = 2 \frac{T_F}{(1 + T_F)} \]  

where \[ T_F = \frac{2 k (d - w) + \sinh 2 k (d - w)}{2 kd + \sinh 2 kd} \]  

and the wavenumber \( k = 2\pi / L \)

Kriebel and Bollmann favourably compared predictions from the above solution with a range of test data and the mathematically derived eigenfunction expansion methods of Losada et al (1992).

Kriebel and Bollmann confirmed the findings of Peirson and Cox (1989) in that the Wiegel theory overestimated wave transmission in deepwater conditions whilst underestimating in shallow water. Peirson and Cox noted that the method of predicting forces on a single wave barrier as contained in the US Army Corps of
Engineers Shore Protection Manual (1984) was overly conservative due to the assumption that the transmitted wave is 180° out of phase with that of the incident wave – a restricted series of wave flume experiments resulted in phase lags not exceeding 60°. Over an extended range of conditions, Kriebel et al (1998) utilising eigenfunction expansion solutions and near prototype scale laboratory tests have found the phase lag to vary with wave period and be generally less than 90°. The eigenfunction predictions of wave forces were validated against the experimental data and found to provide a reasonable upper-bound solution – the Shore Protection Manual (1984) method of estimating forces again shown to be overly conservative.

Double Walled Low Reflection Wave Barrier

A double walled structure is effective at reducing the reflection coefficient because waves reflecting off the front barrier are out of phase with those reflecting off the rear barrier. The theoretical ideal separation between front and rear barriers can be readily shown to be \( L/4, 3L/4 \) or \( 5L/4 \) where \( L \) is the wavelength. For a separation of \( L/2 \) there would be little to no effective reduction in wave reflection.

For many small craft facilities even a separation of \( L/4 \) can be cost prohibitive. The introduction of porosity in the front barrier has been found to assist in reducing wave reflections with separations significantly less than the theoretical optimum \( L/4 \). In studying a full depth solid rear wall with porous front wall structure, Li (1995) indicated that the optimum separation could be as low as \( 0.18L \). For many small craft facilities the concept of a double wave barrier structure as shown in Figure 2 is most appealing. Major benefits include: (i) little impact on water circulation which can continue below the penetration depth; (ii) the horizontal deck connecting the two barriers can be utilised for pedestrian and/or vehicular traffic; and (iii) control of wave reflections (optimised by incorporation of porosity in the front wall) and reduction of adverse impacts on surrounding areas.

![Figure 2. Definition sketch for double walled low reflection wave barrier.](image-url)
Testing Program

To examine the behaviour of low reflection double wave barrier structures, an extensive experimental testing program was undertaken in the random wave flume at Water Research Laboratory, School of Civil and Environmental Engineering, University of New South Wales. The flume is 32 m long, 1 m wide and 1.2 m deep. Waves are generated by a single paddle hydraulic wave actuator at the upwave end. Wave energy absorption at the downstream end is achieved with porous plates and a sloping mat of synthetic hair. Double barrier structures for testing were mounted in a specially constructed force measurement rig located 24 metres away from the wave generator. The test rig with load cell arrangement is shown in Figure 7. Model double wave barriers were constructed from marine ply or transparent rigid acrylic for a range of vertical heights, widths/separations between front and rear walls and perforation porosities of the front wall.

The testing program examined transmitted and reflected wave behaviour for varying water depth \((d)\), wavelength \((L)\), incident wave height \((H_i)\), barrier penetration \((w)\), double barrier separation \((B)\), and front wall porosity \((p\%)\). The above water crest level \((R_c)\) was initially set above wave runup level to eliminate any overtopping.

Wave heights were measured with twin wire capacitance wave probes at various locations upwave and downwave of the test rig to determine incident \((H_i)\) transmitted \((H_f)\) and reflected \((H_r)\) wave heights and thus the dependent parameters of wave transmission \((K_f = H_f / H_i)\) and reflection \((K_r = H_r / H_i)\) coefficients.

The range of the governing independent non-dimensional terms examined in the testing was:

- Porosity of front wall \(p\%\) 10% to 30%
- Water depth to wavelength ratio \(d/L\) 0.2 to 0.6
- Barrier penetration to depth ratio \(w/d\) 0.2 to 0.6
- Barrier separation to depth ratio \(B/L\) 0.1 to 0.3
- Wave steepness \(H/L\) 0.02 to 0.10

More than 250 independent conditions were tested for wave transmission and reflection behaviour. Force measurements were restricted to the reduced set of conditions directly related to the Royal Prince Alfred Yacht Club structure in which significant wave breaking and overtopping of the structure occurred due to the low deck crest level required.
Test Results

Preliminary testing for a selected range of $d/L$, $w/d$ and $B/L$ confirmed the results of Li (1995) in that reflections were minimised for an optimum front wall porosity of about 20%. A 20% porosity was also found to be optimum for practical construction and operational purposes such as incorporation of reinforcing steel in concrete panelled porous walls and minimising effects of marine growth. The majority of testing was subsequently carried out for front barrier porosity of 20%.

As indicated in Figure 3, wave steepness was found to have little effect on wave transmission and reflection coefficients.

![Figure 3: Double barrier transmission ($K_t$) and reflection ($K_r$) coefficients, varying $H/L$ (porosity = 20%, $d/L = 0.5$, $w/d = 0.5$ and $B/L = 0.21$)](image)

As indicated in Figures 4 and 5, wave reflections were minimised for barrier separations $B$ less than 0.20$L$. The sensitivity of reflection coefficient to barrier separation was found to increase for reduced barrier penetrations in deeper water conditions generally giving rise to increased wave transmission. In most applications $B/L$ may be reduced to a suggested practical (and near optimum) value of 0.15 with little increase in reflected wave energy above the measured minimums. With near optimum 20% front wall porosity and double wall separation of 0.15$L$, reflection coefficients less than 0.3 were achievable for penetration ratios $w/d$ less than 0.5.
Figure 4: Double barrier, $K_r$ variation with $B/L$ and $d/L$ (porosity = 20% and $w/d = 0.3$)

Figure 5: Double barrier, $K_r$ variation with $B/L$ and $w/d$ (porosity = 20% and $d/L = 0.4$)
In Figure 6 the measured transmission coefficient $K_f$ is compared to the value $K_{ts}$ given by Kriebel and Bollmann (1996) in equation (1) for a single wave barrier. Over a wide range of $H/L$, $d/L$, $w/d$ values the Kriebel and Bollman method was found to reasonably predict the wave transmission even for the porous front double barrier structures provided the barrier separation was less than the suggested optimum of 0.15$L$. With increasing barrier separations above 0.15$L$ the double barrier can significantly further reduce wave transmissions below values achievable with a single barrier. It is, however, more efficient to achieve lower wave transmissions by increasing the penetration rather than widening the separation of the double barrier structure.

![Figure 6: Ratio of double barrier transmission coefficient ($K_f$) to single barrier transmission coefficient of Kriebel and Bollmann ($K_{ts}$), versus B/L](image)

The experimental test program clearly indicated the ability of a porous front walled double wave barrier in providing low wave reflections concurrent with
adequate wave protection (low wave transmission). The concept has been recently utilised at Royal Prince Alfred Yacht Club.

Royal Prince Alfred Yacht Club – double walled low reflection wave barrier

Royal Prince Alfred Yacht Club (RPAYC) on Pittwater in Sydney’s north required a new breakwater as part of an upgrade of its marina facilities. The breakwater was to provide protection for a system of floating marina units and replaces an aging slatted timber structure. To gain construction approval the structure had to meet the requirements of Pittwater Council. These included minimisation of wave reflections, visual impact (structure crest to be not more than 1.25 m above Mean Sea Level) and impact on current or sediment flows. Waves at the site are boat wakes or locally generated short period wind waves, with the longest fetch being at an angle of 55° to the required breakwater alignment. For the established design wave conditions (significant height 1 m and period 2.8 seconds), both the wave transmission and reflection coefficients were required to be less than 0.3. Bed materials consist of sands and silts over rock. Water depths range up to 11 m.

Following a design process that considered a number of options a double walled low reflection wave barrier was chosen as the best solution. The basic concept described above was refined for the particular application with detailed 2D wave flume and 3D wave basin modelling at Water Research Laboratory. The 2D testing was used to optimise the configuration of the double wave barrier - specifically the front wall porosity, the penetration depth and separation width. 2D detailed wave loading measurements by load cells incorporated hydrostatic and dynamic impact force components acting on both the seaward porous and rear solid barrier walls. The 3D testing was carried out to determine wave attenuation and reflection characteristics of the structure under angled wave attack. 3D wave induced forces (perpendicular and axial load components) on an instrumented 5 metre double barrier panel were measured under angled wave attack. The force testing arrangements of load cells are shown in Figure 7.

The adopted design double wave barrier is shown in Figure 8. The double barrier structure is supported by raking piles capped with concrete blocks at 5 m spacings. Panels (5 m long x 3.12 m deep) and decking (2 m wide) straddle the space between the supports. The total length of the structure is approximately 200 m. The front (seaward) wall panel is perforated with thirteen 500 mm holes, resulting in 17% porosity. This arrangement was arrived at after consideration of marine growth as well as code requirements for reinforcing steel and concrete cover. Two small holes are located in the rear wall at about the high water level to reduce buildup of floating debris.

Figure 12. Maximum wave force vs water level (T=2.8s, 90°)
Figure 13. Wave forces within a wave period (H=1.35m, T=2.8s, 90°, WL=0m)
Selected T/8 time steps do not necessarily coincide with peak forces
In Figure 9 the single solid barrier/skirt reflection coefficients of 0.7 to 0.8 were reduced to 0.3 by the addition of a second barrier/skirt (porosity 17% placed L/6 seaward in 10m water depth). As indicated in Figure 9, wave reflection was relatively insensitive to the water level/penetration depth. In contrast, as indicated in Figure 10, wave transmission varied markedly with water level. The transmission coefficient $K_t$ was maintained at less than the design required value of 0.3 for water levels within the spring tide range and for approach wave angles from 55 to 90 (orthogonal) degrees. The increased wave transmission at water levels above High High Water resulted from overtopping of the deck at the imposed low crest level of 1.25m MSL.

An example 2D total force test trace under monochromatic waves is given in Figure 11. The variation of total force with water level is shown in Figure 12. Under design wave conditions the recorded maximum shoreward force (water levels between MLWS and MHWS) was 12 to 13 kN/m whilst the seaward forces (not shown) peaked at 8 kN/m. Sensitivity testing for waves more extreme than the design 1m was undertaken. The resulting total 2D forces and distribution of wave forces on the double barrier structure are included for 1.35m wave conditions in Figures 12 and 13.

Conclusions

The effectiveness of a second perforated barrier seaward of a solid wave barrier in reducing wave reflections and simultaneously improving wave protection has been demonstrated. The resulting indicated optimum seaward wall porosities and overall widths can be readily incorporated into practical structural designs for small craft facilities in relatively sheltered waters with limited wave periods. For longer wave periods the width required to provide low wave reflections (as well as low transmission) will generally become structurally and cost prohibitive.

The ability to reduce wave reflections to low levels was paramount in the acceptance and success of the recently constructed double walled low reflection wave barrier structure at Royal Prince Alfred Yacht Club.

The double walled wave barrier structure is clearly suited to reinforced concrete fabrication techniques similar to those already widely used in precasting of culverts. In addition to vessels being able to berth at the structure, the connecting deck can be readily utilised for pedestrian and/or vehicular traffic.

WAVE OVERTOPPING OF RUBBLE MOUND BREAKWATERS

Mogens Hebsgaard\textsuperscript{1}, Peter Sloth\textsuperscript{1}, and Jørgen Juhl\textsuperscript{2}

Abstract

A general expression for the overtopping discharge of a rubble mound breakwater has been derived utilising the general experience on this subject found in the bibliography and from the results of comprehensive series of model tests carried out at Danish Hydraulic Institute (DHI). The expression includes the important breakwater parameters (geometry of the breakwater profile) and the environmental parameters, and has been derived for applications with non-breaking waves in front of the structure. In research studies, model test series were carried out on pure rubble mound breakwater profiles with quarry rock as armour layer. Through results from projects carried out at DHI, the expression was extended to include different armour types and to describe the influence of a superstructure.

The aim has been to set-up a reliable expression, which is simple, general and easy to use. Previously, predictions of overtopping discharges have been based either on expressions including empirical constants for different shapes of the breakwater profile, on very complicated expressions or on diagrams giving the overtopping discharges as function of the layout of the breakwater profile and the environmental conditions.

2235
Introduction

Research on overtopping of rubble mound breakwaters has been undertaken at DHI during the last couple of decades. Since 1993, a large number of tests have been carried out as part of a research study on overtopping with the aim to determine the overtopping discharge as a function of the geometry of the breakwater profile and of the environmental parameters. On the basis of the test results, an expression on the functional relationship between the overtopping discharge and the breakwater parameters and the environmental parameters has been derived.

All research tests were carried out with quarry rock as armour, but the derived expression has been extended also to include artificial blocks as armour layer by using the test results from projects carried out in the past.

The overtopping discharges measured in the model have been transformed to prototype values in order to get the results as easily accessible and understandable as possible. It has been the intention to focus on overtopping discharges in the range where there will be a risk of damage to structures, vehicles, installations and persons behind the breakwater. According to for instance reference 1, limited damage may occur for an average overtopping discharge of $10^{-6}$ m$^3$/s per metre run of the breakwater, but serious damage may take place if the average discharge exceeds $10^{-5}$ m$^3$/s per meter run. If the average overtopping discharge exceeds $10^{-3}$ to $10^{-2}$ m$^3$/ms, the discharge will be so large that the damage to possible installations behind the breakwater will be severe. In case of such large overtopping discharges, the exact discharge is not interesting, but only the stability of the crest and the rear side. Accordingly, the present paper has focused on average overtopping discharges from $10^{-6}$ m$^3$/ms to $10^{-3}$ m$^3$/ms.

Model Set-up and Test Programme

Physical model tests have been carried out partly in a wave flume partly in a wave basin at DHI with the purpose to measure the average overtopping per metre run of the breakwater. All tests were carried out with long-crested waves generated on the basis of a Pierson-Moscowitz wave spectrum. The modelled profile and the definition of the breakwater parameters are shown in Figure 1.

The investigated profiles were traditional rubble mound profiles with core, filter and armour layer and without superstructure. The armour layer was quarry rock. The size of the rocks was so large that significant damage to the structure for the investigated wave conditions could be avoided during testing. The tests were all carried out with horizontal seabed in front of the profile.
The overtopping discharge was defined as the average amount of water passing the rear side edge of the breakwater crest.

The tests were carried out with different wave conditions and different breakwater parameters. The following parameters were varied.

**Wave Conditions:**
- Significant Wave Height \( H_s \) (m)
- Peak Wave Period \( T_p \) (s)
- Wave Steepness \( s_p = H_s \cdot 2 \cdot \pi \cdot g \cdot T_p^2 \)
- Wave Direction \( \beta \) (°)

**Breakwater Parameters:**
- Water Depth \( h \) (m)
- Crest Freeboard \( R_c \) (m)
- Crest Width \( b \) (m)
- Seaside Slope Angle \( a \)
- Type of Armour

The following ranges of parameters were investigated in the model studies. The values are given in model measures. The values in brackets being the model values interpreted at a linear scale of 1:40.

**Investigated Wave Conditions:**
- \( H_s = 0.05 \) to 0.11 m (2.0 to 4.4 m)
- \( T_p = 1.0 \) to 2.0 s (6.3 to 12.6 s)
- \( s_p = 0.018, 0.025, 0.030 \) and 0.045
- \( \beta = 0^\circ, 10^\circ, 20^\circ, 30^\circ, 40^\circ \) and 50°
All tests were carried out with irregular, long-crested waves. Most of the tests were carried out with wave steepness of $s_p = 0.018$ and 0.030 and with perpendicular wave attack ($\beta = 0^\circ$).

**Investigated Breakwater Parameters:**
- $h = 0.350, 0.375$ and $0.400 \text{ m}$  
  ($h = 14.0, 15.0$ and $16.0 \text{ m}$)
- $R_c = 0.100, 0.075$ and $0.050 \text{ m}$  
  ($R_c = 4.0, 3.0$ and $2.0 \text{ m}$)
- $b = 0.16, 0.21$ and $0.26 \text{ m}$  
  ($b = 6.4, 8.4$ and $10.4 \text{ m}$)
- $a = 1.5, 2.0$ and $2.5$
- Quarry rocks (100 - 180 g)  
  (6400 - 11500 kg)

**Formulation of the Overtopping Expression**

The expression for the average overtopping of rubble mound breakwaters given in this paper is derived from the results of the model tests described above, but the evaluation of the expression has been inspired by previously developed overtopping formulae given in the literature. Owen, 1980 (see for instance references 1, 3, 5 and 7), has formulated one of the best known expressions. Various authors have elaborated on the formula to include different types of armour, different roughness of the layer, etc.

Owens formula expresses the overtopping $Q (\text{m}^3/\text{ms})$ as:

$$Q = Q^* \cdot (g \cdot T_m \cdot H_s)$$

where

- $Q^*$ is a dimensionless expression for the overtopping discharge
- $Q^* = A \cdot \exp(-B \cdot R^*/r)$
- $A$ and $B$ are constants depending on the geometry of the profile such as the slope of the seaside armour and elevation and width of the berm
- $R^*$ is a dimensionless expression for the freeboard, i.e., the vertical distance between the still water level and the crest level

$$R^* = \frac{R_c}{T_m \sqrt{H_s \cdot g}}$$

- $R_c$ is the freeboard of the breakwater (m)
- $T_m$ is the mean wave period (s) of the incoming wave train
- $H_s$ is the significant wave height (m) of the incoming wave train
- $g$ is the acceleration of gravity (m/s$^2$)
- $r$ is a 'run-up reduction factor' or a description of the roughness of the armour layer
The formula includes the effect of different slopes of the seaside armour through the constants A and B, which however, are difficult to understand physically. The run-up reduction factor is a measure of the run-up level relative to a smooth impermeable slope.

Goda presents design diagrams for the overtopping discharges at block mounded seawalls covering different wave steepness and seabed slopes in front of the seawall (reference 2).

Jensen et al tried to include the geometry of the profile through a representative 'width' of the breakwater (reference 10). This 'width' was defined as the distance from the point where the profile intersects with the still water level to the position from where the overtopping was measured. In this way, both the slope of the breakwater and the crest width were taken into consideration.

Van der Meer et al give formulae which can be used to determine overtopping discharges at dikes, sloping revetments and seawalls (reference 4).

Juhl and Sloth present an expression for estimating the overtopping discharges of breakwater profiles armoured with quarry rocks (reference 9). The expression was based on some of the model test results, included in this present paper, and considers both the geometry of the profile, the wave height and wave period.

\[
Q = Q^* \sqrt{g \cdot H_s}
\]

\[
Q^* = \exp \left[ -17.505 - 4.201 \ln(s_p) + (1.869 + 1.198 \ln(s_p)) \left( \frac{a^{3.3}(2R_c + 0.35b)}{H_s} \right) \right]
\]

[3]

a is the slope of the armour layer
b is the width of the crest (m)

The expression includes the actual shape of the breakwater, i.e., the slope of the armour layer, the width of the crest and the freeboard, but does not include, for instance, the type of armour.

For \[ a^{3.3}(2R_c + 0.35b)/H_s > -4 \], i.e., for small values of the wave height compared to the freeboard, expression [3] gives larger overtopping for larger wave steepness. For smaller values of this factor, the overtopping discharge will increase with decreasing wave steepness. Whether this assumption is correct is difficult to tell from the test results, as no clear tendency was found.

In the evaluation of the new expression, both Owens formulae and Juhl and Sloth's formulation were considered. With the basis in the model tests, Juhl and Sloth found a representative dimension, which could describe the influence of the geometry of the profile [3].
\[ C = a^{0.3}(2R_c + 0.35b) \]

This dimension, which can be taken as a representative 'width' and/or as a representative crest 'freeboard' of the breakwater, was included in the new expression. It was investigated if an expression in the following form would fit the model test data.

\[ Q = Q' \sqrt{g \cdot H_s^3} \]

\[ Q' = k_1 \cdot \ln(s_p) \cdot \exp \left( \frac{k_2 \cdot C \cdot (s_p)^2}{H_s} \right) \quad [4] \]

where \( k_1, k_2, c1 \), and \( c2 \) are constants.

The best fit to the data was obtained with \( k_1 = -0.3 \), \( k_2 = -2.9 \), \( c1 = 1 \) and \( c2 = 0 \). The derived expression has then the following form

\[ Q = Q' \sqrt{g \cdot H_s^3} \]

\[ Q' = k_1 \cdot \ln(s_p) \cdot \exp \left( \frac{k_2 \cdot C}{H_s} \right) \quad [5] \]

with \( k_1 = -0.3 \) and \( k_2 = -2.9 \). Applying a roughness factor or a wave run-up reduction factor for the armour layer of \( r = 0.55 \), which is a recognised value for quarry rock slopes in two layers (see for instance reference 1), the expression will be as follows.

\[ Q' = k_1 \cdot \ln(s_p) \cdot \exp \left( \frac{k_2 \cdot C}{rH_s} \right) \quad [5a] \]

\[ k_1 = -0.3, \quad k_2 = -1.6, \quad C = a^{0.3}(2R_c + 0.35b) \]

**Verification of the Expression, Quarry Rock Slope**

Figure 2 shows the results of all tests, which were carried out in the wave flume compared to the results obtained by using expression [5].

As previously mentioned, the overtopping discharges are given in 'nature' values assuming a linear scale of 1:40. These tests were carried out with wave steepness of 0.018 and 0.030, \( R_c = 2, 3 \) and 4 m, and \( a = 1.5, 2.0 \) and 2.5.

Figure 3 shows the influence of the crest freeboard for an armour layer slope of 1:2, Figure 4 shows the influence of the slope (all tests) and Figure 5 shows the influence of the wave steepness (all tests).
Figure 2  Comparison of measured and computed overtopping discharges, all data from flume tests

Figure 3  Comparison of measured and computed overtopping discharges, influence of crest freeboard, $\alpha = 2$
It is seen that the measured and the computed overtopping discharges in most cases are in good agreement with each other.
Overtopping under Oblique Wave Attack, Quarry Rock Slope

The tests carried out with different wave directions relative to the breakwater alignment have been analysed, and the influence of wave direction on the overtopping discharge has been fitted into the formula [5]. Generally, the tests showed that the overtopping discharges for a wave obliqueness of 10° are almost the same as for head-on waves, and that the discharges are reduced significantly for wave obliqueness larger than 20°. The influence of the wave obliqueness has been included in the overtopping expression as shown in [6].

\[
Q^* = k_1 \cdot \ln(s_p) \cdot \exp\left(\frac{k_2 \cdot C}{rH \cdot \cos \theta}\right)
\]

where

\[k_1 = -0.3, \quad k_2 = -1.6, \quad C = a^0.3 \cdot (2R_c + 0.35b)\]

\[\theta\]

is the oblique angle (relative to head-on wave direction)

Figures 6 and 7 show the results of all tests carried out in the wave basin. Figure 6 shows the results of the tests carried out with a crest freeboard of 2 m, and Figure 7 shows the results of the tests carried out with crest freeboards of 3 and 4 m.

From Figure 6, it is seen that the expression gives a very good description of the overtopping discharges for the lowest crest freeboard, whereas the results presented in Figure 7 for the two other investigated freeboards give too low, respectively too high, estimated overtopping discharges.
Figure 7  Comparison of measured and computed overtopping discharges, influence of wave direction, Re = 3 and 4 m, sp = 0.018, 0.025, 0.030 and 0.045

Overtopping for Different Types of Armour

Results from overtopping tests, which have been carried out as part of projects at DHI, have been used in order to test the expression on different armour layer stones/blocks.

Results from four different projects with different armour types are shown in Figure 8. It should also be noted that the models in all four regarded projects were constructed with a sloping seabed in front of the breakwater.

The wave and breakwater parameters for the four projects are given in Table 1.

The results from the tests show that the run-up reduction coefficients (r) to be applied should be ~0.65 for grooved cubes, ~0.60 for quarry rock/grooved cubes, ~0.65 for rounded stones, and 0.55 for Accropodes in one layer.

Considering the deviations in test set-up for the different projects, it is found that there is rather good agreement between the measured and the estimated overtopping discharges. This indicates that the expression will give reasonably good results for other armour types when applying reasonable values of the run-up reduction factors.

Influence of Superstructure at the Crest

On the basis of the results from projects carried out at DHI, expression [6] has been extended to include breakwater profiles with a superstructure at the crest. Two different layouts were included in the measured data, a ‘low’ respectively ‘high’ crested structure, see Figure 9.

It was found that the overtopping discharges for both ‘low’ and ‘high’ superstructures could be described by the expression

$$Q^* = k_1 \cdot \ln(s_p) \cdot \exp\left(\frac{k_2 \cdot C}{rH_s \sqrt{\cos \theta}}\right)$$

$$[7]$$

$k_1 = -0.01$,  
$k_2 = -1.0$,  
$C = a^{0.3}(2R_c + 0.35b)$  
$\theta$ is the oblique angle (relative to head on wave direction)
The expression is apart from the constants $k_1$ and $k_2$ identical to the expression for pure rubble mound breakwaters.

Results from the tests with different types of armour layers show that the run-up reduction coefficient ($r$) to be applied should be $-0.65$ for grooved cubes, $-0.55$ for quarry rock, $-0.65$ for rounded stones, and $0.45$ for Dolos in two layers.

![Figure 9](image)

**Figure 9** Layout of 'low' respectively 'high' superstructure

**Concluding Remarks**

A general expression for the overtopping discharge of rubble mound breakwaters has been proposed. It includes the influence of wave obliqueness and different types of armour. The expression is valid for rubble mound breakwaters both with and without superstructures.
\[
Q = Q' \sqrt{g \cdot H_s^3} \\
Q' = k_1 \cdot \ln(s_{op}) \cdot \exp\left(\frac{k_2 \cdot C}{rH_s \sqrt{\cos \theta}}\right) \\
C = \left(a^{0.3} \cdot (2R_c + 0.35 \cdot b)\right)
\]

The following values for \(k_1, k_2\) and \(r\) are recommended:

- \(k_1 = -0.3, \quad k_2 = -1.6\) for pure rubble mound structure
- \(k_1 = -0.01, \quad k_2 = -1.0\) for rubble mound structure with superstructure

- \(r = 0.65\) for an armour layer of rounded stones in two layers
- \(r = 0.65\) for an armour layer of grooved cubes (Antifer units) in two layers
- \(r = 0.55\) for an armour layer of quarry rock in two layers
- \(r = 0.55\) for an armour layer of Accropodes in one layer
- \(r = 0.45\) for an armour layer of Dolos units in two layers

It should be realised that the expression for other types of armour than quarry rock has been verified through model tests with different model set-ups, with sloping seabeds, different model scales, etc., than used in the research study. In spite of this, the results of the verifications show that [8] gives good estimates on the overtopping discharges.

It is, however, found that further research will be needed to obtain an understanding of the importance of

- Breaking waves in front of the structure
- Seabed slope in front of the structure
- Berm structures
- Influence of wind on the overtopping discharge.

Directional Wave Overtopping Estimation Model and Experimental Verification

Tetsuya Hiraishi and Haruhiro Maruyama

Abstract

The accurate estimation of wave overtopping quantity is of great importance for the design of seawalls to protect artificial islands constructed offshore. The estimation model for overtopping rate in multi-directional waves is proposed and it is experimentally verified. The numerical results demonstrate that the overtopping rate in multi-directional waves becomes smaller than in uni-directional waves when the incident principal wave angles are near to the normal to sea wall face. The result becomes reverse when the wave angle is more than 30°.

Introduction

Artificial islands are widely under construction and plan to create a new area for the human-conscious space like a promenade, marina and recreational parks as well as the residential and commercial area. An artificial island is surrounded by sea walls which need a specified crown height to prevent serious wave overtopping. When the wave overtopping volumes become very large, the human conscious space like a promenade and a green belt are heavily damaged. Meanwhile, a high barrier may cause the disconnection between the water front and inner land. The lower crown height is more beneficial to make a wide human conscious space. Therefore, the crown heights of sea walls in an artificial island to reduce the wave overtopping rate under the appropriate allowable levels should be determined with high accuracy (Franco, et.al., 1994).

Wave overtopping rates have been studied on the basis of the results in the two dimensional channel test (Goda, et.al., 1975). They proposed a practical formula estimating the wave overtopping rate on the vertical and block-armored

1 Wave Laboratory, Port and Harbour Research Institute, Nagase 3-1-1, Yokosuka, Japan 239-0826

2249
sea walls in shallow water region with an uniform slope. Uni-directional waves have been employed in the experimental study for wave overtopping mainly because of the lack of the facility generating multi-directional waves in a laboratory. The laboratory works employing multi-directional waves are strongly desired as real sea waves have characteristics of directional random waves of which energy propagates to various directions. In the paper, we discuss the applicability of estimation model of directional wave overtopping rate at vertical sea walls in deep water area.

Numerical Simulation for Directional Wave Overtopping

A new approach to estimate the wave overtopping rate is needed for the design of seawalls in deep water area where the wave directionality appears remarkably. To estimate the wave overtopping rate in multi-directional waves, the evaluation of that for waves propagating obliquely to the sea wall face is needed. Takayama et al. (1982) suggest that the wave overtopping rate of oblique incident waves may become smaller than that of the normal incident waves. We assume that an infinite vertical sea wall is arranged on the x-axis and that the incident waves are perfectly reflected at the sea wall. Figure 1 shows the imaginary seawall model for numerical simulation. The water surface elevation at the front of sea wall is expressed in the single summation method (Takayama and Hiraishi, 1989) as follows;

\[
\zeta(x,t) = K \sum_{n=1}^{N_s} 2a_n \cos(k_n \sin \theta_n + \sigma_n t + \epsilon_n)
\]

where, \( \zeta(x,t) \) is the water surface elevation at the point \( x \) and time \( t \). The subscript \( n \) denotes the value for the \( n \)-th component wave. In the eq. (1), \( a_n, k_n, \theta_n, \sigma_n \) and \( \epsilon_n \) represents the amplitude, wave number, wave angle, angular frequency and random phase respectively. The wave angle is measured clockwise from the normal line to seawall face. The number \( N_s \) is the total number of the synthesized component waves. The indication \( K \) is the coefficient for the consideration of wave non-linearity and breaking introduced by Goda et al. (1975). In this study, assuming that the water depth in front of the sea wall is enough deep, we employ the following expression;

\[
K = \frac{\zeta}{H} = \min \{ [1.0 + a_b H^{1/3}/h], c_b \}
\]

where, 'min' means that the minimum value in \{ \} is adopted. In the vertical sea wall, we employ \( a_b=1.0 \) and \( c_b=10 \).

Figure 2 shows the image of wave overtopping. When the water surface elevation becomes higher than the crown height, the wave overtopping occurs.
The wave overtopping rate $q$ is calculated as follows:

$$q = \begin{cases} 
C(\zeta - h_c)^{3/2} & (\zeta \geq h_c) \\
0 & (\zeta < h_c) 
\end{cases} \quad (3)$$

where $C$ is the wave overtopping coefficient given by $C_o \sqrt{2g}$. The value of $C_0$ is determined by:

$$q = C_0 \sqrt{2g} (\xi - h_c)^{3/2}$$

Figure 1 Sketch of sea wall model in numerical simulation

Figure 2 Wave overtopping image at vertical wall
is determined as the estimated \( q \) agrees with the measured \( q \). The consideration for the value of \( C_0 \) is done in the later chapter. The symbol \( h_{c*} \) represents the virtual crown height for oblique component waves. The virtual crown height \( h_{c*} \) is evaluated as the linear superposition of the function \( \lambda_n \) standing for the variation of uni-directional wave overtopping rate for the incident angle.

\[
h_{c*} = \left[ \sum_{n=1}^{N} \frac{S(f_n) \Delta f_n}{m_0} \lambda_n \right]
\]

\[\lambda_n = \frac{h_{c0}}{\beta_n} \]

where, \( f, S(f), \Delta f \) and \( m_0 \) denotes the frequency, spectrum density, interval of representative frequency and total wave energy. The symbol \( h_{c0} \) represents the original crown height of sea wall.

The function \( \beta_n \) is the dimensionless modification factor of crown height for \( n \)-th component waves. It corresponds to the ratio of crown height in oblique incident wave giving a specified overtopping volumes to that gives the same volume in normal incident waves. The factor is determined later according to the variation of overtopping rate in uni-directional waves.

The amplitude of \( n \)-th component wave is given by

\[
a_n = \sqrt{2S(f_n)\Delta f_n \Delta \theta_n}
\]

where \( \Delta \theta_n \) represents and the angle band of \( n \)-th component. The directional spectrum is the product of the frequency spectrum and directional function. The modified Bretschneider–Mitsuyasu type spectrum (Goda, 1987) and Mitsuyasu–type directional function modified for engineering simplification (Goda and Suzuki, 1975) were employed as the wave energy spectrum and directional spreading function respectively. The modified frequency spectrum is expressed as,

\[
S(f) = 0.205 H_{1/3}^2 T_{1/3}^2 (T_{1/3}/f)^{-5} \exp[-0.75(T_{1/3}/f)^{-4}]
\]

where \( H_{1/3} \) and \( T_{1/3} \) represents the significant wave height and period. The modified Mitsuyasu–type directional function is given by,

\[
G(\theta; f) = G_0 \cos^{2s}(\frac{\theta - \theta_p}{2}) \quad (-90^\circ < \theta < 90^\circ)
\]

where \( \theta_p \) is the principal direction and \( G_0 \) the normalized coefficient expressed as ;
The parameter $s$ is the angular spreading coefficient determined as follows;

$$s = \begin{cases} (f/f_p)^5 S_{\text{max}} & : f < f_p \\ (f/f_p)^{-2.5} S_{\text{max}} & : f > f_p \end{cases}$$

(10)

where $S_{\text{max}}$ denotes the angular spreading parameter representing directionality of wave energy, and $f_p$ the peak frequency of wave spectrum. In the simulation, we assume the wave overtopping volumes are measured in the measurement boxes with the width of $\Delta x$ behind the sea wall as shown in Fig.1. The total overtopped water volume $Q_i$ in the $i$-th box is evaluated as,

$$Q_i = q(t) \Delta x$$

(11)

The component value $q_i$ is calculated in eq.(3). The averaged wave overtopping rate $q$ for a sea wall is estimated as,

$$q = \frac{1}{N_b} \sum_{i=1}^{N_b} \frac{Q_i}{t_i \Delta x}$$

(12)

where $N_b$ is the total number of the boxes. Compared with the several computation results with different condition, the following number are adopted in the computation;

$$\Delta x = 10\text{m}, \ N_b = 10, \ N_s = 300, \ t_0 = 20\text{min}$$

(13)

Experimental Setup

Figure 3 shows the arrangements of experimental models in a directional wave basin. Along a side, a directional random wave generator with 60 paddles each 50cm wide is installed. The generator is possible to reproduce oblique regular waves, oblique uni-directional waves and directional random waves with the principal wave direction normal to the generator face. A continuous vertical wall to represent an offshore vertical breakwater is installed parallel to the generator face with the distance of 6.4m. The total length of the vertical wall is 18m and the both of edge sides are slightly bent to protect the effects of diffracted waves. A measurement box for wave overtopping volumes is attached at the backside of center part of seawall to obtain the total overtopped volume $Q$. In the
In the experiment, the wave overtopping rates are analysed for the case of (i) uni-directional waves with oblique incident angle and (ii) multi-directional waves with normal principal wave direction. The single summation method is employed to synthesize the wave signal to generator.

In the experiment, the scale is 1/100 and the water depth is fixed to be 38m in the prototype. The crown height $h_c$ are 6 and 8m. The significant wave height $H_{1/3}$ of incident uni- and multi-directional waves is 6 and 8m. The significant wave periods are changed from 11.3 to 14.1s. In the case (i) uni-directional waves, the incident wave angle varies from 0 to 45°. In the case (ii) multi-directional waves, the principal angle is 0° and the target $S_{\text{max}}$ is changed from 10 to 100. Figure 4 shows the example of wave directional function measured at the wave gage array located at the measurement box without seawall model. The Extende Maximum Entoropy Method (Hashimoto et. al., 1994) was employed to analyze the directional spectrum. The experimental wave represented in the solid line is generated with the target of $S_{\text{max}}$=100. However, the peak height of directional function in the experimental waves is not as tall as the theoretical peak height for case of $S_{\text{max}}$=50. The reduction of angular concentration may be caused by the finite length of generator.
Figure 5 Correlation of $S_{\text{max}}$ and $G(\theta_p)$

So, the angular spreading in the experiment is evaluated according to the peak value of directional function measured in the wave basin. **Figure 5** shows the correlation of the parameter $S_{\text{max}}$ and the measured $G(\theta_p)$. The values of $S_{\text{max}}$ are evaluated employing Fig. 5 after the values of $G(\theta_p)$ is obtained in the spectral analysis.

**Determination of Experimental Coefficient**

In the numerical simulation model, the overtopping coefficient $C_0$ and the crown height modification factor $\beta_n$ should be evaluated in the experiment. Those values are derived from the comparison between the measured and estimated results in uni-directional wave condition. **Figure 6** shows the variation of the error between the estimated and measured wave overtopping rates in uni-directional waves with the normal incident angle for the value of $C_0$. The ratio of wave overtopping rate becomes about 1 for both cases of $T_1/3=11.3$ and 14.1 sec when $C_0$ becomes 0.3. Therefore, in the simulation model, $C_0=0.3$ is adopted. This value is smaller than the value proposed by Goda et al. (1976).

**Figure 7** shows the ratio of overtopping rates in oblique uni-directional waves to those in the uni-directional waves with the incident angle normal to wall face. The ratio becomes more than 1.0 in case of oblique incident waves with 7.5°. When the angle becomes larger than 7.5°, the overtopping rate decreases as the incident angle increases. When the angle becomes 45°, the rate becomes

![Figure 6 Error ratio of estimated to measured wave overtopping rate](image-url)
Figure 7  Variation of uni-directional wave overtopping rate and crown height modification factor for incident wave angle

slightly larger than those in case of $\theta = 30^\circ$. The reason why the overtopping rate becomes maximum at the angle slightly apart from the normal is not clear. However, our results demonstrate that the overtopping wave rate has tendency to become large when the incident angle becomes slightly different from the normal. The modification factor for crown height is determined so that it represents the effects of oblique wave components to reduce the wave overtopping rates.

In Fig. 7, the overtopping rate decreases rapidly as the angle increases in the range of $\theta < 30^\circ$. Meanwhile, the variation of wave overtopping rate becomes small for the range of $\theta > 30^\circ$. Therefore, the modification factor is assumed as follows;

$$
\beta_n = \begin{cases} 
1 - \sin^2 \theta & (|\theta| \leq 30^\circ) \\
1 - \sin^2 30^\circ & (|\theta| > 30^\circ)
\end{cases} 
$$

(14)

The broken line in Fig. 7 indicates the profile of modification factor.

Verification of Numerical Model

Figure 8 shows the comparison between the measured and estimated wave overtopping rate in uni-directional waves. In the following figures, $q^*$ represents the dimensionless overtopping rate given by,

$$
q^* = \frac{q}{\sqrt{2gH_o^3}}
$$

(15)

where $H_o'$ represents the equivalent offshore wave height. The comparison is done for the various cases for different incident angles. The estimated wave
overtopping rates agree well with measured ones. The good agreement between the estimated and measured wave overtopping rates demonstrates that the numerical model with the coefficient of $C_0=0.3$ is suitable for the estimation of uni-directional wave cases.

Figure 9 shows the range of estimation error for uni-directional wave condition. The estimated $q$ are plotted within the range for 50% error of measured values. The estimated error for analytical calculation model proposed Goda(1975) included the estimation error of 100–200% for wave overtopping rates. Therefore, the error in the present simulation model is small and allowable to be employed in the sea wall design.
Figure 10 Comparison of estimated and measured $q^*$ in multi-directional waves
Figure 10 shows the variation of computed and measured wave overtopping rate in multi-directional waves with different angular spreading parameters. The figures represent the comparison between the estimated and measured wave overtopping rate for the various wave height and period conditions. The indication "uni" in the figures shows the case for uni-directional waves. In Fig.10(1), the measured wave overtopping rate gradually increases as the value of $S_{\text{max}}$ increases. The estimated wave overtopping ratea are smaller than the measured ones by about 50%. In case of uni-directional waves, the estimated wave overtopping rate becomes larger than the measured one by 25%. The error is small and allowable for the sea wall design method. The numerical model gives good agreement between the estimated and measured overtopping rate.

In Fig.10(2), the differences between the estimated and measured wave overtopping rates are small at the various angular spreading parameter. The estimated values agree well with the measured ones. In Fig.10(3) for the case of $T_1/3=14.1$s, the agreement between the estimated and measured wave overtopping rate is good except the case of $S_{\text{max}}=75$. For the case of $S_{\text{max}}=75$, the error between the estimated values is about 30%. Therefore, the simulation model is applicable to estimate the wave overtopping rate of directional random waves with different angular spreading parameter.

The good agreements in the cases for multi-directional waves shown in Fig.10 demonstrates that the simulation model is applicable to estimate the wave overtopping characteristics in directional sea conditions.

Wave Overtopping Characteristics in Directional Seas

Figure 11 shows the numerical results for the variation of directional wave overtopping rate for angular spreading parameter in the various crown height. The principal wave direction is normal in the cases. For any crown height cases, the wave overtopping rate becomes large as the $S_{\text{max}}$ becomes large. In the normal principal wave direction, the case of uni-directional waves becomes critical. If the wave directionality is obtained in a construction site, the employment of multi-directional waves may give reduction of the design crown height of sea walls.

Figure 12 shows the variation of multi-directional wave overtopping rates for principal wave direction $\theta_p$. In both cases of uni- and multi-directional waves, the wave overtopping rate decreases as the the incident angle increases. The variation ratio, however, is different between the uni- and multi-directional waves. The wave overtopping rate changes more gradually in case of multi-directional waves. Therefore, the wave overtopping rate in multi-directional waves is smaller than in uni-directional wave conditions for the case of $\theta_p=0$ and 15°. Meanwhile, for the case of $\theta_p=30°$, the wave overtopping rate in multi-directional waves is larger than in the uni-directional wave conditions. The
multi-directional wave condition gives the critical condition to the design. Therefore, in case that the principal wave direction $\theta_p$ becomes larger than $30^\circ$, the multi-directional waves should be considered in the design of seawall.

Conclusions

A numerical model for directional wave overtopping is proposed. The following conclusions are derived from the comparison of numerical and experimental results;

1. The numerical model is applicable to estimate the wave overtopping rates in the both cases of oblique uni-directional waves and of multi-directional waves with the normal principal direction when the overtopping flow coefficients and modified crown height coefficient.
(2) The wave overtopping rates in multi-directional waves become larger than in uni-directional waves in case of the principal wave direction $\theta_p$ more than 30° meanwhile the former ones become smaller than the later one in case of normal and small incident principal angle.

REFERENCES

Part IV: Coastal Processes and Sediment Transport

Rubbjerg Knude (Cliff at Lønstrup)

Tombolo Formation, Liseleje, Zealand
Abstract

Major beach erosion has been occurring along the Nile Delta shoreline. The erosion is primarily caused by diminished sediment transport in the River Nile due to construction of the Aswan high dam.

Egyptian and foreign experts have evaluated various shore protection methods since 1983.

A summary of alternative shore protection methods, including offshore breakwaters, beach sand replenishment, groins, inlet training jetties, etc. is presented.

Introduction

The objective of this study was to investigate a variety of coastal erosion problems occurring along the Nile Delta Shoreline.

The erosion started after constructing the first dam at Aswan, the development of other dams and barrages, and the increased diversion of river water for irrigation purposes.
After completion of the Aswan high dam in 1966, erosion along the Delta coastline accelerated considerably, resulting in the loss of several beaches and blockage of estuaries and navigation channels by sediment, as well as flooding of coastal villages.

Nile Delta Coastal Erosion Problems

Due to the resulting economic losses and the great importance of this national problem, the Egyptian Government conducted several studies since 1960 through several Egyptian and international consultants.

The areas in which erosion problems are critical along the Nile Delta Coast between Port Said City east and Alexandria City west are:

1) Alexandria Beach,
2) Baltim Beach,
3) Burullos,
4) Elgamil Strip,
5) Ras-Elbar Beach, and
6) Rosetta Promontory.

Field Data For The Egyptian Northern Delta Coastline

Most recent data were collected by the Egyptian Academy for Scientific Research and Technology, Suez Canal Research Center, The United Nations Development Program (UNDP), Coastal Research Institute and the Egyptian Shore Protection Authority.

Several shoreline changes from 1895 to 1988 at the Rosetta and Damietta promontories were recorded. Shoreline survey studies were based on data available from two aerial photographs taken in 1955 and 1983. The old shoreline was obtained from topographic maps, admiralty charts, satellite photographs and the Egyptian Survey Department maps.

Shore Protection Plans

In order to develop a shore protection plan, the Egyptian Government awarded a contract for the protection of the Rosetta area to a French consulting firm in 1983. In 1985 the Egyptian Government awarded a contract to an American consulting firm to prepare a General Master Plan for the protection of the Nile Delta Coast. In 1987 the Bilateral Panel for the Nile Delta Coastal Zone Management appointed a Dutch consulting firm to investigate the feasibility of protecting the Ras-Elbar area. Table 1 indicates several shore protection alternatives.

Conclusions

The study concluded that:

a. Planning for the whole region is more realistic and will create an interactive plan for the whole coast.

b. Further studies are recommended to cover all problem areas along the Nile Delta coast.

c. It is strongly recommended to develop and to improve the record-keeping procedures in a standard uniform format.

d. Evaluating the existing shore protection measures by analyzing the field data and comparing it with the calculated data.

Modelling the Morphological Sensitivity of Large Nontidal Coastal Areas to Climatological Changes

H. Weilbeer and W. Zielke

Abstract
This paper deals with two-dimensional hydrodynamical and morphological modelling of a large nontidal coastal area located at the German coast of the Baltic Sea. This work has been carried out in order to consider the morphological response of this region caused by climatological changes. The morphological processes in this region are mainly wave-dominated, hence a shallow water wave model was coupled with a vertical integrated flow model. Stationary simulations for waves, currents and sediment transport are carried out for a large range of meteorological situations, which were defined due to a statistical analysis of the output fields of a coupled ocean–atmosphere global circulation model. The wave parameters of this surface wave model are used as input to coastal area models.

The calculated morphological trends obtained for different meteorological situations show good agreement with the morphological changes observed in this area. By combining and weighting the individual situations the resulting flow field and sediment transport for known meteorological events can be found. The morphological sensitivity to climatological changes of the coastal area is investigated by applying this methodology to different climate scenarios.

Introduction
The prediction of the morphological behaviour of a coastal zone, for present or future environmental conditions, is a task for a coastal area morphodynamic modelling system. A system of this kind consists of coupled wave, flow and sediment transport components, which are able to describe the dynamical behaviour of the simulated area due to the feedback of morphological changes to the hydrodynamical conditions (de Vriend et al., 1993a, Nicholson et al. 1997).

In the coastal area presented in this paper, a quantification of sediment transport and of the morphological behaviour under changed environmental conditions is carried out. The

1 Institut für Strömungsmechanik, Universität Hannover, Appelstr. 9A, 30167 Hannover, FRG
investigated domain covers an area of about 90 km by 60 km, and is located at the German coast of the Baltic Sea (Figure 1). Attention is concentrated on the morphological behaviour of the outer coast formed by the peninsula Fischland, Darß and Zingst. Observations have shown that the Western coast of Fischland and the Northern coast of Zingst are erosion zones. At Darßer Ort, which is found between these erosion zones, accretion is observed. It is important to note that this area is located at a coast nearly without any tidal movements. Thus the definition of boundary conditions for the hydrodynamical models is very difficult due to the absence of periodical water level oscillations.

Waves and wave-driven currents are highly important for the sediment transport processes in this region, so emphasis was laid on the simulation of the hydrodynamical conditions in the coastal area, especially in the nearshore zone. For that purpose, a coupling of the free surface model TELEMAC-2D (Hervouet, 1993) and the wave model HISWA (Holthuijsen and Booij, 1989, 1995) due to wave-induced forces has been carried out.

The idea is to discern the effect of hydrodynamical forces on various coast sections for specific wind situations by wave and flow modelling on a large scale. The results calculated by the wave and the flow model are suitable for sediment transport calculations with regard to erosion as well as accretion zones. By combining calculated typical situations it is intended to develop scenarios which are to show the morphological sensitivity of any particular coast section to changing conditions.
In the following text, hydrodynamical simulations and sediment transport calculations will be described and scenario results will be presented and discussed with regard to their sensitivity to climatological changes.

**Hydrodynamical Simulations**

Flow and wave conditions in the area under research must be thoroughly understood, since the results will be decisive for the qualitative and quantitative representation of the sediment transport results, which in turn are required for the morphological findings. In order to obtain experience in the use of coupled models and in the spatial resolution required in the models, initial studies for a schematic test case have been carried out (Weilbeer, 1998).

![2D-Momentum-Equation](image)

**Source Terms:**

- **Waves**
  \[ S_i = \frac{1}{\rho \cdot h} \cdot \frac{D \cdot T}{L} \cdot k_i \]

- **Bottom Friction (WCI)**
  \[ S_i = \frac{1}{\rho \cdot h} \cdot Y \cdot (\tau_c + \tau_w) \]

- **Wind**
  \[ S_i = \frac{1}{\rho \cdot h} \cdot \rho_{air} \cdot c_D \cdot u_{10} \]

- **Eddy Viscosity:**
  \[ \nu_T = M \cdot h \cdot \left( \frac{D}{\rho} \right)^{1/2} \]

![Figure 2: Coupling of Models](image)

A significant influence of grid-scale on the diversity of the hydrodynamic results was evident in these coupled wave and flow computations. The flow model as well as the wave model requires a spatial resolution of at least 10 m in order to reproduce satisfactory results. This resolution is vital since the waves, particularly in nearshore regions, undergo a number of transformations and have a high spatial variability. Furthermore, it was evident that more reliable results were obtained, if the wave-driving forces were calculated using the dissipation formulation (Dingemans et al., 1987). Wave–Current–Interaction is also considered due to an enhanced bottom friction using the parameterization of Soulsby et al. (1993), the wind stress is considered due to a coupling with an atmospheric model (Hinneburg et al., 1998) and the eddy viscosity is expressed in terms of the dissipation rate D (Battjes, 1975) (Figure 2). The most relevant processes for a wave–driven coastal area model are considered (Johnson et al., 1994, Péchon et al., 1997).
These findings were the basis for the development of the model of the outer coast. For the wave model, high resolution is necessary in the nearshore region and demands a nesting of the area. Consequently, an elaborate nested grid system for the wave model has been developed (Figure 3) and also the FE-mesh of the flow model has been highly resolved along the shoreline in order to meet all requirements.

First the wave model is run for the entire area with a spatial resolution of approximately $\Delta x/\Delta y = 125/250$. The boundary conditions for the eight nested grids defined in advance are retrieved from the model. Next, the nested grids are calculated with a spatial resolution of approximately $\Delta x/\Delta y = 10/25$. The wave parameters (wave height, period, wave length, dissipation etc.) required for the successive models are interpolated onto the nodes of the FE-mesh.

![Nested Grid System](image)

**Figure 3: Nested grid system used for wave modelling**

Defining the boundary conditions for the wave and the flow model presented a considerable problem for the region under consideration. The flow model requires boundary conditions at two open boundaries. It has been mentioned above that there is no periodicity as in tidal areas. Consequently, the boundary conditions have to be interpolated either by water levels measured in the area, or from a larger scale hydrodynamic model of the Baltic Sea.
However in this particular application the free surface elevation at the open boundaries in the flow model were kept constant, since noticeable water level elevations will only occur during an extreme storm event. It is true that such events will affect the bottom morphology of the area, but they cannot be completely represented by applying a method like the one used here. Instead, attention was paid to the definition of boundary conditions, i.e. wave heights $H$, wave periods $T$ and incident wave direction $\text{DIR}$ along the open boundary of the wave model.

Figure 4: Modelling concept to assess the climatological impact on local coastal zones

Figure 4 presents the procedure for the compiled model application. The climate input comes from global climate computations carried out at the German Climate Computation Centre (DKRZ). Wind fields calculated for a span of 13 years (1981 – 1994) were ex-
tracted and taken as input data for a sea motion model of the Baltic Sea (HYPAS, Günther et al., 1979, Kolax, 1998). The wave data output from this model are used as basis for defining typical situations.

First, the events were classified into 8 wind velocity classes and 12 wind velocity directions. A reduction of the input data is required in order to simplify the hydrodynamic input conditions (Steijn, 1992, de Vriend, 1991, 1993b). For the required values H/T/DIR the above hindcast results, considering regional wave measurements, were used as boundary conditions for the wave model (HISWA). In addition, variable wind fields were used corresponding to the direction and the velocity classes.

As a consequence of the geometry, the waves can be included only in half the number of direction classes, reaching from the Southwest to the Northeast section. Since, however, the predominant wind direction in the region is West, the main directions are accounted for. The other flow fields are generated exclusively by wind-induced forces.

![Figure 5: Current pattern near Darßer Ort (Northwest)](image)
The computation times necessary for the high-resolution models limit their applicability. Continuous simulations cannot be carried out with these coupled models. A recoupling of calculated water levels and current velocities — and so a real interaction between currents and waves — is equally difficult to realize. Instead, boundary conditions and driving forces were kept constant for each situation, until stationary flow conditions had been established.

Figures 5 and 6 show as an example the current and sediment transport patterns near Darβer Ort, which are created when the wind and wave direction is from Northwest at a wind velocity of 12.3 m/s and a wave height of approximately 1.5 m. The strong longshore currents in front of Fischland as well as the protecting effect of Darβer Ort are clearly visible.

Measured time series of wind data or data obtained from climate models can be used to form statistical wind distributions in accordance with the above classification. The number of occurrences (described by a Weibull distribution) leads to calculations of factors for the weighting of typical meteorological situations. As long as no changes of bathymetry are taken into account, the individual results can be combined, thus helping to find the resulting flow and sediment transport.
This procedure was carried out with a wind data series gathered over 20 years (Beckmann, 1998). Figure 7 shows the weighting factors for the average distribution of the time range 1970 – 1990. Climate scenarios are represented by such a wind distribution, for example by a distribution for one year with extremely much Western wind, or a contrasting year (1976) with extremely little Western wind (Weilbeer, 1998). Other wind distributions could be found from measured wind data series, or else extracted from model calculations for different climate scenarios (e.g. doubling or tripling the carbon dioxide (CO₂) content in the atmosphere).

![Figure 7: Weighting factors for a mean wind distribution](image)

The flow resulting from this distribution is shown in Figure 8. The flow direction (represented by the arrows) is always East, as can be observed in nature. The varying flow velo-
cities are clearly recognizable. It is particularly satisfying that the highest velocities, and consequently the probably highest hydrodynamical forces are found in those regions which are known to be erosion zones. This is due to the location of the coast line of Fischland, which is oriented nearly perpendicular to the main wind direction (West) and to the steep slope of the bathymetrie in front of Fischland. The dissipation of the wave energy offshore this coast section is rather small.

This interpretation regarding the hydrodynamical forces is a rather positive evidence. Further analyses of the hydrodynamic results, e.g. regarding bottom shear stresses, could be carried out.

**Sediment transport:**

This method was used for the calculation of the net potential sediment transport as well. It is practicable, in this case, to use a so-called ISE-Model (Initial-Sedimentation-Erosion) (de Vriend et al., 1993b). Starting from the wave and flow conditions already found, the sediment transport can be calculated in a separate run completely decoupled from the hydrodynamics. The formulations of Bijker and Van Rijn (van Rijn, 1989) on potential sediment transport due to currents and waves are used for the calculations. Then, by weighting the individual events in the way already described above, the possible resulting sediment transport is calculated.

The calculations led to annually averaged rates of sediment transport which are distinctively different. If the rates of sediment transport which arise from average conditions are taken as reference values, the rate of transport in front of Fischland is reduced up to 40% at the scenario with a weaker west wind and amplified up to 40% at the scenario with a strong west wind. The differences are not as big at the locations Westdarß and Darß Ort. A bigger rate of sediment transport already at the medium wind conditions led to smaller differences (±25%) at the other scenarios.

Another system behavior can be recognized east of Darß Ort. The resulting capacities of sediment transport are growing towards the east in front of Zingst, but the differences between the scenarios are not as clear as on the west coast.

It is noteworthy that if one compares the different formulations of transport then the fuzziness in the quantitative description of sediment transport only effects the absolute rates. The percentage changes of different wind scenarios are in general very small, although comparisons of certain events lead to bigger differences in the rates of transport. It follows that this technique can produce realistic statements on the sensitivity of this coastal area for climatic fluctuations if the present conditions are modeled accurately.

Unfortunately there are hardly any clues about how to assess the reliability of the model results at this time. Therefore they could only be checked for plausibility up to now. The growth of area at Darß Ort suggests the order of magnitude, but can not directly be used for a model validation.
Figure 9: Resulting sediment transport for three different climate scenarios. Potential sediment transport is calculated using the formula of van Rijn (1989)

It would, generally speaking, be possible to carry out morphodynamic calculations, but in reality they would not be feasible due to the size of the area. Application of models of this kind is limited regarding time scale and spatial scale. Successful calculations have been carried out in small coastal areas only, in order to find out, for example, about the changes in the bathymetry, due to constructions, such as breakwaters or groynes (Nicholson et al., 1997). The boundary conditions again are to be considered, since the effect of wave chronology, e.g. the succession of events may be decisive for a morphological development (Southgate, 1995).

Therefore, the described way was used to show the sensitivity of this coastal area to changing environmental conditions. The techniques presented here have potentials which are not at all exploited yet. Further principle and sensitivity studies can be conducted easily by using different transport formulations with more detailed approaches concerning for example suspended sediment or total load formulas.
Conclusions
A method for carrying out two-dimensional hydrodynamical numerical simulations in a large non-tidal area has been presented, with the intention to give forecasts on possible morphological trends due to changed environmental conditions. By coupling a wave model with a flow model with (wave-) boundary conditions coming from a larger numerical model, the hydrodynamical situation and the resulting sediment transport for single events can be calculated. By combining such situations, scenarios can be developed which can be used for investigating the morphological sensitivity of this particular section of the coast.

\textbf{Abstract}

For an efficient protection of the north coast of the Dutch Waddensea island Texel, a long dam was constructed in 1995. The position of this dam is on the southern swash platform of the ebb tidal delta of the Eijerlandse Gat: the tidal inlet between the two Waddensea islands Texel and Vlieland. The long dam changed the hydro-morphological conditions in this tidal inlet. The changes in the inlet's morphology have been monitored through regular bathymetry surveys. This paper describes some of the most remarkable changes that occurred in the inlet after the construction of the long dam. The impact of the long dam on the inlet's morphology and the adjacent shoreline stability has been examined with the use of a medium-term morphodynamic model. From a comparison between the observed and predicted morphological changes it followed that the model was able to simulate the large scale morphological response of the inlet system. However, on a smaller scale there were still important discrepancies between the observations and the predictions.

\textbf{Introduction}

The Dutch Government decided in 1990 to maintain the coastline at its 1990-position by means of artificial sand nourishments. However, at certain coastal sections, where nourishments appear to be less effective, alternative coastal protection methods could be considered. The north-coast of Texel (Figure 1) appeared to be such a coastal section.

Over a distance of some 6 km, the north-coast of Texel has lost in the last decades on average about 0.5 million m\textsuperscript{3} sand per year. Before 1995 the maximum coastline retreat was 5 - 10 m/year at the most severely eroded northern sections. According to the formalised Dutch Coastal Defence Policy (Rijkswaterstaat, 1990), this erosion was combatted through regular sand nourishments. However, these nourishments became less and less effective. Alternative coastal protection measures were considered for this coast, like groynes, offshore breakwaters, long dam(s), revetments; most of them in combination with initial beach nourishment. Detailed numerical model studies were

2281
carried out to investigate the effect of the alternative measures and their cost-efficiency to combat the erosion. A long dam (700 m from the MLW-line) was finally chosen (Rakhorst, De Wilde and Schot, 1997).

The long dam was constructed in 1995 at the northern end of the north coast of Texel (at RSP 30.5 km), in combination with nourishment and dredging works. The morphological changes that took place afterwards were monitored, which gave valuable data for a comparison between predicted and actually observed morphological tidal inlet responses.

In recent years, process-based morpho-dynamical modelling has developed rapidly. In the present study the available dataset for the long dam case has been used to check and validate the model. The model parameters were set as much as possible identical as the ones in the “old model” from 1993; however this time with the latest versions of the applied software DELFT3D (Roelvink, Boutmy and Stam, 1998). A comparison between the renewed predictions (improved hindcast) and the field observations was made and valuable information was obtained on how to set up and operate similar models and to know their weak and strong points.

The tidal inlet “Eiierlandse Gat”

The ebb tidal delta, the inlet throat and the flood tidal basin are shown in Figure 2 (situation as in 1993; before the dam construction). On the ebb tidal delta, the pattern of tidal channels can clearly be recognised, as well as the presence of shallow areas and delta bars. The ebb-dominant inlet throat channel “Robbengat” will be of special
importance for the present study. The flood tidal basin is, in contrast to the other Waddensea flood tidal basins, a closed basin: only during storms, exchange of water takes place across the watersheds.

Figure 2 The tidal inlet "Eijerlandse Gat"

The particles size of the seabed and the beach sediments ranges between 150 and 350 μm: coarser in the tidal channels than on top of the shallow areas or on the beaches.

The tide is semi-diurnal with neap, mean and spring tidal ranges of, respectively, 1.35 m, 1.70 m and 1.90 m. Tidal wave propagation is from south to north. Waves are moderate, with a mean annual wave height (at deep water) of $H_s = 1.2$ m. The yearly average wind speed is 7 m/s from south-southwesterly directions. Storms (larger than 7 Beaufort) mainly come from northwesterly directions.

What has been done in the last decades?

The southward migration of the Robbengat was stopped succesfuly in 1948 and 1956 with the construction of two slope-protection schemes on the north-side of Texel (inside the inlet throat). Ongoing erosion of the north coast of Texel (south of the above-mentioned slope-protection works) was combatted in 1979, 1985 and 1990 by artificial sand nourishments of 2.5 to 3 million m$^3$, each time. The actual lifetime of the last nourishment was shorter than what was expected beforehand.
In the period 1990 - 1993 different studies were carried out to find more efficient methods to protect the north-coast of Texel (e.g. Negen, 1993, Ribberink and de Vroe, 1991, 1992, Hartsuiker, 1991, Ribberink, de Vroe and van Overeem, 1993, Rakhorst and Pwa, 1993 - all of them in Dutch and Ribberink, Negen and Hartsuiker, 1995). A first attempt for a full morpho-dynamic simulation of the tidal inlet, including a long dam alternative, was made by Negen (1993). Based on these effect-studies, which also included ecological and cost-benefits studies, it was concluded that a long dam at the northern end of Texel would be the most cost-effective for maintaining the north-coast of Texel.

In 1994 a 1.3 million m$^3$ sand nourishment was carried out on the north coast of Texel. This was necessary as the 1994-position of the coastline had already receded behind the reference 1990-position. The sand for this nourishment was reclaimed from a borrow area below the MSL -20 m depth contour (i.e. below the closure depth, so from outside the active coastal system).

![Figure 3 Drawing of the long dam and dredging works](image)

Construction of the long dam at position RSP 30.5 km (Figure 2) commenced in April 1995. By July 1995, the dam had reached its most seaward tip at 700 m from the most seaward MLW-line; or 800 m from the dunefoot. Also in early 1995, an additional 0.7 million m$^3$ sand was replenished along the north coast of Texel. Another 0.4 million m$^3$ sand was placed in the neck of the dam (Figure 3), also to make the construction site better accessible for construction equipment. This 1.1 million m$^3$ sand was borrowed by a cutter suction dredger from an area between the expected scour hole and the inlet channel Robbengat (Figure 3). The idea behind this was to initiate the
development of a new ebb tidal channel in southward direction, and consequently to let the ebb tidal delta develop more in front of the north coast of Texel, which on the longer term could also benefit the sand balance of the north-coast of Texel.

Observations

The long dam and dredging works changed the tidal flow regime and wave conditions around and in the immediate vicinity of the dam. It also affected the tidal flow to and from the flood basin. Figure 4 shows for the area around the dam, the observed pattern of erosion and sedimentation between 1995 and 1997 (two-years period).

![Figure 4 Observed sedimentation and erosion 1995 – 1997](image)

The figure shows areas with significant erosion (such as in front of the tip of the dam, and to the north of the dredged borrow area), as well as areas with significant accretion (such as in the dredged borrow area and to the southwest of the ebb tidal delta). The figure also clearly shows the accretion along the coastlines on both sides of the dam. Below, some details of the observations are given:

Scour hole

The scour hole in front of the tip of the dam developed more rapidly than expected. The maximum depth reached MSL -18 m already in September 1995, that is only two months after the dam was finished (note that the local depths at this point were only MSL -5 m). The slopes on the dam-side of the scour hole are very steep, namely 1:2 to 1:3 (vert:hor), which led to the placement of an extra rubble layer after completion of the dam and later again in December 1996 (Rakhorst, De Wilde and Schot, 1997). The wet volume of the scour hole in m$^3$ below MSL -5m is given in Table 1.

Table 1 Development of the scour hole.

The maximum depth reduced considerably in the winter of 1996 / 1997, where it is noted that the winter of 1995 / 1996 hardly had any westerly storms (which is an anomaly). Without the occurrence of high waves, the scour hole apparently developed first in vertical direction, before it widened in horizontal direction.

**Dredged hole**

The borrow area north of the dam (Figure 3), which was intended to develop into a tidal ebb-channel, indeed changed in that direction. The maximum dredged depths down to MSL -15 m reduced rapidly to not deeper than MSL -10 m two years later. While the MSL -7 m depth contour of the dredged borrow area and that of the inlet channel Robbengat were not connected in June 1995, they were in March 1997 (see Figure 5). Once the borrow area stretched in east-west directions and became "connected" with the inlet channel Robbengat and with the scour hole, it migrated in northward direction under the influence of the eastward resultant sediment transport and the west-to-east tidal wave propagation.

Figure 5 Movements of the MSL -7 m depth contour
Coastal area north of the dam
Immediately after the dam construction, significant accretion rates were found in the area to the north of the dam. This area continued to accumulate sand (Figure 4), albeit at a steadily slower rate. In the period July - September 1995 a resultant sand accumulation of more than 70,000 m$^3$ per month was found in an area of some 0.4 km$^2$. About one year later this accretion rate had reduced to some 30,000 m$^3$ per month. Between the coastline of Texel, the dam and this accretion area, a small shortcut gully was present till early 1998, when it silted up.

Coastal area south of the dam
If we consider an area from the dunefoot to a shore-parallel line through the tip of the dam, and from the dam to a position 2.5 km south of the dam (Figure 4), then the total sand accumulation in this area in the period 1995 - 1997 is 475,000 m$^3$ per year. This accretion can be attributed to the effect of the long dam; nourishments have not been carried out in that period.

If we disregard the upper part of the profiles, above MSL -1.5 m, then the observations show that initially erosion took place (70,000 m$^3$ in the period July - September 1995). In volumetric sense not much changed in the foreshore area in the winter of 1995 / 1996. But after the winter of 1996 / 1997, when westerly storms had occurred, accretion of more than 300,000 m$^3$ was observed. This demonstrates the importance of higher waves for the shoreward transport of sand from greater depths.

Model predictions
A numerical model of the entire tidal inlet system including the long dam and dredging works (Figure 3) was set up. The model is based on the DELFT3D software package, which is described in more detail elsewhere in these proceedings (Roelvink, Boutmy and Stam, 1998). The model computes the tidal wave propagation, the tide-, wave- and wind generated flow conditions, the short wave conditions, sediment transport and seabed changes. The model is of the medium term morphodynamic type (MTM-model: De Vriend, e.a., 1993). A limited number of input conditions (waves, tides, wind) have been selected in such a way that they represent the annual sediment transports.

Figure 6 shows, as an example, the computed tide-averaged sediment transports in the vicinity of the dam for one of the selected wave conditions “West-High” (at deep water: $H_s = 3.1$ m, $T_p = 7.6$ s, from 268° N). These transports follow after one year of morphodynamic simulation, so when the deepest portion of the dredged borrow area have already largely silted up.

An interesting detail in the resultant sediment transport patterns was observed near the dredged borrow area. Here, the resultant sediment transport at the start of the morphodynamic simulation is directed from two sides towards the center of the borrow area, leading to a steady siltation of the center of the dredged hole. The flood-dominance on the west-side of the borrow area is due to relaxation effects: during flood the incoming concentration vertical is over-saturated while during eb the incoming concentration vertical is under-saturated.
A direct confrontation between the model predictions and the observations is given in Table 2 below. It gives the volumetric changes over a period of two years (1995 - 1997) for the five areas as indicated in Figure 3. It is noted that this table is not the only source for comparison: for that it lacks too much information on details of smaller scale phenomena.

Table 2: Computed and observed volumetric changes (1995 – 1997)

From the confrontation of the predictions with the observations it follows that:

- The predicted volume of the scour hole is much smaller than observed. Especially the maximum depth of the scour hole was not predicted (MSL - 7 m in stead of MSL -18 m).
- The dredged borrow area north of the dam also stretched and aligned with the inlet’s channel Robbengat in the computations. It even showed a tendency for a northward migration although not at the same rate as in the observations. A weak point is that the computed total volumetric changes in the large area NorthWest does not correspond with the observations.
The accumulation of sand north of the dam was not predicted by the model. This could be related to the smaller scour hole (less sand available) or could be due to a too much restricted horizontal eddy exchange just behind the dam.

The computed accretion south of the dam is almost half the observed accretion. Apparently, too much of the longshore sediment transport is directed in seaward direction along the dam, in stead of being stopped. This may also be one of the reasons why the computed scour near the tip of the dam remains so limited.

The conclusion that follows is that predictions with a state-of-the-art numerical morpho-dynamical model using “standard model settings”, may still differ considerably from actual developments. This is even more true when looking at smaller-scale morphological developments.

Sensitivity computations

The following series of sensitivity computations with the numerical model were carried out to get a better understanding of the behaviour of the model and to improve our knowledge on how these type of models should be designed and operated for the current type of applications:

- Computation with a one-week storm-condition;
- Computation not with a full harmonic analysis of the tide, but by only applying the A0, M2 and M4 tidal constituents. The phases of these constituents were then varied to study the sensitivity of the tide-averaged sediment transport on the modelled phase difference between the M2 and M4 constituents;
- Computation with another tidal schematization;
- Computation with a different model boundary at the tidal flood basin;
- Computations with different values for the dispersion coefficient in the flow and sediment transport modules;
- Computation including a schematised reproduction of spiral flow;
- Computation with an adjusted bed roughness. The spatial differences in the bed roughness have been determined in such a way that it reflects the influence of larger-scale horizontal eddies on the bed shear stress. The applied method can only be regarded as a first attempt to schematise the complex influence of large-scale turbulence on the sediment transport capacities behind structures like the long dam;
- Computation with a different chronology in the wave and tidal conditions.

It goes beyond the scope of this paper to present the findings from the above set of model computations. Details can be found in Roelvink, van Holland and Steijn (1998). Yet, the following recommendations followed for improving the model:

- Take into account the actual chronology in the wave conditions for the simulated period. As stated before, the season 1995 / 1996 was completely different in terms of westerly heavy winds, than the 1996 / 1997 season. In the improved model hindcast (see below), it was therefore decided to run the model for its first year with no waves, and for its second year with a schematisation of the actually occurring wave
conditions. This appeared to be especially important for the rapid development of the scour hole.

- Take into account the effect of spiral flow. This phenomenon appeared to be important for the curving of the new channel through the dredged borrow area. Spiral flow also appeared to be important for additional sand movement towards the inner bend of the curved channel, that is towards the accretion zone north of the dam.
- Use spatially varying bed roughnesses, in such a way that they represent the effect of increased turbulence behind the long dam.

Results from the improved model hindcast

With the improved model a new hindcast was made of the morphological developments in the period 1995 - 1997. Table 3 summarises for the same areas as in Table 2, the computed and observed volumetric changes after one year (1996) and after two years (1997).

b) After 2 years (1995-1996)

Table 3: Comparison between predicted and observed volumetric changes

Figures 7 and 8 further show the computed sedimentation and erosion patterns in the vicinity of the long dam, respectively after one and two years of morphodynamic simulation. Figure 8 can be compared with Figure 4, which was based on the observations.
Figure 7 Computed sedimentation and erosion 1995 – 1996 (no waves)

Figure 8 Computed sedimentation and erosion 1995 – 1997
Conclusions

From a comparison of the results of the improved hindcast with the observations it follows that:

- The maximum depth in the scour hole now is computed at MSL -14 m after six months of simulated time, which is not far from the observed maximum depth of 18 m;
- In the first simulated year there is hardly any accretion south of the dam, which corresponds with the observations. In the next year, when waves are considered in the computations, there is significant accretion, which also fits with the observations.
- The coastal zone north of the dam now also accretes (contrary to the reference computation), which agrees with the observations. In absolute sense, however, there are still discrepancies between the computed accretion rates and the observed ones.
- The model shows that the dredged borrow area quickly develops into a tidal channel (in line with the Robbengat in the inlet throat), which starts to migrate in northward direction. This corresponds with the observations, albeit that the curvature of the channel as well as the migration speed differ.
- The coastal profiles in front of the north-coast of Texel (south of the dam) develop into unrealistic profiles, which would be corrected if cross-shore transport effects by waves were taken into account.

In summary, it can be concluded that the improved model simulates most of the observed morphological changes. The largest uncertainties are the modelling of the turbulence effects around the dam and the modelling of the effect of waves and turbulence on the sediment transport. For a correct representation of the morphological developments, the behaviour of the applied sediment transport formula as a function of the combined flow, turbulence and orbital velocities, is of special importance.

Final remarks

The long dam has been effective in the protection of the north coast of Texel. Contrary to the predictions it has not worsened the situation directly north of the dam. Possible negative consequences for the sand balance of the downdrift island Vlieland have not yet been recorded, but that is probably a matter of time. The morphological response have largely been restricted to the immediate surroundings of the works. But again, this may be a matter of time. After all, the new elongated tidal channel Robbengat has proven to play an important role in the filling and emptying of the flood basin.

Rijkswaterstaat will continue to monitor the situation in the tidal inlet and around the dam. We expect that after some time this data set will form a very valuable source for experimental testing of existing and new model concepts.

Abstract

The Atlantic Ocean coast of Uruguay extends from Punta del Este outer limit of the Rio de la Plata Estuary, to the Brazilian border, over 220 kms. This case study applies to a homogeneous coastal stretch of 80 kms long, north of Punta del Este. The main coastal features are three littoral lagoons, Jose Ignacio, Garzón and Rocha, whose mouths open and close by natural or antropic actions every year. The coastline is formed by 1-2 mm coarse sand on highly reflective beaches. Beach berm is overwashed by the SE storm waves. Landward there is a dune system. This beach-dune structure is approximately 100 m wide. At least three similar morphological structures may be landward identified, which were developed during a period of time when the sea level was about 5 m higher than today's sea level (approximately 5000 years BP). 14C technique applied to chalk samples shows a relative decrease of the sea level in the last 5000 years. Furthermore, gravimetric data shows that there is an anomaly, which supports the existence of an isostatic rise of the continental shelf. As a result, the Atlantic Ocean Coast of Uruguay is prograding. The beach coarse material is provided by the wave action from the continental shelf, while the fine dune material seems to be obtained from the erosion of the land weathered granite.

1 Introduction

The Atlantic Ocean Coast of Uruguay is part of the eastern coast of South America. It extends over 220 km, from Punta del Este, outer limit of the Rio de la Plata estuary to the Brazilian border, at the NE. The case study refers to a part of about 80 km of this coast,
from Punta del Este to Cabo Santa María (La Paloma) (Figure 1). It is an homogeneous and almost straight coastline, oriented perpendicular to the SSE (N 65° E) and whose middle point is at the coordinates 34°45' S and 54°30' W (Figure 2).

The main coastal features are three littoral lagoons, José Ignacio, Garzón and Rocha whose mouths open and close intermittently, each year, by antropic or natural actions. These lagoons constitute a rich and sensitive ecosystem, that has to be preserved, as the remaining coastline, which is still almost unexploited by the tourist trade.

East of Punta del Este, the outlet of the Maldonado River, and 30 km eastern, about in the middle of the studied stretch, José Ignacio rocky point, are located.
To establish the bases for a management plan of this coast, today non-existent, but urgently needed, the long term evolution pattern has to be determined. It must be considered that Punta del Este is one of the main summer tourist resort in South America, and La Paloma placed in Cabo Santa Maria, can be considered the second one in Uruguay.

In this paper the main geological and morphological features of this coastline are considered, as well as the main hydrodynamic variables. The existent gravimetric data and mollusk samples analyzed with the $^{14}$C technique, as well as the recognition of lines of previous coasts, sustain the hypothesis of the prograding character of the studied stretch.

2 Geological and morphological data

This zone of the Uruguayan coast presents a crystalline rock substratum from 500 to 660 million years, which is exposed in some areas and in other is covered by deposits from the cenozoic and quaternary (UNDP, URU.73.007 1980).

The crystalline rocks that crop out in the immediate zone at the east of the José Ignacio Lagoon are intrusive granites, porphyries, with phenocrysts of up to 8 to 10 cm. The
quaternary deposits include clays, sands and mudstones, from the pleistocene, which provide large quantities of detritus sediments to the coastal environment through gullies and ravines.

In the vicinity of Garzon and Rocha lagoons, series of coastal dunes, formed by coarse and very coarse moderately sorted sand, belonging to the recent, can be found (UNDP, URU.73.007 1980). Beaches have steep slopes (about 12%) and coarse sand as large as 2 mm. For example in Las Garzas beach, located approximately in the middle of the stretch, indicative grain diameters are $D_{90}=1.62$ mm and a $D_{50}=0.96$ mm. These are immature sands, both texturally and mineralogically, with evidences of little transportation by rolling.

Behind these beaches there is an eolian dune system of fine sands. That beach-dune structure is approximately 100 m wide. Landwards, it can be easily recognized three similar geomorphologic structures, which were formed in the past (5000 years B.P), when the sea level was about 5.0 m above the present sea level.

Large sandy spits separate the three coastal lagoons from the ocean. These spits are formed by sand provided by the ocean. Their natural opening and closure are produced by the dynamic ocean action over the coast.

3 Hydrodynamics and wave energy flux

The mean sea level

This coast stretch has a semidiurnal astronomical tide regime with diurnal inequality. The difference among the mean high water level and the mean low water level is 0.45 m in La Paloma and 0.54 m in Punta del Este (east and west borders of the studied stretch, respectively). On the other hand the meteorological tide, associated with strong southeastern winds, provokes higher mean sea level. For example in Punta del Este the average of annual maximum levels recorded in this century is 1.41 m and the highest record is 2.15 m. In Cabo Santa Maria the average of annual maximum levels is 1.22 m.

Wave climate

Deep water wave climate was established on the basis of data from the UK Met. Office’s Main Global Marine Data Bank, for the area limited by coordinates 34.0° S, 36.0° S and 55.0° W, 53.0° W. These data were obtained by merchant ships during the period from 01/1949 to 06/1996 and constitute a total of 5558 records of significant wave height, period and direction, grouped at sectors of 30°. Furthermore, the significant wave height exceedence curve obtained by the U.S. Navy GEOSAT with records from November 1986 to March 1989, for a 4° by 4° area (Young I. R., 1996) was used.

These data were compared to the significant wave height satellite records for the region between 35°S to 36°S and 53° W to 56° W, provided by the Global Real Near Real -Time
Significant Wave Height Visualization Program, sponsored by the Colorado Center for Astrodynamics Research at the University of Colorado were recorded by ERS and TOPEX/POSEIDON satellites for a period of 15 months starting in July 1996.

On the other hand wave records obtained during some months between 1976 and 1978, by a non-directional Datawell type buoy which was installed close to Punta del Este were analyzed.

Wave propagation based on the obtained wave climate was computed with a refraction-diffraction model. This parabolic weakly non-linear wave propagation model, named OLUCA-RD, was developed at the Oceanographic and Coastal Engineering Group of University of Cantabria, Spain. Bed contours are given schematically in Figure 2.

Wave propagation with periods in the range 6 and 12 seconds and all the directions which arrive to the studied stretch was computed. In this way, wave direction and wave height at the coast (10 m water depth), that is coastline wave climate was established. Moreover, the net percentage of the annual energy flux arriving to the coast, corresponding to each direction, was determined. The results obtained are shown in Figure 3.

![Figure 3. Wave energy flux in deep water and at the coast](image-url)
Even though in deep water the net annual energy flux spreads in a wide direction range, the effects of the wave propagation over the existing bed contours determine that at the coast the net flux of energy is concentrated on the direction perpendicular to the coast. The vector sum of these results shows that the net annual energy flux over the 10 m depth bed contour is essentially perpendicular to the coastline (Figure 4).

![Figure 4. Resultant annual net energy flux](image)

On the basis of this result it becomes apparent that the net longshore sediment transport is minimum in this stretch of coast. That is verified by the comparative analysis of sand characteristics of the neighboring beaches.

4 Relative sea level changes

It is well known that the relative sea level is the result of the balance between the isostasy, determined by the tectonic activity, and the eustasy or modifications of the sea level due to the changing volume of ocean water or the capacity of ocean basins.

At a global scale it is accepted that the eustatic level in the last 5000 years has been growing. Between 5000 and 3000 years B.P there was a growth of 20 to 30 cm each 1000 years, and during the last 3000 years the sea level has been oscillating or growing with a lower rate. Summing up it can be said that the eustatic level during the last 5000 years has been growing with a rate of 0.01 cm per year.

In the zone under study there exists evidence of the fact that during the last holocenic transgression the sea level had reached a level of +5.0 m relative to today's sea level. As it will be shown in the next paragraph, from those days up to the present, a relative decrease of the sea level up to the current sea level was produced. This statement implies that during the last 5000 years the isostatic change rate was greater than the eustatic change rate.
5 Verification of descendant sea level: prograding coast

Martin and Suguio (Martin, M. and Suguio K., 1989) determined a curve of sea level fluctuation in the holocene period, for three different zones of Brazil. This curve establishes an increase of the relative sea level up to a maximum transgression 5000 years BP, a regression 4000 years BP and successive variations up to present level, with a negative rate of 1 mm per year. Moreover, Bracco and Ures (Bracco et al 1997), (Bracco and Ures, 1998) through $^{14}$C technique applied to mollusk samples confirmed the results from Martin and Suguio (Figure 5).

Furthermore gravimetric data show the presence of a strong anomaly in the zone. The interpretation of this data supports the hypothesis of an isostatic rise for this stretch of the SE coast of Uruguay.

The Figure 6 reproduces an aerial photograph of Garzon lagoon, in which many different paleocoasts can be observed.

Thus, it may be established the hypothesis of a relative sea level decrease, with a medium rate of 1 mm per year, for this stretch of Uruguayan coast. This fact allows to forecast a progression of the coastline in parallel lines to the actual one and perpendicular to the annual net energy flux.
6 Conclusions

In this paper the long term evolution of the Uruguayan coastline between Punta del Este and Cabo Santa María (La Paloma) is analyzed. Based on the existing information the following conclusions may be drawn:

- Gravimetric anomalies show that SE Uruguayan earth’s crust is rising.
- Eustatic world sea level is rising.
- Relative sea level change in this stretch of coast is decreasing.
- The Uruguayan Atlantic stretch of coast between Punta del Este and Cabo Santa María is prograding.
- The progression of the coast is in parallel lines perpendicular to the annual net energy flux.

TURBIDIMETRIC MEASURING OF THE SUSPENDED SEDIMENT CONCENTRATION IN THE COASTAL ZONE

Prof. Dr. Ruben D. Kos'yan1, Dr. Igor S. Podymov2, Dr. Sergey Yu. Kuznetsov3

Abstract

The construction peculiarities of the new model of turbidimeter for measurement of instantaneous values of suspended sediment concentration are described in this paper. The presence of optic negative feed back is the basic feature of this turbidimeter, which allows to eliminate practically completely the temperature instability of light source and of its electronic units. A new model of turbidimeter has given a possibility to create a three-dimensional lattice for the investigations of suspended particle spatial shift. One turbidimeter of the lattice cell is recording continuously the background transparency of examined liquid in a real scale. It gives possibility of continuous controlling not only of the light radiation flux attenuation by suspended particles but and of a ratio between the light flux absorption in researched water column with suspended particles and the light flux absorption in "clean" water. During the field experiments with the help of turbidimeters new data about physical mechanisms of sediment suspension above a smooth and rippled bottom were received.

Introduction

Till now there is no strict mathematical description of regularities of two-phase flux motion. Determination of empirical dependencies describing a process of sediment transport is not possible without instrumental measurements of the suspended sediment concentration. That's why a selection of a reliable method of measuring of instantaneous values of suspended sediment concentration is one of the most urgent tasks.

3Senior Researcher, P. P. Shirshov Institute of Oceanology, Russian Academy of Sciences, 36 the Nahimov prospectus, Moscow, 117851 RUSSIA.
Optical methods which are the most quick-acting ones afford to research high-frequency non-stationary processes within the bottom layer where the concentration of sufficiently large particles of inorganic origin are rather high (> 10 g/dm³).

There are two basic methods of determination of suspended material concentration in water which are based on the optical principle: measurements of attenuation of the light flux radiation (turbidimetry) and measurements of light energy scattered by particles under angles different from zero ones with respect to the direction of incident light (nephelometry). Nephelometers are seldom applicable for the measurements in the coastal zone since calibration characteristics of nephelometers depend greatly on the size of particles suspended in water. For this reason nephelometers are used, as a rule, for measurements of low concentration of homogeneous particles at comparatively large depth.

**Brief theory of turbidimetry**

Bugger's law is in the basis of turbidimetry. In compliance with it the initial flux of $\Phi_0$ radiation passes the distance $l$ in a certain medium and is attenuated by this medium to $\Phi$ level according to formula:

$$\Phi = \Phi_0 \exp(-\varepsilon l), \quad (1)$$

where $\varepsilon$ is the index of light flux attenuation by given medium.

And the fundamental equation of turbidimetry can be written (Onishchenko, Kos’yan, 1989) as:

$$S = bA \frac{1}{l} \ln \frac{I_0}{I}, \quad (2)$$

where $b = \frac{2}{3} \rho_s$;

$S$ - weight concentration;

$A$ is a parameter defining the suspended sediment composition;

$I_0$ and $I$ are output signals for «clean» water and water with suspended sediment consecutively.

And linear dependence between suspended sediment concentration and measured value of $\ln\left(\frac{I_0}{I}\right)$ remains only when the following parameters keep to be invariable in the course of measuring and meet the calibration conditions: suspended sediment composition (parameter $A$); density of grains $\rho_s$; base of instrument $l$; parameter $I_0$, that characterizes optical properties of clean water. When designing
turbidimeter, only measuring base \( l \) is strictly controlled parameter from four mentioned ones. Suspended sediment composition and density of grains \( \rho_s \) causes a methodical error of turbidimetric method, the value of which can be estimated on experimental data and results of calibration. In general case the parameter \( l_0 \) can also lead to additional methodical error. But if an additional channel which gives an information about optical properties of water will be provided in the construction of measuring system, methodical error caused by the change of \( l_0 \) parameter can be considerably diminished.

To control \( l_0 \) parameter it is necessary to define precisely the term «optical properties of water». In our case under optical properties of water we mean the transparency not a clean water but water with such a part of suspended sediments which do not settle and are transported together with water flow. It is known that particles with diameter less than 100 mkm form the transported part of suspended matter. That’s to say, to record \( l_0 \) it is necessary to create such an additional zone of measurements where only suspended particles with diameter < 100 mkm are present.

Two turbidimeters were worked out and constructed for experimental turbidimetric research (Kos’yan et al., 1995). When designing these turbidimeters a task to restrict in size of construction was not raised. That’s why turbidimeters turned out to be bulky and heavy.

Results of field research important for turbidimetry

The turbidimeters were used in several field experiments. In the course of the Russian field experiment «Novomikhailovka-93» a strongly pronounced interrelation between fluctuations of suspended sand concentration and kinetic turbulent energy were revealed in the bottom layer of the surf zone (Pykhov et al., 1995). According to obtained measuring data temporal and spatial scales of turbulent vortexes which have been formed when waves are breaking were also calculated and estimated.

The Russian-German experiment «Norderney-94» confirmed the existence of turbulent mechanism of sand suspension and afforded to determine the scales of variability of turbulent kinetic energy and concentration of suspended sand (Kos’yan et al., 1997).

The analysis of recordings has shown the presence of a sharp increase of suspended sand concentration which coincide in time with corresponding turbulent fluctuations of cross-shore and along-shore velocities.

A typical example of solid particle suspension is given in Figure 1. Wave breaking with the crest spilling occurred at the depth of \( h = 2.36 \) m. Increase of turbulent fluctuations of velocity and splash of concentration may be provoked by horizontal advection of turbulent vortexes with captured sand to the region of the gauge installation.
Figure 2 shows a chronogram of turbulent pulsations of velocity and their hodograph for the case which is demonstrated in Figure 1. An end of vector of turbulent component of velocity shown on the hodograph describes two complete cycles during one second. This indicates the passing of the chain of four vortexes through the gauges, as it is shown in the right lower part of Figure 2. Then neighbor vortexes rotate in opposite direction.

The assess of spatial scales of turbulence afforded to reveal vortex structures from 1 to 10 m. Passing of vortex structure through the measuring point corresponded to the cases of intensive sand suspension. Linear dimensions of some vortexes varied from 0.3 m to 1.5 m, and they were different within one vortex structure. Maximum but not mean values of the vortex dimension were used for the determination of interrelations between vortex dimensions and a distance from the bottom to the surface, because it was not possible to define whether the turbulent vortex had passed through the gauge area by its central or marginal part. The dependence between dimensions of the largest vortex in series and the distance between the bottom and the surface is presented in Figure 3. It demonstrates how vortex diameter grows with the increase of the distance between the bottom and the surface. Such a dependence confirms a classic idea about the proportionality between vortex dimensions and flux parameters.

One can determine precisely the dimensions of turbulent sandy vortexes by using for measurements of three-dimensional grating, in which the distance between gauges may be roughly selected from the diagram shown in Figure 3. Thus, for
Figure 2. Time scales of turbulent vortexes.

example, when measuring in the coastal zone where the distance between the bottom and the surface was 2 m, the largest diameter of vortex was 1.1 m (see Figure 3). Therefore, in order to record extreme values of vortexes of turbulence and concentration, the length of each side of measuring grating must be not less than a half of the largest vortex diameter for coherent conditions of research. In given case it must be not less than 0.55 m. Then the distance between gauges on every side must be 0.275 m, if there are three gauges on this side. Roughly calculated dimensions of grating demand rather rigid requirements for the size of measuring instruments installed on it. It should be added also that the vortex size within one vortex structure may be different.

After complex estimation of the results of field data processing it became clear that turbidimeters of old construction are useless for investigations of spatial-temporal characteristics of vortex structures. Overall dimensions of turbidimeter of old construction allow to place not more
than two gauges in calculated volume of measuring grating. This was the reason for working out a new construction of turbidimeters of less size.

**Structural block-diagram of the turbidimeter**

To be more demonstrative, the structural block-diagram of the turbidimeter is divided into two basic parts (Figure 4): underwater block and above water unit. Underwater block includes: a source of reference voltage, comparator (differential amplifier of error signal), coordinating amplifier, modulator, generator, hardly stabilized current amplifier with a loop of negative feed-back, two light sources with the length of radiated light wave being \( \lambda = 0.67 \) mkm, optical negative feed-back channel and measuring channel: Each of channels includes photoreceiver, photocurrent amplifier and demodulator with filter. Measuring channel differs from optical negative feed-back channel only by presence of the current amplifier with a loop of negative feed-back that is necessary for matching with communication line.

The formation of a beam of light occurs in the following way. Reference voltage formed by the source comes to modulator through the comparator. The modulator makes the modulation of this voltage with the frequency of internal generator. Ripple (pulsating) voltage controls two identical light sources, the role of which is played by luminous radiating diodes with built-in mirror and narrow radiation pattern. Introduced modulation of the light flux eliminates completely the influence of flare spot when working at the shallow depth and thereby considerably decreases an instrument error.

The beam of light from the source 1 passing through investigated water column is attenuated in accordance with the law of light absorption and is perceived by photoreceiver 1. A signal from photoreceiver is amplified by precise photocurrent amplifier, is demodulated, is filtered and in analog form (as a current) comes to the above water unit by communication line. Silicon photodiode serves as photoreceiver. Its dimensions are small, its sensitivity is high. It has temperature stability and a small non-linearity. An angle of registration of a light beam in the receiver is reduced with the help of diaphragm (membrane). Time constant of the measuring channel does not exceed 0.01 s.

The channel of optical negative feed-back is destined for a hard stabilization of measuring parameters of the turbidimeter under the influence of different disturbing factors. Its structure is similar to that one of the measuring channel. Photoreceiver of this channel takes the light from its light source not through the investigated volume of water but by a special light channel. Output signal of the channel of optical negative feed-back is transmitted to the second input of comparator (differential amplifier of error signal) which controls emissive power. As a result, the emissive power is set in such a way, that output current of photoreceiver of the feed-back channel is stabilized.
Figure 4. Structural block-diagram of turbidimeter.
The impact of any disturbing factor (temperature, aging, etc.) provokes the change of output signal of feed-back channel. In its turn the change of this signal leads to the change of error signal, the phase of which is displaced for 180°. As a result, the units of automatic control of initial current of photoreceiver change the power of luminous radiation. An initial value of photoreceiver current of the channel of optical negative feed-back is restabilized in new conditions. Since the channels (measuring and feed-back) are identical, the regularities of current stabilization of photoreceivers also concur in them. Here, a possible dispersion of parameters of light sources and photoreceivers is the factor of instability. And this demands rather strict requirements for the selection of identical pairs. The difference of this construction of turbidimeter from the previous one is the presence of a special (additional) source of light for the feed-back channel. Stability of characteristics of such a structure is somewhat less (Kos'yan et al., 1998). But the technological effectiveness and reliability of the construction is higher, and the cost of turbidimeter is sizably less.

The turbidimeter is connected with the above water unit by the four-core cable. Supply voltage ±15V and midpoint (centroid) is transmitted by three cable lines. Information signal (as a current) functionally connected with suspended matter concentration is transmitted by a separate line. Electronic unit forming the current is made as a self-tuning loop with negative feed-back, the parameters of which (to a certain degree) do not depend on the cable resistance.

In above water unit information signal is transformed into voltage. Then a direct component is removed from the information signal with the help of comparator and reference voltage source. Information signal on the output of comparator of above water unit exists as a voltage functionally connected with the suspended matter concentration. Comparator is built in such a way that in it besides the compensation of a direct component of a signal there is a possibility to change the conversion conductance of the information signal. This simplifies the matching of calibration functions of different specimens of turbidimeters to a single type. (Providing that the linear interrelation is kept between suspended matter concentration and the
attenuation index, as it was mentioned before). And, finally, an information signal passes through the amplifier, which has voltage transmission factor equal to 1, and power amplification factor being 80 dB. Such a power isolation allows to use recorders with different input impedance without distortion of transmitting function of turbidimeter. And the range of input impedance may vary within very broad limits: from 10 to $10^7$ Ohms.

Appearance of the underwater block of turbidimeter is shown in Figure 5.

Laboratory study

Laboratory research was carried out with the view to calibrate the turbidimeter and to assess the influence of different disturbing factors upon the precision of instrument reading.

Sand collected in the course of «Ebro-delta-96» experiment was used for this research. Its granulometric composition is given in Figure 6.

![Figure 6. Curve of granulometric composition of sand used for laboratory study.](image)

Testing of turbidimeter was fulfilled in the tank of 50 liters. The diagram of the installation for these investigations is presented in Figure 7. Two turbidimeters (2 and 3), propeller (4) connected through a drive (5) with electric engine (6), tube for sampling water with suspended sediments were placed into the tank simultaneously.

The electric engine was connected with the power source by the rpm governor (7). A signal from the turbidimeters was loaded into computer through multy-channel
analog-to-digital converter. Sand was poured to the tank bottom. Fluctuations of suspended particle concentration were created by the change of the rotation velocity of the propeller and the change of sand amount. The distance between the water surface and turbidimeter sensors was 21 cm. The thickness of the water column was 37 cm.

Figure 7. Diagram of installation for laboratory study:

1 - tank, 2 - turbidimeter 1, 3 - turbidimeter 2, 4 - propeller, 5 - drive, 6 - engine, 7 - revolutions-per-minute (rpm) governor.

A signal from the turbidimeter was recorded continuously. Sampling of suspended sand was done with the help of siphon roughly during one minute. Values of concentration in codes were averaged during the period of sampling. Before the start of measuring turbidimeter readings were recorded for clean water.

Figure 8 shows a calibration characteristics of turbidimeter for sand with above mentioned granulometric composition.

Figure 9 demonstrates a diagram of fluctuations of suspended particle concentration near the sensors of turbidimeter in the course of calibration. Digits on the diagram show values of concentration obtained by sampling with the help of
siphon. The position of the digits on the diagram corresponds to the time moments when sampling was performed.

Figure 8. Calibration characteristics of turbidimeter.

Figure 9. Diagram of fluctuations of suspended particle concentration near the sensors of turbidimeter in the course of calibration.
Figure 10 shows the change of suspended particle concentration in different places of the laboratory tank. Measurements were performed synchronously by two turbidimeters. These diagrams give an idea of the uniformity of suspended matter distribution in the whole tank space, and allow to judge about the replication of the transmission characteristics of different copies of measuring instrument. In concrete case one equation for two turbidimeters was used for the calculation of concentration. With the help of operating means the coefficients of the turbidimeter transmission functions are made equal ones.

It is evident that particles with grain size being <0.1 mm settle in the flux much longer than larger particles. This affords us to consider suspension with particles <0.1 mm as non-settling one, and in such a way to determine optical properties of «clean water», i.e. background. Measuring zone of one turbidimeter must be protected with filter with cell being 0.1 mm. A device that continuously
records values of the background must be additional one to the total number of gauges.

Appearance of the turbidimeter measuring head with filter is given in Figure 11.

Figure 11. Turbidimeter measuring head with filter.

Conclusions

During the field experiments with the help of turbidimeters new data about physical mechanisms of sediment suspension above a smooth and rippled bottom were received. On its base the contribution of different wave frequency into the formation of sedimentary flux was assessed. The origin of some components of the sedimentary flux was revealed.

Laboratory testing has demonstrated that turbidimeters of proposed structure ensure precise measurements of suspended sediment concentration in a broad range of temperature fluctuations of the environment.

The construction of turbidimeter gives the possibility to build three-dimensional grating for the research of suspended particle spatial shift.

These features makes the turbidimeter an effective instrument when studying sediment transport in the coastal zone.

Characteristics of Suspended Sediment Transport in the Surf Zone of Irregular Waves and their Reproduction by a Cross-Shore Beach Deformation Model

M. Ik en o1 and T. Shimizu1

Abstract

Suspended sediment flux and cross-shore beach deformation in the breaker zone are elucidated experimentally with the CRIEPI's irregular wave flumes of large and middle sizes. Effects of long waves on suspended sediment transport are also investigated with a new experimental system for correct reproduction of infragravity waves bounded by irregular wave groups. Based on the experimental results, the pick up rate from sea bed and convection and diffusion of suspended sediment are modelled, and a new numerical model is developed for cross-shore beach deformation due to irregular waves. This numerical model can well reproduce wave deformation, suspended concentration, undertow, sediment flux and beach topography change.

1. INTRODUCTION

In the surf zone, sea bed sands are picked up violently and suspended sediment transports are more significant. A numerical model for beach deformation due to random waves should be developed by taking irregular time variation of suspended sediment flux into account.

In this paper, first, suspended sediment flux and cross-shore beach deformation in the breaker zone are elucidated experimentally with the CRIEPI's irregular wave flumes of large and middle sizes. Scale effects on beach deformation are also investigated, and a new similarity law of the grain size of beach sediment is applied to irregular waves. Effects of long wave components on suspended sediment transport are also investigated with a new experimental system for correct reproduction of infragravity waves bounded by irregular wave groups.

Secondly, based on the experimental results, the pick up rate from the sea bed and vertical convection and diffusion of suspended sediment are modelled, and a new numerical model is developed for cross-shore beach deformation due to irregular waves. Nonlinear wave deformation, suspended concentration, undertow, sediment flux, and beach topography change in experiments are reproduced by this numerical model.

2. EXPERIMENT

2.1 Experimental condition

Beach deformation tests were performed with two different scales of wave flumes

1 Hydraulics Dept., Central Res. Inst. of Electric Power Industry, 1646 Abiko, Abiko-shi, Chiba, Japan

2317
and compared. One is a large wave flume (205m long, 3.4m wide and 6m deep). The median grain size of sand used is 1mm. Initial beach slopes are changed from 1/10 to 1/50. Incident waves are irregular with JONSWAP spectrum. Significant wave heights and periods are 0.5~1.2m and 3~8s. Sharpness parameter $\gamma$ are 1 or 7 (experimental cases L1~L7; Shimizu and Ikeno, 1996). The other is a middle wave flume (50m long, 0.9m wide and 1.2m deep). The scale of beach deformation tests corresponds to one-fifth the scale of those with the above large wave flume by the Froude similitude. Initial beach slope, significant wave height, period and parameter $\gamma$ are similar values to those with the above large wave flume. Significant wave heights and periods are 0.1~0.24m and 1.35~3.58s (experimental cases M1~M8).

However, using the sand size according to the Froude similitude, the scale effects on beach deformation will occur between the middle and large sizes of tests, as you know. In this paper, the sand size is determined by a new similarity law of the grain size of beach sediment (see Fig.1 ; Shimizu, 1995), based on many different scales of beach deformation tests in regular waves. According to Fig.1, the median grain size of sand is determined to 0.6 mm, which corresponds to one half the scale of sand in the above large wave flume. Comparing both experimental results, the validity of this similarity law is verified subject to irregular waves.

Fig.2 shows the grain size distribution of sands used in the large and middle scale tests. In these experiments, vertical distribution of suspended sediment transport flux in the surf zone are measured simultaneously by optical turbidimeters, electromagnetic current meters and capacitance type wave gauges.

2.2 Verification of a new similarity law of sand grain size

Fig.3 shows the comparison between beach deformation results by large and middle wave flumes. Beach deformation of these cases is erosion type by plunging breaking waves. One is the case L6: $H_s=1.2m$, $T_s=3s$, $\tan \beta=1/10$, and the other is the case M7: $H_s=0.24m$, $T_s=1.35s$, $\tan \beta=1/10$. The formation points of bar and the erosional regions in the large scale test show good agreement with those of the middle
case L6: $H_o=1.2\,m, T_o=3\,s, \gamma =7, \tan \beta =1/10, \text{BLOWRES}$

![Graph showing beach deformation results for case L6.](image)

case M7: $H_o=0.24\,m, T_o=1.35\,s, \gamma =7, \tan \beta =1/10, \text{BLOWRES}$

![Graph showing beach deformation results for case M7.](image)

Fig. 3 Comparison between beach deformation results by large and middle wave flumes

![Graph showing time variation of suspended concentration and horizontal velocity in the surf zone of irregular waves.](image)

Fig. 4 Time variation of suspended concentration and horizontal velocity in the surf zone of irregular waves (case L6 of large scale test)

![Graph showing power spectra of suspended sediment flux.](image)

Fig. 5 Power spectra of the suspended sediment flux $c(t)u(t)$ at the vertical height 20cm above the sea bottom in the case L6 of large scale tests
test. And the velocity of beach changes in the large test also shows good agreement with that according to the Froude similitude in the middle test. And thus, the application of this new similarity law of the grain size (Shimizu, 1995) to random waves is verified.

2.3 Effects of long waves on suspended sediment

Fig. 4 shows time variation of suspended concentration and horizontal velocity near the sea bottom and water surface elevation in the surf zone of irregular waves. According to Fig. 4, the sea bed sand can be seen to be significantly picked up when the horizontal velocity changes not only from onshore to offshore, but also from offshore to onshore.

Effects of long waves on suspended sediment flux are also investigated with a new experimental system, which can correctly reproduce bounded long waves in irregular wave groups by eliminating free long waves generated by a wave maker (BLOWRES; Ikeno and Tanaka, 1996).

Fig. 5 shows the power spectra of the suspended sediment flux $c(t)u(t)$ at the vertical height 20 cm above the sea bottom in the case L6 of large scale tests. In this figure, a fine solid line corresponds to the formation point of bar in the surf zone, and a bold solid line corresponds to the offshore side than it. From Fig. 5, the suspended sediment flux can be seen to be separated into the higher and the lower frequency components as the boundary of 0.07 Hz. Especially, the long wave component of the suspended flux above the bar in the surf zone are much greater than the short components of it. According to these experimental results, three kinds of components such as the steady: $cu$, the shorter waves: $cu_s$, the longer waves: $cu_l$ as the boundaries of 0.16 Hz: middle tests and 0.07 Hz: large tests, are included in the suspended sediment flux due to random waves. So, each component of the suspended flux is evaluated as the time-averaged (net) values of $c(t)u(t)$ obtained by the inverse FFT after cutting the flux except the remarkable frequency region.

Fig. 6 shows the vertical distribution of three kinds of the flux components in the middle scale tests. This corresponds to the middle scale tests (tan $\beta = 1/20$, spilling wave breaking and wider surf zone)
e case of the sea bed slope 1/20, the spilling wave breaking and the wider surf zone. In this figure, the upper figures are the results with the new experimental system for correct reproduction of infragravity waves; BLOWRES. And the lower figures are those without using it; ordinary.

Comparing between the upper and the lower figures, specially, the difference can be seen between the direction and the quantities of long wave components of the suspended sediment flux in the tests with and without eliminating free long waves. This difference becomes more significant in the case of the wider surf zone.

The long period and steady components of suspended sediment flux in the surf zone are generally offshore direction while the short period components of suspended sediment flux are onshore direction. Its steady components increase more than the short and long period components with shoaling and breaking.

3. NUMERICAL MODEL

A numerical model is developed for cross-shore beach deformation due to nonlinear irregular waves. This numerical model consists of the following sub-models.

3.1 Irregular wave deformation

The improved Boussinesq equation (Madsen et al., 1991) with a breaker-induced energy dissipation term (Sato and Kabiling, 1994) is adopted as follows:

\[
\frac{\partial \eta}{\partial t} + \frac{\partial Q}{\partial x} = 0
\]

\[
\frac{\partial Q}{\partial t} + \frac{\partial}{\partial x} \left( \frac{Q^2}{D} \right) + gD \frac{\partial \eta}{\partial x}
= \left( B + \frac{1}{3} \right) h^2 \frac{\partial}{\partial t} \left( \frac{\partial^2 Q}{\partial x^2} \right) + Bgh \frac{\partial^3 \eta}{\partial x^3} + \nu_e \frac{\partial^2 Q}{\partial x^2}
\]

where \( \eta \) is the water surface elevation, \( Q \) is the depth-integrated flow rate in the horizontal direction, \( h \) is the still water depth, \( D \) is the total water depth (=\( h + \eta \)), \( g \) is the acceleration due to gravity, \( B \) is a parameter for improving linear dispersion and equal to be 1/21 (Madsen et al., 1991), \( \nu_e \) is the eddy viscosity for momentum mixing exchange due to turbulence by wave breaking (Sato and Kabiling, 1994).

3.2 Vertical distribution of velocity in the surf zone of irregular waves

Relationship between the horizontal velocity \( u \) at the arbitrary vertical position \( z \) and vertically averaged velocity \( \bar{u} \) is derived by Nwogu (1993) as follows:

\[
u(z,t) = \bar{u}(t) + \left\{ \frac{h^2}{6} - \frac{(h+z)^2}{2} \right\} \frac{\partial^2 \bar{u}(t)}{\partial x^2}
\]

where \( \bar{u}(t) = \frac{\partial h}{\partial x} \), \( z \) is the vertical position positive above the still water level.

In the above Eq. (2a) based on the Boussinesq type equation, undertow caused by wave breaking can't be taken into account. So, the vertical distribution of undertow must be added to the above Eq. (2a) by using another method. In this paper, the vertical distribution of undertow is added as time-averaged velocity based on the eddy viscosity model. The regular wave undertow formula (Rattanapitikon and
Shibayama, 1996) proposed by Okayasu et al. (1990) is modified to apply to irregular wave undertow obtained by the large and middle scale of cross-shore beach deformation tests.

As results, the vertical distribution \( \dot{u}(z) \) of undertow of irregular waves is proposed by taking into account the energy dissipation \( D_u \) due to wave breaking on the basis of the bore model (Thornton and Guza, 1983) as follows:

\[
D_u = \rho g H_s^3 / 4T_s h \\
\dot{u}(z) = \rho^{1/3} D_u^{1/3} \left[ (z+h)/h - 0.5 - 0.22 \ln \left( (z+h)/h \right) \right] - 0.1 \sqrt{gh} H_s \\
\text{where } H_s \text{ is the significant wave height, } \rho \text{ is fluid density, } T_s \text{ is the significant wave period.}
\]

3.3 Suspended sediment concentration

The time variation of sediment concentration due to combined convection-diffusion is calculated by using the following equation:

\[
\frac{\partial c}{\partial t} = w_c \frac{\partial c}{\partial z} + \varepsilon_s \frac{\partial^2 c}{\partial z^2} + \frac{1}{w_c} \exp \left( -\frac{z+h}{L_s} \right) \beta \left( t-\frac{z+h}{w_c} \right) + \frac{1}{L_s} \rho \left( t-\frac{z+h}{w_c} \right) \exp \left( -\frac{z+h}{L_s} \right) \\
\text{where, } c \text{ is the sediment concentration, } p \text{ is the pick up rate from sea bed, } w_c \text{ is the settling velocity (sand grain size 1mm; 0.095m/s).}
\]

\[
L_s = \begin{cases} 
0.15 \pi a f / w_c & \text{for } 2 \pi a f / w_c \leq 18 \\
1.4 \zeta & \text{for } 2 \pi a f / w_c \geq 18 
\end{cases}
\]

where \( \zeta \) is the sand ripple height (0.15m from large experiments), \( f \) is the significant wave frequency, \( a \) is the significant wave amplitude.

\( \varepsilon_s \) is the sediment diffusivity (Nielsen, 1988) as follows:

\[
\varepsilon_s = w_c \left[ 1.24 \exp \left( -40 \left( \frac{\gamma}{\lambda} \right)^2 \right) + 0.2 \right] \\
\text{where } \hat{u} \text{ is the amplitude in a half period by zero-crossing the horizontal velocity near the sea bottom.}
\]

\( w_c \) is the vertical convection velocity of sediment by Sleath (1987) as follows:

\[
w_c = 2 \pi f \delta_{bs} / 2.27 \\
\text{where } \delta_{bs} \text{ is the thickness of boundary layer as follows:}
\]

\[
\delta_{bs} = 0.26 r (a/r)^{0.7} \\
\text{where } r \text{ is the roughness (=d), } d \text{ is the sand grain size.}
\]

\( w_c \), \( \varepsilon_s \) and \( L_s \) are time-varying, corresponding to the zero-crossing amplitude of velocity \( u \) near the sea bottom.

Boundary condition at the sea bottom is as follows:
Fig. 7 Relationship between the time-averaged suspended concentration in a half period by zero-crossing the horizontal velocity near the sea bottom and the Shields number corresponding to a half period just before it.

Fig. 7 shows the relationship between the time-averaged suspended concentration in a half period by zero-crossing the horizontal velocity near the sea bottom and the Shields number corresponding to a half period just before it. These data are measured near the sea bottom forming the bar in the surf zone, where the concentration is the highest in the large and middle scale tests. According to Fig. 7, high correlation can be seen between the suspended concentration and the Shields number just before it. Especially, higher concentration in the large scale tests, which means the pick up rate is much, can be also seen to be proportional to the 1.5th power of the Shields number just before it.

Based on the above experimental results, the pick up rate \( p(t) \) is newly modelled as follows:

\[
p(t) = \alpha_s w_s \rho_s (\psi_{L1} - \psi_2)^{1.5} \delta(t - t_f)
\]  

\[ (3g) \]

where \( \rho_s \) is sediment density (=2.65), \( \delta(t - t_f) \) is the delta function, and \( t_f \) is the zero-crossing time of velocity \( u \) near the sea bottom.

\( \alpha_s \) is a parameter proposed based on experimental results as follows:

\[
\alpha_s = \begin{cases} 
\left( \frac{ho}{Lo} \right) \left( - \lambda + 2.3 \right) & \text{for } \lambda \geq 1.3 \\
\left( \frac{ho}{Lo} \right) \left( 0.62\lambda + 0.2 \right) & \text{for } \lambda < 1.3
\end{cases}
\]

\[ (3h) \]
\[ \alpha_i = \max \left\{ \alpha_i', 0.01 \right\} \tag{3i} \]

where \( \lambda = h / \left( H_0 \cos \beta \right) \), \( H_0 \) and \( L_0 \) are the offshore significant wave height and the wave length, \( \tan \beta \) is the sea bed slope, \( \psi_c \) is the critical Shields number, \( \psi_{c,i} \) means the Shields number of the 'i-1' th zero-crossing wave in a half period. Eq.(3h) and (3i) are based on the experimental results in the cases of \( H_0 / L_0 \geq 0.02 \).

Fig. 8 shows the comparison between the time-averaged suspended concentration computed and measured at the height of 20cm above the sea bottom in the large scale cases of L1 ~ L7. The computed values show good agreements with the experimental values.

3.4 Sediment transport rate and sediment conservation equation

The suspended sediment transport rate is estimated by integrating the sediment flux \( cu \) in the vertical section as follows:

\[ q_s(t) = \int_{-h}^{0} c(z,t) u(z,t) \, dz \tag{4a} \]

The bed load transport rate is estimated by the following formula proposed by Sato and Kabiling (1994).

\[ q_b(t) = \sqrt{\left( \psi_{c,b} - 1 \right) g d^3 \alpha_b \psi_c(t)} \left( 1 + \max \left\{ \psi(t) - \psi_{c,0}, 0 \right\} \right)^{0.5} \mu_b(t) \left| u_b(t) \right| \tag{4b} \]

where \( \alpha_b \) is a parameter (=1), \( \psi_c \) is the critical Shields number.

Therefore, the total sediment transport rate is as follows:

\[ q(t) = q_s(t) + q_b(t) \tag{4c} \]

Finally, the sea bed topography is updated by using the following sediment conservation equation.

\[ \frac{\partial z_b}{\partial t} = - \frac{\partial h}{\partial t} = - \frac{\partial}{\partial x} \left( \hat{q} - e_a \left| \hat{q} \right| \frac{\partial z_b}{\partial x} \right) \tag{4d} \]

where \( z_b \) is the vertical height of sea bed, \( \hat{q} \) is the time-averaged (net) total sediment transport rate, \( e_a \) is a coefficient that reflects the effect of local bottom slope on the sediment transport (=2.0).

During the offshore rush in the swash zone, the total water depth is less than that during the onshore rush so larger velocities will result during the offshore rush. In order to avoid unrealistic erosion, the net total sediment transport rate in the swash zone is linearly interpolated between the zero sediment transport corresponding to the maximum beach run-up height, and the sediment transport at the most onshore side position computing the suspended sediment and bed load rates actually, where the still water depth is equal to \( \Delta z \) divided vertically in combined convection-diffusion computation of suspended concentration (Larson, 1994).
Fig. 9 Computation flow of this new cross-shore beach deformation model
Fig. 9 explains the computation flow of this new cross-shore beach deformation model. In this numerical model, first, the irregularly varying physical quantities such as the wave deformation, the suspended concentration, the cross-shore bed load and suspended sediment transport rates, are computed in the interval of the random wave computation time $t_w$, corresponding to one hundred waves' time. If required, the vertical distribution of undertow by wave breaking is added as the time-averaged values to the time variation of the horizontal velocity at the arbitrary position $z$ obtained by the improved Boussinesq equation. Next, the net total sediment rate averaged by $t_w$ is computed, and input on the sediment conservation equation. This sediment conservation equation continues to be computed until the sea bed update time $t_b$. After passing $t_b$, the sea bed topography is updated. After that, using a new sea bed topography, the above physical quantities are computed in the same interval of $t_w$ and repeated.

4. REPRODUCTION BY THIS NUMERICAL MODEL

4.1 Reproduction of the vertical distribution of suspended concentration, flux and velocity in the surf zone of irregular waves

Figs. 10 and 11 show the comparison between the vertical distribution of time-averaged velocity in the surf zone by computation and experiments. In the computation, the vertical distribution of irregular wave undertow is added to that of velocity by the improved Boussinesq equation. Fig. 10 corresponds to the large size tests, and Fig. 11 corresponds to the middle size tests. According to these figures, computation results with the undertow formula can well reproduce the vertical distribution of time-averaged velocity in the surf zone of irregular waves.

Figs. 12 and 13 show the comparison between the time variation and the vertical distribution of suspended concentration in the surf zone of irregular waves by computation and experiments. In Figs. 12 and 13, computation results include those by pure diffusion without convection and by combined convection-diffusion. According to these figures, suspended concentration by the pure diffusion computation can't reach into the upper area near the water surface and underestimates the experimental suspended concentration. However, the computation results by combined convection-diffusion can well reproduce the irregular time variation and the vertical distribution of experimental results, where suspended sediment with higher concentration reaches near the water surface. Fig. 14 shows the comparison between the vertical distribution of time-averaged suspended sediment flux by computation with combined convection-diffusion and experiments. According to Fig. 14, the computation results can well reproduce the vertical distribution of time-averaged suspended sediment flux.
4.2 Reproduction of wave deformation, beach change and sediment transport rate

Figs. 15 and 16 show the comparison between sea bed changes, wave height deformation and sediment transport rates by computation and large size experiments. Computation results include the cases $H_w=0.24m, T_o=1.35s, \gamma=7, \tan \beta=1/10$.

Fig. 10 Comparison between the vertical distribution of time-averaged velocity in the surf zone by computation and large scale tests

Fig. 11 Comparison between the vertical distribution of time-averaged velocity in the surf zone by computation and middle scale tests

Fig. 12 Comparison between the time variation of suspended concentration in the surf zone of irregular waves by computation and experiments

Fig. 13 Comparison between the vertical distribution of time-averaged suspended concentration by computation and experiments

Fig. 14 Comparison between the vertical distribution of time-averaged suspended sediment flux by computation with combined convection-diffusion and experiments.

Fig. 15 Comparison between irregular wave deformation and sea bed changes by computation and large size experiments.

taking into account the suspended sediment alone, the bed load alone and the total sediment transport. According to these figures, the computation results can well reproduce the experimental sea bed changes, wave height deformation and total sediment transport rate. The suspended sediment transport rate is much greater than the bed load transport rate in the case L6 with larger wave height.
CONCLUSIONS AND REMARKS

1) Beach deformation and suspended sediment flux in the large scale tests showed good agreement with those in the middle scale tests. And thus, the application of this new similarity law of sand grain size (Shimizu, 1995) to random waves is verified.

2) In all cases, the difference can be seen between long period components of suspended sediment flux in the tests with and without eliminating free long waves. This difference becomes more significant in the case of the wider surf zone.

3) The long period and steady components of suspended sediment flux in the surf zone are generally offshore direction while the short period components of suspended sediment flux are onshore direction. Its steady components increase more than the short and long period components with shoaling and breaking.

4) This numerical model can well reproduce irregular time variation such as nonlinear wave deformation, suspended concentration, velocity and sediment flux and beach topography change.

5) Suspended load is much greater than bed load in the case of large wave height.

ABSTRACT: This paper reports on the results from a field test of the Bailard energetics sediment transport model. Model predictions agreed well with observed and measured volumetric change in the inner surf zone under erosional as well as accretionary conditions, occurring over a 72 h long storm event. The observed formation of a nearshore bar was reproduced by the model; bar formation was predicted to be due to a sediment transport convergence generated by seaward directed undertow and landward directed incident wave asymmetry.

INTRODUCTION

Attempts to model cross-shore sediment transport and profile evolution under varying energy conditions has been a major concern within coastal science and engineering and a fairly large number of sediment transport/morphodynamic models exist (e.g. Roelvink and Brøker, 1993). These models have generally been tested using laboratory data as sufficiently detailed high-quality field data are scarce.

An exeption to this has been the energetics model (Bagnold, 1966) and derivations thereof (Bowen, 1980; Bailard, 1981). The Bailard model which uses measured velocity moments as input has been tested in the field by e.g. Guza and Thornton (1985), Russell et al. (1995), Thornton et al. (1996) and Gallagher et al. (1998).

This model generally predicts offshore sediment transport events fairly well; these events occur as a response to mean currents and low-frequency waves during high-energy conditions. Onshore directed transport due to incident waves associated with beach recovery is generally poorly reproduced by the model (Russell et al., 1995; Thornton et al., 1996). A major reason is that the model does not consider phase-changes between velocity and sediment concentration which occur during oscillatory wave motions over

¹Institute of Geography, University of Copenhagen, Øster Voldgade 10, DK-1350 Copenhagen K., Denmark. e-mail: taa@geogr.ku.dk.

²Scarborough College Coastal Research Group, The University of Toronto at Scarborough, 1265 Military Trail, Scarborough Ontario M1C 1A4, Canada.
a rippled bed; ripples mainly occur during low and moderate energy conditions.

In this paper, we test the Bailard energetics model using a data set which was collected during a 3½-day moderate storm event at Skallingen on the Danish North Sea coast. During this event, the inner nearshore was subjected to fairly large morphological changes involving an initial onshore bar migration followed by renewed bar formation and finally onshore migration of the newly formed bar. The model was capable of reproducing these morphological changes. Model predictions are also compared quantitatively with measured volumetric changes as well as with suspended sediment flux which was measured during the event.

THE MODEL

Predicted sediment transport was computed from the Bailard-model following the methodology of Thornton et al. (1996), where cross-shore sediment transport is predicted by

\[ q_x(t) = K_b(u_x^r u_x^r + u_x^m u_x^m) - K_{bg} u_x^r + K_s(u_x^r u_x^r + u_x^m u_x^m) - K_{sg} u_x^r \] (1)

where

\[ u_x = (u_x^2 + v_x^2 + u_x^2 + v_x^2 + 2(u_x u_x^r + v_x v_x^r))^{1/2} \] (2)

and

\[ K_b = \frac{\rho \rho_c \rho \alpha \gamma \tan \phi}{P_{pp} \rho \tan \phi}; \]
\[ K_{bg} = \frac{\tan \beta \tan \phi}{P_{pp} \rho \tan \phi}; \]
\[ K_s = \frac{\rho \rho_c \rho \alpha \gamma \tan \phi}{P_{ss} \gamma \tan \phi}; \]
\[ K_{sg} = \frac{\tan \beta \tan \phi}{P_{ss} \gamma \tan \phi} \]

\( u_x, v_x \) are the mean cross-shore and longshore velocities, respectively; \( u_x^r, v_x^r \) are the oscillatory cross-shore and longshore velocity components, \( \beta \) is beach slope, \( w_x \) is sediment fall velocity and \( \tan \phi \) the angle of repose; \( \alpha \) is the pore space factor = 0.6. The bedload and suspended load efficiency factors \( e_b, e_s \) were set at 0.21, 0.025 (Bailard, 1981). \( c_f \) was determined from \( c_f = f_c/2 \) with \( f_c = \exp(5.213(k/A)^{104.5.977}) \), where bed roughness \( k_s \) was set to 5D_{50} for a flat mobile bed and \( A \) is the oscillatory velocity amplitude; \( A = u_{max}/7/2 \pi \) with \( T \) being the peak spectral density. \( c_f \) was on the order of 0.003-0.004 depending upon location within the profile. These parameters were kept constant at all times; no further adjustments were undertaken.

In eq.(1), the first two terms are the bedload transport terms due to oscillatory and mean cross-shore currents, respectively; terms four and five are the corresponding suspended load terms while the final two terms are due to gravity. \( u_x^r \) was further subdivided into incident wave and infragravity wave components using Fourier-filtering.

THE FIELD EXPERIMENT

The field experiment was conducted during October 1995 in the shallow inner surf zone
at Skallingen. Four instrument stations, termed S1-S4, spanned the inner nearshore bar and two additional stations (S5-S6) were deployed on the beach and only submerged during high tides and/or storm surges (Figure 1). The instrument stations were each equipped with one Marsh-McBirney OEM512 electromagnetic current meter, initially installed at 0.23-0.34 m above the bed and vertically adjusted at each low tide (if possible) to compensate for bed level changes. The sensors were oriented to record positive flows landward and to the north; errors in orientation are estimated to be within +/- 3 degrees. Sensor offsets which were on the order of < 0.02 m/s were removed prior to data analysis while sensor gains were computed according to the manufacturer's specifications.

Figure 1. The cross-shore profile of the instrument transect surveyed prior to (Oct.16) and after (Oct.21) the storm event. Locations of the instrument stations as well as bar designations are indicated.

The stations were also each equipped with 3 OBS 1-P optical backscatter sensors (installed at nominal elevations of 0.05, 0.10 and 0.20 m above the bed) while pressure sensors were deployed at S1 and S5. All sensors were sampled at 4 Hz for periods of 34 minutes each 1-1½ hours during the event.

Bed elevation and hence morphological changes were recorded at each low tide through the experiment using a cross-shore array of twenty-eight ½-inch steel rods, spaced at 5 m increments along the instrument transect from x=50-185 m (Figures 1 and 2). The distance from the top of the rods to the sand was measured using a graduated rod fitted with an endplate. As the bed was always flat and tightly packed at low tide, survey errors were small and estimated as +/- 0.5 cm. Potential cumulative errors across the survey section are thus +/- 0.7 m^3/m.

Figure 2. Time-distance diagram of the morphological evolution of the beach/inner surf zone during the experiment (tidal cycles 5-10). Note the trough formation at x = 170 m and the onshore migration of bar 2b into the survey area during tidal cycle 10.
The storm event was characterized by moderate wave energy with a maximum significant wave height of $H_s = 1.9$ m seaward of the surf zone (Figure 3). Depending upon tidal stage, waves broke between stations S1 and S2. Wave periods were 7-8 seconds and the winds which were oblique to the shoreline generated relatively strong southward directed longshore currents, on the order of 0.7-0.9 m/s. The longshore currents were tidally modulated with maximum currents occurring at high tide when local wave energy level (radiation stress) was at a maximum.

Measured cross-shore mean currents were initially directed landward across the nearshore bar (Figure 4). At this time, cross-shore currents at the bar crest (S3) were also tidally modulated but in this case with maximum currents at low tide when incident wave dissipation was large and the breaking waves assumed a roller-like shape. Also, the sensors were relatively higher in the water column. Current velocities reached $+0.38$ m/s at the bar crest, and these landward directed flows are interpreted as being due to onshore wave- and bore-induced mass transports forming the onshore-directed limb of a rip circulation cell feeding the rip current south of the instrument transect (Aagaard et al., 1998). During the second half of the event, cross-shore currents at S3 (and S2) as well as the tidal modulation of these currents reversed; at this time the maximum currents at S3 occurred at high tide with velocities on the order of $-0.05$-$0.1$ m/s. The rip circulation was locally replaced by an undertow (Aagaard et al., 1998).
RESULTS AND DISCUSSION

Bed elevation changes in the beach/inner surf zone region are shown in Figures 2 and 5. The morphological evolution can be separated into three phases: Initially, the inner nearshore bar (bar 2a) migrated onshore during tidal cycles 5-7. Sediment was eroded from the crest of the bar and deposited in the trough and on the beach face. The second phase somewhat overlapped the first (tidal cycles 7-9) and was associated with trough excavation on the seaward slope of the bar (around x = 170 m) with renewed bar formation (bar 2b) seaward of the survey area (Figure 1). The final phase occurred during cycle 10 and was associated with onshore transport of sediment. The inner trough infilled and bar 2b migrated into the survey area. In plan view, the inner bar was initially slightly convex to the shoreline, with the instrument transect (located at y = 0 m) crossing the highest point of the bar (Figure 6). At the termination of the event, bar 2a had merged with the shoreline slightly updrift of the instrument transect and it was oriented obliquely to the shore. Note that the rip channels located at y = +/- 175 m (Figure 6) remained stable in position. The main areas of erosion/accretion were located at the updrift and downdrift ends of the bars.

Figure 5. Changes in bed elevation at survey rods (Δz), and the cross-shore profile over tidal cycles 5-10. The left-hand ordinate refers to Δz, while the one on the right refers to elevation above Ordnance Datum. The dashed line in the upper panel is the profile at the termination of tidal cycle 4.
Figure 6. Three-dimensional views of the topography at the field site prior to (October 15) and after (October 21) the storm event. The bottom graph shows positive and negative bed elevation changes. The instrument transect was located at $y = 0$ m.
**Predicted sediment transport**

Figure 7 shows model-predicted sediment transport rate at stations S1-S4. Computed sediment transport rates and directions are in qualitative agreement with the observed morphological changes. During cycles 5-7, sediment transport was directed landward at all stations; transports at S4 were, however, very small as this station was located in the trough where sediment concentrations were small due to decreasing incident wave energy. During cycles 7-9, a transport divergence existed between S2 and S3 corresponding to the trough formation at this location. Simultaneously, there was a transport convergence between S1 and S2 resulting in the formation of bar 2b. Finally, tidal cycle 10 was characterized by a reversal to the initial transport conditions with onshore transport across the bar(s). Transport rates at S4 gradually increased as bar 2a migrated through this station and sediment concentrations increased. According to the model, suspended load was significantly more important than bedload, on average ranging from a high of 88% of the total load at S2 where incident wave energy was at a maximum, to 68% at S4.

Bed elevation changes at the inner edge of the survey area were almost consistently nil (Figure 5). Assuming a closed landward boundary to the profile and assuming a lack of longshore sediment transport gradients (which appears not unreasonable; Figure 6), net volumetric change within the survey area should match the sediment transport rate at the seaward edge of the area, i.e. at S2. In Table 1, predicted net volumetric transport at S2 over individual tidal cycles (ΔQ) is compared with volumetric change landward of S2 (ΔV). In the table, the agreement between predicted and measured volumetric change was excellent in 4 out of 6 cases. During cycles 6 and 9, the model overpredicted the volumetric transport by a factor of 1.7 and 2.4, respectively, resulting in a factor 2 overprediction of the sediment loss over the entire event. Examining the patterns of cut and fill (Figure 6), it is not evident that the overprediction should be mainly due to longshore sediment transport gradients.

Table 1 also compares the sediment balance over bar 2a (bounded by S2 and S4) with predicted sediment transport balance between these two stations. In this case, the correlation was excellent in 3 cases. During cycles 6 and 7, the model underpredicted the loss from the section, associated with onshore sediment transport at S4. This was at least
partly due to the current meter at S4 being very close to the bed (< 0.1 m) as the bar migrated onshore and almost buried this station. The model again overpredicted the sediment loss during cycle 9.

Table 1. Volumetric change (ΔV) between S2 and the most landward survey rod, and between stations S2 and S4, as well as predicted net sediment transport (ΔQ) onshore/into (+) and offshore/out of (-) these sections. Values are in m³/m shoreline.

Predicted transport vs. measured flux.

Predicted suspended sediment transport rates at S2 and S3 were compared with the sediment flux measurements using the backscatter sensors (Figure 8). Net sediment flux was estimated from these sensors by linearly integrating individual flux estimates from (nominal) elevations z = 0.025-0.275 m. True elevations changed when the bed eroded/accreted. Obviously, such a comparison cannot validate quantitatively any of the two methods; a large part of the suspended sediment transport is expected to occur at elevations below the lowermost OBS-sensor and the concentration profiles are not linear. Nevertheless, within the inner surf zone where bores predominate, vertical sediment concentration gradients are expected to be relatively small due to the high levels of turbulence (Yu et al., 1993). Therefore, it should be possible to assess the qualitative performance of the two methods relative to each other.

Figure 8. Model-predicted suspended sediment transport versus measured suspended sediment flux at stations S2 and S3. Positive values are directed onshore.
At S3, where measured vertical sediment concentration gradients were generally small, the correspondence between the predicted transport and the measured flux was very good. Data gaps at this station indicate instrument exposure; at S2 the gap represents a period when the OBS-sensors became dislodged and buried. At S2, measured vertical sediment concentration gradients were generally quite large and the correspondence between predicted transport and measured flux was poor except towards the end of the event.

The discrepancy between these stations may have been due to a number of factors. First, vertical mixing appears to have been stronger at S3. Furthermore, bed elevation changes at this station were relatively small (Figure 5) and the sensors were adjusted vertically at each low tide. This was not the case at S2 where bed elevation changes were larger and it was difficult to access this station at low tide. E.g. when the sensors were reinstalled around hour 50 (Figure 8), they could not be deployed sufficiently close to the bed. At this time, the lowermost sensor was at \( z \approx 0.12 \) m. As the bed gradually accreted, the correspondence between measurements and predictions improved significantly.

**Sediment transport mechanisms**

In Figure 9, the predicted suspended sediment transport has been separated into contributions from mean flows and oscillatory incident and infragravity wave components. The Figure illustrates transport rates at stations S1-S4 on three occasions representing the three morphological stages identified earlier. The first example (hour 10) represents the phase when bar 2a migrated landwards. According to the model, this was mainly accomplished by incident wave asymmetry accompanied by onshore directed mean flows on the bar crest. The second phase (hour 49.5) occurred when a trough was excavated between S2 and S3 and bar 2b formed between S1 and S2. This evolution appears to have been mainly due to the reversal of the mean flows which became offshore directed seaward of S3, representing an undertow. The result was a transport divergence between S3 and S2, and a convergence between S2 and S1. At the latter, mean transport became weak and increasingly opposed by incident wave asymmetry. The final example (hour 72) is taken from the time when both bars migrated onshore. At this stage, mean currents had decreased and consequently, onshore directed incident wave asymmetry dominated the inner surf zone.

Figure 9 illustrates a number of important points. First of all, predicted incident wave transport became offshore directed at S2 during tidal cycles 8 and 9 (represented by hour 49.5). This was not a response to an overall reversed incident-wave asymmetry. During the sample run at hour 49.5, velocity asymmetry at high frequencies (computed from \( u'^2/(u'^2)^{0.5} \) and using high-pass filtered time series) was small (+0.071) but positive, i.e. onshore directed. At the preceding high tide (hour 44) incident wave asymmetry was +0.22. Thus, incident wave asymmetry was tidally modulated as would have been expected as asymmetry has been found to decrease into the surf zone (Thornton and Guza, 1989), and at low tide, S2 was further from the breakpoint. The asymmetry was, however, always onshore directed. The reason for the predicted offshore directed transport at wind wave frequencies was that \( u_t \) (Eq. 2) tended to be maximum under incident wave troughs at S2.

The waves were incident north of the shore-normal, generating southerly (negative) longshore currents. Figure 10 shows an example of longshore and high-pass filtered cross-
Many cases appears to have been refracted against the current at this time. The reasons for this are not known, however.

Returning to Figure 9, net sediment transport at oscillatory infragravity wave frequencies tended to be relatively small even though a transport divergence was consistently located between S2 and S3 with onshore directed transport in the innermost surf zone, and more offshore trending transport further seaward.

Finally, as already noted, the mean currents were depth-dependent with respect to directionality. At bar crests (bars 2a and 2b), and particularly at low tide (Figures 4 and 9), the currents were directed onshore while they were directed offshore in larger water depths. This indicates a presence of feed-back mechanisms between topography and mean
current circulation, implying that on gently sloping beaches and in cases when the bar is close to the water surface, e.g. in the intertidal or upper subtidal zones, there will be a tendency towards a generation of rip cell circulation as the water brought onshore by mass transport cannot escape seaward as an undertow. At Skallingen, rips channels are rarely absent from the inner surf zone.

DISCUSSION AND CONCLUSIONS

In the present study, a vertically homogeneous cross-shore velocity field has been assumed in the sediment transport computations. This might seem inappropriate as most models as well as several laboratory and field studies have demonstrated a tendency for vertically segregated flows, with onshore directed mass transport in the upper part of the water column (generally above trough level) and seaward directed flows in the lower parts. At first glance, the tidally modulated cross-shore current observed at S3 during tidal cycles 5-8 might suggest this scenario as the current sensor was relatively high in the water column at low tide, and vice versa. However, a number of points contradict this interpretation. First, predicted sediment transport rates and directions agreed well qualitatively with the observed volumetric changes, and in most cases quantitatively as well. Second, around low tide rips were visually observed approximately 175 m south (and north) of the instrument transect throughout the event. Third, an undertow did develop at S3 during cycles 9 and 10 (Figure 4) due to reversed longshore pressure gradients (Aagaard et al., 1998). It is not evident why this shift would occur if current direction depended upon sensor elevation as maximum and minimum tidal elevations were relatively constant during all tidal cycles (Figure 3). Finally, the tidally-modulated flow at S2 was far from systematic, suggesting that a simple velocity response to relative sensor elevation did not exist, at least at this station.
Therefore it is concluded that the energetics model is potentially capable of predicting sediment transport rates under high-energy field conditions in the inner surf zone, to within a factor of 2 or 3, provided that longshore velocity components are included in the sediment stirring term. The model appears quite robust as no adjustment of free parameters occurred. On most occasions, there was a close agreement between predicted and measured volumetric change, particularly considering the potential survey errors. While this is probably fortuitous, the model only failed significantly during one tidal cycle.

Previous field tests of the model (e.g. Russell et al., 1995; Thornton et al., 1996) have indicated problems with predicting transport due to incident waves, particularly during onshore sediment transport conditions, and the model has generally been incapable of simulating beach recovery. This was not the case here, probably because the bed in these shallow water depths was generally flat; no evidence of bedforms was observed. The energetics model assumes a zero phase-shift between velocity and sediment concentration; this assumption is violated in the case when the bed is rippled.

The data presented here provide strong support for the concept of nearshore bar formation due to undertow. Approximately half-way through the event, an undertow developed locally at S2 (and later at S3), probably because of reversed longshore pressure gradients (Aagaard et al., 1998). The undertow weakened and became opposed by incident wave asymmetry at S1, resulting in the development of bar 2b.

Finally, this study has suggested an existence of morphodynamic interactions in the nearshore, involving feedbacks between hydrodynamics and topography, exemplified by the dependency between bar topography/water depth and mean flow directions. Apart from the presence or absence of longshore pressure gradients which are intimately linked to longshore (non-)uniform bar topography, the mean flow pattern, i.e. offshore-directed undertow versus onshore-directed rip feeders, seems to be constrained by water depth. In shallow water (bar crests and/or low tide), there was a tendency towards onshore directed mean currents over the bar while offshore directed mean flows prevailed in larger water depths (in troughs, during high tide and at S1).

Field Observations of Small Scale Sedimentation Processes

Daniel M. Hanes¹ (member, ASCE), Eric D. Thosteson¹, Yeon-Sihk Chang¹, Craig Conner¹, and Chris E. Vincent²

Abstract

A series of field experiments have been conducted to investigate small-scale sediment dynamics near the seabed in the nearshore region. The experiments took place at the U.S. Army Corps of Engineers Field Research Facility, in Duck, North Carolina, U.S.A., where the seabed typically consists of fine to medium sized sand. An array of instrumentation was deployed at various locations across the surf zone and nearshore region between depths ranging from 1 to 5 meters. Examples of suspended sediment measurements are presented along with examples of observed bedforms. We observed that the suspension of sand tends to occur at low frequencies that correspond to the time scale of wave groups. Small wave ripples are also found to evolve over similar time scales. We explore the linkages between the suspension of sediment and the evolution of small wave ripples, and show that the size of the ripples plays a significant role in determining the amount and distribution of suspended sediment.

Introduction

Small-scale sedimentation processes are responsible for the movement of sediment grains in the coastal zone. We use the term “small-scale” to describe those processes affecting the sediment dynamics and hydrodynamics on spatial scales ranging from the size of the sediment grain up to approximately 1 meter. This range of spatial

scales typically covers the thickness of the turbulent wave boundary layer, as well as small wave ripples that often are found on the seabed.

A series of field experiments have been conducted to investigate small-scale sediment dynamics near the seabed in the nearshore region. The experiments took place at the U.S. Army Corps of Engineers Field Research Facility, in Duck, North Carolina, U.S.A., where the seabed typically consists of fine to medium sized sand. An array of instrumentation was deployed at various locations across the surf zone and nearshore region between depths ranging from 1 to 5 meters. The instruments measured the local hydrodynamics using a pressure sensor and 3 axis Acoustic Doppler Velocimeter (ADV). The suspended sediment concentration was measured with a three frequency Acoustic Concentration Profiler (ACP), and the local bedforms were measured with a Multi-Transducer Array (MTA). Surficial sediment samples were also obtained at most sites, as well as water temperature, turbidity, and video images when the water wasn’t too turbid. A schematic of the instrumentation is shown in Figure 1.

Littoral Sedimentation Process Measurement System

![Instrumentation Schematic](Image)

Figure 1: Instrumentation Schematic

The data were obtained over a variety of wave and current conditions, and exhibit high variability in both the suspended sediment concentration and the bedform geometry. This paper will focus on the scales of variability. In particular, we will examine the temporal variability in the concentration of suspended sediment near the seabed, and the variability in the spatial scale of the bedforms.
Background

In steady, unidirectional flow, suspended sediment flux is calculated at a fixed depth from the product of the water velocity and the suspended sediment concentration. In the presence of waves the concentration of suspended sediment and the velocity of the water are generally not in phase, but a phase relation exists between the two quantities. This results in a component of sediment flux that depends explicitly on the time varying components of velocity and concentration. Several investigators have shown that because of this coherent transport component, significant sediment transport can occur in a direction different from that of the mean water velocity (Jaffe et al., 1985; Hanes, 1988; Vincent et al., 1991). Furthermore, this coherent transport has been shown to be frequency-dependent by using the cospectrum of measured velocities and concentrations (Hanes and Huntley, 1987). In view of the importance of this coherent transport component, accurate modeling of the transport of sediment in the presence of waves requires instantaneous time series of both water velocity and of suspended sediment concentration.

The importance of this intermittent sediment suspension on the time scale of waves has been parameterized for monochromatic waves in the surf zone by use of the Dean number (Dean, 1973).

\[
D = \frac{H_b}{wT}
\]  

In eq. 1, \(H_b\) is the breaking wave height, \(w\) is the sediment fall velocity, and \(T\) is the wave period. For low values of the Dean number, sediment movement is onshore, but at some critical value, the direction becomes offshore. Basically, the parameterization is based upon the assumption that sediment is elevated to some height at the phase corresponding to the passage of the wave crest. The quantity and direction of net sediment transport then depends on the fraction of the suspended sediment which settles before flow reversal occurs - which introduces the importance of the settling velocity of the sediment and the period of oscillation. As an instantaneous predictive model, use of the Dean number is complicated too extensively by the frequency interactions of random seas. As a conceptual model, the Dean number parameterization illustrates the 'memory' or 'history' effect of the sediment suspension process that results in the above mentioned concentration phase lag. It also illustrates some parameters important in its characterization: height of suspension, sediment fall velocity, and wave period.

Suspended Sediment Observations

Previous research has indicated that significant variation in suspended sediment concentration occurs at frequencies below those of the incident waves, particularly at those frequencies associated with wave groups (Hanes, 1991). More recent work outside the surf zone has verified this result, showing concentration variation at wave group frequencies - even when no infragravity energy was present in the wave power spectrum.
Such a case is shown in figure 2, which shows the frequency spectrum of the concentration time series measured 1 cm above the seabed. Note in this figure the high representation at low frequencies, despite the lack of energy at these frequencies in the bottom velocity spectrum, shown in figure 3. The same study showed that these low-frequency variations in suspended sediment concentration can actually dominate the concentration spectrum (Thosteson, 1997). Moreover, the coherence between the squared magnitude of the bed velocity (chosen for the envelope or group detection properties) and the concentration is very high at these frequencies (as is apparent in figure 2), with the peak in concentration lagging slightly behind the peak in the envelope time series. These results are interpreted, as in the Dean number parameterization, to be a consequence of the history effect of sediment suspension, but on a much longer time scale. Interestingly, it is not difficult to conceptualize additional mechanisms that vary substantially on the time-scales of wave groups and that could contribute to this history effect of sediment suspension. Such mechanisms include variation in turbulence intensity, fluidization and consolidation of sand beds (which could enhance the erosion potential of the bed), bedform geometry, boundary layer stability, etc.

![Figure 2: Frequency spectrum of concentration time series measured 1 cm above the bed. Solid line indicates coherence with square of bottom velocity magnitude > 0.60.](image.png)
Figure 3: Frequency spectrum of bottom velocity with 80% confidence limits.

Figure 4: Phase of transfer function between near bed concentration and square of bottom velocity (envelope).
Figure 4 shows the phase of the transfer function between near bed concentration and the square of the bottom velocity (the envelope at low frequencies in absence of infragravity motion). As seen from examination of figure 4, the low-frequency phase of the transfer function could be well approximated by a linear fit. This is significant, because a linear phase response in the frequency domain corresponds to a constant time lag in the time domain.

Bedform Observations

Bedforms consisted mainly of two different types. Wave formed ripples were measured with heights up to 2 cm and lengths from 10 to 15 cm. Mega-ripples, with heights of 5 to 10 cm and lengths of 75 to 150 cm were also measured. Each of these bedform types sometimes occurred alone, and other times both types were superimposed. For example, Figure 5 illustrates the bedforms when both types were present. The center section of the MTA has higher resolution, and is blown up in the lower plot to show the smaller scale bedforms. The lines in this figure represent a sequence of scans (bedform measurement) separated in time by 1 minute; the lines have been displaced vertically by 1 mm in order to better see them. These measurements were obtained outside the surf zone in a depth of 3.9 m with a surficial sand size $D_{50} = .19$ mm, under conditions with $H_{mo} = 0.50$ m, $T_p = 10.7$ sec.

Interestingly, under very similar conditions, but closer to the breaker zone, the smaller scale ripples were not present, as seen in Figure 6. These mega-ripples were observed in a depth of 1.6 m, just outside the surf, with a surficial sand size $D_{50} = .19$ mm, under conditions with $H_{mo} = 0.53$ m, $T_p = 9.8$ sec. It would appear that the threshold for sheet flow has probably been exceeded in this case.

![Figure 5: Small and mega-ripples](image)
Bedform-suspended sediment interactions

For examination of the temporal variability of the bedforms, the equivalent ripple height is utilized. The equivalent ripple height is defined as the height of a sinusoidal bedform with the same standard deviation as measured by the linear array. The lower plot in Figure 7 shows the variation of the equivalent ripple height for 16 minutes during
a run with a significant wave height of 0.55 meters and 9 second waves. In the upper plot of Figure 7 is the velocity magnitude squared, again used to make the passing wave groups apparent. It is interesting to note the decrease in equivalent ripple height each time a group passes, particularly the large group occurring within the 7 to 9 minute range of the plot.

Shown in Figure 8 is the time series of concentration profiles collected during the same 16 minutes presented in Figure 7. The darkest areas in the plot represent the highest concentrations, while the lighter areas show the lowest concentrations. The concentration is seen to increase with passing groups, as discussed previously, but the most dramatic concentration event occurs at nearly the same instant as the reduction in ripple height.

**Summary**

Suspended sediment concentration has been shown to vary most significantly on the temporal scale of wave groups. Bedforms of various spatial scales and geometries are seen to be similarly dynamic, often reduced in amplitude or wiped clean during wave group passage. In addition, the variability of suspended sediment concentration and
bedform geometry are seen to be linked to one another. Continuing and future research of these processes with increasingly more advanced instrumentation, improved methods of data analysis, and measurements higher in resolution will improve our understanding of these processes and their roles in the process of sediment transport.

LITTORAL TRANSPORT UNDER COMPLEX WAVE FIELDS: PECÉM, NORTH EAST BRAZIL

Berry Elfrink1, Domenico Accetta2, Berenice Motta Vargas2 and Wagner Santos Scisinio Dias2

Abstract

In connection with the design of new marine facilities a hydraulic study was carried out at Pecém, NE Brazil. The project comprised mathematical modeling of waves, nearshore hydrodynamics and sediment transport before and after the construction of the offshore harbor in front of Ponta do Pecém. The wave conditions are characterized by the simultaneous occurrence of sea and swell from different directions. The littoral current generated by the sea becomes detached at the headland. A shore-connected spit develops under these circumstances. During periods of predominant swell the spit erodes. The main impact of the harbor is a further reduction of the littoral drift W of the headland, which causes increased sediment accumulation immediately W of the headland and coastal erosion W of the city of Pecém.

Introduction

Presently an offshore harbor is being constructed in front of the city of Pecém, approximately 40 km west of Fortaleza in NE Brazil, see Fig 1. The harbor is located approximately 2 km offshore. In connection with the design of the new marine facilities, a coastal impact assessment was carried out (Danish Hydraulic Institute 1997). The location of the harbor is shown in Fig 2.

The coastline of Ceará is characterized by curved sandy beaches, interrupted by small rocky headlands. The beach material consists of medium to fine sand with a median grain size of the order 0.25-mm. Since several years the coastline in front of Pecém is subject to

1 Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark
2 Instituto de Pesquisas Hidroviárias, Rua General Gurjão 166, Caju - Rio de Janeiro, CEP: 20-931-040 Brazil
erosion. An analysis of aerial photographs has revealed that the coastline in front of the city has retreated with approximately 50 meters during the last 25 years. The coastline erosion is not homogeneous along the coast but varies from approximately 4 m/year at the western edge of Pecém to approximately 2m/year at its eastern boundary. Approximately 500 m further towards west, a slight beach accretion was observed locally.

Fig. 1  Location of the project site

Fig. 2  Location of the new offshore harbor of Pecém scale 1: 60,000.
Variations in the coastline position occur during the year. In the period from November until April, beach erosion occurs due to swell coming from the Northern Hemisphere. During this period rock is exposed at many locations at the beach. From May until November, the wave conditions are dominated by sea waves.

The project site is characterized by a stable wind climate. The wind speed and directions are fairly constant through the year. The main wind direction is E-ESE. The most frequent wind speed is 6 - 8 m/s from E.

Along the entire coastline, high eolian dunes extend to several kilometers away from the coast and form a dominant morphological feature of the landscape. The height of the dunes exceeds 30 m in some locations. Their orientation corresponds to the prevailing wind direction, which is approximately 95° N. The dunes consist of marine sand with a slightly better sorting than the beach sand. Close to the shoreline, the dunes are active. Aerial photographs show that the dunes migrate with an average speed of approximately 6 to 7 m/year. The older dunes further away from the coastline are fixed by vegetation. Depending on the coastline orientation, the coastal dunes act as a sink of sediment in the coastal sediment balance. Due to the dominating winds from easterly directions and the coastline configuration at Pecem, sediment loss due to wind transport is only of importance at the eastern side of Ponta do Pecém.

The wave conditions are characterized by the simultaneous occurrence of swell and sea from different directions. Sea approaches the coast at Pecém under large angles. Due to refraction and diffraction around the headland, a part of the wave energy reaches the shore. The area E of Ponta do Pecém is considerably more exposed to the action of sea waves than the western side.

Although the tidal range is approximately 3 meters, tidal currents are very weak, of the order 0.1 m/s. These currents are of minor importance for the nearshore sediment transport. The main effect of the tides is the cross-shore shift of the sediment transport patterns, which is dictated by the water levels. During ebb, wave breaking occurs on the shoals in front of the city of Pecém at a distance of several hundred meters off the coast. During flood, the headland becomes partly inundated.

**Wave conditions**

Between 1991 and 1995 INPH has carried out wave measurements in Fortaleza by means of a Wave rider located at a distance of approximately 1 km offshore of the port of Mucuripe. The wave buoy was located at a water depth of 15 m. (INPH 1986a).

Since March 1997 wave data has been recorded with a directional Wave-Rider, which is located approximately 4 km offshore of Pecém in a water depth of 17m. These measurements provide detailed information about the spectral characteristics of the wave conditions. In order to obtain reliable statistics, measurements carried out over several years are necessary. However, the wind conditions at the present site are fairly constant.
throughout the year. The measured wave height statistics showed good agreement with the data from Mucuripe and were assumed representative for the present site.

Fig. 3 shows an example of a measured wave spectrum at Pecém. A clear bimodal distribution of the wave energy distribution can be noticed. The first peak occurs at frequencies of approximately 0.06 to 0.1 s\(^{-1}\) corresponding to wave periods of 10 to 16 s. The mean direction of the waves with these frequencies varies between approximately 20° N and 45° N. These waves represent the swell originating from the Northern Hemisphere. The second peak represents sea, with frequencies typically in the order of 0.12 to 0.3 s\(^{-1}\), corresponding to wave periods of 3 to 8 s. The direction varies between approximately 75° N and 120° N.

The usual way to apply the wave data in coastal studies is to represent the wave spectrum by a few statistical parameters. Typically the significant wave height \(H_s\) and the peak period \(T_p\) are used in sediment transport studies. If these parameters were used to characterize the wave conditions, information about the structure of the spectrum would be lost. The use of the peak wave period would only represent sea, as the short wave components usually are predominant in the spectrum. Further, the calculated mean wave direction would not resemble the observed direction from neither the swell nor the sea waves, but instead some average angle, which does not represent the natural conditions. The littoral sediment transport is very sensitive to parameters such as the wave height, period and especially the wave direction. Small errors in these parameters may lead to considerable errors in the calculated sediment transport rates. The sediment transport mechanisms under swell waves are quite different from those under short period waves.

**Fig. 3** Typical wave spectrum at Pecém. Two distinct peaks can be observed with frequencies of approximately 0.08 and 0.12 s\(^{-1}\) representing swell and wind waves (sea) respectively. The wave directions of the two dominant wave components are varying from approximately 30° N for the swell to approximately 120° N for the sea waves.
and thus care must be taken in the representation of complex sea states as in Pecém by these assumptions. Therefore, it is important to distinguish the swell from the sea and treat them separately in the sediment transport calculations.

In order to distinguish between sea and swell an analysis was made of the measured wave energy spectra. Each spectrum was subdivided in a discrete number of frequency intervals. For each interval a wave height was calculated according to the measured energy density in the respective interval. In this way, the wave energy spectrum was transformed to a number of individual wave events characterized by a wave height, period and direction. A statistical analysis was performed on all investigated spectra. From this analysis wave climates for each month of the year were derived. A dominance of sea is observed for the period from July to October. From December to April swell is dominant. The intermediate months show the occurrence of both wave types simultaneously. Fig. 4 shows the derived climates for January and July with a predominance of swell and sea respectively.

![Wave conditions at Pecém](image)

**Fig. 4** Observed wave conditions at Pecém. Left: January (Swell dominated) Right: July (sea dominated)

A number of characteristic wave conditions were simulated with a 2D wave model developed by DHI. The model is based on the parabolic approximation of the elliptic mild slope equations and includes dominant wave transformation phenomena such as refraction, shoaling, reflection, bottom friction and breaking. In these simulations, sea and swell were treated separately.
Figs 5 shows simulated wave fields for an offshore wave height $H_s$ of 1.75 m, a peak period of 7 s and a mean offshore wave direction of 82.5°. These wave conditions occur frequently in the area and contribute significantly to the net annual drift. Simulations for the present situation and the situation after establishment of the marine facilities are shown. East of Ponta do Pecém, the bathymetry is quite regular and the wave field is seen to be more or less uniform along this part of the coast. At the breaking point, the angle between the wave crests and the coastline is large, of the order of 45 degrees. This causes strong longshore currents that are able to transport large amounts of sediment along the coast.

At the western side of the headland, the wave field is rather complex due to the irregular bathymetry. The waves refract around the headland and approach the coast under a large angle. The area immediately W of Ponta do Pecém is sheltered by the headland. In front of the city of Pecém, wave breaking occurs far away from the beach due to the shoal that is located here. However, the shoal in front of the city does not provide much shelter for the incoming waves due to the large angles of incidence. Waves from these directions propagate between the headland and the shoal and reach the coast at Pecém under large angles.

The new harbor has a strong sheltering effect on the waves coming from easterly directions e.g. sea waves. The area of influence covers the entire area between the headland and the city of Pecém.

Fig. 6 shows the wave fields in the vicinity of Ponta do Pecém for swell. The convergence of the wave crests towards the headland is clearly seen. Immediately W of the headland, the coast is sheltered from wave action due to the headland. However, the shadow area is much smaller for swell waves than for sea waves.

*Scale 1:70,000 Left: present situation, Right: including new harbor*
The propagation of swell towards Pecém is not drastically affected by the harbor. Swell approaches the shore from offshore angles between approximately 20° to 45° N. The area where the sheltering by the harbor is maximal is located approximately 1.5 km E of Ponta do Pecém.

Scale 1:70,000 Left: present situation, Right: including new harbor

Nearshore hydrodynamics

In order to study the 2D wave driven currents, a number of hydrodynamic simulations were carried out with DHI’s hydrodynamic model MIKE 21 HD. This is a general modeling system for the simulation of water levels and flows in estuaries, bays and coastal areas. The model solves the unsteady depth integrated flow equations. The driving force in the present simulations originates from the radiation stress field calculated with the wave model as described in the previous section.

The wave-driven current pattern for the present situation and after establishment of the harbor is shown in Fig. 7. The wave conditions correspond to sea ($H_s = 1.75 \text{ m}$, $T_p = 7\text{s}$, $MWD = 82.5^\circ \text{ N}$).

The littoral currents are considerably stronger at the eastern side of Ponta do Pecém than on the western side. This is due to the more exposed character of the beaches on the eastern side. The littoral current follows the shoreline until it reaches the head of Ponta do Pecém. Close to the headland, the flow is slightly accelerating due to a local convergence of the depth contours. West of the headland, the current becomes detached from the shoreline. The flow velocities are highly reduced in this area. At a distance of
approximately 1 km W of the headland, the current reattaches to the shore and its strength gradually increases towards W. Due to the irregular bathymetry in front of Pecém, complex nearshore current patterns can develop.

The presence of the harbor strongly reduces the littoral current velocities W of Ponta do Pecém. The harbor induces a large-scale eddy at the offshore edge of the headland. The littoral current becomes partly directed into the harbor basin, which may cause additional sedimentation problems inside the harbor.

**Fig. 7** Wave driven current fields for the present situation (Sea).

*Offshore wave conditions: Hs = 1.75, Ts = 7s, MWD = 82.5° N
Scale 1:55,000. Left: Present situation, Right: including new harbor*

Simulated wave driven flow fields due to swell are shown in Fig. 8. At both sides the currents are directed away from the headland.

**Fig. 8** Wave driven current around the headland for the present situation (Swell).

*Scale 1:15,000. Offshore wave conditions: Hs=0.5m, Tp=14s, MWD=30°*
The flow velocities $W$ of Ponta do Pecém are not significantly affected by the presence of the harbor. At the eastern side, the flow is slightly reduced due to the sheltering of the harbor. The maximal differences occur at a distance of approximately 1.5 km E of Ponta do Pecém.

Nearshore sediment transport

The complex sediment transport patterns for the present site were simulated with DHI's 2D sediment transport model MIKE 21 ST (Sand Transport). This model calculates the sediment transport of non-cohesive sediment due to the combined action of currents and waves. Model calibration was performed upon available data of the Port of Mucuripe-CE, (see INPH 1986b). For a detailed description of sediment transport mechanisms in currents and waves, the reader is referred to Fredsøe and Deigaard (1992).

The results of the wave and current simulations were used as input for the sediment transport calculations.

During predominant sea relative large transport rates occur E of Ponta do Pecém. The harbor does not affect the littoral transport rates significantly in this area. Along this coastal stretch, at a distance of approximately 1 km E of the headland, the littoral transport is locally directed offshore.

At the western side of the headland, the littoral transport becomes detached from the shoreline. The sediment transport rates are reduced significantly for the new situation due to the decreased wave action and the associated strength of the wave driven current. The magnitude of the sediment transport is reduced considerably by the sheltering effect of the harbor on the nearshore hydrodynamic conditions in this area. With the presence of the harbor, the littoral transport at Ponta do Pecém continues further offshore than for the present situation without harbor and less, if any, sediment is passing Ponta do Pecém.

For swell waves, the littoral sediment transport pattern looks quite different. The coastline orientation in the area of Pecém varies from approximately 355 degrees N in front of the city to approximately 55 degrees N along the coastal stretch E of Ponta do Pecém. Due to this coastline configuration, the littoral current is directed towards E at the eastern side of the headland and towards W at the western side. The resulting littoral drift is therefore always directed away from Ponta do Pecém; towards E at the eastern side and towards W at the western side.

In this way, swell counteracts the sediment accumulations due to sea. East of Ponta do Pecém, swell reduces the net littoral transport rates towards the headland. On the western side of the headland, a part of the accumulated material is transported towards the shore by cross-shore transport mechanisms. Further towards West, swell gives rise to an additional westward drift.
During periods with prevailing swell, the spit developed during periods with predominant sea erodes. If the swell domination lasts for sufficiently long time, the coastline in front of Pecém erodes because the westward littoral drift due to combined sea and swell exceeds the sediment bypass around Ponta do Pecém, which is reduced due to the action of the swell.

Cross-shore sediment transport

In the calculations of littoral sediment transport the wave orbital motion was assumed described by one single wave with a constant height, period and direction. In case of longshore sediment transport this assumption is justified as the longshore transport is dominated by the longshore current and to lesser degree by the wave orbital motion, which is almost perpendicular to the coast in the surf zone.

However, the wave motion and the resulting shear stress are important for the calculation of the cross-shore sediment transport. The net cross-shore transport is determined by factors such as the strength of the undertow, the asymmetry of the wave orbital motion and the mass transport under progressive waves. In the present case the wave conditions are characterized by the simultaneous occurrence of sea and swell from different directions. In order to estimate the onshore sediment transport immediately W of the headland, an existing model for non-cohesive sediment transport was extended to include the effect of simultaneous occurrence of sea and swell. The basis for the model is DHI's sediment transport modeling system LITPACK. This model calculates the bedload and suspended load due to combined wave/current motion. The bedload is calculated from the sediment characteristics and the instantaneous bed shear stress, which was calculated from the solution of the turbulent wave boundary layer (Fredsoe 1984). The suspended load is calculated from the diffusion equation for suspended sediment (Fredsoe et al. 1985). Here the sediment exchange factor is taken equal to the eddy viscosity, which contains contributions of the wave boundary layer, the mean flow and the turbulence due to wave breaking (Deigaard et al 1986). The mean flow is calculated from the force balance across the water column (Deigaard 1993 and Elfrink et al 1996).

For the present application, the wave orbital motion was described by a linear superposition of a short wave component and a long wave component with different directions. Both components were assumed to occur as groups. The respective contributions to the total orbital velocity were calculated from 5th order Stokes’ or cnoidal theory, depending on the local Ursell number. Fig. 9 shows an example of the wave orbital velocity composed of 2 wave groups with mean periods of 6 and 11 seconds. The angle between the short waves and the long waves was 60 degrees.

The orbital velocities were used to calculate the bottom boundary layer under the complex wave field. Fig. 10 shows the shear velocities, $U_f$, derived from the boundary layer solution.
Fig. 9  Instantaneous bed orbital velocities due to different wave groups.  
Top: Longshore component, Bottom: Cross-shore component

Fig. 10  Instantaneous shear velocities due to different wave groups.  
Top: Longshore component, Bottom: Cross-shore component
The resulting sediment flux, $Q_t$, in the cross-shore and longshore direction is shown in Fig. 11.

**Fig. 11  Instantaneous sediment flux due to different wave groups. Top: Longshore component, Bottom: Cross-shore component**

The model was applied to estimate the onshore transport of sediment from the headland to the coastline W of it. It was found that the transport capacity under swell waves was increased due to the presence of short waves and vice versa. Even in cases where the two wave groups were taken perpendicular to each other.

**The coastal sediment budget and future coastline evolution**

The 2D simulations and the wave statistics were used to calculate the annual sediment balance.

**Present situation**

Along the beaches E of Ponta do Pecém a net littoral drift of the order of 350,000 m³/year is transported towards W. The headland causes the littoral current to become detached
from the shoreline. A total volume of approximately 90,000 m$^3$/year is transported offshore of Ponta do Pecém.

West of Ponta do Pecém, net onshore directed sediment transport occurs due to the reattachment of the littoral current and the net onshore sediment transport in (Non-breaking) swell waves.

West of the headland, the littoral transport is of the same order of magnitude as along the eastern side. The drift due to the sea waves is reduced due to the orientation of the beach and the sheltering of the headland. However, the importance of the drift due to the swell has increased, due to the larger angle between the swell waves and the coastline.

In the area immediately E of the city of Pecém, local gradients in the wave heights exist due to the irregular bathymetry. Here the littoral drift is reduced which gives rise to small accumulations. Further towards W, the littoral drift increases which causes erosion at the western edge of Pecém. This erosion/sedimentation pattern is confirmed by field observations.

**Situation after establishment of the harbor**

The main effect of the harbor is a strong reduction of the potential sediment transport rates due to sea waves in front of Ponta do Pecém and westwards, which results in increased sediment accumulations in front of and immediately W of the headland. A total sediment volume of the order of 115,000 m$^3$/year will initially accumulate in this area.

The flow velocities of the detached littoral current are strongly reduced due to the presence of the harbor. However, the transporting capacity of the swell is not affected in the immediate vicinity of the headland. A net onshore transport rate under swell waves of the order of 30,000 m$^3$/year was calculated. Approximately 85,000 m$^3$ sand will accumulate in front of Ponta do Pecém by means of a shore-connected spit.

Further West, the net littoral drift rates are reduced due to the sheltering of sea by the harbor. However, the combination of the reduced sediment supply and the reduced transport capacity of the littoral currents gives rise to erosion rates of the same order of magnitude, although slightly smaller, as for the present situation.

Further towards W, the effect of the harbor will vanish, which means that the littoral drift gradually increases from Pecém towards west. This leads to erosion between Pecém and Taiba.

From the calculated erosion/ sedimentation rates the annual coastline movements were estimated. East of Ponta do Pecém, the coastline is fairly stable. The accumulation of sediment due to the gradients in the littoral drift is of the same order of magnitude but slightly smaller than the net loss of sediment due to the wind. This gives rise to a slight coastline erosion of the order of 1 - 2 m/year. Variations occur during the year due to seasonal variations in the wave and wind conditions. The presence of the harbor does not
affect the coastline dynamics in this area. However, in the long run the accumulations in front of the headland will change the coastline orientation in this area. This will cause coastal sedimentation. This coastline progress will start immediately E of the headland and proceed gradually in eastern direction.

After establishment of the harbor a shore-connected spit will start to develop from the headland. The spit will grow both in the offshore- and western direction. A part of the accumulated sediment will be transported by the action of swell. The total accumulation in the offshore region is of the order of 85,000 m$^3$/year. The presence of the spit itself will have an impact on the wave and current conditions along the beach W of Ponta do Pecém. Wave diffraction around the spit may cause a local divergence of the littoral current and the resulting sediment drift. This may lead to temporary coastline erosion immediately W of the projection of the spit on the coastline. This erosion process will proceed along the coastline as the spit develops. The erosion stops when the spit becomes attached to the coastline.

After establishment of the harbor the coastline erosion rates west of Ponta do Pecém, are of the same order of magnitude as for the present situation. A general coastline retreat of approximately 2 - 3 m/year must be expected due to the decrease of sediment bypass around ponta do Pecém.

Conclusions

A net annual littoral transport of the order of 350,000 m$^3$/year occurs along the entire coastline. Seasonal variations in the coastline position occur due to dominance of sea or swell during different periods of the year. Net erosion along the entire coast was observed.

Sea and swell have different effects on the net littoral sediment transport. Sea initiates strong littoral currents and relatively high transport rates along the coast E of Ponta do Pecém. Along the western side of the headland, the littoral drift is strongly reduced due to the sheltering provided by Ponta do Pecém and the different orientation of the coastline. The headland acts as a bottleneck for the littoral transport. This is of crucial importance for the stability of the coastline in front of the city. The topography of Ponta do Pecém forces the littoral current to become detached from the shoreline W of the headland. The sudden reduction in potential transport rates causes sediment accumulations around Ponta do Pecém.

The swell causes a sediment transport directed towards E at the eastern side of Ponta do Pecém and towards W at the western side. This transport pattern counteracts the accumulation of sediment around Ponta do Pecém due to sea. Sediment transport towards the shoreline occurs due to the sediment transport mechanisms associated with non-linear wave motion. During periods of predominant swell the sediment supply around the headland is strongly reduced. This causes beach erosion at the western side of Ponta do Pecém during the southern summer.
The main effect of the new harbor on the littoral transport is a general reduction of the potential sediment transport from Ponta do Pecém towards West. The littoral drift along the eastern side of the headland is initially not significantly affected by the harbor. The sediment bypass around Ponta do Pecém becomes heavily reduced. The reduced transport capacities W of Ponta do Pecém cause the development of a permanent shore-connected spit in the lee side of the headland. This accumulation will proceed in both northern (offshore) and western (longshore) directions. A net accumulation of the order of 85,000 m³/year is estimated.

Further W of the headland the littoral drift will be reduced due the presence of the harbor. However, the gradients in the littoral drift along the shore are more or less the same as for the present situation. West of the city of Pecém, the sheltering effect of the harbor will vanish. This causes a gradual increase of the littoral drift rates between Pecém and Taiba and will give rise to increased coastal erosion in this area.

Morphological Modelling using a Modified Multi-layer Approach

Henk J. Steetzel¹, Hans de Vroeg², Leo C. van Rijn³ and Jean-Marie Stam⁴

Abstract

One of the topics of the National Dutch research program COAST²000 focuses on the long-term (50-100 years) and large-scale (1-100 km) morphological problems of the Dutch coast and the implications for coastal management. Examples of such problems are the effects of climate change and sea-level rise on a partly protected coastline, the long-term effects of on-going sand nourishments, the far-field effects of large-scale land reclamation and of the required sand-mining etc. Within this framework a pilot version of a conceptual model (the so-called PONTOS-model) has been developed, basically capable of simulating the morphological evolution of the Dutch coast at the above-mentioned spatial and temporal scales. This present paper focuses on the theoretical background of the model. The results of a preliminary application of the model for the closed coastal section of the Dutch coast between Hoek van Holland and Den Helder are also presented.

The actual PONTOS-model is based on the multi-layer concept, in which the cross-shore profile is schematised as a number of mutually coupled layers, defined between fixed profile depths. These layers interact through cross-shore transport. In longshore direction the layers respond to gradients in the longshore transport generated at the profile regions they represent. The main input of the model, to be provided by the user, are the characteristics of the coastal stretch to be studied, including the initial positions of the various layers and offshore hydraulic conditions in terms of wave and tidal climate tables. On the basis of these data the yearly-averaged sediment transport pattern is computed and finally used for the assessment of the coastal evolution.

Introduction

For national decisions regarding coastal management it is important to understand the long-term (50-100 years) effects and large-scale (1-100 km) implications of both natural processes and major coastal engineering projects. Examples of natural processes are the effects of climate change and sea-level rise on the sandy coast partly protected by groins or sea-walls and, in relation to this, the long-term effects of coastline maintenance by on-going sand nourishments. Problems related to major

⁴ National Institute for Coastal and Marine management/RIKZ, The Netherlands
coastal engineering projects are the far-field effects of large-scale land reclamation and the effects of the large-scale sand-mining necessary for such projects.

One of the topics of the national research program COAST*2000 focuses on understanding these long-term large-scale morphological effects and on developing tools to quantify them. Within this framework, a model is being developed, capable of simulating the morphological evolution of the Dutch coast at the required spatial and temporal scales.

Morphological characteristics of complicated coastal systems can be described using different modelling approaches. One such an approach is process-based modelling where the physical processes involved are described mathematically, combining a detailed fluid-flow model with a sediment-transport model. By successive iteration the dynamical evolution of an area can be simulated. For the analysis of the predominant processes and circulation patterns, wave, current and sediment transport, process-based models appear to be useful. However, they are less suitable for simulating long time periods, as they require large computation effort and the numerous iterations and accumulation of rounding-off errors may lead to unrealistic results. PonTos uses a different approach, which is more behaviour-oriented [Steetzel et al., 1998]. The physical processes (i.e. cross- and long-shore transport) are parametrized in simple relationships which respond to input conditions of wave and tidal climate and sea-level. The combined effects of the processes result in the morphological evolution of the coastal system. The resolution of simulations is smaller than would be available with a process based model, but the results in terms of the distribution of erosion and sedimentation after, e.g. a 50 year-period, seem more realistic. Moreover, because of its approach, this model is easier accessible more user-friendly than most process-based models. The results of the pilot version of this model (the so-called PONTOS-model) indicate that it is a promising tool to simulate and quantify the morphological implications of the problems just described.

The multi-layer model

The model is based on the multi-layer concept, in which the cross-shore profile is schematised as a number of mutually coupled layers, defined between fixed profile depths, see Figure 1.

![Figure 1: Layer schematization used in the model](image-url)
These layers interact through cross-shore transport. In longshore direction the layers respond to gradients in the longshore transport generated at the profile regions they represent. The present model uses a rectangular grid, with the \( x \)-axis in longshore direction, whereas the \( y \)-axis in the seaward direction. The \( z \)-axis is directed upward with the zero level at the reference level. As a consequence of the definition of the \( y \)-axis, a positive cross-shore transport implies movement of material in seaward/downward direction. In the present model, the cross-shore profile is schematised into five horizontal layers and two additional zones. Each individual layer is denoted with an index \( j \), ranging from \( j = -1 \) to \( j = 5 \), in which layer \( j = 0 \) to \( 4 \) refer to physical layers. The first physical layer, with index \( j = 0 \), refers to the dune layer. Subsequent layers refer to layers positioned further seaward, as shown in Figure 1. The actual position of a layer has to be assessed from the sediment balance of the cross-shore profile. The characteristic layer position \( y_j \) for a layer with thickness \( d_j \) between lower level \( Z_{j+1} \) and upper level \( Z_j \) is the average position computed from:

\[
y_j = \frac{1}{d_j} \int_{Z_{j+1}}^{Z_j} y(z) \, dz
\]

Depending on the actual shape of the local cross-shore profile, the characteristic layer position is located between the position of the depth contours of the boundaries.

**Governing equations**

For a specific computational cell with width \( \Delta X_i \) \( (= X_i - X_{i-1}) \) the increase of volume \( \Delta V_{ol,j,i} \), is computed from:

\[
\frac{\Delta V_{ol,j,i}}{\Delta t} = (Q_{x,j,i-1} - Q_{x,j,i}) - (Q_{y,j,i} - Q_{y,j,i+1}) + \frac{\Delta S_{j,i}}{\Delta t}
\]

in which \( Q_{x,j,i} \) refers to the (total) longshore transport in layer \( j \) at position \( X_i \), \( Q_{y,j,i} \) refers to the cross-shore transport at level \( Z_j \) in the interval \( X_{i-1} \ldots X_i \) and \( \Delta S_{j,i} \) corresponds to a source or sink term in cell \( (j,i) \).

Using the concept of a layer-approach, the volume in a specific cell or layer is represented by the specific position of the layer in cross-shore direction. A change in a cell’s volume, \( \Delta V_{ol,j,i} \), in layer \( j \) and cell with index \( i \) yields a cross-shore shift in the characteristic position of layer \( j \), denoted as \( \Delta y_{j,i} \) according to:

\[
\Delta y_{j,i} = \frac{\Delta V_{ol,j,i}}{d_{j,i} \Delta X_i}
\]

in which \( d_{j,i} \) denotes the thickness of layer \( j \) in the interval \( X_{i-1} \ldots X_i \).

Substitution of this translation yields:

\[
\frac{\Delta y_{j,i}}{\Delta t} = \frac{Q_{x,j,i-1} - Q_{x,j,i}}{d_{j,i} \Delta X_i} - \frac{(Q_{y,j,i} - Q_{y,j,i+1})}{d_{j,i} \Delta X_i} + \frac{\Delta S_{j,i}}{d_{j,i} \Delta X_i \Delta t}
\]

In this equation \( Q_x \) refers to the longshore integrated magnitude, viz. taken into account the width of the cell \( \Delta X_i \). Using \( q_y \) (expressed in \( m^3/m^1/yr \)) instead of \( Q_y \) (expressed in \( m^3/yr \)) yields:
\[
\frac{\Delta y_{j,t}}{\Delta t} = \frac{(Q_{x,j,t-1} - Q_{x,j,t})}{d_{j,t} \Delta X_i} - \frac{(q_{y,j,t} - q_{y,j,t+1})}{d_{j,t} \Delta X_i} + \frac{\Delta S_{j,t}}{d_{j,t} \Delta X_i \Delta t}
\]

The assessment of the longshore transport for each individual layer and the cross-shore transport rate at each intersection is discussed in the next.

**New formulations**

Earlier versions of this model [Steetzel, 1995] had the drawback that the interaction between the layers and their response in the longshore direction was determined by a series of pre-defined constants, which had to be determined by the users based on process-based models or on empirical data, see e.g. [Bakker et al., 1988]. This puts considerable restraints on the practical use of the concept. In the present set-up of the model these pre-defined constants have been replaced by formulations to compute cross-shore and longshore sediment transports directly within the model on the basis of external conditions such as wave climate, tidal conditions, bathymetry and sediment characteristics. In this way a very user-friendly behaviour-oriented model has been formulated. As such, the multi-layer concept is now more suitable for the evaluation of changes in a coastal system [Steetzel, 1997c, 1998].

**Climate schematization**

The model uses yearly mean wave climates at the seaward boundary as input. Specifically, wave conditions must be described on the $Z_5$-depth contour (e.g. at NAP-20m for the Dutch coast). This climate schematization forms the main driving force of the model.

**Wave climates**

A local wave climate is schematised as a set of individual conditions. These individual conditions are described by a number of parameters, namely:

- the significant wave height $H_s$ (at the deep water boundary);
- the accompanying peak wave period $T_p$;
- the angle of wave approach $\theta_o$;
- the storm-related set-up $h_s$;
- the fraction of occurrence of the combination of previous four parameters.

The wave climate consists of a distinct number of individual conditions for which the total fraction of occurrence equals 1. The longshore variation of the yearly wave climate is taken into account by relating a specific wave climate to a specific longshore position.

Using the yearly-mean wave climates as starting-point, the effect of long-term changes in the governing parameters such as wave heights and wave direction, can be taken into account by a correction of some of the parameters.
Tidal climates

The astronomical conditions are schematised using the mean features of the astronomical climate, viz. the vertical and horizontal tide. A local tidal climate is schematised as a limited number of individual tidal conditions, each having a specific percentage of occurrence. These individual conditions are described by:
- the astronomical water level elevation \( h_a \);
- the accompanying longshore tidal velocity \( v_a \);
- the reference depth \( d_a \) for which \( v_a \) is specified;
- the fraction of occurrence of the combination of former three parameters.

The tidal climate consists of a number individual conditions for which the total fraction of occurrence equals 1.

The local vertical tide is described by an overall fluctuation of the water level, denoted as \( h_a(t) \) with respect of the reference level. During a year, a large range of individual \( h_a \)-values will be present. For schematization purposes however, only a limited number of them will be used. The distribution of the tidal velocities over the profile is computed with the Chézy-equation.

The longshore variation of these time-averaged climates is taken into account by relating a specific tidal climate (viz. a tidal climate table with a specific index as discussed later) to a specific longshore position. Using the yearly-mean tidal climates as starting-point, the effect of long-term changes in the governing parameters such as:
- mean water level,
- tidal range and
- tidal velocities,
are taken into account by a specific corrections of the parameters. E.g. a gradual sea level rise is taken into account by adding the absolute change in the mean water level, denoted as \( \Delta h_a(t) \), to the astronomical elevation \( h_a \).

Transport formulations

Processes that have been schematised up to an acceptable level for the present version of the PONTOS-model are:
- the rate and distribution of the wave-induced cross-shore sediment transport;
- the rate and distribution of the wave-induced longshore sediment transport;
- the rate and distribution of the tide-induced longshore sediment transport;
- the effect of groynes on the longshore transport rate,

although some of these formulations will need some further improvement during a later stage of the model development.

The following processes have been conceptually developed and will be implemented in a later stage of the model development:
- refraction and shoaling of waves;
- diffraction around structures;
- flow contraction around structures like cross-shore dams.
In the following the main characteristics of both the cross-shore interaction and the longshore transport assessment is discussed briefly.

**Cross-shore transport**

The cross-shore interaction between the layers is based on the principle of a wave-based equilibrium profile. Deviations from this equilibrium slope result in a cross-shore exchange of sand between the layers. The rate of adjustment depends, amongst others, on relative water depth and local sediment characteristics. For both the equilibrium slope and the transport rates, formulations have been derived, partly based on empirical formulae and partly based on the results of a series of computations carried out with a process-based model. The process-based computations involved the main processes determining the cross-shore transport i.e. wave asymmetry, gravity and the undertow compensating for the mass-flux above the wave troughs. Relevant input parameters are wave climate and sediment characteristics [Steetzel, 1997a/b].

In the PONTos-model, the wave-induced cross-shore transport $q_{y,w}$, for a specific hydraulic condition (water level and waves) at a certain depth is computed from:

$$q_{y,w} = q_o F_b \left( \frac{s}{s_e} - 1 \right) \left( \frac{s}{s_e} - 1 \right)^{\beta - 1}$$

in which the $s$ denotes the actual local bed slope and $s_e$ refers to the local equilibrium slope and $\beta$ equals 2.0. Due to the terms on the right-hand side, a relatively too steep slope, viz. $s > s_e$, yield offshore directed, viz. positive transport.

The $F_b$-function describes the relative transport rate as a function of the $d / H_s$-ratio according to:

$$F_b = \exp \left[ \frac{-d}{\alpha H_s} \right]$$

in which $\alpha$ equals 1.5. The coefficient $q_o$ was used for calibration.

In the following the equation for the term $s / s_e$ will be derived.

In the model, the equilibrium slope $s_e$ is expressed in terms of the offshore hydraulic conditions and the characteristics of the bed material.

For a concave cross-shore profile as a starting point, this function is schematised as:

$$s_e(d) = s_0 F_s$$

in which $s_0$ refers to the bottom slope at the water level and $F_s(d)$ describes the vertical variation assessed from:

$$F_s(d) = \left( 1 + \frac{d}{\alpha_s H_s} \right)^{-\gamma}$$

The slope in the model at layer boundary $Z_j$ denoted as $s_j$ is assessed using the mutual distances between the two layers, according to:

$$s_j = \frac{Y_j - Y_{j-1}}{(d_{j-1} + d_j)/2}$$

If for the equilibrium profile this mutual distance is denoted as $W_j$, the characteristic equilibrium slope $s_{e,j}$ can be assessed from:
Consequently, the relative slope in the transport formulation is computed from:

\[ s_j = \frac{Y_j - Y_{j-1}}{W_j} \]

yielding the source term for the assessment of the cross-shore transport rate \( q_{x,j} \) as discussed before.

**Longshore transport**

Formulations for both the wave-induced and the tide-induced longshore transport are implemented in the model. These formulations are also based on series of computations carried out with a process-based model. Relevant input parameters are wave climate, horizontal and vertical tide and sediment characteristics.

The wave-induced longshore transport, denoted as \( q_{x,w} \) (expressed in \( m^3/m^1/yr \)) is generated by oblique incident waves which generate an longshore current in the breaker zone mainly. The wave-induced transport rate mainly depends on the incoming wave energy and the direction of wave propagation relative to the coastline. For the assessment of the wave direction the offshore direction is used in the present set-up of the model. An approach to account for the effects of wave refraction will be taken into account in the next version of the model.

The total, viz. cross-shore integrated wave-induced longshore transport \( Q_{x,w} \) for a specific wave condition and grid cell, is computed from:

\[
Q_{x,w,j,i} = F_i \ c_{w,0} \left( \frac{H_s^2}{D_{50}} \right) (\phi_c - \phi_w) \exp \left( -c_2 (\phi_c - \phi_w)^2 \right)
\]

in which \( \phi_c \) denotes the orientation of a specific layer, \( \phi_w \) the direction of the incoming waves and \( c_2 \) a constant. The coefficient \( c_{w,0} \) is used for calibration.

![Figure 2: Shematization of wave-induced longshore transport](image-url)
The above equation accounts for the total wave-induced long-shore sediment transport, which then has to be distributed over the different layers. In the present version of the model, this is schematised as a triangle, as illustrated in Figure 2. The fraction of the total transport present in a specific layer is defined by the factor $F_z$, with $0 \leq F_z \leq 1$. This factor is derived from the triangle schematization, depending on the level of the upper and lower boundary of the layer relative to the water level.

The distribution of this transport over the various layers is schematised as a triangle in the present version of the model, as illustrated in Figure 2. Depending on the level of the upper and lower boundary of the layer relative to the water level, the magnitude of the fraction $F_z$ can be assessed.

The tide-induced transport, denoted as $q_{sx,t}$, is determined by the tidal currents, and is furthermore affected by the water depth, the sediment characteristics, and the presence of waves (stirring up the sediment).

In the PoNTos-model, the tide-induced longshore transport $q_{sx,t}$ for a specific hydraulic condition (water level, wave and tidal current) is computed from:

$$q_{sx,t} = c_{r,0} (D_{so})^{2.2} (v_s)^4 \left[ 1 + 2 \frac{H_k^{1.5} T_p}{d v_s^2} \right] \left( \frac{A_y}{A_z} \right)$$

in which the term in between squared brackets accounts for the effect of additional stirring due to the presence of waves and the coefficient $c_{r,0}$ is used for calibration. The $\Delta y/\Delta z$-term on the right-hand side is needed to transform the transport rate per m$^1$ in cross-shore direction to a rate per m$^1$ in vertical direction needed for the layer-concept. To assess the transport in a specific layer, the computed rate has to be multiplied by the height of the layer (to be derived from the width in cross-shore direction).

A simple formulation for wave diffraction has been defined to account for the modified wave field around structures. In a later stage it is envisaged to also defined and include the effect of flow contraction around structures [Steetzel and de Vroeg, 1997].

**Conceptual validation**

The present model has been conceptually validated for a large number of theoretic cases, specifically to check the mathematical implementation of the developed formulations. In addition, the following cases have been studied in more detail:

- the evolution of a cross-shore profile for individual waves and wave climates;
- the impact of changing tidal conditions (sea-level rise);
- the behaviour of a closed coastal section for perpendicular, oblique and spatially varying wave conditions;
- the effect of a single groyne;
- the effect of nourishments.
In Figure 3 as an illustration, the cross-shore evolution is given for an initially steep cross-shore profile using one single wave condition as a forcing agent.

As can be seen from the right-hand panel, the final equilibrium profile is reached asymptotically in time. In addition to this relatively simple example the effects of wave climates, additional tidal climates, large-scale nourishments and sand mining, climate change and sea level rise have been studied in more detail.

**Application of the pilot-version**

The PoNTos-model is designed in such a way that it is generally applicable. A specific application has been carried out for a part of the Dutch coast. This application focuses on the uninterrupted coast, excluding therefore the delta coast in the south and the tidal inlets in the north of the Dutch coast. The goal of this application was to show the ability of the model to simulate the large-scale transport patterns along the Holland coast, taking into account the non-uniform wave and tidal climate [Steetzel et al., 1998].

**Set-up**

For the study of the Dutch coast using a multi-layer model, the overall contour of the whole Dutch coastline was schematised using a series of straight and curved lines. The position and orientation of the coastline contours have been transferred to this new co-ordinate system, using this reference line and resulting in a stretched coastline. For the present application, the central Dutch coast (i.e. the Holland coast) was modelled in more detail, with the southern boundary at \( X_m = 98 \) km and the northern boundary at \( X_m = 208 \) km, resulting in a stretch of 110 km. The layer positions were derived on the basis of the JARKUS data-set (dataset with results of yearly nearshore surveys with fixed rays). For this first model set-up the layer positions were determined for a number of specific JARKUS profiles (year 1990) in order to implement the main bathymetrical features of the Dutch coast in the model (See Figure 4).
The long-term wave data from the stations Light Vessel Goeree, Noordwijk and Eierland were used to schematise the along-coast varying wave climate. The tidal climate along the coast was characterised by a "morphological tide". This is a tide which is considered to be representative for the neap-spring tidal cycle. In order to account for the non-linear relationship between the sediment transport and the flow velocities the tidal range of the morphological tide is somewhat larger than the mean tidal range. For this first application of the PONTos-model for the Dutch coast, the basic computations were carried out with one representative tide for the entire central coast, as derived on a depth of NAP-8m near Noordwijk.

**Calibration and verification**

The simplified representation of the coastal structures does not allow for a detailed verification of the sediment balance and coastline development in the region next to these structures. For this reason both long groynes and harbour breakwaters have not yet been included in the verification of the model for the Dutch coast.

Verification and calibration of the model has been carried out in 4 steps:
- step 1: Verification of the wave-induced longshore transports
- step 2: Verification of the tide-induced longshore transports
- step 3: Verification of the cross-shore transports
- step 4: Verification of the sediment balance

**Results**

The basic runs for the longshore transports show promising results. Without any fine-tuning or calibration, the results show a fair similarity with the more detailed computations based on computations with a process-based model as presented by van Rijn (1995, 1997), see Figure 5. The transports in the upper part of the profile are
based on the wave-induced transports only. If the tide is included in the upper part of the profile, the net northward transports are somewhat larger. If the effect of wave refraction between the seaward boundary and the breaker zone is included in the model, the resulting transports can be expected to change somewhat.

In the regions with the relatively gentle profile in the central section of the model area, the computed cross-shore transports are rather high. This can be expected on the basis of the cross-shore concept which is based on an equilibrium slope. The relatively small variations in the wave-climate along the coast do not justify the relatively large variations in the profile slope. It is expected that some calibration of the equilibrium

![Diagram](image)

Figure 5: Comparison of computed wave-induced longshore transport [Van Rijn, 1995,1997].
slopes in some regions along the coast will be necessary for a fine-tuning of the model. Variations of the sediment size should be taken into account in a detailed verification.

The response of the model is as can be expected on the basis of the modelled processes. Considerable improvement is possible if the effect of structures is modelled in more detail. The results presented in Figure 6 give the impression that in that case fine-tuning of the model is very well possible.

Conclusions regarding the application

The first application of the pilot-version of the Pontos-model for the central Dutch coast yields promising results. On the basis of simple schematization procedures for the wave- and tidal climate the direction and magnitude of the net yearly transports show a fair agreement with the results of the more in-depth study of van Rijn (1995, 1997).

For this first application of the model, attention has been focused mainly on the sediment transports. Detailed calibration of the model on the basis of the sediment balance was not yet possible, since some important effects were not yet included in the model. These are:
- the effect of wave diffraction around large structures;
- the effect of flow contraction around large structures;
- the effect of wave refraction;
- the interaction between tide- and wave-induced currents in the surf zone.
